"The seeds of Eucalyptus may be planted at different periods of the year, according to regions and climates. With us the best time is the spring—in March, April or May—for if the seed is sown at that time, the young plant will have sufficient strength to support the cold of the following winter. In forming a plantation of Eucalyptus, it is of prime necessity to decide upon the object to be attained, that the species may

be selected best suited to accomplish it. If, for example, it is desired to obtain timber in as short a time as possible, *E. globulus*, *E. Mulleri* or *E. gomphocephala* should be planted. If very heavy wood is desired, then *E. marginata*, *E. rostrata* and especially *E. polyanthema* should be used. If it is a question only of obtaining handsome trees for the decoration of parks or avenues, one would choose naturally the species most remarkable for the beauty of their growth, for the dense shade cast by leaves and by their abundant flowers, such as *E. robusta*, *E. cornuta*, *E. botryoides* or *E. leucoxylon*."

These short extracts will give, perhaps, an idea of the scope and character of Monsieur Naudin's contribution to dendrological science. For the full account of the Eucalyptus, as known in Europe, however, we must refer our readers to the paper itself, which, it seems to us, might with great advantage be reprinted in this country for the benefit of the rapidly increasing class of people whose homes are in southern California, where the cultivation of these trees is every year becoming a more important industry.

Notes.

The Messrs. Putnam are about to publish a "Leaf-Collector's Hand-book," prepared by Professor Charles F. Newhall.

The Russian Department of Agriculture and Farming proposes to introduce the cultivation of the Opium Poppy into the Caucasian region.

Among the pretty names applied by the Japanese to their Chrysanthemums are: "Snow on the Leaf of the Bamboo," "Thin Cloud," "Gold Dragon," "Spray-capped Wave" and "Star-lit Night."

A well of clear water which existed near what is now the city of Dublin was called, in Celtic times, "Fain-Usk," and the name, in a curiously altered form, has been preserved to our own times in that of Phœnix Park.

The Massachusetts Agricultural Society has doubly honored *Spiræa Japonica*, var. *grandiflora*, by awarding it a first-class certificate and a silver medal at recent meetings. It is a new and much improved form of the familiar *S. Japonica*.

Among the most beautiful of the shrubs in Central Park at this time is the Ramanas Rose (*Rosa rugosa*), and especially the white variety. In grace of form, richness of foliage and beauty of flower and fruit, this shrub has hardly a superior.

A correspondent of the *American Florist* writes that the Village Improvement Society of the town of Winchester, a suburb of Boston, has inaugurated the commendable practice of distributing to the school-children flower-seeds and bulbs, with the offer of certain premiums to those who excel in the culture of the same. The children have entered into the scheme with great enthusiasm.

Professor Trelease issues, in a separate volume, from the second annual report of the Missouri Botanic Garden, his revision of the American species of Epilobium growing north of Mexico. Thirty-eight species are described, some of them being now characterized for the first time, and the paper, which is one of the most important of the recent contributions to North American botany, is enriched with forty-eight full-page lithographed plates, showing the habit and structure of the different species.

In that old and curious book, the "Rarities of New England," the Touch-me-not, or Jewel-weed (*Impatiens fulva*), is called the "Humming-bird-tree," and is thus quaintly described: "This Plant the Humming-bird feedeth upon, it groweth in wet ground, and is not at its full growth till July, and then it is two Cubits high and better, the Leaves are thin and of a pale green Colour, some of them as big as a Nettle Leaf, it spreads into many Branches, knotty at the setting on, and of a purple Colour, and garnished at the top with many hollow dangling Flowers of a bright yellow Colour, speckled with deeper yellow as it were shadowed, the Stalks are all hollow as a Kix and so are the Roots, which are transparent, very tender and full of a yellowish juice." Its leaves are declared to be a remedy for the effects of Poison Ivy and to be good for "Bruises and Aches upon Stroakes."

Steps are now being taken by members of the Royal Scottish Arboricultural Society to secure a fund for the foundation of a Chair of Forestry in the University of Edinburgh, and to endow it properly. The subject has been before the society for many years, and has received the cordial support from the most eminent forest-students of the day. During the two last sessions of the University a forestry class has been successfully taught by Dr. Summerville. The interest shown in this course has been considerable, and points to the desirability of establishing in Scotland, on a permanent basis, the study of forestry as a science. Dr. Summerville's lectures have been supported by a grant from the senate of the University, but there is now reason to fear that this aid will be withdrawn unless a permanent endowment fund is provided by local effort. It is thought that $25,000 will be required for this purpose; about $7,500 of this sum have already been received by the University and by the Highland Agricultural Society of Scotland.

From the annual report of the City Parks Association of Philadelphia, it appears that during the past year two parks, Weccacoe Square and Bartram's Garden, have been opened to the public, while two more, Northwood Park and Juniata Park, bid fair to be opened. The final acquisition, after a century of neglect, of Bartram's Garden is an achievement for which all good citizens will be grateful. Four new parks have been placed on the city plan by Councils, and an ordinance was passed last winter providing for grass-plots and the planting of trees along the sidewalks of the streets and avenues of the city, which are seventy feet wide, and over, from house-line to house-line. Other progress has been made in the matters concerning which this association interests itself, and no doubt the work done by it, and the efforts of its individual members, have exercised a marked influence in keeping alive public interest in the necessity of open squares and pleasure-grounds in the city. It is to be hoped that similar associations will be formed in other cities.

The idea so often recommended that winter as well as summer should be considered in the arrangement of country-places, was thus charmingly set forth by Joseph Addison in the *Spectator* for September 6th, 1712: "I can by no means think the verdure of an evergreen comparable to that which shoots out annually and clothes our trees in the summer season. But I have often wondered that those who are like myself, and love to live in gardens, have never thought of contriving a winter garden, which should consist of such trees only as never cast their leaves. . . . When Nature is in her desolation and presents us with nothing but bleak and barren prospects, there is something unspeakably cheerful in a spot of ground which is covered with trees that smile amid all the rigors of winter, and give us a view of the most gay season, in the midst of that which is most dead and melancholy. I have so far indulged myself in this thought that I have set apart a whole acre of ground for the executing of it. The walls are covered with Ivy instead of vines. The Laurel, the Hornbeam and the Holly, with many other trees and plants of the same nature, grow so thick in it that you cannot imagine a more lively scene. The glowing redness of the berries with which they are hung at this time, vies with the verdure of their leaves. . . . It is very pleasant at the same time to see the several kinds of birds retiring into this little garden spot, and enjoying themselves among the branches and foliage, when my great garden . . . does not afford a single leaf for their shelter."

The tenth bulletin of the Central Experimental Farm of the Ottawa Department of Agriculture is devoted mainly to the treatment of the disease known as Apple Scab. This fungus, which has been long known, has come to be so serious in many parts of Canada that orchards of Fameuse Apples which, ten years ago, yielded from sixty to seventy-five per cent. of first-class fruit, now give no more than twenty-five or thirty per cent., the remainder being "seconds" or "thirds." The late Mr. Charles Gibb once stated to the Montreal Horticultural Society that in his orchard the effect of this disease was so marked that his apples brought an average of only twenty-five cents a bushel, while, if they had been free from the spot the same variety would have sold for seventy-five cents a bushel. To this reduction in selling price must be added the loss resulting from diminished size, which is quite as serious, so that the total direct and indirect depreciation of value, when compared with that of first-class fruit, would be about in the proportion of one to four. The bulletin goes on to give an account of the fungus (*Fusicladium dendriticum*), which has been often described, together with an account of experiments to show that carbonate of copper in simple mixture or suspension with water is a very effective remedy. The experiments confirm what has been often stated in these columns, that the application should be made early, that is, the first one should be made before the blossoms open and the second soon after they have fallen. The liquid should be distributed in a fine spray by proper nozzles, and, although the trees do not need to be drenched, they should be completely moistened.

GARDEN AND FOREST.

NEW YORK, WEDNESDAY, JUNE 3, 1891.

TABLE OF CONTENTS.

Matters of Taste.

THE expression, "It is a matter of taste," is often used to signify that no rules or principles can be applied to the subject which is thus indicated, and it is a popular notion that a matter of taste supplies opportunity for absolute choice or caprice, and that one decision or preference is as good and as appropriate as another. But the faculty of discerning beauty, order, congruity, proportion, symmetry and whatever constitutes excellence in landscape-gardening requires cultivation and intelligent direction. The notion that whatever accords with the whims or preferences of the owner is for that reason fit and right, is constantly used to justify all kinds of unintelligent and unpleasing arrangement of the grounds about dwellings.

It is every year becoming more important to obtain general recognition in this country for the truth that in matters of taste, appearance or beauty, pleasing effects do not depend on caprice, but that the character of results is determined by the arrangements and conditions of each particular case—that is, by facts and principles which should be recognized and regarded in practice. Of course there are often matters pertaining to the plan and treatment of the grounds about dwellings which afford opportunity for unrestricted choice. These are usually features or questions of comparatively slight importance, and the preferences of the owner constitute the only standard of judgment which it is necessary to apply. The error which constantly leads to undesirable results is the popular belief that all matters of taste are of this character; that they lie outside of the realm of rules and principles, and that what pleases the owner of the grounds is necessarily good.

If people could be brought to recognize the distinction between the two classes of subjects or questions connected with the arrangement and treatment of grounds about dwellings, the one made up of matters in which one method may be as good as another and the owner's choice is the only law, the other requiring the application of an intelligent and cultivated judgment in order to reach any satisfactory result, it would be the means of greatly improving the appearance of thousands of places, and it would also increase the value of residence property in nearly all the towns of our country. The appearance or effect of permanence, and of the peacefulness and comfort which ought to belong to a home, can be produced only by the adaptation of means and plans to these ends. The position of the house in the grounds, and the relation between its character and that of its permanent surroundings, the disposition of shrubbery and of roadways, and the connection between the lawns and the public streets or highways, are all questions requiring intelligence for their decision. There are principles and laws involved which cannot be safely disregarded, and pleasing effects and impressions can result only from arrangements and combinations which are in their nature adapted to produce them. An unsightly building may be made to appear more distant, and less intrusive and aggressive, by a hedge or line of shrubbery which does not conceal half of its height, and this effect follows whether it is expected and understood or not. A small lawn fronting a public street or roadway which is a wide area of dust, with only a ragged, irregular edging of grass, may have in itself a pleasing effect if it is in some way definitely separated from the street. The limit or barrier may be a slight fence, hedge or wall, but a plain line of demarcation is necessary between the homogeneous and successful expanse of greenery on the one side, and the chaotic domain of ugliness on the other. While the barrier is maintained—it may be a barrier for the eye only—the verdant smoothness of the lawn makes a satisfactory impression. It is so much that has been redeemed from the waste which still exists beyond the wall, and for this outside desolation the lawn is clearly not responsible. But if the limit between the lawn and the street is removed, then the unsubdued ugliness of the street becomes a part of the lawn, and the lawn is dominated and dwarfed by it, and appears unfinished and unsuccessful.

An Interesting Rediscovery.

MRS. J. G. SMYTH, of Greenville, South Carolina, sends us fresh flowers of *Lonicera flava*, gathered by herself on Paris Mountain, probably in the very spot where this plant was last seen growing wild by any botanist. This was in the year 1810, when John Fraser, a Scotch collector, paid a visit to Paris Mountain and gathered seeds or roots of this plant and sent them to England. From the descendants of these plants of Fraser's kept in gardens has been preserved the knowledge of this beautiful species. Last year a figure and description of *Lonicera flava* were published in this journal (vol. iii., 187, f. 187), and the interest this excited in what appeared to be a "lost plant" led our correspondent to investigate Paris Mountain, a low outlying spur of the Blue Ridge which rises from the plain close to Greenville. Her search was successful, and on the 27th of April Mrs. Smyth found the Honeysuckle in flower, and now sends us specimens with this note:

The plants were found, and this was the only place, on the north side of the mountain, a hundred and fifty or two hundred feet from the top or highest point of the mountain, which is 2,054 feet above the level of the sea. The Lonicera was growing in a very rocky place, about fifteen or twenty feet square, a place which looked, except for the many and large rocks scattered over it, as if it might have been a cleared spot. All around and about it the original foliage of the forest had never been disturbed, tall Oaks and Chestnuts, and the thick undergrowth of Azaleas and Rhododendrons forming a dense shade. The soil is rich and black from the long accumulation of leaf-mold, damp and rich, and just such a soil as the Rhododendron grows and thrives in. The stems are not more than two feet high, but I thought would have grown longer if there had been any support for them to cling to and run on. The roots send out long runners, and these send up shoots from every little point, so that in trying to get a root one might pull up yards and yards before it would break.

Lonicera flava is one of the rarest of American plants, and although it has been known from the very beginning of the century, there is apparently no evidence that it grows anywhere except in this one spot on Paris Mountain. Mrs. Smyth's most interesting discovery removes another from the now short list of plants known to our early botanists, but unknown to their successors. Now that Darbya, Shortia and *Lonicera flava* have been found again, *Gordonia Altamaha* and *Illicium parviflorum* are the only prizes left among species known to have existed to reward the botanical collector in the south Atlantic states. It is a curious fact that both of these plants, like *Lonicera flava*, have been preserved in gardens for nearly a century, although all recent efforts to find them in their native haunts have failed.

In another column of this issue a correspondent expresses a mild disappointment in the gardens of Bermuda because they fail to display that richness and variety of material which one would expect to find in such favorable soil and climate. No doubt there is some justice in this criticism, but the same is true of the gardens in nearly every other portion of the civilized world. The fundamental error usually consists in ignoring the peculiar natural conditions of the place and endeavoring to construct a garden or to modify a landscape in accordance with some foreign ideal. The perfect English lawn is a delight to every one who sees it under English skies, but over a large portion of the world greensward is unknown and impossible, and in such places it is worse than a waste of energy to strive for any garden effects in which a stretch of clipped grass is the prevailing feature. And even in certain regions where grass might be persuaded to grow with careful nursing such lawns may be misplaced, as, for instance, among the rocky ledges, dwarf Cedars and scrub Birches of our wild north-eastern coast. In the same way a sub-tropical garden rarely looks happy in the north, even during the heat of our short summers, and if this tender vegetation could be induced to thrive it would still appear misplaced among the sturdy trees and shrubs and herbs which look fearlessly forward to the approach of winter.

The true method everywhere, and this is the first canon of all garden art, is to study the native and peculiar beauty of the place and then endeavor to unfold and enhance it, resisting every temptation to give it an alien air by decorating it with foreign and incongruous finery. This is the fundamental charm of all the famous gardens of the world. The English lawn itself is beautiful in England because it is the legitimate outgrowth of English natural scenery, while the Park of Muskau and the gardens on the shores of the Mediterranean emphasize the same teaching. In every successful instance art comes to the help of nature, working in accordance with the informing spirit of the scene. Wherever, on the contrary, attempt is made to oppose or thwart nature the end will be disaster. It would not be strange if the Bermudians had committed some errors of this sort. If they have endeavored to provide themselves with English gardens in a latitude south of that where the finer grasses thrive, their lawns will give them little satisfaction. It would be a natural mistake on their part to try the strictly tropical plants which clothe some of the West Indies with such luxuriant beauty, for they have intimate commercial relations with these islands, and, of course, are familiar with their flora, but Tree-Ferns and Crotons could hardly endure the chill of the more northern islands. Again, these islanders are in the habit of visiting our northern states in summer, and, after enjoying the singular beauty of our flowering shrubs and trees and hardy plants, they have endeavored to naturalize many of them. Here, too, failure was inevitable. Plants which can endure a long winter are rarely hardy enough to survive an almost endless summer, and, therefore, most of the Hybrid Perpetual Roses and scores of shrubs and trees from our nurseries have been planted in Bermuda only to perish.

But, although mistakes may have been made in planting on these islands, we must acknowledge quite as serious and even more prevalent errors at home. Taken as a whole, Bermuda scenery has a singular charm for northern eyes, and the possibilities of gardening there are endless. Most of the delightful plants which thrive just outside the borders of the tropics would here make themselves at home, and, having been developed in similar climatic surroundings, would blend harmoniously with the native growth. Olives, Laurels, Myrtles, Magnolias, Rhyncospermums, Laurestinus, Gardenias and Pittosporums, with Cycads, Yuccas, Aloes, Agaves, Euphorbias and other plants which brighten the gardens of southern Europe, ought to thrive here. The Cherokee Rose, if introduced, might soon be as common as it is in our southern states, while *Pinus Cubensis* and other southern conifers ought to live happily among the native Cedars.

But, after all, there are only a few chosen spots in all the world where the art of the gardener is so little needed as it is here to supplement the beauty with which nature has already endowed them. Instead, therefore, of regretting that man has done no more to enhance the beauty of these islands, we ought to be grateful that he has done so little to mar it.

Sir Christopher Wren as a Gardener.

One usually connects the name of Sir Christopher Wren only with the erection of city churches, but he deserves at least a little niche in the memory of those whose chief concern is with plants and with the useful or ornamental disposition of the surface of the ground. I cannot discover what share he may have taken in arranging the grounds of the country homes he built or altered, but we can fancy that he may have been active in this direction, for the art of gardening was then still in its strictly formal phase, the immediate surroundings of great country houses were architectural in design, and clients were wise enough to know that the same artist who planned the structure itself should be consulted about its accessories. Moreover, there is historical witness to the fact that once at least he shared in the arrangement of a famous garden. About the year 1690 Queen Mary engaged Wren to make alterations in Cardinal Wolsey's former palace of Hampton Court; and, though I cannot find any detailed account of what his work on the gardens was, it is known that they were included with his purely architectural problems. "Queen Mary," says Wren's latest biographer, Miss Phillimore, "though she amused herself with planning the gardens and making suggestions, had yet the wisdom to defer to Wren's better taste and knowledge. Her husband, with characteristic obstinacy, insisted on his own ideas, thereby dwarfing the cloisters and marring much of the architecture. It is, however, fair to say that King William always owned that the defects were his, the merits Wren's; and these merits were very great as any one who knows the fine old palace, with its rich red brick, its arcades and the quaint formal gardens, will readily allow. He built, at about the same time, the Pavilion and the Ranger's House in Bushey Park."

But it is in Wren's writings that we find what will be of most interest to the readers of Garden and Forest. No man ever worked harder at his own profession than he, even during the later years of his long life; yet he found time to investigate many other intellectual questions and occasionally to write about them. An article, "On the Surface of the Terrestrial Globe," is mentioned by biographers, but is no longer extant. Another, however, "On the Rising of Sap in Trees," has been preserved. In full it exists only, I believe, in a manuscript inserted in a volume of the "Parentalia," a folio book of family memoirs published by Sir Christopher's grandson, and now itself a rarity. But some extracts from it are printed by Miss Phillimore and are valuable as showing how such a subject was approached, just two centuries ago, by a man who, although he was not a naturalist, had one of the acutest and most cultivated intellects of the time.

"It is wonderful," writes the great architect, "to see the rising of the sap in Trees. All will bleed more or less when they are tapped by boring a hole through the Bark, some very considerably, as the Birch, which will afford as much liquor every day almost as the milke of a cow; in a Vine when a bough is cut off it will if not stopped bleed to death. Now by what mechanism is water raised to such a height as in Palmitos to 120 foot high? A skillfull Engineer cannot effect this with-

out great force and a complicated engine, which Nature does without sensible motion; it steals up as freely as the water descends; the reason of this is obscure as yett to naturalists." Various theories which Wren then quotes are not explained by his biographer, but, she tells us, he shows by a little marginal drawing "that the onely Vicissitudes of heat and cold in ye aire is sufficient to raise the sap to the height of the loftiest trees." Mechanical explanations are then given to refute the idea that there is "a secret motion in nature contrary to that by which plants aspire upwards." And in conclusion Wren says: "But though I have shown how the sap may be mechanically raised from the Root to the top of the loftiest trees, yett how it comes to be varyed according to the particular nature of the Tree by a Fermentation in the Root; how the Raine water entering the Root acquires a spirit that keeps it from freezing, but also gives it such distinguishing tastes and qualities, is beyond mechanical Philosophy to describe and may require a great collection of Phenomena with a large history of plants to shew how they expand the leaves and produce the Seed and Fruit from the same Raine water so wonderfully diversified and continued since the first Creation."

Special students of such questions would be glad to see the explanatory passages omitted from these quotations, although, of course, we can understand how they did not find a place in a general biography of the architect. But it is certainly interesting to discover that a man so practical and sensible as Wren, seems to have anticipated a day when even such secrets as the transmutation of inert into living matter would be explained. Unfortunately, our "collection of Phenomena" and our histories of plants, vastly though they have increased during the past two centuries, have brought us no nearer to the reading of riddles of this sort.

When discussing the condition of the churches of London and the best way of repairing them, Sir Christopher once wrote: "As to roofs, good oak is certainly the best, because it will bear some negligence. The churchwardens' care may be defective in speedy mending drips; they usually whitewash the church, and set up their names, but neglect to preserve the roof over their heads. . . . Next to oak is good yellow deal, which is a timber of length, and light, and makes excellent work at first, but, if neglected, will speedily perish; especially if gutters (which is a general fault with builders) be made to run upon the principal rafters, the ruin of the church may be sudden. Our sea-service for oak and the wars in the North Sea make timber at present of excessive price. I suppose, ere long, we must have recourse to the West Indies, where most excellent timber may be had for cutting and fetching."

Wren lived, as I have said, before the time when naturalistic methods of gardening art were introduced, and very long before the establishment of great rural cemeteries for the reception of the dead of cities. In his day it was customary to bury in churchyards and actually within the walls of churches, even in the densest parts of London. But he was too intelligent a man not to protest against so dangerous a practice, and, in one of the many reports on architectural and urban questions which he wrote, we find what his conception was with regard to the proper disposal of the dead. If they are not interred in or near the city churches, he says, "It will be enquired, where then shall be the burials? I answer, in cemeteries seated in the outskirts of the town. . . . A piece of ground of two acres in the fields will be purchased for much less than two roods among the buildings; this being enclosed with a strong brick wall, and having a walk round, the two cross walks decently planted with yew trees, the four quarters may serve four parishes, where the dead need not be disturbed at the pleasure of the sexton or piled four or five upon one another or bones thrown out to make room. . . . It may be considered further, that if the cemeteries be thus thrown out into the fields, they will bound the excessive growth of the city with a graceful border, which is now encircled with scavengers' dung-stalls." To-day we should hardly consider such cemeteries a "graceful border" to a city, although, it must be confessed, too many in America are encircled by the more unpleasant heaps of refuse with which Sir Christopher desired to do away. His words convey, I may add, an exact picture of many cemeteries still in use near European towns; but, though they are much larger than the churchyards which preceded them, the horrible results of overcrowding cited by Wren as existing in such yards may often be witnessed within their wider yet now insufficient and inelastic walls. I have myself seen, in German cemeteries in the outskirts of cities of the first class, even the piling of three or four bodies one upon another, and this not in portions devoted to the poor, but in lots owned by aristocratic families.

Native Shrubs of California.—VI.

AGAINST the five or six native species of Plum with which the Atlantic states are credited, the Pacific coast has only one, though this appears in different localities under two very well marked varieties. The type is *Prunus subcordata*, Benth. (Pl. Hartav., 108). The variety *Kelloggii*, Lemmon (Piltonia, ii., 67), is not well known, and may possibly, at some future day, be admitted in the rank of a species. But the species, in the typical form, is common in many parts of California, though along the seaboard it is so rare as to have escaped the notice of all the early explorers, Menzies, Chamisso, Douglas, and even Nuttall. Not until the year 1847, when Hartweg botanized up the Sacramento to the foothills of the Sierra, was our Wild Plum brought to the knowledge of botanists.

It is a common observation that, in many genera of plants common to the Old World and the New, it is the Pacific coast species, rather than those of Atlantic America, which make the nearest approach to Old World types; and this holds good in respect to the Californian Plum. It is more intimately related to *Prunus domestica* and other European or Asian Plums than are any of the Atlantic coast species. Indeed, the Atlantic group, by their divergence from the Plum-tree genus in one or two particulars, were what led certain eminent botanists to regard Plums and Cherries as congeneric. In the Old World the Plums, as a genus, have this fine mark, that their leaves are rolled up from edge to edge in the bud, while the Cherries all have theirs folded together lengthwise. But all the Plum-trees indigenous to Atlantic North America have been found to agree with the Cherry-trees in that their foliage is conduplicate in the bud. Our *Prunus subcordata* is not at agreement with its American cousins in this regard, but has that rounded foliage, convolute in the bud, which betrays its closer affinity with the species of another continent. In the color, texture and flavor of its fruit it is, however, quite like the other American Wild Plums, and the quality is variable, according to the locality. And, although exotic Plums are cultivated with all success in almost every part of California, the improvement of our native species has not been neglected. In some instances cultivated seedlings from this parentage are said to have already yielded fruit very superior in size and quality to the last products of the wild tree.

As above intimated, the shrub is not common except in the lower altitudes of the Sierra Nevada. There, and especially toward the northern parts of the state, it is plentiful along streams, where, attaining the shape and dimensions of a small tree, it forms considerable thickets, and, in places remote from the older and fruit-growing settlements, the wild plums are valued, and are, in fact, not far inferior in quality to some of the domestic sorts. In the coast range I know of no locality where the species is at all common. One small clump of it, in a cañon a few miles east of Oakland, and another on the grounds of the University at Berkeley—in a secluded nook, where it is no doubt spontaneous—are all I have been able to record as Bay-district stations for it. These bushes flower in March, and the blossoms, of rather large size for those of a wild Plum, in fading assume a rosy tint, such as I have not otherwise noticed in Plum blossoms.

Neither the Atlantic slope of North America nor the Pacific slope proper has any native species of the Peach and Almond genus, Amygdalus; but the Mexican region, including its northern extension, the Interior Basin of the United States territory, has, perhaps, three or four. At least one of these, *Amygdalus Andersonii*, Greene (Fl. Fr., 49), comes within the borders of California, east of the Sierra Nevada, and is no rarity among the rocky hills and mountains which enclose the great Colorado Desert of the southern counties. The shrub was first made known to botanists under the generic name of Prunus, and hence it has been called the Desert Plum. But whoever sees it in flower will recognize it at a glance as congeneric with the Peach and Almond, rather than with the Plums. When out of bloom it is about as inconspicuous as other desert shrubs, for the foliage is both small and sparse. Its associates are the smaller Agaves, Yuccas, and the bristling Opuntias and other Cacti which prevail in those verdureless and almost rainless districts; and then, rooted firmly in the scant soil of crevices and fissures of sunburnt rocks, in February it clothes itself with a fine display of rose-red blossoms, and so becomes an ornament to a hard landscape otherwise enlivened at this season only by the red and yellow of certain Cactus-blossoms. The shrub is low and bushy, perhaps seldom attaining a man's height; and to its flowers there succeed in their season the small velvety drupes, scarcely more than a half-inch long, which, when ripe, divest themselves of their

thin fleshy external coat, after the manner of the common Almond, and expose a small, nearly smooth putamen, or nut. I have not heard of any attempts to cultivate this native Almond, either in the fertile and fruitful regions of California proper or elsewhere. It is even something of a rarity in the herbariums of the botanists, though this is owing simply to the fact that the desolate and uninviting regions which it inhabits are so seldom visited and so little cultivated by even the most zealous of botanical collectors.

University of California. *Edward L. Greene.*

New or Little Known Plants.

The Japanese Hamamelis.

THE Witch Hazel (*Hamamelis Virginica*) of eastern America, with its bright yellow flowers which cover the branches late in the autumn as the leaves, which are then orange and scarlet, are falling, is one of the most common and best known of our woodland shrubs or small trees. The genus is confined to eastern America, where a single species occurs, and to eastern Asia, with a Japanese species, and another which has been discovered recently on the mountains of central and western China. The characters which are used to distinguish these plants are not important, and to botanists, who look to species largely, and do not give great weight to geographical distribution as a factor in their establishment, the three Witch Hazels might be considered forms of one species, slightly differentiated by local surroundings.

Hamamelis Japonica (Fig. 45), as it appears in the Arnold Arboretum, can only be distinguished from our American plant by its rather smaller and somewhat thicker, more prominently veined leaves of a duller green on the upper surface, and by the fact that the flowers appear in February or in early March instead of in the autumn. The number of the nerves of the leaves by which Siebold & Zuccarini (*Sitz. Akad. Münch.*, iv., ii., 193) endeavored to distinguish the Japanese from the American species is variable, as has already been pointed out by Franchet & Savatier ("Enum. Pl. Jap.," ii., 368); and in our cultivated Japanese plant the leaves are very constantly five or six-nerved, like those of the American species. The color of the inner surface of the calyx-lobes has also been used to distinguish the Japanese plant. On many of the plants cultivated in Europe, and in the wild specimens gathered in Japan which I have seen, the inner face of the revolute calyx-lobes is dull red. The effect of the contrast between the red color of the calyx and the bright yellow of the petals is striking and handsome, and makes this form the most attractive, probably, of the Witch Hazels at the time of flowering. But this color of the sepals does not seem to be constant. On the plants in the Arboretum, which were originally derived from Segrez, the interior of the calyx is dull yellow-brown, and the flowers can hardly be distinguished from those of the American plant except in their rather smaller size. Another difference between the Japanese plant, as it appears in the Arboretum, and the American species is found in the size of the persistent fruiting calyx, which in the Japanese plant is confined to the base of the fruit, while in the American plant it varies from a third to half the length of the capsule. The relative size of the mature calyx to the fruit appears to vary, however, on different individuals, and therefore does not afford a character of much value. Siebold & Zuccarini (*l. c.*) found that the calyx was attached to the base of the fruit only; Sir Joseph Hooker (*Bot. Mag.*, t. 6659) found the same to be true on all the specimens he was able to examine, while Franchet & Savatier (*l. c.*), on the contrary, remarked that "in all the specimens of *H. Japonica* with ripe fruit that we have before our eyes the degree of adherence of the fruit to the calyx differs from a quarter to nearly a half; not one of them is attached by the base only; and it is not possible to consider this peculiarity as a specific character." Franchet & Savatier speak of the flowers of the Japanese and of the American species as identical, and it is possible, although hardly probable, that the flora of Japan may contain two species—one with the red calyx of the plant, which seems to be the only one cultivated in England,* and the other with the yellow flowers of the plant which is figured on page 257. It is interesting in this connection as bearing, perhaps, on the tendency of Hamamelis to vary in the color of its flowers to note that I have recently received flowers of the American Hamamelis with bright red petals found on a wild plant in Malden, in this state.

Hamamelis Japonica is described as a small tree in its native country. Here it forms a spreading shrub of straggling habit, four or five feet high, with stout ashy-gray branches which are at first pubescent but become glabrous in their second year, and marked, like those of the American species, with small pale lenticels. The leaves are obovate, sinuately crenate and sharply toothed above the middle, five or six-nerved, rounded or acute at the apex, wedge-shaped or contracted into a narrow rounded base, long-petioled, with prominent midribs and nerves grooved on the upper surface. They are dark green and glabrous above, and are coated on the lower surface with pale or rufous persistent pubescence, and are from two to two and a half inches long by an inch or an inch and a half broad. The flowers are produced in subsessile clusters. The calyx is a quarter of an inch across, with lobes which are rounded at the apex, slightly ciliate on the margins, dull orange-yellow, and reflexed at the flowering period. The petals are strap-shaped, three-quarters of an inch long, rounded or truncate at the apex, and bright canary yellow. The filaments, like those of the American plant, are short and stout, the fertile anthers opening from the front. The carpels are silky-pubescent, with filiform styles. The capsule is subglobose, rather less than half an inch long, covered with bright brownish tomentum, and surrounded at the base only with the remnants of the calyx.

Hamamelis Japonica grows very slowly here, and, from present appearances, will never become a tree. It is very hardy, and the first shrub of the year to flower in the Arboretum. The flowers are bright and cheerful, and their earliness gives to this plant considerable value as a garden-plant, apart from the botanical interest which is attached to it. The red-flowered form is not in the Arboretum, but, judging from the figures which have been published of it, it is a more desirable garden-plant than the form which is figured in this issue, and the most showy member of the genus. *C. S. S.*

Ravenea Hildebrandtii.

THIS elegant little Palm was discovered in the Comoro Islands, between Madagascar and Zanzibar, by the German collector after whom it is named, and was introduced by means of seeds into the Berlin Botanical Gardens for 1878. Two young plants were obtained from that establishment for Kew in 1879, and five years afterward one of them, a male, flowered and was figured in the *Botanical Magazine*, t. 6776. Shortly after this the second plant flowered and proved to be a female; the photograph reproduced on page 259 represents the latter in fruit here in February last. This plant is only four feet high, and it has a naked stem a foot long, by one and a half inches in diameter, with an onion-like base. The leaves are a yard long by two feet across; the pinnæ are smooth, pointed, dark green on both sides; the petiole channeled and covered with gray furfuraceous scales. The female spadix is slender, four feet long, with an elegant panicle, bearing pea-like fruits of a bright scarlet color. These remain on the plant several months, and as they are ornamental they add considerably to the beauty of the plant. Mr. Wendland, of Hanover, informs me that he has obtained several crops of perfect seeds from his plants by placing the male inflorescence upon the female plant when in flower. This Palm is as elegant as *Geonoma gracilis* and as sturdy as a Kentia. It deserves to take a prominent place among garden Palms,

* This is the *Hamamelis arborea* of Masters (*Gardeners' Chronicle*, 1881, 216, f. 38), which is referred by Hooker to *H. Japonica*.

Fig. 45.—Hamamelis Japonica.—See page 256.

its small size, free habit, elegance, good constitution, being all in its favor, while in the freedom with which it flowers and produces seed we have an exceptional character among dwarf Palms.

According to Hildebrandt it ultimately forms a tree six to eight feet high, and it grows on the mountains of Comoro at an elevation of about 4,000 feet.

Kew. *W. Watson.*

Foreign Correspondence.

London Letter.

A LONG and exceptionally trying winter has at last come to an end, and has been succeeded by weather which, for warmth and brightness, equals anything we usually experience here in midsummer. Nearly a fortnight of this excessive warmth has produced a change in the garden quite magical in its suddenness, for the gloomy appearance worn by every tree and shrub and herb a fortnight ago has given place to a wealth of healthy green leaves and gay flowers everywhere. Never were the orchards of the London market-gardeners so heavily laden with flowers. Plums, Cherries, Apples, Pears, in fact, all kinds of fruits, have flowered so abundantly, and in some cases set so well, that already the prophets have foretold a ruinously heavy harvest of fruits. The orchard is the most beautiful part of the garden now, far more beautiful, indeed, than any other part ever is. This leads one to again call the attention of garden-makers to the value of many of these fruit-trees in purely decorative gardening. Where such trees as the Almond, double Peach, double Cherry, and several of the Plums and Crabs are used the effect at this time of year is charming. But we need not stop at the double-flowered and rare species of these. There is no more beautiful tree than an old Apple heavily laden with its big bunches of pink blossoms; but who ever plants the Apple for the same purpose as the Lilac and Laburnum?

Daffodils of all kinds and in all sorts of places—on beds, in grass, by the side of the lake and in tufts among the collections of shrubs—have been very effective; as also have Hyacinths, Tulips, Anemones and Ornithogalums. English gardening has developed very considerably in the direction of out-of-door spring flowers. We have almost entirely left the ancient practice of attempting to grow flowers only in set beds in summer, and allowing the garden to lie undressed for the remainder of the year. There is abundant material with which, by a little management, a garden may be made interesting and beautiful from January to December. Bulbs play an important part in this as a matter of course, although we are by no means limited to them. We had the Spurge Laurels, the Witch Hazels, the yellow Jessamine, the beautiful Forsythias and many others long before the Primrose and the Snowdrop came. These were followed by Magnolias, Brooms, Rhododendrons, the Daffodils and such like heralds of spring. Now there is a great wealth of flower attractions everywhere, Lilacs, more Rhododendrons, the chaste Exochorda, Choisyas and Kalmias. Besides these, the out-of-door beds are gay with the flowers of *Milla biflora*, a charming plant for carpeting small beds such as surround specimen shrubs on lawns; Muscari, several species, most effective when used like the Milla; Irises, Primulas, especially *P. Japonica*, one of the most beautiful of all spring flowers, and as happy in an English garden as the common Primrose. Species of Tulipa are employed for furnishing small beds, and they are, at least, as pretty in color-effect as the most brilliant of the common kinds. The garden is the most pleasant place in the world at this time of year—that is, a well-furnished, nicely arranged garden, wherein the birds come to live and sing all day, and the plants have some new surprise for us almost every morning. Eternal spring might not be delightful, but spring after the frost and smoke and fog of last winter is most enjoyable. When the sun shines long and warm the plants in the houses soon wake up and rush into vigorous growth, so that houses vie with the garden in the open air in interest at the present time.

At Kew there are many noteworthy plants in flower, and perhaps I cannot do better, this week, than enumerate some of the most interesting.

Amorphophallus campanulatus seems to have excited some American horticulturists recently, and it excites most people here, too, when in flower, for the fœtid odor of its large bell-like inflorescence is most repulsive. There are a dozen or more flowers of it open in the stoves at Kew, as well as plants bearing only the large umbrella-shaped leaves. The largest examples have a spathe about nine inches long and a foot across, and colored green, mottled with gray, except about the mouth, where the color is lurid brown; the large misshapen spadix entirely fills the centre of the bell and is colored dark brown.

Phyllocactus.—This genus of Cactus has at last found favor with some of the leading English horticulturists, and there is therefore a prospect of its becoming as popular in gardens as it deserves to be. Cacti are neglected because they are not known. Many of them lack the qualities essential in a good garden-plant, but there are also many which possess them to the fullest extent. Phyllocactus is a case in point; no plants are more easily grown, none flower more freely, while in size, form and richness of the color of the flowers they are as grand as Tree Pæonies. At Kew there is a large collection of kinds, and many of them are in flower now. There are crimson, scarlet, rose, pink, white and cream-yellow varieties, some as large as the flower of the Victoria Water Lily, others only a little larger than the Epiphyllums. The French and German growers have raised many beautiful kinds of Phyllocactus, but one of the best—namely, J. T. Peacock, which is a giant and of the richest colors—was raised in England by the man after whom it is named.

Cineraria cruenta and C. lanata (aurita) are charming plants in the greenhouse at this time of year. They have all the beauty and elegance of the best of the Michaelmas Daisies, and they are as easily managed as the common Cinerarias. The first-named is the progenitor of all the big-flowered popular varieties, which find universal favor, while *C. lanata*, so far as I know, has never altered in character since it was first introduced from the Canary Islands, nearly a hundred years ago. Its flowers are each about as large as a shilling, white, with mauve tips, and they are very fragrant. I recommend these two plants to every one interested in beautiful-flowered plants for the cool greenhouse.

Aristolochia Goldieana is again in bloom. It is a most extraordinary plant, the size and form of the flower being quite sensational. It would be easy for a man to hide his head completely in the upper part of the flower, which, in shape, resembles an old-fashioned Dutchman's pipe. As in the case of many other gigantic and wonderful plants this Aristolochia is a native of tropical Africa, where, in the region of Old Calabar, it was first discovered and sent to England by a missionary some twenty years ago.

Rosa simplicifolia has apparently become quite established in a cool sunny greenhouse here, where there are two large bushes of it in the most perfect health and flowering freely. Although never likely to become a popular garden plant, yet it is a most interesting Rose, the character of its stems, its monophyllous leaves, suggesting some species of Berberis rather than a Rose, and its small, deep yellow flowers being altogether exceptional among Roses. Probably the hybridist may be able to make something of it, for in habit it is a perfect garden plant, and its leaves are elegant and pretty in color, being a glaucous, almost silvery green.

Solanum Wendlandii.—This plant is now magnificent. It is certainly one of the very finest of large stove climbers, its habit being to branch freely, and on the end of every branch there is produced, in spring, a large cymose raceme of rich lavender-blue flowers. It appears to prefer a sunny, moist, tropical house where, if possible, it should be planted in a bed of rich soil. It will continue to flower all summer.

Streptocarpus.—These plants have sprung into popularity with a bound, a result largely due to the foresight and skill of Messrs. J. Veitch and Sons, who have taken them in hand and crossed and recrossed all the best of the varieties originated at Kew. This year the seedlings at Chelsea are a great advance on anything previously seen, some of the flowers almost equaling Gloxinias in size and colors, while the foliage is much more convenient than it was in the first hybrids raised. There can be no question now of the merits of this Cape genus of *Gesneraceæ*. The progress already made with them is remarkable, and if Mr. Heal, Messrs. Veitch's clever hybridizer, can go on improving them at the present rate, we may soon see Streptocarpus rivaling, if not eclipsing, Gloxinia itself.

London. *W. Watson.*

Cultural Department.

Notes on Shrubs.

FLOWERING Cherries and the flowering Crab-apples have blossomed unusually well in the vicinity of Boston this season, the Apples being particularly noticeable for the fullness of their bloom.

One of the very earliest of Cherries to blossom was the Chinese *Prunus tomentosa*, the seed of which was received at the Arboretum from the mountains about Pekin, China. It is a bushy little plant, which appears to be at its full size when from six to eight feet in height and with fully as great diameter. Its earliest blossoms this season began to open about the 20th of April, and at the same time the leaves were well advanced. As the flowers are sessile, or nearly so, and are partly concealed by the growing foliage, they are not so graceful or showy as those of some other species. Its fruit, however, gives

Fig 46.—Ravenea Hildebrandtii in Fruit. See page 256.

promise of usefulness, as the medium-sized, light red-colored cherries which it bears are of quite a pleasant flavor even in this wild state. The stone is rather large, but by cultivation and selection the size of the cherries could be increased, and small-seeded farms adopted and propagated by division. The extremely early-flowering habit has usually prevented a large crop of the fruit here on account of cold weather and frosts which occur at the time; but, otherwise, the plant seems perfectly hardy in a winter like our past one. Last year the plants appeared somewhat injured, although the winter was not considered nearly so severe and the cold was not so great. Apparently, the injury then was due to other causes besides cold alone.

There is so much confusion regarding the nomenclature of the ornamental Japanese Cherries which have been introduced into cultivation that it is almost impossible to know exactly what kind or form will be received when ordering from different nurserymen. There are two distinct types of these plants, and they appear to pass interchangeably under a dozen different names. Both are often considered by botanists as forms of the Chinese and Japanese *Prunus Pseudo-Cerasus*. Whatever their origin may have been, they are certainly quite distinct from a horticultural point of view. The earliest-flowering of the two opened its first flowers this season in the last days of April and first week in May, before any of the leaves appeared. These flowers are large and semi-double; the buds, or outer petals, are deep pink or red, and the opened flower pinkish white within, which soon turns to a distinct rose-color, that deepens with the age and fading of the flowers. The leaves come out when the blossoms are fading. They are of a very dark green color, tomentose above and beneath, the pubescence being very dense on the under side. This is the plant which, besides many other names, is often sold as *Prunus Watereri*. It is the most showy and ornamental of those introduced here.

The other form of these Japanese Cherries does not begin to open its blossoms until at least ten days after the first form, and when the latter one is in full bloom the blossoms of the early one have faded. The flowers of the late one are pure pearly white, with rarely the faintest suggestion of pink, but there is a variation with the outer petals distinctly rosy-colored. As the flowers fade they do not change to the dark rosy color of the other. The leaves are light green, and they are already large and well developed before the blossoms appear. They differ markedly from the other form in being perfectly smooth or glabrous on both surfaces. This form is not nearly so floriferous as the early-blooming kind, and, although very beautiful, its flowers are much hidden by the foliage. Among other names this is often sold as *Prunus Sieboldi flore albo pleno*, or *P. Sieboldi flore roseo pleno*, according as the blossoms are pure white or have the outer petals of a pink or red color. It is apparently the *Prunus serrulata* of Lindley.

These double-flowering Chinese or Japanese Cherries should not be planted with the expectation that they will become large trees, for, although they have the single-stemmed tree form, they do not attain the height of many of our native plants which are classed as shrubs.

Arnold Arboretum. *J. G. Jack.*

The Hardiness of Japanese Bamboos.

THE Bamboos, the noblest of all the grasses, have not only the merit of utility, but the growth of many varieties is characterized by such grace and distinction that they are among the handsomest ornaments of gardens and plantations. Lately much attention has been given to some of the Japanese varieties, among which may be found widely distinct habits, ranging in height from three feet to forty feet, and with foliage varying both in breadth and color. In a small state many of these varieties are useful, grown in jars, for in-door decoration—a use to which they are much put by the Japanese. Florists will find these useful additions to their stock of decorative plants, as they are not only light and graceful in effect, but they will help to break the monotony of the Palms. But their beauty is better shown when grown in large masses in the open air; where rightly placed, they have capabilities of striking effects in the landscape. *Bambusa Metake* has been long known in gardens and is of undoubted hardiness, but there are numerous Japanese varieties which are now obtainable, and many of them will be of great value if they prove entirely hardy. Most of these are said to come from the warmer parts of Japan, but I have been much encouraged, in testing a small selection of varieties last winter, to believe that many of them are hardy in this latitude, and require scarcely any protection. The varieties tested were planted early last spring, and, while apparently well established, they made no great vertical growth. They were in rather stiff loam, where no stagnant water could remain at the roots. They remained during the winter without any protection to the stems and with no mulch over the roots. Six of the seven varieties exposed passed the ordeal safely and are now making vigorous growth. There was, however, an apparent difference in their resistance to severe weather, but this may have been due to less-matured growths. The past winter was not extremely cold, the thermometer only once dropping to zero, but was a fairly average one as to temperature and moisture. They having lived through this without the slightest protection, there seems no reason to think that they will not pass safely through an exceptionally severe winter if the roots are well protected by mulching. It might also be well to provide wind-breaks, though the foliage of most of the varieties could not probably be preserved during an ordinary winter under any protection in this climate. Such varieties as *B. Ragamowski* may be an exception in this regard, since they have hard, firm leaves which would be retained if protected from scorching. *B. Simoni* also has persistent foliage. In detail, the varieties tested are given in the order of apparent hardiness.

B. Simoni, leaves quite persistent, and plant untouched. *B. viridi-glaucescens* and *B. aurea* lost their leaves, but the stems were untouched. *B. Ragamowski* had its leaves scorched. *B.* (*Arundinaria*) *quilioi* lost its leaves, and its stems were slightly touched. *B.* (*Phyllostachys*) *nigra* (Korochiko of Japan), top killed, but now pushing from the roots. This black-stemmed variety is said to attain a height of thirty feet, which would indicate more vigor than it has shown with me.

B. angulata (variety with knotty joints) was entirely broken up, root and branch, by the frost. *B. Castilloni* (Kimmeichiku of the Japanese) was grown in the house, but is apparently as vigorous as the hardiest ones. Bamboos do not often show their distinct characteristics before the second year, and should be planted in permanent quarters. They form thickets by pushing out horizontal short-jointed stems in every direction. These emit roots, and break at every joint, so that a well-established plant soon becomes the centre of a large clump.

Of course, as these plants grow tall, conditions may arise which would prevent their being hardy in this latitude. For instance, an exceptional winter might cut the top growth severely if not matured, but the root-action is so strong that there seems little doubt that the damage would be confined to the tops even in the worst seasons.

Elizabeth, N. J. *J. N. Gerard.*

Wild Flowers around St. Louis.

THE variety of wild flowers in this immediate section is interesting though much smaller than in New England. The species are repeated more than in the east, due to the sameness of the soil and situations. *Phlox pilosa*, now in flower, is a handsome species, hardly excelled by any other of the perennial class in the richness and variety of shades of its flowers, which vary from a pinkish purple to a rosy red, and occasionally almost white. It grows usually in tufts from ten to fifteen inches high. It transplants better than the other species, for, by taking plenty of soil with its roots, it may be moved when in full bloom without wilting at all. It will thrive in any ordinary garden soil. *Oxalis violacea*, though not very abundant, is common here, and the flower is rich pinkish purple or violet-tinged. It is not very lavish in blooming, and one seldom sees more than two at one time on a stem, and I have never noticed more than one stem to a plant. It grows in thinly shaded places. The Dwarf Larkspur (*Delphinium tricorne*) has been in flower here for more than a week. It is, I believe, the first of the perennial Larkspurs to bloom. Though quite common in thin woodlands it seems to be nowhere abundant. It seldom grows over a foot high, bearing at the summit of its almost naked stem a flat spike of six to ten bluish purple or sometimes white flowers, which are a little more than an inch wide and alternate on either side of the radix of the spike. It bears transplanting well, and when in flower is an attractive plant. The spikes are borne on ample stems for cutting, and should be useful in making bouquets.

The little white-flowered variety of the Blue-eyed Grass (*Sisyrinchium Bermudianum*, var. *albidum?*) is common here in some places. It grows about a foot high, and bears in a cluster near the summit several pretty white flowers, with a yellowish centre, half an inch wide. Its stems are ample for cutting, and it is certainly a plant worth cultivating.

If there is any one plant that seems to thrive here better than the average it is the May Apple or Mandrake (*Podophyl-*

lum peltatum). It can be found in almost any thinly shaded location that is not wet, and makes a very strong and healthy growth. Unlike most plants, it seems to be avoided by cattle and other animals, for it is in the pastures and fallow fields that it thrives best. In pastures, where the cattle had eaten off nearly every green thing, and where hogs had dug over a good portion of the ground around them, I have seen large thrifty patches of this plant untouched.

There are few of our native perennials more attractive in their natural homes than the Spiderwort (*Tradescantia Virginica*), which is quite common here. It is smaller than in cultivation, and, though it is a valuable plant in our gardens, it seems to lack the charm that it has in the woods. Its rich blue petals, golden yellow stamens, and dark green sepals and leaves are a pleasing combination of color. The ten to twenty flowers which are borne on a stem do not open at once, but come in long succession, and prolong the flowering season. *Cynthia Virginica* is also common here, and is just coming into flower. It selects the shade in this region, though when cultivated in New England it seems to prefer the full sunlight.

Botanical Garden, St. Louis, Mo. *F. H. H.*

Succulents for Bedding.

IN certain locations a bed filled with plants of a succulent character may be used with good effect, notwithstanding the stiff and formal habit of growth common to so many plants of this class. But, while of formal appearance, there is yet great variety of form to be had in the various genera usually considered under this heading, and, by a proper admixture of types, a very pleasing result may be attained. Among the plants so used are some of the Euphorbias. *E. Canariensis*, *E. grandidens*, and *E. hystrix* are all odd-looking plants, with leafless, or comparatively leafless, stems that are stiffly branched like some of the Cereus. The first two species are unarmed, while *E. hystrix* is ornamented with long spines. It should be remembered, however, that all of the Euphorbias are more or less poisonous, and consequently some care should be taken to avoid getting any of the sap from these plants into a scratch or sore on the hands.

Almost any of the Cereus also may be used with good effect in the succulent bed. Moderate-sized specimens of *C. giganteus*, *C. flagelliformis*, *C. serpentinus* and others are recommended. The Agaves, of course, should be well represented. The familiar *A. Americana* and its variegated varieties are all desirable plants for this purpose, the latter especially so. *A. filifera* is another good species, and has the advantage of being quite a moderate grower. The leaves are six inches to one foot in length, and from one to one and a half inches in width, gradually tapering to the usual terminal spine; they are dark green in color, the edges being gray and more or less ornamented with gray threads, from which it receives its specific name. *A. schidigera* is another handsome species and of somewhat similar character to the last-named. *A. appalanta* is a striking species, and has rather broad leaves of bluish green color, edged with brown and terminated with a long brown spine. *A. horrida* is a distinct type with numerous bright green leaves with gray borders; both the margins and tips of the leaves are armed with sharp spines. Several varieties of this species have been named and distributed, and, in common with the whole family of Agaves, are well adapted for out-door use in summer.

For filling in and carpeting among the larger plants some small-growing species are necessary, it being essential to the appearance of succulent beds that they be filled moderately close; the slow-growing character of most of these plants is well known, and for this purpose there is nothing superior to the Cotyledons, or Echeverias, as many of them were once known. Of the Cotyledons there are several that deserve special mention, among them being *C. secunda glauca*, *C. Mexicana* and *C. Peacockii*. All of these are small growers and of compact rosulate form, and are therefore among the most useful. For variety, *C. agavoides*, which grows somewhat like a small Agave, and *C. metallica*, with leaves of a peculiar combination of purplish metallic tints, and about six inches in length and also in breadth, may be considered, while for distinct character and pleasing effect *C. orbiculata* is one of the best. The latter is of moderate growth, and has nearly round fleshy leaves that are thickly covered with white farinose powder. *Cotyledon lurida* and *C. Pachyphytum* are also interesting species, the latter being formerly known as *Pachyphytum bracteosum*.

Kleinia repens is an old plant that may also be used effectively in the class of bedding referred to. It has thick fleshy leaves of a bluish green color, covered with a glaucous bloom, and the plant is of dwarf-branching habit. As an edging some of the Houseleeks are useful, the tiny *Sempervivum arœnoideum*, with its web-covered rosettes of leaves, being a pretty variety for this purpose, as is also *S. calcareum* and *S. fimbriatum*.

Holmesburg, Pa. *W. H. Taplin.*

Points of Merit in Asparagus.

THERE has been a good deal of discussion as to whether this vegetable should be blanched or green, and some, claiming that blanched shoots only are really fit to eat, refer for proof to the long, tender and delicious shoots served up in France, where only blanched Asparagus is used. Others say the brown or blanched portion is always tough, woody, and flavorless, and only the green portion should be used; that we must never cut or break below the surface. We think a little consideration of how the plant grows will disclose the cause of this difference of opinion. The young shoots of Asparagus expand and elongate very fast at first, but with decreasing rapidity. The hardening or development of woody fibre commences at the base of the shoot and extends upward, slowly at first, but with gradually increasing rapidity until it overtakes the elongating point about the time it breaks into branches, and the entire shoot becomes hard and inedible.

An Asparagus-shoot, or bud before it becomes a shoot, is woody at the point of juncture with the collar from the first, so that if we cut it at the collar when it is ever so small the lower part will be woody and tough, and we shall have to cut it at a proportionately greater distance from the collar, as the shoot elongates, to avoid this woody portion; so that, if we plant shallow and cut much below the surface, we shall always have woody butts, and to avoid them we cut above ground and have green and tender shoots. If, however, we plant deeply (or better still, follow the French method and plant shallow and thin, during the cutting season banking up over the plants with light, friable soil, or other suitable blanching material) we may have long, perfectly blanched shoots, but far enough from the collar to insure tender blanched asparagus without woody butts. The secret is, cut your shoots at a distance from the roots proportionate to their age.—*Professor W. W. Tracy, before the Michigan Horticultural Society.*

Vegetable Garden Notes.

AMATEUR gardeners often wait for what they call a favorable season to transplant vegetables. After a hard summer rain they hasten to get plants and set them in the muddy soil. This is bad practice, as men of experience know. Plants should not be set immediately after a heavy rain, while the soil is soaking wet, for the packed earth hardens in the sun and bakes into a dry cake about the roots of the plants. If planted just before a rain, they would have taken hold at once. But we cannot select a day before the rain with any certainty. It is safer always to transplant when the soil is moderately dry. Have the plants in a bucket of water, to keep them fresh, make holes large enough to contain the roots without crowding, let an assistant fill the holes with water, put in the plant, then fill the hole with earth, press the soil closely about the roots and cover the surface—that is, mulch the plants with dry earth. In this way the ground will not bake, and the growth of the plants will be unchecked. Tomatoes and Sweet-potatoes particularly need this treatment.

I gathered a beautiful crop of little pickling onions on May 21st. These were sown in February and are now fully ripe, and the ground is free for other crops. Of course, this is earlier than they can be had at the north, but I mention it to note the fact that even at the north a crop of these little Queen Onions can be grown in time to use the ground for late Cabbage, Salsify, Beets or Carrots. Sown at the same time with these the Giant Rocca Onion is still growing, and will probably keep on growing all summer. For family use we prefer the Queen Onion for all purposes. Those grown early will not keep, but we can sow them here in September and let them remain for use all winter where they grow. At the north this Onion will mature a crop if sown early in August.

We are much pleased with the Parker Earle Strawberry from one season's trial. Hoffman is still here the earliest good berry. Cloud is nearly as early, but is small, soft and worthless. Bubach No. 5 lacks productiveness, but is a fine spring sort. Jessie is early, large and good; our market-growers are planting it largely. We have a promising number of seedlings at the station, but, of course, nothing will be done with any of them until tested at other stations.

A Grape called Winchell was sent to us this year with the statement that it is the same Grape that has been sent out as "Green Mountain." We planted it alongside the Green Mountain received last year. So far it differs widely in the appearance of its foliage from the Green Mountain.

Experiment Station, Raleigh, N. C. *W. F. Massey.*

Syringa pubescens, of which a figure was published in these columns (vol. i., page 415), is one of those plants which improve with age. The large plants in the neighborhood of Boston, raised in the Arnold Arboretum from seed sent by Dr. Bretschneider from Pekin, have flowered better this year than ever before, and have proved that this species is one of the most beautiful Lilacs in cultivation. The individual flowers are not large, and the clusters are smaller than those of the other species; they are produced, however, in the greatest profusion, and quite cover the branches. The flowers are at first a delicate rose-color, but, before fading, become almost white; they are deliciously fragrant. *Syringa pubescens*, which must not be confounded with the plant sometimes cultivated in European gardens under that name, but which is really the *Syringa villosa* of Northern China, and probably identical with the Himalayan *S. Emodi*, is perfectly hardy even in our most severe climates, and nurserymen will do well for themselves and for the public by placing it within reach of all planters of hardy, handsome-flowered shrubs.

An Abundant Rust.—The well-known and destructive orange rust of the Blackberry (*Cæoma nitens*, Schw.) is very abundant this season. Specimens have been received at the station from various parts of the state, and during a recent trip through the south it was observed in many places. It is a showy rust, and the fungus not infrequently gave a decided orange color to the infested areas. This rust is one of those that penetrate all portions of the plant and live within the tissues from year to year. When new shoots and leaves form, it quickly spreads from the old parts and shows itself in countless yellow spores, usually in large blotches upon the under side of the leaves. On account of its perennial nature, it is difficult to eradicate this pest by spraying, and the best method is to remove the diseased plants, roots and all, and burn them. As the rust spreads from plant to plant by means of the spores, spraying, if done at the right time, would tend to prevent the spread of the rust.

Correspondence.

Bermuda in May.

To the Editor of Garden and Forest:

Sir,—It is not surprising that the genial climate of Bermuda should attract so many winter visitors from our northern states. A sea-voyage of less than three days, and one which a fast steamer might easily make within forty-eight hours, suffices to bring them to shores that are green the year through, and yet to an air so equable that the fervors of the summer sun are rarely oppressive or enervating, because the heat is so constantly tempered by breezes from the sea. The change in the political and social atmosphere is quite as striking, for the American citizen will suddenly find himself in a loyal English colony where even the negroes—perhaps the most active and intelligent specimens of their race to be found in all the world—speak with a perfect English accent, where fleet or fortress is forever in sight to manifest the imperial power of Britain, and where a large proportion of the men one meets on the street wear the uniform of her army or navy.

The great mass of those who flee to Bermuda to escape the rigors of winter return in April, so that the impressions one receives from a flying visit in late May may be worth recording. The islands are not at their best until June, it is said, and, perhaps, the time is not far away when this will be a favorite haunt for the summer tourist from New York, who could hardly find elsewhere a week or a fortnight of rest and change so perfect and so convenient as that furnished by a trip over cool seas to these breezy islands.

One need not expect any touch of the sublime in the landscapes here, for it would not be possible to crowd many natural objects which inspire awe by their vastness or sublimity within a long and narrow chain of islands containing altogether an area of some twenty square miles. But the land, what there is of it, is pleasantly diversified in surface, rising at one point to an altitude of some 200 feet; and the ever-present sea of itself suffices to insure every wide prospect against the charge of being tame or commonplace. One charm of the sea, by the way, is its marvelous and indescribable color, for the water over these coral reefs outrivals the azure of the sky in the richness and depth of its blue. There are occasional inland views where, in happy valleys, the sea is shut out of sight by encircling hills, and here, at times, one is reminded of New England, with roads winding along Pine-woods with an undergrowth of Ferns. No Pines are here, it is true, but the Bermuda Cedar, at a little distance, constantly suggests the Pine, and on a nearer view it shows so close a relation to our common Red Cedar that there is nothing strange or unfamiliar in its presence, although the species is confined mainly to these islands. When Juan Bermudez, nearly 400 years ago, was feeling his way along the treacherous reefs which surround them, he saw the islands covered with forests of these trees, which then attained to stately proportions. These forests have been cut and re-cut since, and yet they form the most conspicuous growth upon the island to-day; indeed, the larger proportion of the surface seems forest-clad, for wherever the land is left to itself the Cedar "comes in." It would be naturally supposed from the shiploads of onions and potatoes that reach our markets from Bermuda in the spring that every rod of the scanty territory was under plow or spade, but the visitor's first surprise, and one from which he can hardly recover during a brief sojourn, is, that he rarely finds these articles of export growing in large fields—indeed, an acre would pass for a considerable plantation here—but generally in little pockets a rod or so across, where the red soil is deep enough to furnish root-room for the plants, while all about them the rock is thinly covered or thrusts its massive shoulders quite above the ground.

Next to the forests, clothing the hills which slope toward the shore, one who for the first time sails in sight of them through the tortuous channel which leads to Hamilton is struck with the white houses which nestle in their foliage. These are all built of the light friable limestone of the island, which is so soft that it can be readily sawed into blocks. Even the roofs are made of thin stone plates, and the whole building is whitewashed till it glitters. In spite of this shining color the houses have no staring or obtrusive effect, but being substantial and low they only serve to deepen the color of the green about them, making the landscape more cheerful and investing it with a more home-like and human interest.

Once on the land, the roads are among the first objects to invite attention. Very few level acres can be found on the islands, but these old highways adjust themselves most graciously to the contour of the hills and the curving of the shores, winding in and out apparently without purpose or direction. But in so small an area there is little need of railway directness, and one is glad to lose a little time in travel where there is so much of it in a day. At every turn there is a changing prospect, a new arrangement of sea and shore, of cliff and dell, of Lily-fields and Oleander-hedges. Broken pieces of the soft stone spread upon the road-bed at once pack into a smooth surface over which a wheel delights to roll, and its gray tone blends most happily with the prevailing colors of the landscape. And then the fences, which generally are objects whose ugliness needs some excuse, are here a positive ornament. They are walls constructed of the same sawed-stone blocks and cement which are used in all the island architecture, and they would stand for a century here, where there is no frost to heave them, unless they should chance to be crowded over by the roots of some pushing tree. They seem to have been built along the roads generations ago when slave-labor was abundant, standing everywhere square and firm—now as parapets along the brow of some cliff whose base is beaten by the sea, and again as retaining walls against the face of some cutting—usually bare, gray and honeycombed with age, but often draped and garlanded with Maurandya and other vines, or overhung by huge masses of Cactus. They are always picturesque, and, like all solid, hoary and weather-beaten structures, are agreeably suggestive of antiquity. These, then, are the leading features of the landscape which are permanent: a narrow stretch of land, with a rolling and often a rugged surface; bold shores surrounded by a sea of an unspeakable blue; open fields with scant, coarse grass, which leaves them rather brown than green; forests of Cedar with blue-gray foliage; snow-white cottages and a web of roads in a close net-work, uniting with each other at every conceivable curve and angle. Over all hangs a translucent atmosphere which dims the distance, mellows the outline of objects nearer by, and softens away the glare of every intense color. Very beautiful and impressive are the shifting combinations of these simple elements under such a sky.

The efforts of the Bermudians in the past to improve the scenery by planting do not seem to have been as successful as one could wish. So many treasures for gardens in such a climate could be found by searching that one marvels at the scanty catalogue of materials used in the most elaborate places, and yet the gardens are by no means devoid of interest or beauty. Just now the most conspicuous of plants is the Oleander, which grows and spreads with such persistence that many of the islanders count it a nuisance. To a stranger, however, there are few more attractive objects than the great mass which ultimately forms from a single parent stem in rich soil. These are often twenty feet high, with branches arching to the ground in a circle whose diameter more than equals the height—green mounds starred all over with bright flowers which range from pure white through shades of pink to almost crimson in some cases. All that is needed to start an Oleander-hedge is to place a row of cuttings in the ground, and one often sees a broad belt of these plants extending entirely around the boundary of some estate. The Chinese Hibiscus is, perhaps, next to the Oleander in abundance, and it seems equally luxuriant. In many places these plants are sheared into formal hedges, and the great flowers open on the smooth face of this verdurous wall as freely as on the plants which are left to develop into fair-sized trees. *Tecoma Capensis* is another plant which is largely used in hedges, and, just now, it is brilliant with orange-colored flowers, while *T. stans*, one of the most beautiful of yellow flowering shrubs or small trees, is at the height of its bloom. The Tamarisk, here as elsewhere, shows its sturdiness against the salt-laden gales of the sea-coast, and has been planted very largely and with good judgment in exposed places on the shore. The gorgeous blooms of *Poinciana regia* had not yet appeared, but its relative, *P. pulcherrima*, was growing and blooming everywhere. Occasionally fine masses of Bamboo are seen, and these, with the native Palmetto (*Sabal Blackburniana*), the ever-present Banana, and some of the hardier Palms, are the most distinctly tropical features of the scenery, although the Poinsettias, Pomegranates, Bignonias (especially *B. pentaphylla*, known here as the White Cedar), the so-called Sand-plant, *Erythrina speciosa*, with brilliant scarlet flowers on bare branches, and large specimens of the India Rubber-tree wear a strange look to northern eyes. Of course, this is not meant to serve as a complete list of the garden plants of the island, but only to recall those which were sufficiently conspicuous at this season to impress a casual visitor. Space would fail to mention the striking individual plants, like the two fine "Gru-Gru" Palms (*Astrocaryum aureum*) at Mount Langton, but Roses ought not to be omitted, for, although our hardier kinds do not flourish here, those with some blood of the Teas or other tender strains, like Lamarque, for example, were bearing fine flowers in profusion. In the Governor's grounds a superb specimen of *Rosa bracteata* showed that the soil and climate were well adapted to this beautiful species.

How readily some plants will become naturalized when they find favorable conditions is shown by the case of one of the Jessamines (*J. gracile*) which was brought to the islands in 1840. It soon escaped from cultivation, and now it is clambering over the rocks and making an almost impenetrable tangle in the woods of a broken region near the famous Walsingham tract. It is a delightful vine with glossy and fragrant white flowers, and it seems strange that more general use has not been made or it. It would make a charming addition to the landscape if allowed to clamber over the walls along the highways. Occasionally one sees a European Elder, which grows here with great vigor, and is always a beautiful tree. The islanders seem to have caught the European habit of setting it close to the sides of their houses, and it shows to great advantage against their walls. This masking of the house-foundations with shrubbery, however, is no more generally practiced than it is in the United States, but these stone houses would seem to offer excellent opportunities for making such connections with the earth. By one cottage along the road which winds about the north shore stands a pair of Agaves close to the front wall, one on either side of the entrance of a narrow loggia, and the sharp stiff leaves against the white stone produce an effect that no one who drives by them will forget.

All the world knows how extensively the bulbs of the great Easter Lily are cultivated here, and the more beautiful old Ascension Lily, *L. candidum*, flourishes equally well, while Hippeastrums (Amaryllis) and Freesias grow like weeds. At many seasons the fields are brighter than the gardens, but Bermuda is a land of flowers at all times. Our northern states in late May are so attractive that one hesitates about leaving them even for a short absence. But when a few hours can land us amid the vegetation of the tropics, under a new sky and encircled by a strange sea, the change will prove a pleasing one, and the return will bring a keener appreciation of the rare loveliness of our northern spring.

New York. *S.*

Dionæa muscipula as a Window-plant.

To the Editor of GARDEN AND FOREST:

Sir,—One of your correspondents has recently written of the Rattlesnake Plantain as a window-plant, and perhaps some experience with the little Venus' Fly-trap (*Dionæa muscipula*), also as a window-plant, may prove of interest. Early last March five melancholy little plants were given to me by a friend to whom they had been sent from their native haunt near Wilmington, North Carolina. I planted them in a deep pot, which I set in a dish of water in a sunny window. They drooped for a while, but soon became acclimated, and began to send up fresh leaves and long straggling flower-stalks amid a flourishing crop of grass and Chickweed. Beyond giving them plenty of water, little attention has been paid to them, and now my Dionæas are in fine condition, blooming well and exercising their insect-catching propensities to the best of their ability. It was hard to understand how the apparently thin, delicate, little leaves could catch flies nearly as large as themselves, but they certainly do hold them with a murderous grasp. Once I tried to help the plants, and after some trouble caught an unusually large fly, and with a pair of forceps held the tempting morsel between the two valves of a leaf. They very promptly closed on the poor fly, who struggled in vain to escape. Since then my plants have been a daily source of interest, though I let them pursue their insectivorous habits without further help from me. Their leaves are mostly over three inches long, including the curious blade-like stem; the flower-stalks are eight to ten inches tall, and bear at the apex a small cluster of buds and flowers. The latter are about an inch across when fully expanded, the five white petals almost transparent and very delicately veined, and the fifteen fluffy little anthers are light yellow on slender white filaments.

It is a pretty little plant, and certainly a most original and amusing one to watch.

New York City. *Anna Murray Vail.*

Recent Publications.

The New Potato Culture, by Elbert S. Carman. The Rural Publishing Company, New York.

For a dozen years or more Mr. Carman has been making experiments in hybridizing and cultivating potatoes, and in this volume he has collected what he considers the most important results which seem to be demonstrated by his tests. What he claims primarily is, that potatoes should be planted in a trench—say ten inches deep and as many wide. So far as can be gathered from a rather diffuse explanation of the method, the practice advocated is to loosen the bottom of this trench, fill in some five inches of soil, and on this mellow bed to drop the seed-pieces, say a foot apart, and then fill in the remainder of the soil and give level culture. It is claimed that the trenches conserve moisture, which is essential to a good crop. The deep planting also encourages the formation of tubers in two or three planes or tiers, one over the other, so as practically to increase the area of the field by growing one crop above another. The plan also offers some convenience for the application of fertilizers. No doubt, in some soils the trench system would pay well, although it may be questioned whether any revolution in the general method of cultivating the potato is at hand, as the title of this book would seem to indicate.

Many interesting trials with various so-called chemical fertilizers are here recorded—trials made to ascertain the proper proportion of the various elements of plant-food, and the best time and place for their application. All such experiments are indecisive, on account of the small area occupied in the test, the varying conditions of different seasons, and the short time during which they have been conducted. Still they afford valuable hints to the thoughtful cultivator, and they ought to encourage additional experiments on a larger scale in many different soils and climates. Many instructive directions for producing new seedling varieties are given, as well as for the preservation of potatoes during winter, the amount of "seed" to be used, for improving varieties, for mulching, and so on.

The book lacks methodical and systematic arrangement, but a very complete index goes far toward correcting this fault, and Mr. Carman's careful and long-continued studies deserve grateful recognition.

Notes.

It is claimed that Castor-beans grown in California average three times the size of those grown in the east.

The Rhododendrons in the Central Park have never been finer than this year. They were at their best about the 25th of May, when the glen at the north end of the Park was a beautiful sight.

A Washington correspondent writes of the beauty of some fine specimens of *Cladrastis lutea*, or Yellow-wood trees, in the Capitol Park. They have a symmetrical form, with clean bark, smooth twigs and rich green foliage, and are now in full bloom, bearing graceful racemes of snowy pea-shaped blossoms, which have a delicate perfume.

The Horticultural Society at Elizabeth, New Jersey, recently offered a package of China Aster seeds to any girl or boy who would apply for them and agree to grow and enter them for competition at the exhibition to be given in September. Over 500 packages have been distributed. This incident contains a practical suggestion for individuals and societies.

A long-continued blooming season is certainly a great recommendation for any plant used to ornament public parks. None is more remarkable in this respect than the Moss-pink. Early in April its flowers began to unfold in the Central Park; by the 20th of the month they were in full bloom, and on the 25th of May the wide mats they form had not yet wholly lost their rosy color.

A new species of Lilac, discovered in Thibet and western China by Prince Henry of Orleans and his companion, Monsieur Bonvalot, is described by Bureau and Franchet under the name of *Syringa tomentilla*. Its affinities are with *Syringa pubescens*, from which it differs in its longer and narrower leaves, pubescent especially on the lower surface, and by the nearly entire calyx.

The most conspicuous blossoms in the Central Park, after the Forsythias, the Lilacs, the Wistarias, the Judas-trees and the Dogwoods had had their day, were those of the many species of Spiræa which, in every direction, spread their close white clusters. Fortunately the park authorities do not think it needful to "trim" shrubs like these, and the wisdom of leaving them to their own graceful inclinations must have been apparent to every one who noticed how beautifully their long branches drooped toward the grass, uniting the verdure of the ground with that of the shrubberies above.

According to the *Brick, Tile and Potteries Journal* successful experiments have been made at the Technological Institute, in Charlottenburg, Prussia, with regard to the use of sawdust as a building material. Mixed with certain refuse mineral products the sawdust is compressed into excellent bricks, which are very light, are impervious to moisture, and are uninflammable even when brought into direct contact with flame. The same journal says that a French writer recommends the use of sawdust instead of hair for mixing with mortar, the special combination named being two parts of lime, five of sand, one of cement and two of sawdust.

A correspondent writes from Manchester, Massachusetts, for information as to the best methods of protecting apples against various insects. Different remedies are needed for different attacks, but just now it is good general practice to spray the trees with the Bordeaux Mixture, containing in addition Paris Green at the rate of one pound to 200 gallons of the mixture. This will prove useful against the Apple-scab as well as against insects. Bulletin Number 13, just published by the Massachusetts Agricultural College Experiment Station, contains an admirable summary of practical directions for the preparation and use of remedies against insects and fungi injurious to fruit.

A circular recently issued by the Forestry Commission of New Hampshire might well be imitated by similar bodies in other states. It invites the people to give facts and suggestions regarding fires in the forest; to note the places in mountain regions where new roads and paths are needed; to record the effects of denudation on the volume of water in the rivers and streams; to point out views of unusual beauty or natural objects of scientific or picturesque interest, access to which has not yet been rendered easy; and to report upon the value of timber-lands as investments, as well as upon any new or unusual uses to which timber or other forest-products are being put by manufacturers. If the people of the state generally respond to these invitations, a mass of very interesting and ultimately beneficial information will unquestionably be collected.

In his "Common-Place Book" Southey quotes from Pierre Huet, a French critic of the seventeenth century, a passage which proves that the garden roller was not then, out of England at least, a familiar implement. Writing of the garden of Lord Paulet, at Hinton, St. George's, Huet says: "It is very different from the common style of English gardens. These are usually walks of sand, made perfectly level by rolling them with a stone cylinder, through the axis of which a lever of iron is passed whose ends, being brought forward and united together in form of a triangle, serve to move it backwards or forwards, and between the walks are smooth grass-plots, covered with the greenest turf, without any other ornament." The garden of Lord Paulet, we are then told, "is a meadow divided into several compartments of brick-work which are filled with flowers."

A writer in the *Sun*, of this city, recently remarked, that in spite of the attitude taken by certain prominent men toward the multiplication of railroads in the Adirondacks, "the feeling against them is intense and almost warlike in the hearts of thousands who have seen the woods before and since railroad building began there. 'In 1884,' said one New Yorker, 'I entered the woods below Malone, and fished and hunted through a great reach of as absolutely wild forest as I ever saw. Fish and deer were plenty, and wild nature was luxuriant. Three years later I went there again. The whole area where I had hunted before was waste and bare—all burned over and desolate. A great sand desert was one feature of the country, and the rest was a litter of blackened stumps. Miles of the forest had been irrevocably destroyed, for not even time can replace the original woods. That was what followed the building of one little railroad in the Adirondacks.'"

No single plant does more to ornament the Central Park than the Wistaria. On the many arbors and shelters over which it is trained its spring display of blossoms is enchanting, while after these have fallen its thick, yet graceful, foliage forms an impenetrable canopy of shade without producing too heavy an effect. But if less useful, it is perhaps still more beautiful where it has been planted close to isolated trees and allowed to twine itself among their branches. When the tree is a conifer the contrast of its stiff and dusky green with the paler green and the lilac blossoms of the creeper is perhaps a little too pronounced. But on deciduous trees the Wistaria often combines with its support in a manner as harmonious as it is striking. A most beautiful instance of such a combination could be observed a week or two ago on the East Drive, near the Seventy-second Street entrance, where a Linden of moderate size and symmetrical growth was completely covered with Wistaria, yet so loosely draped that its development had not been hindered and the character of its own leafage could still be seen. From its lowest branches to its topmost twigs it was thickly hung with the fragrant lilac clusters, so that it wore the aspect of a gigantic bouquet composed of flowers and of two kinds of foliage; and this aspect it preserved for many consecutive days. In another part of the park the same plant displayed itself in a different, but almost equally charming, way. Here an arbor runs at right angles to the drive, opening directly upon it between closely flanking trees and shrubs. The Wistaria that had been planted to cover this arbor had spread over the trees as well, so that one saw an archway, apparently composed entirely of flowers, supported by masses of green, over which the blossoms were more loosely spread.

Catalogues Received.

Dr. L. P. Britt, 37 College Place, New York, N. Y.; Britt's Automatic Safety Bit.—Wilfred A. Brotherton, Rochester, Mich.; Catalogue of Michigan Wild Flowers for Parks, Gardens, Bogs, etc. List of Plants for Carp Ponds. Also, Wholesale Trade List of Michigan Wild Flowers, Trees, Shrubs and Ferns.—Dammann & Co., San Giovanni a Teduccio, near Naples, Italy; Wholesale Catalogue of Bulbs, Roots and Orchids.—F. W. Devoe & Co., cor. Fulton and William Sts., New York, N. Y.; Catalogue of Artists' Materials.—Wm. Baylor Hartland, 24 Patrick St., Cork, Ireland; Daffodils for the Trade.—L'Horticulture Internationale, Brussels, Belgium; New Orchids, Established Exotic Orchids, Nepenthes, Ornamental Plants for Conservatories and Winter Gardens, Palms, etc.—A. W. Livingson's Sons, Columbus, Ohio; Vegetable and Flower Seeds.—Pitcher & Manda, The United States Nurseries, Short Hills, N. J.; Descriptive Catalogue of New and Rare Plants. Also Price List of Hardy Perennials, including Alpines, Aquatics, Orchids, Ferns and Small Shrubs.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, JUNE 10, 1891.

TABLE OF CONTENTS.

Railroads in the Adirondacks.

THE failure of the last Legislature of this state to provide for a forest-reservation in the Adirondack region has been followed by an energetic effort on the part of several railroads to build lines across the entire region. The sudden interest which has been aroused in the question of forest-preservation by the efforts of these railway companies to secure the right of way across the lands which now belong to the state is somewhat surprising, in view of the fact that so little effective work has been done hitherto toward protecting these woods from other encroachments of this sort. If the proposal to set aside a portion of these elevated forest-lands for public use had been a novel one and there had been no time to arouse popular interest in the necessity of such a step, we might infer that the great organs of public opinion in the state had just awakened to the fact that there was such a forest and that it was in danger. But the truth is, that it is now twenty years ago since a commission was appointed, with the Hon. Horatio Seymour at its head, who were directed to "inquire into the expediency of providing for vesting in the state the title to the timbered region lying within seven counties designated, and converting the same into a public park." Even then it was reported by these commissioners that the land of this vast region, once owned by the state, had been largely conveyed away to purchasers who had bought it for timber and bark, excepting a tract of a quarter of a million of acres which had been transferred at the price of five cents an acre to the Sacketts Harbor and Saratoga Railroad Company. It was stated, too, that the small fraction of the territory still held by the commonwealth was in detached parcels, amounting in all to less than 40,000 acres.

At that early day much of the land had been stripped of its timber and had been abandoned by the owners after this had been removed, because it was not worth to them even the taxes due on wild land. In this way great tracts were sold for arrears in taxes and left in the possession of the state as not worth these claims until the lands lying under such condemnation had again been covered with timber enough to make them desirable when they were again bought from the state, to be again abandoned when stripped of everything valuable upon them. Of course this process has been continued ever since. The magnificent Hemlock forest has fallen before the demands of the tanneries along the eastern, southern and western borders of the wilderness, and the timber, after the bark was stripped from it, has been left to perish. Where the lumber has been cut away the remaining wood has been consumed in charcoal kilns or worked up into paper pulp or destroyed by fire.

Railroads have already done their share toward helping on this desolation. The forests along parts of the Chateauguay Railroad have been transformed into a literal waste. The destruction has been absolute and utter; the very stumps have been burned out, together with the humus which had accumulated from a forest-deposit of thousands of years, until no green thing has escaped, and there is no hope of future growth to cover the scorched ground and fire-cracked rocks. Not only does such a road furnish an opportunity for the speedy carrying away of all marketable lumber, but it makes profitable the conversion of all the remaining wood into charcoal, so that every particle of verdure within reach is obliterated. This is a universal law, for what is true of the desolation along this Chateauguay road is true, and worse, if possible, along the other railroads which have penetrated the forest. All this ruin has been going on for years, and the people of the state have taken no effective measures to arrest it. Perhaps the present torrent of discussion means that all the work which the friends of the woods have been doing for years in the way of protesting and educating the people to an appreciation of their value has at last begun to bear fruit, and if so, this must be counted one of the few encouraging signs of progress toward a proper treatment of our natural resources.

It is true that the Reservation Act passed some years ago gave fair promise of greater security to the woods, but, somehow, the commission appointed under it failed to inspire the public with confidence, and although it is claimed that they have done much to prevent trespassing on the state land, the people's park seems as far away from accomplishment as it was when they were appointed. The last activity of the commission, however, has borne some fruit. They have taken steps to prevent a railroad from crossing the lands already in possession of the state, and in the conflict which has followed the Attorney-General has given an opinion which, if sustained, will prevent the building of any line over the state lands in the Adirondacks without special legislative enactment. If this opinion is sound law, it follows that the other railroads which are now built on state lands must be driven out as trespassers. Even this, however, may not prevent the consummation of the most ambitious of these new schemes, for it is asserted that a railroad can be built across the forest for its entire width and keep on private property all the way.

Of course, the success of this plan would be a public calamity. We are aware that the projector of this road is himself a large forest-owner, and we have no reason to question the sincerity of his intention to hold this vast property in forest forever. But, even if it is admitted that this would be possible during his life-time, it must not be forgotten that the permanent preservation of a forest can never be assured until it is under the control of an undying owner. All experience has proved that forests are never safe so long as they are held by private owners. The time must soon come in their history when they are transferred to alien hands and when it will become the absolute duty of some one who has them in charge to realize the greatest immediate

money return which it is possible for them to yield. The forest, then, is doomed to fall; and when that crisis comes to this particular forest, the railroad which pierces it through will make its destruction easy, certain and complete. There is no permanent safety for the Adirondacks until it is owned in fee-simple by the state, and even then it will never be free from attack until the people of the state have been educated to realize its paramount public value.

Of course we appreciate the truth that there should be a steady income from a permanent forest; that such a utilization of its products will not depreciate the value of the forest as a reservation; that, indeed, the forest will be safer for yielding an income, and that to yield an income there must be facilities for removing timber. But it is quite possible to accomplish this by a system of narrow-gauge gravity roads through the tract, together with timber slides and such other appliances as lumbermen of the present day are familiar with. Even if one or more first-class railways through the woods would make such transportation easier and cheaper, their simple presence would destroy the essential value of the Adirondacks as a resort for rest and recreation. The fundamental charm of this region is its remoteness from the great lines of travel and disturbing human activities. If the woods were crossed and recrossed with railroads, settlements would spring up at their intersection, the deer would be frightened from their ranges, the fish in the streams and lakes would be caught for city markets, and the wildness would be chased away with the game. The place would still have attractions, but it would no longer be a wilderness. It would be a commonplace collection of mountains and woods and lakes, with the ordinary conditions of work-day life forever in sight. The strangeness and romance would all vanish, and with them the temptation to tent-life in the presence of untamed nature. It will be hard enough, even under the most favorable auspices, to save the woods with all their suggestions of remoteness and separation from the ordinary conditions of life, but it will be absolutely impossible to do so if railroads are allowed to penetrate them.

A Fountain at Potsdam.

THE picture on page 271 shows part of the façade of one of the minor palaces at Potsdam, near Berlin, and the fountain which its windows overlook. The composition is a charming one in the rather severe classic style which was in favor toward the end of the last century. Although at first sight it may seem odd that the basin of the fountain has a balustrade on one side only, a good reason for this can easily be divined. A balustrade was needed on the side next the house to connect the fountain with the steps, and, by means of these, with the main architectural motive, and to give it dignity when seen from the house. But had it been continued on the further side it would have formed a sharp line against the vegetation beyond, whereas now the eye must pass to this without hindrance, and the little sheet of water must seem to blend naturally with its surroundings. Animals spurting water from their mouths are not often agreeable objects, and we may possibly wish that these lions might be replaced by figures of another sort. Still, they have a stately air, befitting the character of the architectural scheme as a whole, and their descending lines of water contrast well with the great ascending shaft in the centre. The alternating figures and urns on the balustrades are entirely happy features, and, of course, the little pavilions are admirably designed to repeat and support the "motive" of the palace front.

But we wish particularly to call attention to the way in which the whole composition gains by the presence of the thick masses of foliage. As we look from the point where the photograph was taken they form a delightful background for the fountain, and at the same time frame the palace, concealing its extent, and thus giving the imagination a chance to act. And in the view of the fountain from the palace they must be equally effective, revealing more or less of it as the spectator changes his standpoint, be it ever so slightly. If we fancy these masses of foliage pushed back so as to reveal the whole façade and to give a free sight of the whole fountain from its windows, how greatly the scene loses in both dignity and poetry! Nor would it be so beautiful were the shrubberies less dense, allowing the eye to pass between the trunks of the trees. Just this mass of vegetation, solid below and more broken and graceful above, was needed to give its full effect to the architectural group.

California Plants for California Gardens.

SOME time or other the thought that the proper plants to grow in any given place are those native to it, may perhaps spread until it finally reaches popular acceptances. Heretofore it has been the custom in most places to fill the garden with exotics—in fact, anything not indigenous to the locality has always been considered the correct thing to give space to and to grow, if possible. The more care and labor required to make such plants succeed, the nearer right has been thought the choice made. But this is a mistake. The proper plants for California gardens are California plants. Have we any lack of attractive things? Look at the foot-hills! Behold the sandy fields by the seaside and the sheets of gold, of pale yellow and blues and most lovely harmonious grays that cover them over. Is anything more brilliant ever seen in gayest garden or park-border elsewhere?

What we need to do is simply to bring together the splendid collection nature offers us, and that is now so widely scattered over the state. These things she has planted where they are likeliest to succeed, in stony and sandy soils upon which the grasses and civilized weeds that love rank feed are not disposed to intrude and choke them out. We cannot bring these all into one garden, but we may into any one town or county.

Each garden could show a different group. The annuals I would place in the wide, depressed gutters at street-sides, but the bulbous plants and more striking perennials in the borders against and around the house. The shade-lovers, that is to say, the Violets, Trilliums, the Actæa, the Thalictrum, the Anemone, the Trientalis, and all such modest things in size and dress, not to forget the Ferns, would find room out of the sun's way on the house's north side.

If need be, the town trustees could furnish the seed for the gutter plantation, and the town marshal could vary his usual round of duties by filling a gardener's place for a while.

The true California flower season lasts from March to mid-June, inclusive, though afterward here and there a bright spot lingers where some perennial, possessed of deep-feeding roots and a longer or later flowering period, has established itself. These are candidates for the garden I have in mind as its fixed features.

The practice of irrigating garden-ground in summer should be abandoned, because unhealthy, as all confess it to be. Our new scheme for the garden makes this shelving of the hose not only a possibility but a desirability, as the plants we are about to adopt know only a continuous dry summer, and, furthermore, have learned by long practice where to find all the water they need.

It is to be hoped Senator Stanford will bring together, within the ample grounds of the University at Palo Alto, the entire flora of California, so that we may all see just what may be done in the way of furnishing well a series of gardens with native plants only.

[These notes are taken from an article in the *Pacific Rural Press*, and we reproduce them because they present a truth of more than local application. Of course we would not confine the selection of garden-plants in a given region entirely to those that are native there, but the first qualification of a beautiful plant is health and vigor, and when native plants are selected, we are sure, to begin with, that they are adapted to the climate. No one will exclude exotic plants that will thrive, and our own gardens in the spring would sadly miss the Snowdrops, Tulips and Daffodils, the Peonies, Irises and Poppies, which have come to us from distant countries. Nevertheless, it is true that American plants are too rarely seen in American gardens. This is not only true of our shrubs and small trees, which are among the most beautiful to be found in the world, but it is true of herbaceous plants, which can be procured in almost endless variety. It may be added, for the benefit of those who are anxious to decorate their gardens with plants that are rare, that our own Trilliums, Uvularias, Sanguinarias, Erythroniums and many others would be much more strange to the eyes of the ordinary visitor than the exotic garden-plants, which everybody cultivates.—Ed.]

Recent Botanical Discoveries in China and Eastern Burma.—VII.

Davidia.—I have previously said something about this remarkable tree, but as we have since received at Kew abundant specimens of it collected by Dr. A. Henry, with further information respecting the tree and its home in the west of China, it may not be thought superfluous to devote another paragraph to it, especially as it would probably prove hardy in the northern United States and in the United Kingdom—at all events, in the wilder parts. Like the Chinese Tulip-tree, it would seem to have become exceedingly rare, for Dr. Henry met with only one specimen of it during his long journeyings in Hupeh and Szechuen. As already related, the Abbé David first discovered it, now some twenty-one years ago, in the district of Moupine, eastern Chinese Tibet. This locality is about seven days' march west of Chingtu, the capital of Szechuen, and David spent nine months there, with most valuable results to science. The principal mountain range rises to an altitude exceeding 16,000 feet, and David succeeded in scaling the summit. He was located at an altitude of about 7,000 feet, and to reach this place had to cross a ridge about 10,000 feet high. The main ridge he found beautifully wooded up to 11,500 feet, with charming flowery meadows above, and no permanent snow. Davidia grew on the skirt of the forest, at an elevation of 6,500 feet, associated with a large Cerasus, bearing small red fruit, with a gigantic Corylus, with a corky barked Quercus, and with various Laurels and Figs. Judging from this description of the vegetation one would not expect it to be hardy except in the most climatically favored parts of the United Kingdom; but Dr. Henry, who is at present in England, is of opinion that it is hardy enough to flourish generally in our climate. Henry found it near south Wushan at about the same elevation that it grows in Tibet, and I am indebted to his kindness for the following particulars of his rediscovery of this remarkable tree:

"As one ascends the Yangtze, in that part of its course known as the 'rapids and gorges,' one comes to the little village of Psishih, which lies on the right bank, and marks the political division of the Szechuen and Hupeh provinces. Southward from the river the boundary line is a tremendously deep ravine, through which rushes a stream to join the Yangtze. One cannot get up this ravine, so narrow it is, and so full of cataracts, with wonderfully grand walls of almost perpendicular rock rising on either side to a height of 3,000 or 4,000 feet! While on my botanical trip of 1888 I staid for some days close to the head of the deep part of the ravine, inland a few miles from the river, in the cottage of an old Roman Catholic lady, named Mrs. Huang. There the ravine widens into a valley, skirted by a high and precipitous mountain range on the eastern side, on the western side by an extended flattish country. A few miles higher the western mountain range curves round to the east, and in this curve, some three or four miles in area, where the streamlet rises, is a bit of 'old wood,' as the Chinese term it, or 'virgin forest,' as we should call it, walled in on three sides by cliffs. Near the forest, in the midst of a few trees which evidently formed part of the 'old wood' before the farmer had encroached, we came, on May 8th, in view of a striking tree, all green and white in alternate patches, like some curious arrangement in checks. This was a specimen of the *Davidia involucrata*, the only one I or my coolies saw during a six months' trip over hundreds of miles of wild country. The tree was, on this day, in full bloom, and was between twenty and thirty feet high. We were immediately told two or three names for it by local natives, but nobody really seemed to know anything about it, except that it was very rare, growing all alone, without a rival, in what had been a part of the ancient forest."

Later in the season, Dr. Henry sent his coolies into the same country again and they obtained fruit, but, unfortunately, not perfect seed. I believe seed was sent to France by the Abbé David, for the late Professor Decaisne, writing to Sir Joseph Hooker in 1871, said, "I have been informed that the Davidia is in cultivation in the nursery of André Leroy, at Angers." However that may have been, I can find no record of its having been raised. That it, of itself, is almost worth a journey to its home the figures we have of it bear sufficient testimony. The foliage and young wood, in the absence of flowers or fruit, would pass for a Lime; but when in flower, as stated by Dr. Henry, the tree must present a very striking appearance. The two large bracts enclosing each bead of flowers are pure white, and the numerous anthers are red. Each inflorescence or head of flowers consists of a large number of stamens seated on a club-shaped receptacle, without any trace of calyx or corolla, and usually one female or hermaphrodite flower obliquely situated in the midst of the stamens. Sometimes this flower has five imperfect stamens springing from the neck of the pistil and alternating with as many minute calyx-lobes; sometimes the stamens are wholly wanting; sometimes the inflorescence contains no female flower. The fruit or seed-vessel is woody and contains three or more cells with a solitary seed.

The botanical affinity of Davidia is with Nyssa (Tupelo, Pepperidge or Sour Gum trees of North America), though it has nothing in common in its general aspect. Singular to say, Dr. Henry also discovered a species of Nyssa, which has been named *N. Sinensis*—the genus, however, previously known to be represented in India as well as in North America. A new genus of the same affinity—*Camptotheca acuminata*, discovered by the Abbé David at Kinkiang, was collected by Dr. Henry in Hupeh; and yet another new member of this somewhat anomalous group of trees was discovered by Dr. Henry in Szechuen, namely, *Toricellia angulata*, figured in Hooker's "Icones Plantarum" (plate 1893). Interesting as these trees are, botanically, not one approaches Davidia in ornamental character. The last Toricellia may be deserving of notice. It is a tree fifty feet high, with sharply lobed leaves in the way of a plane, and pendent inflorescence of inconspicuous flowers.

How We Renewed an Old Place.

VIII.—AN ANCIENT ORCHARD.

THE whole farm at Overlea might well come under this head, for it abounds in Apple and Pear-trees, which are scattered about it, from the point at the north to the foot of the hill on the south.

Tall, fuzzy old settlers they are, with mossy trunks and gaunt branches; but, like the ancient New England human stock, they die game, and are useful to the end. The weather-beaten old Seckels, which look perfectly hopeless, still produce stout, brown, rosy little pears, as sweet as honey, if not much bigger than an overgrown bumble-bee, and the venerable Bartletts, which we threaten every year to cut down because they look so shabby and disreputable in their torn and mossy old jackets, put off the evil day by mollifying us every September with a crop, which, though not large, still serves to purchase them a reprieve.

One of the conspicuous ornaments of the level space below the northern terrace of the house is an old Pear-tree we call Methusaleh, which was transplanted in 1779, and, in spite of its great age, still bears a profusion of hard, sweet pears, which the housewives consider excellent for coddling or preserving with barberries.

This ancient and honorable old continental, which stands some fifty feet in its stockings, girths ten feet and three inches a foot from the ground, and has a coat so beautifully wrinkled and seamed with age that our artist friend tells us a Japanese would beg a bit of the bark for a curio, and exhibit it as a precious and artistic possession.

In the spring its venerable poll is snowy with blossoms, and though its great trunk is quite hollow within, the six huge branches into which it separates near the base, spread wide and strong, and send out from their broken tops vigorous young shoots, on which the fruit grows profusely.

We suppose this to be the original well-known Cushing Pear-tree, as this farm was a part of the colonial grant to Matthew Cushing in 1634, and was the Stammhaus of that widespread race, which held the property in the Cushing name for 243 years, the land having descended by will from one to another, so that we hold the first deed and paid the first money that was ever given for it.

The Apple-orchard proper, which is in the shape of a flat-iron, lies in the point of the place, which is quite filled by three or four enormous old trees, which have grown to a great height, and had, when we came, immense branches that arched over and almost swept the ground, their huge mounds of rosy bloom in spring making a wondrous sight.

Since then, with a vague idea of improving them, though some of the wise ones tell us it is a mistake to meddle with such old trees, we have had them pruned, that the sun might shine more directly upon the apples, which failed to color properly in the dense shade. Also, the ground beneath them has been plowed, to the great detriment of their small roots, which, owing to the marshy ground below, lie very near the surface.

Last year was not their bearing year, and not until this autumn can we tell the results of this surgery. The plowing

was not done so much for the trees as for the grass, which had been fairly driven out by the encroachments of the Money-wort, which has escaped from the garden and runs riot over the place; and the pruning was as necessary for the hay-crop as for the fruit, for the great Elm hard by helps to shade all that part of the grounds, and even now the grass, when cut, has to be transported into the open to be cured.

The year we took possession, three trees at this point—a Baldwin, a Rhode Island Greening and a Russet—furnished us with about a dozen barrels of apples. In addition, there are in other parts of the place more old-fashioned trees, like the Seek-no-Further and Early Sweet, that are extremely useful and fairly productive in spite of their years and infirmities. One of the latter trees is quite a curiosity, for half of it is wholly denuded of bark, as if it had been struck by lightning, and the trunk is perfectly hollow, but the grafted stem still sends out very strong and healthy-looking shoots that yield an abundance of fine rosy-cheeked fruit every other year.

The Canker-worm has meddled very little with these trees, but the Web-caterpillar has to be waged constant war upon, both in spring and fall, and last summer, owing to the preceding mild winter, this pest was particularly active and ubiquitous.

A row of Plum-trees against the east foundation-wall of the old house, which still stands and makes a good shelter for our Raspberry-bushes, seem as if they would do well if we could only cope successfully with the murderous black knot, with which we found them perfectly covered. In 1889 all the diseased portions were cut away, and last summer they sent out a quantity of tall, healthy branches, but no blossoms, from their closely polled stems; we purpose this spring to try the effect of salt bags in the crotches of the limbs, which, we have been told, is a successful way of keeping off the Curculio. But from what we read of the necessary efforts to get rid of this pest, we fear that the plums would hardly be worth the trouble, for it seems as if nothing less than a Salvation Army would suffice to combat this persistent beetle sinner.

In our orchard are Iron Pears of the good old kind that would serve for ammunition in a field-piece, in case of war, and some rickety-looking Lawrences, that bear excellent fruit in generous quantities; and there is a picturesque Crab-apple-tree which grows quite too near the great Elm to furnish any decent fruit, though it does its best, and strews the ground beneath it with its stony red and yellow fruit. The old Cherry-trees were too worthless, so we cut them down. Peaches we have none, though we are told they would thrive against the hill, as they like a northern exposure. We are now preparing to plant a fresh Apple-orchard, which ought to be ready to bear by the time the old trees quite give out, and we should be grateful for suggestions as to the best kinds for domestic uses, and whether the trees will be more likely to thrive in the moist or in the dry part of the grounds.

But there is a charm about this unproductive old orchard, with its wilderness of venerable shrubs along the fence, that no thrifty modern row of fruitful trees will ever possess. As one sits there in the shade on a sunny day, with the white petals drifting down from their lofty summits, there is a murmur of bees among the foliage, of robins chattering among the twigs, a rustle of leaves and flowers in the gentle breeze, that seems the essence of the many summers gone that have helped to swell their great boles, and to increase their majestic height. From under the arch of branches the green meadow is visible, with wooded hills rising from its margin, among which nestle cottages, white and red, with the faint smoke curling lazily from their chimneys up to the blue sky, flecked with round white clouds. How many years the old trees have looked out upon the quiet meadow, and for how many generations have they dropped their rosy fruit!

In this new country of ours we yearn for stability, for tradition, for something to link us with that past which goes back so little way behind us here. Perhaps the grafts on these old limbs were brought from England by the early settlers who peopled the old colony. Under their shade the sturdy Puritan has leaned upon his spade and remembered the orchards of his native land, which he was never to see again; and now, as the vision grows before our dreaming eyes, we climb the ladder of the past, and are again in Lincolnshire, and the choir-boys are chanting softly in the distance, and the bells are ringing from St. Andrew's Church, of the other Hingham, the gray towers of which we see afar off, instead of the quaint spire of our old meeting-house, whose ten-score years of life seem so little in the older world, where they reckon time by centuries instead of decades.

But the boom of the bells resolves itself once more into the humming of bees, the venerable towers are but the shaggy trunks around us, and we are awake once more, under the bending boughs of the old orchard, with only a robin for a chorister.

Hingham, Mass. *M. C. Robbins.*

New or Little Known Plants.

Alnus maritima.

THIS very rare tree, which is still little known in gardens, differs from other Alders in that its flowers are produced in the autumn. Alders usually flower very early in the spring, either some time before the leaves appear, or with or just after their appearance. *Alnus maritima*, however, flowers in August and September, the flowers being produced on shoots formed during the previous spring. The female catkins do not enlarge very much after fertilization until the spring, and do not mature until the following September or until the flowering period comes round again. On this tree, therefore, flowers and ripe fruit appear simultaneously. This fact, which is the most remarkable thing about this tree, was entirely overlooked in the last monographs of the Alders published in Europe, although it has been known here for a hundred years, or ever since the Seaside Alder was first noticed.

Alnus maritima (see page 269) is a slender glabrous tree, rising occasionally to the height of twenty-five or thirty feet, with a trunk sometimes three or four inches in diameter covered with smooth pale brown bark, stout obtuse glabrous winter-buds, and glabrous zigzag branchlets marked with small white lenticels. The leaves are oblong or obovate, two and a half to three inches long, acuminate or rounded at the apex, wedge-shaped at the base, sharply and remotely glandular-serrate; they are borne on slender petioles an inch or an inch and a half long, and are bright green above and rusty brown on the lower surface. The stipules are thick, oblong-pointed, an eighth of an inch long, dark reddish brown and early deciduous. The fertile catkins are usually solitary from the axils of upper leaves; they are an eighth of an inch long, and are borne on stout stems three or four times their length; at maturity they are obtuse, an inch long, half an inch broad, and dark brown or nearly black, with thickened conspicuously lobed scales and wingless fruit. The sterile catkins, which are usually racemose-clustered, are long-stalked and vary from an inch and a half to more than two inches in length; they are developed from the axils of the upper leaves and droop gracefully from the ends of the branches.

*Alnus maritima** was known to Humphrey Marshall, who described in the "Arbustum Americanum" its peculiarity of flowering in the autumn. Muehlenberg and Charles Pickering, the distinguished naturalist of the Wilkes' Exploring Expedition, were familiar with it, and, in later days, Mr. William M. Canby found it in a number of places on the coast of the lower peninsula of Delaware and of Maryland, where it grows on the edges of streams, although not directly on the sea-shore as its name would seem to imply. This Alder abounds on the banks of the Nanticoke River at Seaford, Maryland, near the high-tide mark and lower down. Here it mingles with the common southern Alder (*Alnus serrulata*), the Sour Gum, the Taxodium, the Red Maple, the White Cedar, and other swamp and muddy-shore trees. Mr. Canby found it also growing plentifully along the shore of Wicomico River at Salisbury in Maryland, both above and below tide-water, and along mill-ponds and head-water streams in the same locality. What appears to be the same plant was collected by Hall on the banks of the Red River in the Indian territory. Of the western tree and of its distribution, however, more infor-

Betula Alnus maritima, Marshall, "Arbust. Am.," 20

mation than now exists is needed. It occurs in closely related forms in Japan * and in Manchuria.†

Alnus maritima was introduced into cultivation by Mr. Thomas Meehan, who, in 1878, sent it to the Arnold Arboretum. Here it makes a small shrubby tree now six or eight feet high. It is usually hardy, although in the winter of 1885 the plants in the Arboretum were killed down to the ground. As a garden-plant this Alder has considerable beauty, especially in the autumn when it is covered with its large, bright, golden-colored catkins of male flowers which hang from the ends of the slender branches.

New Orchids.

Cypripedium × Dauthieri, var. Poggio Gherardo, Ross, is a very pale form of *Cypripedium Dauthieri*, in which the purple-brown of the upper sepal is confined to its lower half, the upper part being green with a white border; the petals and lip are also paler than usual. It appeared in the collection of Signor H. G. Ross, of Florence, Italy.—*Gardeners' Chronicle*, April 4th, p. 426.

Cycnoches Rossianum, Rolfe.—This is a very interesting species of this sportive genus, which has flowered in the collection of Signor H. G. Ross, of Florence, on several occasions. In 1889 male and female flowers were produced on either side of the same pseudo-bulb, though on other occasions the males only appeared. The male racemes are pendulous, long and slender, with somewhat distant flowers, which are heavily barred with reddish brown, on a yellowish green ground. The female flower was erect and solitary, much larger and wholly green. It was purchased as *C. Warscewiczii*, which, however, is quite distinct, having very much denser male racemes of wholly green flowers. This makes, at least, the fifth species of which both sexes are known.—*Gardeners' Chronicle*, April 11th, p. 456.

Masdevallia Rolfeana, Kranzlin, is a pretty species, said to be allied to *M. velifera*, Rchb. f., which flowered in the collection of Messrs. F. Sander & Co., of St. Albans, during last July. The flowers are of a rich chocolate-brown, except the base of the tube, which is honey-colored; their length is two and a half inches, of which more than half belongs to the tails. Its native country is not recorded.—*Gardeners' Chronicle*, April 18th, p. 488.

Odontoglossum × dellense, O'Brien, is a pretty form of *O.* × *excellens*, in which the sepals and petals are more spotted than usual. It appeared in the collection of Baron Schröder, of The Dell, Egham. The variability of *O.* × *excellens* is now very well known. *O. Pescatorei* and *O. prænitens* are given as the supposed parents of the present plant, but after comparing an authentic flower with *Botanical Magazine*, t. 6229, I am quite satisfied that *O. triumphans*, and not *O. prænitens*, is the other parent. The lip of the last-named rare species is quite distinct in character.— *Gardeners' Chronicle*, April 25th, p. 521.

Masdevallia macrochila, Regel.—This is figured and described as a new species, allied to *M. bella*, Rchb., f. It appears to me identical with *M. Chestertoni*, Rchb., f., a species discovered by Chesterton in New Granada, and imported by Messrs. F. Sander & Co., of St. Albans. The present plant has the perianth somewhat less spotted than the form figured in the *Botanical Magazine*, t. 6977, but the species is variable in this respect.— *Gartenflora*, xl., p. 170, t. 1344, figs. 4 and 5.

Stanhopea graveolens, var. Lietzei, Regel, is a pale yellow form of this somewhat variable species, with the front lobe of the lip densely spotted with reddish brown, and a narrow orange band round the hypochile. It is said to have been imported from Brazil.— *Gartenflora*, xl., p. 201, t. 1345.

Kew. *R. A. Rolfe.*

Foreign Correspondence.

London Letter.

English horticulture has risen to the dignity of possessing a "Worshipful Company of Gardeners," a kind of City Guild which has been "resurrected" in the hope that it may be able to afford some assistance to gardening in this country. It has begun to do something by proposing "to make provision for the due and proper teaching of the technique of the craft, and to examine and issue certificates of efficiency to the craftsmen." How this is to be done has not been divulged. The "technique of the craft" can only be taught by actual experience in good gardens. There is no sure and certain road to success in horticulture through the lecture-room, and examinations, as generally conducted, often place the theorist and mere paper man in front of the practical and genuine gardener. A man must begin at the potting bench and wheelbarrow and work right through the whole if he wants to have a real grip of the technique of good horticulture.

Cape Bulbs.—A lecture on these plants was recently given at a meeting of the Royal Horticultural Society by Mr. James O'Brien, whose knowledge of and skill in growing them is exceptional. The lecture was devoted chiefly to cultural matters, such as temperatures, resting seasons, soils and water. Many cultivators are apt to overdo the more delicate Cape Bulbs in the matter of water and temperature. It is true that in England the climate is not such as to render the cultivation of Cape plants an easy matter, but there are, nevertheless, means by which it is possible to grow most of them. In America, no doubt, you would do Cape plants better and easier than we do, as you have more sunlight in winter and hotter summers than we have here. Cape Crinums, Hæmanthus, Nerines, Cyrtanthus and many similar plants would be splendid garden-plants in lands where there is plenty of sunlight and hot summers. The most beautiful and varied of bulbous plants are found at the Cape, but we do not pay very much attention to them in England. Cape plants are almost certain to be introduced again in quantity in consequence of the recent rush of Englishmen to that part of Africa, so that there is some hope that many more beautiful and useful additions may be made to the few Cape Bulbs we have already. A few Crinums, Vallota, Nerines, Lachenalias, Ixias, Sparaxis, Freesia and *Amaryllis belladonna* are the pick of these, but they are only a modicum of what is known to be good among the bulbous plants of that region. Gladiolus, Watsonia, Cyrtanthus, Crinum, may be indicated as genera of which the few known in cultivation are only a small fraction of what are known to botanists. Only last year three new and very beautiful species of Gladiolus and one of Cyrtanthus were added to the cultivated collections at Kew, where their distinctness at once attracted the attention of specialists.

Gesneriads.—The Belgians can teach us how to grow these plants. In the nurseries of Monsieur Louis Van Houtte one may see house after house filled with beautiful examples representing scores of different genera, such as Gesneria, Dicyata, Ligeria, Nægelia, Tydœa, etc. The bright colors and great variety of the flowers of all these plants are charming, and they are so easily cultivated that beginners can grow them quite successfully. Monsieur Van Houtte says: "From July to October our houses are filled with every kind of Gesneriad in flower. They are mostly the result of hybridization in our nursery. Their colors are bright and charming, and, without exaggeration, they may be said to include all the colors of the rainbow."

I am indebted to Monsieur Van Houtte's manager, Monsieur Eckhaut, for the following details of cultivation as practiced by him:

Plant all the tubers in small pots on March 15th in light soil. Give little water at first, and keep the temperature of the house at about seventy degrees. In about a fortnight plunge the pots in a hot-bed of about eighty degrees, and in six weeks from the time of starting the plants should be repotted into three-inch pots. This time use a compost of rotten horse-dung or cow-manure, two parts, and one part of peat or leaf-mold, with a good sprinkling of silver sand. "But don't be afraid of manure, for these plants revel in it." Give them a temperature of seventy-five degrees now and plenty of water. Repot again in a month, and, after plants are established, give plenty of sun and air.

I have seen these plants as grown by Monsieur Van Houtte, and very charming they are.

Anthurium Scherzerianum.—I recently saw in the garden of Monsieur Warocque, Mariemont, near Brussels, a magnificent group of large specimen plants of this Anthurium. Each plant was a yard or more in diameter, and bore from thirty to sixty flowers. They were all of the very best varieties, the spathes being exceptionally large and banner-like, and rich in color. The plants entirely filled a large lean-to house. The value of this Anthurium was never more abundantly demonstrated, for the house itself was a beautiful picture; the flowers are of the very best for room-decoration, as they remain fresh several weeks when cut and placed in water. Would not this plant be a good subject for the grower of flowers in quantity for market? It is easily managed, it blooms freely and regularly every year, and its flowers have sufficient brightness of color and singularity of form to recommend them to every one.

Cacti.—These plants have hitherto been so neglected by English horticulturists that they are scarcely ever seen except in botanical gardens. There is, however, a prospect of their becoming popular again, as several of the London nurserymen have begun to grow them, and one firm—namely, Messrs. Carter & Co., the well-known seed merchants—have issued an illustrated catalogue of the most striking species. Meanwhile, in Germany, Cacti have become so popular that a monthly journal is to be devoted entirely to them, under the title of *Monatsschrift fur Kaktunkundi*. It is edited by Paul Arendt, and issued from Berlin, and every number contains an original drawing of a Cactus. The first number contains articles upon 1. Cacti at Exhibitions; 2. Watering Cacti; 3. *Mamillaria longimamma* and *M. uberiformis;* 4. *Echenocactus contractus*, with illustration; 5. Soils for Cacti; 6. How and Why Cacti are Grafted; 7. Notes on Cacti.

Tree Pæonies.—At several plant exhibitions held recently in London collections of varieties of *Pæonia Moutan* have attracted a large share of attention on account of the exceptional size, color and beauty in form of their flowers. Japan and China have recently contributed many beautiful varieties distinct from those previously known here, and as several of our leading London nurserymen have turned their attention to these plants they bid fair to again become popular in England. At the present time there are comparatively few gardens in which the Moutan is represented, and the only explanation one can find for this is that the plants are not known by most cultivators, while the nurserymen have allowed them to drop out of their collections. There are few more beautiful pictures in the garden than a big bush of *P. Moutan* covered with its gigantic blooms, which are developed in June. The plants are perfectly hardy in the coldest parts of England, but they require protection from spring frosts, as they begin to grow very early in the year. Almost all colors and shades except blue are represented in the many varieties we now possess. Besides their value in the shrubbery these Pæonies are useful when grown in pots and forced a little, so that their magnificent blooms are available for the conservatory in April and May. Messrs. Veitch, of Chelsea, Kelway & Sons, T. S. Ware and G. Paul are the principal dealers in these plants here.

Rhododendron Vaseyi is a useful addition to the hardy spring-flowering species and hybrids which form a conspicuous feature in many English gardens at this time of year. It has grown and flowered freely every year since its introduction to Kew, and this year its interest has been added to by the flowering in the open air at Kew of a pure white variety among a batch of seedlings procured from America. Cultivation has soon affected the character of this plant in regard to flower color, and we may reasonably look forward to soon realizing the hope held out by a writer in Garden and Forest two years ago—namely, that this Rhododendron would be the origin of a distinct and valuable race of early-flowering hardy kinds.

Cultural Department.

A Home Supply of Tree Fruits.

THE selection of fruit-trees for a private orchard will be controlled by quite different principles from those that govern in the planting of trees for the production of market fruits. For these, standard, well-known, productive and vigorous kinds must be taken, in order to secure profitable results. In the home orchard none of these requirements need recognition, since the grower is also the chief consumer of its products, and home tastes and needs stand prominent. Very few of our choicest tree fruits of any species are as profitable when grown for market as the coarser sorts. Even for the most select trade, beauty in fruits is essential, for decorative effect upon the table is as much sought after as intrinsic quality. I do not mean to say that quality is immaterial anywhere; but where very plain and insignificant-looking apples, pears, peaches and plums are actually the choicest in flavor, and this is really true in many instances, their high quality alone will not suffice to make them profitable.

In small private orchards there is usually no difficulty in giving the highest culture, and the choicer varieties seem particularly to require this in order to reveal all their merits. Many sorts that would be very unprofitably planted in an orchard receiving only moderate care, may be made more

productive by extra attention. Even in fruits, the rule prevails that the best are the most costly.

The rule to limit planting to a few standard sorts has no validity in the private orchard. One may set as many varieties as one fancies, and may be continually adding to these as experience gives knowledge. Usually, unless at a distance from markets, it is not desirable to plant many culinary sorts, as these can be often more cheaply purchased than grown, especially where space is limited. But it must be remembered that some of this class are much better for special purposes than the best kinds grown for eating out of hand. This is particularly true of pears and peaches, grapes and strawberries. Firm-fleshed fruits that retain their shape in cooking are universally preferred. These may be sometimes much improved by being cooked in the juice of finer dessert sorts.

Selections will necessarily be controlled by the requirements of climate, but this rule is less severe in the private than in the commercial orchard. By choosing a sheltered spot, and by top-grafting on hardy stocks, the private grower will be able to succeed tolerably with many sorts that it will not pay to plant for the market. I should be disposed to advise those who are about to begin the formation of their home orchards to select some of the best varieties of their own neighborhood —the fancies of their childhood, perhaps. There are a large number of excellent sorts in every long-settled locality that are not generally known, and which would perhaps grow nowhere else so well. I should counsel the avoidance of too many trees of a single sort, however good. One tree, when it is well established, will usually produce all of its sort that a single family will utilize, while variety is always agreeable. Besides, where a good many varieties are grown, we are more sure to have a good supply every year.

Those who are not familiar with varieties will desire to have some suggestions as to their particular choice in this respect; but in a periodical of wide circulation it is difficult to give lists suited to various sections. Local inquiries will give the most satisfactory results, but as our American Pomological Society has a membership of continental extent, a selection from the best tree fruits on its list is here appended. The early varieties are named first, and so on to the last named, which are the latest sorts.

Apples.—Summer Rose, Yellow Transparent, Early Strawberry, High Top Sweet, Primate, Early Joe, Garden Royal, Fall Wine, Porter, Chenango, Aromatic Carolina, Haskell Sweet, Rambo, Gravenstein, Fameuse, Shiawassee, Wealthy, Wagner, Yellow Bellefleur, Hubbardston, Jonathan, Lady's Sweet, Melon, Buckingham, Baltimore, Grimes' Golden, American Golden Pippin, Newtown Spitzenberg, Mother, Northern Spy, Swaar, Hunt Russet, Romanite, Westfield.

Pears.—Bloodgood, Clapp's Favorite, Madeleine, Dearborn, Giffard, Quimper, Rostiezer, Tyson, Souvenir, Ansault, Bartlett, Andrews, Bilboa, Boussock, Clairgeau, Comice, Dix, Foster's Seckel, Frederick Clapp, Gray Doyenne, Dr. Reeder, Dana's Hovey, Doyenne d'Alencon, Easter Beurré, Josephine of Malines, Lawrence, M'Laughlin, Winter Nelis.

Plums.—De Montfort, Hudson Gage, July Green Gage, Belgian Purple, Bradshaw, Denniston, Green Gage, Imperial Gage, Jefferson, Lawrence, M'Laughlin, Prune of Agen, Smith's Orleans, Washington, Bavay, Coe's Late Red, Coe's Golden Drop, St. Catherine.

Peaches.—Alexander, Amsden, Beatrice, Cole's Early, Early York, Hale's Early, Tillotson; Albert, Amelia, Early Grosse Mignonne, Royal George, Thurber, White Imperial; Alexander Noblesse, Coolidge's Favorite, George IV., Grosse Mignonne, Malta, Morris' White, Oldmixon Free, Oldmixon Cling, President, Susquehanna, Van Zandt, Wheatland; Cook's Late, Crawford's Late, Druid Hill, Heath Cling, Hyslop Cling, Late Red Rareripe, Petite Imperial, Stump the World.

Cherries.—Belle d'Orleans, Early Purple, Knight's Early, Rockport; Osceola, Belle de Choisy, Bigarreau, Black Eagle, Black Heart, Black Tartarian, Coe's Transparent, Elton, Governor Wood, Hovey, Napoleon, Olivet; Reine Hortense, Downer's Late, Red Jacket.

Newport, Vt. *T. H. Hoskins.*

Bagging Grapes.

At the last meeting of the New Jersey Horticultural Society, Mr. W. H. Goldsmith, of Newark, read an instructive essay on Grape-culture. The following extracts from it show that the practice of covering the clusters with paper-bags has not yet been abandoned in the most successful vineyards:

Next to spraying, I consider bagging as an essential in profitable grape-growing. With me it is not only equally important, but more so, and if I could not use both I should use bags in preference to the Bordeaux mixture. In fact, I have done this when circumstances have given me but one selection. In the use of bags I have had an experience of several years, and so pronounced has been my success with them that I can unhesitatingly recommend the practice as one of the most efficient safeguards to the preservation of the crops. In 1884, out of a vineyard of 700 Niagaras, we bagged the fruit on about 200 vines. During the summer the foliage on the entire vineyard was almost completely obliterated by mildew. The fruit not bagged became hard and did not ripen, while the clusters over which the bags had been placed ripened nicely and were finely flavored. This one experience settled in my own mind the value of bags, and ever since I have used them. The summer and fall of 1889 were perhaps as trying to vineyards as any in the memory of the members of this society, and yet I had grapes as finely flavored and as well ripened as I have had at any time since I began their cultivation. Owing to bad weather I had succeeded in putting on but one spraying of Eau Celeste over the entire vineyard, and making but one application of the Bordeaux mixture upon about one-quarter of my vines, but I had succeeded in getting bags on nearly all my fruit. Of course, in such a season, it is almost impossible to get ahead of the mildew, and it even affected grapes that were bagged, but when my fruit was placed alongside of fruit that had not been bagged it needed no second view to determine what had been the effect of the treatment. The work of putting on bags is no small item; indeed, it is one of the costliest necessities. During the past season I put on about 66,000 bags at a cost of $130. Aside from the matter of cost, the work itself must be done not only during the busiest season of the year, but, to get the best results, the period during which the bags should be applied is comparatively short. As soon as the clusters have set, the work should begin, and be pushed as fast as possible until completed. If it could all be done at once it would be much better, as the sooner the bunches are covered the less danger will there be of loss from mildew. In the early part of last season I put some bags over clusters that had not bloomed, and found it answered as well as where the sets had already formed. In no case, however, should the work be done while the Grapes are in blossom.

It might be supposed that those bags are best which are least susceptible to the destroying influences of the weather. I have oiled bags and bags made of parchment which were sent me as samples and highly recommended, as, in addition to their being less liable to be destroyed by the weather, they may be taken off and used successively through several seasons. The fallacy of this is apparent when we consider that far the heaviest item of expense in bagging is the labor of putting the bags on. Wet weather does not injure the bags, as they are protected by the foliage from the direct effect of storms. The bags I use are the common manilla one and a half pound paper bags put together in the old way, with corners square, and they are so flimsy as to frequently tear down the sides while being put on the vines, and yet, when I come to take them off in the fall they are quite difficult to tear, as the action of sun and moisture has toughened them. Before the bags are put on the grapes the corners of both tops and bottoms should be cut off. This can be done rapidly by a broad chisel, and serves the twofold purpose of enabling the top to be closed up neatly over the cluster and allowing any water that may get into the bag to drain out. In putting the bag on care should be taken to pin the top above the lateral from which the cluster depends, as otherwise if the pin is put through the bag around the small stem of the cluster it will be found that the wind blowing the bag about will break the cluster from the vine. This happened in my vineyard when I first began the practice of bagging, and I had the opportunity of seeing a large number of bags on the ground, and in each one a cluster of grapes.

Aside from the question of mildew, bagging will have to be resorted to in the future to protect our vineyards from the ravages of a pest that threatens to become nearly, if not quite, as destructive as both mildew and black rot together. I refer to the small black worm which we find taking up its quarters in the grape some five or six weeks before ripening. This insect is hatched from an egg deposited on the side of the berry by a fly resembling somewhat the common house-fly. As soon as it is hatched it goes to the seeds, and after permanently injuring the berry it will go to the next, and so on until it has spoiled several. I have seen bunches in my vineyard containing scarcely one good grape. This pest has attacked our vineyards for a number of years, and is doubtless known to a large number of grape-growers. Its depredations have usually been so limited as to call for no special notice, but

during the past two seasons it has increased to such an extent as to seriously alarm the grape-growers in our section. The best and, in fact, only preventive I have yet discovered is the paper bag, as the fly will not enter it to deposit its eggs.

Grapes that have passed the summer in bags come out in the fall looking better than those exposed to the weather. The berries, being free from weather-marks, present a fresh green look.

Notes on Irises.

Spanish Irises.—These are just passing away and giving place to the "English" varieties. These bulbous Irises are among the most attractive of the family, having numerous flowers with bright colors. They are hardy in a not too wet position; a satisfactory one being the second line under the south side of the house, where the first line is preferably vines, the foliage of which will serve as a background and foil to the Iris flowers. My bulbs seem to be too close to the house, especially in a season like the present, when exceptional dryness has rather shortened the blooming season. The bulbous and Oncocyclus Irises are the most interesting of the family, and among the most interesting plants of any family. Those who grow a selection of these, however, give hostages to care, as many of them are decidedly miffy, and unless they have a suitable location, they live but decline to bloom, and the worst of it is that a location which pleases one year seems to lose its charm the next. Take, as a familiar example of the Oncocyclus section, *I. Susiana*. This is a plant familiar to gardens for several hundred years, and probably every year it has been discussed by the gardeners, the most skillful ones of this generation still continuing the annual discussion. There seems to be a consensus of opinion that the proper culture consists in planting late in a sheltered position and drying off thoroughly after blooming. With all such care, however, it will be frequently found that some slight thing, like dryness, will cause them to go blind or refuse to flower. It is a curious commentary on garden skill that one finds this Iris blooming annually in gardens where no care is given to it, the owner, happily, oblivious usually to the interest of the plant. Thanks mostly to Herr Max Leichtlin, our gardens have been enriched by a number of interesting Oncocyclus Irises—Lupina, Gatesii, Paradoxa and others of their kin, such as Leichtlinii and Korolkowi. These, with the old *I. Iberica*, are an interesting and beautiful lot for those who enjoy fine plants which are interesting in care and beauty. These notes on culture refer, of course, to growth in the open, which seems the proper place for hardy plants. Frame and pan culture of hardy subjects does not seem to me an attractive occupation, even if a crop of flowers is more certain.

Iris Pallida Dalmatica—the great Dalmatian flag—is one of the most attractive and among the largest of the family. It has broad, noble foliage, and the large flowers are of a pleasing light lavender, with an orange beard. They are freely produced on stocky erect stems, without laterals, some three to four feet tall. The plant in bloom has an appearance of distinction and beauty, and is worthy a prominent place in the garden. A delicate odor adds the last charm to this variety.

Iris Monnieri is a beardless Iris, with fragrant clustered flowers, which are light lemon-yellow. The plant is attractive, but not showy, except as grown in masses.

Elizabeth, N. J. *J. N. Gerard.*

Roses.

THE time is at hand when Roses for blooming under glass should be replanted, and early planting gives a decided advantage to the cultivator, because plants so treated have a chance to become thoroughly established before winter sets in. The system of planting in shallow benches, now so generally used, gives many advantages, not the least of which is the smaller bulk of soil to be handled in emptying and refilling, always a laborious operation, especially in hot weather. But the system has the disadvantage of requiring more frequent repairs than the solid-bed plan, and the item of lumber makes a considerable difference in the expense-account of any large establishment. As a preservative, a thorough painting with crude petroleum should be given to all the wood-work of the benches; and even a good coat of whitewash will arrest decay to a greater or less extent, and also tend to prevent the spread of fungus in the soil.

The depth of soil required for successful Rose-forcing need not exceed from three to five inches. Indeed, some of the best Roses sent into New York have been grown in benches containing about three inches of soil, the high quality of the flowers being secured by judicious feeding and regular temperature.

At the time of planting, a slight shade on the house is beneficial if the weather is very hot, but this should not be allowed to remain on the house after the plants begin to grow, for firm wood is desired rather than long, sappy growth. In the selection of plants for this purpose, of course none but perfectly healthy stock should be used; good stout plants from three-inch pots being a satisfactory size, and naturally more convenient than larger ones if the bench is very shallow.

As frequently noted before, it is not well to attempt to grow a collection of Tea Roses in a forcing-house, as all do not flourish under precisely the same conditions, but when two or three varieties are planted, and these are grown well, much more satisfaction will be given.

The Hybrid Perpetuals that were forced early in the season will now be in full growth, and require an abundance of water and free ventilation, and if intended for an early crop will soon need ripening off by a gradual restriction of the water-supply until only enough is given to prevent the wood from shriveling.

In any establishment where space is an object, the box system for forcing Hybrids is a great convenience. Under this method about six plants are set in a box three feet in length by fifteen inches in width, and five or six inches deep, and the boxes being placed out-doors until needed, when they are brought into the heat and treated much the same as pot Roses, but usually with a better result. After the crop has been cut the boxes are removed to make room for a fresh lot, and may be put in a cold frame or emptied out for replanting.

Among the Hybrids it will be well to include some of Heinrich Schultheis for early forcing. This large and handsome deep pink variety has proved to be decidedly one of the best for this purpose. By using it for the first crop, and following with Anna Alexieff, Anna de Diesbach, Mrs. John Laing and Ulrich Brunner, a good crop of blooms may be expected. After January a much more extended list of Hybrid Perpetuals may be used for forcing, but the list named will be found most satisfactory for early winter.

The dark-colored sport from Catherine Mermet, Waban, will probably be the most extensively tested novelty of the season, the sales of the various agents having been very large, and, judging from the flowers shown last winter, it promises to bear out the high claims made for it. If these claims should be verified the parent of this variety will be remarkable for having produced the best white—The Bride—and also the best pink sport thus far introduced.

Holmesburg, Pa. *W. H. Taplin.*

Myosotis palustris semperflorens.—Why is it we do not see more of the Forget-me-nots in gardens? Several of them are really good, such as *M. alpestris*, *M. dissitiflora* and others, but the ever-flowering variety I have named is to be relied on to flower for six months of summer, and is just now as beautiful as a Forget-me-not knows how to be. Our long borders were edged with cuttings rooted and planted in September last, where they grew rapidly in the fall, and they now form a band eighteen inches wide around the garden that is very pleasing, and the more so as they will flower all summer. This variety is perfectly hardy, roots rapidly either as cuttings or where it grows in the open ground. *M. alpestris* and its white variety flower about two weeks earlier, and then they are past for the rest of the season. The white Forget-me-not is not worth the room it occupies. What is known as the Giant Forget-me-not (*Omphalodes verna*) is a lovely plant where it succeeds well. I have heard of its becoming perfectly at home in old gardens in Massachusetts, but I could never persuade it to make itself contented, but purpose to try again as the opportunity to secure plants may occur.

S. Lancaster, Mass. *O. O.*

Nymphæa Marliacea chromatella.—The water-garden during the last few days has made rapid progress, and its charms draw one irresistibly to its side for the first enjoyment of the morning. Marliac's yellow Water Lily, which is now in bloom, is undoubtedly one of the handsomest and most satisfactory of hardy Nymphæas, beautiful both in flower and leaf. It has been claimed at Kew that this variety is a cross of *N. tuberosa* with a yellow kind, probably *N. flava*, and it is there known as *N. tuberosa flavescens*. From its growth here it seems more probable that it is a hybrid of *N. alba candidissima*, Mr. E. D. Sturtevant, I believe, thinking it a cross of this variety with *N. flava*.

Elizabeth, N. J. *G.*

Sweet-potatoes.—To the market buyer in the northern cities the Jersey Nansemond is the type of a good sweet-potato. The northern practice of cooking sweet-potatoes by steaming them leads to a demand for a dry potato. The Nansemond, as grown in the sandy soils of New Jersey, is certainly one of the most handsome of sweet-potatoes. Coming southward, on the eastern shore of Maryland, the Nansemond is even drier and much sweeter than the New Jersey product, and in south-east Virginia these qualities are still further intensified. In the sandy soils of eastern North Carolina the Nansemond grows so dry as to be really choking when baked. Hence the southern dislike for this variety, for southern people always bake sweet-potatoes. But the character of a sweet-potato is largely the result of soil as well as climate. This Nansemond, grown in the clay lands of Pennsylvania, just across the river, is not the potato it is in New Jersey, and even in the south, when grown on the red clays of the mountain regions it loses all the dryness which makes it acceptable to northern people, without developing the sugary sweetness which makes the southern people prefer the yams. With all my early prejudice in favor of a dry, yellow sweet-potato, I find myself rapidly dropping into a preference for the sweeter baked yams. North Carolina ought to produce the finest of dry Nansemonds for the northern markets, and probably will do so when our market gardeners cease to insist that northern people shall prefer what is relished here and try to grow well what northern people want.

Experiment Station, Raleigh, N. C. *W. F. Massey.*

Correspondence.

The Preservation of Beautiful and Historical Places.

To the Editor of Garden and Forest:

Sir,—The interest which has been awakened in the preservation of beautiful and historical places is certainly extending, and it is worthy of all possible encouragement. The Waverley Oaks at Belmont, near Boston, whose story is so well told in Garden and Forest, vol. iii., p. 85, and which were so admirably illustrated in the same number, ought by this time to have been saved beyond any possible accident. The entire region which they occupy is a most interesting one, not only to the botanist but to the geologist, and, in fine, to every lover of the beautiful. It was not, however, my object in this article to dwell upon the Oaks, although pages might be written upon their value, but to call attention to a charming bit of wild scenery in their immediate neighborhood, which should by all means be included with the territory containing the famous trees. This consists of a wooded dell, through which runs a brook having, in the course of 200 feet, a descent of fifty or sixty feet. The stream at the commencement of its descent is caught in the jaws of a rocky ravine, which narrows rapidly for some distance, and when released the water rushes along over a comparatively level rocky bed among the roots of the bushes and wild grasses that wave and nod to the action of the tiny eddies, until, arrested in its course by a perpendicular barrier of rock, it turns abruptly and foams and frets with redoubled speed to its final plunge over a precipice of twenty feet. Beautiful at all times, the brook, when swollen at certain seasons, is really grand and impressive, becoming a true torrent, rushing with a violence and impetuosity that would seem impossible to one who sees it in its more gentle moods. The dell, not only in the immediate neighborhood of the fall but throughout its entire length, is characterized by fine forest-trees of several varieties, by precipitous sides and rocky ledges, and clothed with a vegetation peculiar to such localities. From the heights, distant views of the surrounding country can be caught through the openings, the whole forming a scene of picturesque beauty not surpassed in many mountainous districts. The vagrant brook, emerging from the glen, crosses the public highway under a bridge, winds demurely about through the lowland, moistening the roots of the lordly Oaks, and disappears finally in distant meadows. In former years, when the property was in the possession of acquaintances, a drive to Belmont in the late summer afternoon and a view of the falls was always the special entertainment offered to our friends, and it was one which never failed to gratify.

There is another locality which for its attractions should be reserved. In the south-eastern portion of the township of Newton, close upon the outskirts of Brookline, and almost within the sound of the bells of Boston, lies the sheet of water which for two centuries has borne the name of Hammond's Pond. Encircled by its border of forests, craggy eminences and picturesque surroundings, it has retained in a remarkable degree its primitive wildness and beauty. Its peculiar secluded position, affording rest, protection and food, still attracts the migratory water-fowl in their appropriate season, while the neighboring woods and thickets are the chosen breeding-place of innumerable songsters, and in them the red fox digs his hole unscared. No poet has ever sung its praise, and yet its charms are perennial. Whether in the bloom and joy of spring, when its borders are whitened with the panicled Andromeda; in the early summer, when its surface is bright with the glossy leaves and fragrant flowers of the Water-lily; in the days of autumn, when it reflects the glorious coloring of the Maples—its vicinity has been, and is still, the chosen haunts of the botanist and lover of rural quietude. Here Bigelow, Boot, Tuckerman, Emerson, Oakes and others have discovered and described countless specimens of its abundant flora; here, too, scholars of less note have found inspiration and encouragement in their communion with nature.

Beyond the western boundary of the pond is a large grove of Hemlocks, remarkable for their great size, height, symmetry and beauty, the approach to which is over a wooded hillside and by a descent through a narrow ravine. Within the grove, and on its southern border, is a craggy peak made up of large fragments of rock piled one upon the other in a confused Titanic mass. Within the crevices and cavities thus formed upon its northern slope, and protected from the sunlight by the deep shade of the trees, masses of snow and ice linger long after their disappearance elsewhere, while Ferns and other shade-loving plants grow in profusion, forming with the lichens and mosses a "rockery" that no art could imitate. From its summit wide stretches of country, embracing the graceful outline of Wachuset, and the bolder one of the Great Monadnock, in the far horizon, are visible, while all about is yet a forest-region, with grassy paths and openings, but partially invaded by dwellings and farms. No doubt there are districts of interest and value lying within a short distance of many towns and cities. It would be wise to secure them for public use before they are destroyed, as they certainly must be. No better investment than such a purchase could be made, and in many cases the cost would be comparatively trifling, if an effort were made to secure the land without delay.

Chestnut Hill, Mass. *Daniel Denison Slade.*

Recent Publications.

The Silva of North America, a Description of the Trees which grow naturally in North America, exclusive of Mexico, by Charles Sprague Sargent, illustrated with figures and analyses drawn from nature by Charles Edward Faxon, and engraved by Philibert and Eugène Picart. Volume II. *Cyrillaceæ–Sapindaceæ*. Large 4to, pp. 117; 47 plates. Houghton, Mifflin & Co., Boston and New York.

The second volume of this work, which has just been issued, equals its predecessor, noticed in these columns six months ago, at the time of its first appearance, in the high quality of the descriptive matter it contains and in the faithfulness and beauty of the illustrations, which are not surpassed by those published in any work devoted to the natural history of the New World. The trees belonging to four only of the natural families of plants are included in this volume. These are the *Cyrillaceæ*, the *Celastraceæ*, the *Rhamnaceæ* and the *Sapindaceæ*. Two of the three genera of Cyrillaceæ are represented in the North American silva by Cyrilla and Cliftonia, both monotypic and both found in the southern Atlantic and Gulf states, although Cyrilla occurs also in the West Indies and in Brazil. They are both small trees and both are ornamental, especially Cliftonia, which is evergreen, and which covers itself in the spring with short racemes of pale pink fragrant flowers. The Titi, as this tree is called where it abounds, is a feature of the vegetation in some parts of the south, occupying, as it does, great areas of swampy land with impenetrable thickets. Both Cyrilla and Cliftonia were, it appears, at one time inhabitants of Bartram's garden in Philadelphia; and, where the climate will permit of it, both will repay cultivation.

Three genera in *Celastraceæ* appear in The Silva—Evonymus, Gyminda, a genus separated from Myginda by Professor Sargent with a single West Indian and south Floridan species, a small tree of no commercial importance or utility, and Schæffaria, a genus of two species, one Texan and the other tropical American. The last becomes a small tree and was once not rare on the Florida keys, before the Bahaman wood-choppers invaded them and carried away all the large trunks to send to England, where the wood has been used as a substitute for Box-wood. The great genus Evonymus, in

which some forty species are now distinguished and which contains some of the most ornamental and valued of garden plants, is barely represented in the North American silva, and of the four or five species which inhabit our territory only one is admitted as a tree. This is the familiar Burning Bush or Wahoo of the eastern states, *Evonymus atropurpureus*, a small tree often met with in country gardens, although far less attractive as a garden-plant than some of the Old World species. We note, in passing, that the author adopts the early and classical orthography, and writes Evonymus after the manner of all modern continental authors, although Americans and Englishmen usually still write Euonymus.

The genera of *Rhamnaceæ*, most botanists will agree, are difficult to limit satisfactorily; and in some genera like Rhamnus and Ceanothus specific characters are not easy to find. Arborescent representatives of six genera are admitted into The Silva; of these, three are confined to the south Floridan keys, one is Texan. Rhamnus extends across the continent, as does Ceanothus, although it is in California only that species of this last genus attain the dignity of small trees. Some idea of the different views competent botanists may sometimes have in regard to plants in this family can be had from an examination of the synonymy of the plant here called *Rhamnidium ferreum*, the Black Iron-wood of the Florida keys and of the West Indies—a tree which has been referred to no less than seven different genera, to all of which it bears not a little resemblance. Professor Sargent now enlarges the Brazilian genus Rhamnidium to receive it, although it is a question whether it could not better form the type of a new genus, for where there are such wide differences of opinion about the genus to which a plant belongs, it is pretty safe to say that it does not belong to any recognized genus, and is best considered a new type.

None of the North American *Rhamnaceæ* become trees of large size, and none of them possess any great economic importance with the exception of the Pacific coast Frangula (*Rhamnus Purshiana*), here considered to include the California as well as the more northern tree. This is the largest of the North American species of Rhamnus, becoming sometimes a handsome tree forty or fifty feet high in the forests of conifers which surround the shores of Puget Sound. The bark contains to a large degree the cathartic properties peculiar to all the Buckthorns, and has become an article of some commercial importance, supplying as it does the basis of the popular remedy Cascara sagrada. Two plates are devoted to this species, the first showing the ordinary California form, with thick, rather narrow, almost persistent leaves; the other, the form with the large thin leaves developed in the moist mild climate of the north-west coast, a curious narrow-leaved mountain form found on the California Sierras, which Professor Greene considers a distinct species, and the tomentose variety of southern California and Mexico.

But that portion of the volume which is devoted to the *Sapindaceæ* will probably be found the most interesting to the general reader and to all persons who are fond of trees as trees without regard to their botanical characters and relationships, for in this family are included the Horse-chestnuts and the Maples, two genera which contain some of the most beautiful and highly esteemed of all ornamental trees. North America boasts of a number of Horse-chestnuts, Buckeyes as they are more commonly called in this country, and of these three grow to the size of trees. The genus is not a large one in the number of species, although gardens have long been decorated by a number of hybrid and seminal varieties raised chiefly from the European Horse-chestnut, a tree much more familiar to most persons, except professional botanists, than any of our native species. The true home of this plant remained, it appears, a mystery for fully three centuries after its introduction into the gardens of western Europe, and it is only in quite recent years that it has been found growing wild in the mountains of northern Greece. It is interesting to note that it reached western Europe by the way of Constantinople, where it appears to have been commonly cultivated before 1557; at least, in that year the Flemish traveler, Busbeck, then Ambassador of the Archduke Ferdinand, found it in the capital of Solyman II., and sent it to Mattiolus, in Vienna, from which city it gradually spread through Europe and North America. The fruit first known as *Castaneæ equinæ* was so called because of its reputed efficacy in the treatment of horses for broken wind. None of the American species equal the Grecian tree in size or in the beauty of their flowers, although our Alleghany *Æsculus octandra*, or Sweet Buckeye, rises to the respectable height of ninety feet, and the flowers of the California representative of the genus are extremely delicate and beautiful. More beautiful than any of our Horse-chestnuts is the curious Spanish Buckeye, a small tree of Texas and of the adjacent parts of Mexico, and the only representative of the genus Ungnadia, which, we read, is one of the most attractive and ornamental of the small trees of North America, when its branches in early spring, still bare of leaves, are covered with clusters of bright pink flowers, which enliven the sombre glades and mountain-slopes of a region in which trees and shrubs with showy flowers are not very abundant. This plant has been occasionally cultivated in our southern states, and ought to find a place in the gardens of those parts of the world where the climate is not too severe for it.

North America is not rich in the number of its Maples as compared with eastern Asia, which must be considered the headquarters of the genus, although nine species are found in different parts of the continent and are described in this volume. They are more common in the east than in the west, and, while the number of species is not great, individuals are so multiplied in some parts of the country as to make them important and conspicuous features of our forest-vegetation. This is particularly true of the Scarlet Maple and of the Sugar Maple, which are among the largest, and, economically, the most valuable trees of the genus, especially the latter, which is one of the most important of our timber-trees, besides furnishing nine-tenths of all the maple-sugar manufactured in the world. These two trees vary greatly in the size and shape of their leaves, even in a genus remarkable for leaf variation, and we should have been glad to have seen another plate devoted to the large-leaved form of the Sugar Maple, which is common in Michigan and other western states, and which varies so conspicuously from the typical eastern Sugar Maple that many observers, differing from the views expressed by Professor Sargent, regard it as a distinct species. Justice, too, can hardly be done to the Red Maple without some pictorial representation of the narrow, nearly entire-leaved form, which is often met with in the swamps of the Atlantic sea-board south of New Jersey, and which, in some parts of the Gulf states, is one of the most common forms assumed by this very polymorphous species. But of course it would be impossible to illustrate all the forms of foliage assumed by many of our trees, especially those which grow over wide areas of diversified climate. Sixteen plates are devoted to the genus. Certainly nothing can be more successful than Mr. Faxon's rendering of the graceful foliage, flowers and fruit of the Box Elder in one of the best plates of the volume, and equally good are his figures of the less familiar West Indian and Floridan Exothea and of the fruit of *Sapindus Saponaria*, the West Indian Soap-tree, "the tree that furnishes sope berries like a musket bullet that washeth as white sope." These, with another species of Sapindus and with Hypelate, complete the list of trees described in the second volume, which in conscientious research, in the wide range of learning and the sound judgment displayed, is altogether a credit to American scholarship.

It is dedicated to the memory of George Engelmann, the German physician, who made for himself a home in St. Louis, and, in the hours snatched from a large and successful practice, found time to become one of the wisest and profoundest of the botanists who have studied the American flora, and the acknowledged authority upon some of the most difficult families of plants. A worthier name could not be put in the place of honor in a volume of this character, for no man has ever studied our trees more faithfully or gathered together so much information about the Oaks, the Pines, the Junipers and the Firs of the silva of North America.

Notes.

A school of biology, in connection with the Sea-side Assembly, will be opened on the 7th of July at Avon-by-the-Sea, New Jersey.

The Yellow-wood trees just passing out of bloom in Central Park have been unusually beautiful this year. Some of the specimens are forty feet high and nearly as broad.

The great Chrysanthemum exhibition which is to be held in this city the first week of November will cover 30,000 square feet of surface. $6,500 have been offered for premiums.

The twenty-third session of the American Pomological Society will be held at Washington on the 22d, 23d, 24th and 25th of September next. Secretary Brackett promises that the official programme will be issued at an early day.

At the Geneva (New York) Experiment Station some careful tests were made last year between imported and American-grown seed of Cabbage and Cauliflower, and the result con-

firmed the experience in other stations, that the seed grown in Puget Sound, Washington, and on Long Island was equal, at least, to the best imported seed.

Taste has indeed changed since the middle of the seventeenth century, when Sir Christopher Wren wrote from Paris: "Fontainebleau has a stately wildness and vastness suitable to the desert it stands in." Who now would think this palace architecturally "wild," or characterize as a "desert," the beautiful forest that surrounds it?

The *Maryland Farmer*, in advocating the advantages of intensive culture, states that an irrigated vegetable-garden two and a half acres in extent, in the suburbs of Paris, employs three men, two women and a horse, the work of the latter being to pump the water into the reservoir for distribution and to draw the loaded cart to market before daylight in the morning. The average product of this little garden, at Paris prices, is $4,000 a year.

At the last session of the Minnesota Legislature some thirty-five sections of land were set apart, to be known as the Itaska State Park, and dedicated to the perpetual use of the people. Under the act a commissioner is empowered to procure for the state from the owners of land within the limits of the park concessions to the state by contract or deed, subject to the approval of the Governor. When any tract of land within the limits of the state park cannot be secured in this way the commissioner is authorized to institute proceedings to condemn the land and to convert it to use as a park.

Mr. A. L. Hatch, writing from Hill Crest Experiment Station, Wisconsin, to the *Rural New-Yorker*, in regard to the sunscald of Apple and other fruit-trees, says that the best remedy in that region has been found to be "medicated straw." Straight Rye straw, which has been dipped in whitewash containing some carbolic acid and Paris green, is set about the tree closely and extended up among the branches as far as practicable, being tied in several places. Thus prepared and put on, the protection lasts several years, or until the growth of the tree will make its renewal desirable. The medication serves as a preventive of injury from insects, mice, rabbits and borers.

A circular has just been issued by the Division of Entomology of the United States Department of Agriculture which gives in the space of half a dozen pages condensed information concerning several of the more important insecticides. Formulas are given for preparing kerosene emulsions, resin washes and arsenical mixtures, together with directions for their use and the necessary cautions to be exercised. Of course, all the points given here have been published before, but the department is doing good service by issuing in this available form answers to those questions which experience has proved are most often asked by correspondents when they begin to look about them for help against some invading insects.

A late bulletin of the New York Agricultural Experiment Station reports renewed success in using potassium sulphide, or liver of sulphur, as a remedy against Gooseberry-mildew. Liver of sulphur costs less than twenty cents a pound, and as only half an ounce of it is dissolved in a gallon of water this is an inexpensive remedy, since one gallon will spray ten or twelve large bushes if applied with the usual spraying nozzle. Of course, where a few plants are sprayed with a syringe more of the liquid will be required. The spraying should begin as soon as the leaves unfold, and should be repeated every fifteen or twenty days. Gooseberries are among the most desirable of fruits for home use, and they are very remunerative as market crops where they can be grown, for buyers are willing to pay almost any price for bright green fruit.

In Tulare County, California, near Lindsay Station, Mr. J. J. Cairns is preparing eighty acres of land to be planted in fruit. The land is a mixture of clay and sand loam, so that it is easily tilled, but has never been irrigated, and, for lack of facilities, it must be watered, if at all, with a pump from wells. It is necessary, therefore, that the land should be placed in the best condition for holding water, and Mr. Cairns took off all but two plows from his gang, weighted it, and sent it into the soil to a depth of from twelve to thirteen inches with the aid of a ten-mule team. Following this team came a subsoil plow, to which fourteen mules were attached, and this tore up the subsoil to a depth of thirty inches from the surface. These statements are given on the authority of the *Tulare Register*, and if the land does not absorb and hold all the moisture which falls upon it from the skies, or any other source, there is no efficacy in deep plowing. This piece of land will be watched with interest for a year or so.

In an article published in the *Journal of the Royal Horticultural Society*, Mr. Maurice L. de Vilmorin states that a single manufacturer in the year of 1889 preserved 400,000 kilograms of sorrel, a salad herb which is as much appreciated in France as it is neglected in England. This was said to illustrate the statement that France raises so many vegetables, which from their nature are not qualified to undergo long journeys, that factories are found everywhere for preserving them, and that their good quality, combined with the care taken in their manufacture, gives them a market value throughout the world. Not only green peas, French beans and tomatoes are canned in immense quantities, but asparagus and several other vegetables, including the sorrel above mentioned, are similarly treated, and three-fourths of the product is exported.

Interesting as showing the prevailing fashion in tree-planting in New England, is the account of the census of the Salem trees made in 1859, when it appears 2,651 trees were standing in the city streets, and that of these 1,656 were Elms, 353 were Maples, and, strangely enough, 110 were Cherry-trees. "The total disappearance of these Cherry-trees, as they were removed owing to the nuisance caused by the foraging of boys," Mr. Robinson suggests, "is an answer to those writers who advocate the planting of fruit-trees in the public streets." But in other countries, where boys are better disciplined than they are in the United States, fruit-trees are successfully and very profitably grown along the borders of the highway, and such trees in Germany and other European countries have proved most profitable investments both to abutting land-owners and to village corporations.

The Metropolitan Museum of Art has now been opened for two successive Sundays, and has been visited by probably 25,000 persons, a large proportion of whom were evidently working people who are unable to visit the galleries on week days or evenings. It is a noteworthy fact that the examples of work in wrought iron, which few persons on week days stop to glance at, were constantly surrounded and discussed by groups of workmen. Why should there not be a movement toward the Sunday opening of the Museum of Natural History, where artisans of many kinds might find pleasure and profit? The Jesup collection of American woods, for example, is interesting to the botanist and the landscape-gardener, but it has also a mine of information and suggestion for the carpenter, the cabinet-maker, the wood-carver and the architect. It is argued that admission to these museums on Sunday may lead to the toleration of amusements of a less elevated character; but it is not so probable that the opening of the libraries and the museums will prove "an entering wedge for the admission of the Continental Sunday" as it is that such opportunities will open the hearts and minds of workingmen to the admission of new light which will increase their knowledge, intelligence and ambition. The so-called experiment of Sunday opening has been tried in Boston and Philadelphia for fifteen years, with great advantages to the people who have availed themselves of these privileges, and the Continental Sunday has given as yet no signs of its arrival.

Dr. J. A. Lintner writes that the Pear-midge, *Diplosis pyrivora*, has appeared in Catskill, where it is said that ninety per cent. of the fruit on the Lawrence trees in one orchard are affected, while other varieties, like Anjou, Seckel, Bartlett and Bosc, are attacked to some extent. Hitherto this most dangerous enemy of the Pear has only been reported in one locality in the United States, that is, at Meriden, Connecticut, where it was probably introduced some ten years ago in Pear-stock imported from France, and, a few years thereafter, almost entirely destroyed the crop on the Lawrence and seriously injured other varieties. Effort was made to exterminate it before it spread farther by picking the entire crop in an off year and destroying it, and it was believed that the pest had been brought under control. So far as ascertained now the invasion is confined to an area with a radius of about three miles, but it may be much more extensive. Fruit growers in New York state and elsewhere are requested to make search on their Lawrence trees first, and then on other Pears, and report the result to Dr. Lintner, at Albany. The infested fruit can be recognized at once by the fact that its upper three-fourths is enlarged and irregularly swollen, and has a different color from its base. When cut open perhaps from ten to twenty pale yellowish footless larvæ will be disclosed, each about one-tenth of an inch long and pointed at the ends, much resembling the larvæ of the Wheat-midge. If this pest is confined to a few localities Dr. Lintner thinks that it can be exterminated by united effort.

GARDEN AND FOREST.

TABLE OF CONTENTS.

Village Woods.

ALMOST every week we hear that one or more of our thriving young cities have been enabled by some special legislation to acquire land to be used in the future as a public park. Very often it is the case that this land includes some picturesque glen through which a brook flows, or some old forest, or a lake-front or other natural feature of peculiar interest. This is all commendable, and there is no danger that too many parks will be made. Indeed, in almost every case which has come under our observation it is probable that the investment will pay a substantial money return in the improved value of property, without counting the still greater advantages which will come to the city of the future from the increased health and comfort and enjoyment of the citizens.

In smaller towns, too, there is usually some square or green which is utilized as a place of public assemblage, and which is bright with grass and flowers and attractive with the shade of venerable trees; but it rarely seems to occur to the inhabitants of smart villages that some public ground would be to them a most valuable possession. In many cases there is a neighboring grove to which the villagers resort for public gatherings. Of course, this is in private hands, but the people are welcome there when Fourth of July is to be celebrated or on such occasions as Sunday-school anniversaries, and farmers' picnics, and harvest-homes. We can call to mind several bits of woodland which serve a purpose like this, and which visitors always have in mind when they think of the villages near which they stand. But woods are never safe in private hands, and when the time comes, as it too often does, that the grove is felled for firewood or for lumber, the destruction of the trees is felt to be a distinct public loss.

This train of thought has been suggested by what has recently happened in a thriving village in northern New Jersey. Within a short walk of the town-hall a beautiful grove of hard-wood timber, some ten acres in extent, has stood as long as the oldest villager can remember. Through the kindness of successive owners it has been practically a public park for all, and in its shade have been held neighborhood gatherings of every sort for generations. It has been the haunt of the school-children, where spring flowers and autumn leaves were gathered. Visitors from the city have found in it a special attraction in a region which is in itself distinguished for rural beauty. In short, a great many people, when they think of the village, will think of this grove as one of its prime attractions. But the owner has been offered what he considers a fair price for the timber, and the grove is doomed. When the gray old trees fall the country-side will lose much of its beauty, and the village will be bereft of one of its most interesting features.

In such a case as this it seems plain that it would have been a public benefit if the grove could have been spared to the village. Of course, it is not every owner who can afford to give his property for the general good, but certainly the purchase of such a grove by the village would have been from every point of view a wise outlay of public money. Perhaps it would not have been difficult in this instance if any public-spirited citizen had taken the matter in hand to have raised sufficient money to save the grove, but in most states there is no way in which unincorporated towns can get possession of tracts of land for such purposes and hold them. In the state of New York there is a law which permits an association of citizens to hold land for public use and to appoint their own successors. Under this law landholders are encouraged to make donations of property to public use, and associations can be formed to buy such property where purchase-money is needed, and for this reason the action of the Legislatures of New York and Massachusetts, which makes such transfer of land possible, is to be commended.

But, in addition to laws for securing such village common-woods or public parks, there is also needed a more general feeling that they are worth having. Every one admits the advantages of securing some bits of rural scenery for the use of people in crowded cities. But people in villages are not shut out from the enjoyment of rural scenes. It is their privilege to see grass and trees, and to have familiar intercourse with natural objects, so that the commanding arguments for city parks do not apply to their condition. But, after all, the advantages of some common meeting-ground, for one purpose or another, are very obvious, and those villages which bestir themselves to save from destruction the groves or glens with which their names are associated will never repent of the labor and money expended in the cause. There is no question that such an acquirement of common property will pay in a broad way. It will give a stimulus to local pride and public spirit. It will strengthen the ties which attach the young people to their homes and to home interests. It will promote social feeling and neighborly kindness. It will add to the reputation of the village for enterprise and forethought and general enlightenment, and it will help to secure for the neighborhood that good name and fair fame which is to be as highly prized by a community as by individuals.

THE timber in the grove alluded to above has been sold to the owners of one of the portable saw-mills which are moved around from place to place in northern New Jersey and are making a market for the little collections of trees left standing upon the farms of that region. For many years these saw-mills have been helping to supply the market with hard-wood timber from Indiana, Ohio and that part of the country, but it is only of late years that they have invaded the east. In the aggregate they cut over an immense area of land, and as their proprietors are shrewd enough to combine for holding down the prices, the growing scarcity of timber is not felt in the market. These little supplies, gathered in from various sources, keep the market full, and this full market is constantly used as an argu-

ment against the assertions that are made by prudent men concerning the gradual destruction of the timber of the country.

If the trees on these scattered woodlands were allowed to grow up again the work of these portable mills would not be so much of a calamity, but, too often, when farmers find their trees cut away they endeavor to break up the land and add to the area of their cultivated fields. As a rule, too much land is already under the plow, and this new clearing simply means a few more acres of poorly tilled land and no increase of income. That is, the farm would generally yield a larger income if the wood had been allowed to stand, and if the labor and money put in the new ground had been expended upon that already under tillage. Indeed, in a great many instances it would be profitable for the farmers of the country to allow the broken, or sterile, or stony portions of their land to grow up in timber, and give more thorough culitvation to what remains. Where these mills have been operated for any considerable time one can see that the country loses much of its beauty, which is a more important matter than it seems, for a well-wooded country has attractions for city visitors and city buyers which enhance the value of real estate to an appreciable degree. But, besides this, it may be questioned whether the opening of the country to the sweep of the cold winds in winter, and drying winds in summer, does not have an appreciable effect on the general fertility of any region.

But, after all, these voracious little mills are only one other device used by this generation in its haste to get rid of its inherited forests. There is little reason to hope that any salable tree will be allowed to stand. The promise of future forests in the country seems to rest with the children, and depends upon their proper education. Who is to write the school-book which shall inspire our future citizens with an adequate appreciation of the value of forests as a natural resource, and of their functions in relation to soil and climate and health? Not the least of the benefits of early instruction of this sort would be its help toward establishing a personal friendliness for trees and toward the creation of a public sentiment which will protect them from wanton destruction at least.

Mr. John Robinson has begun, in the *Salem Gazette*, the publication of a series of articles on "Our Trees." From the first of these papers it appears that there are about 125 different trees growing naturally or cultivated in and about Salem. Of these sixty-four are natives of eastern Massachusetts and seventeen come from the other parts of the United States. Salem is, therefore, a very good centre from which to study trees, and Mr. Robinson's papers cannot fail to stimulate much interest in the subject. In the introductory article Mr. Robinson calls attention to the fact, which has often been insisted on in these columns, that people who are familiar with humbler plants, and this applies, too, to learned botanists, have a very slight acquaintance with trees. "Nearly every one," he remarks, "can tell an Elm from an Oak or a Willow from a Pine, but the difficulty seems to be in telling the Oaks and Pines apart, to distinguish the Pines from the Spruces or the Birches from the Hornbeams, or separate the many foreign trees in cultivation from the native species." "And a little observation," he tells us, "will serve to fix nearly all of these trees in mind and add much pleasure to town walks and country rambles. When a good example of some tree is found it should be carefully watched from the earliest warming up of its blood, so to speak, by the spring sun through all its various phases of bursting buds, flowers and fruit, and falling of its leaves. Methods in observation are thus acquired which can be applied to other things in life. By this out-of-door study much more satisfactory results will be obtained than by merely trusting to match flowers or fruit to description and figures. Although books are valuable aids, Nature never will confine herself to plates, which must be typical rather than universal in their scope."

A sunset, a forest, a snow-storm, a certain river-view, are more to me than many friends, and do ordinarily divide my day with my books.—*Emerson.*

Winter Studies of the Pine Barren Flora of Lake Michigan.—V.

The greater part of the woody growth found in a Pine Barren will naturally be sought among the evergreens. Five kinds of these are present, making, with the Larch, six species of conifers. These are closely associated with deciduous trees, or have been supplanted by them, for many of the Pines and Cedars have been destroyed by fire, and Oaks and Poplars have taken their place. But when protected a new growth of Pine is made, the White Pine or the Gray Pine, according to locality and conditions of the soil. Protection is difficult in a region traversed by several railroads, and must be restricted to quite limited areas. Hence, some of the problems of forestry may be advantageously studied in a section of country no larger than the one which embraces the wild lands at the head of Lake Michigan, where the trees have to struggle with the carelessness and wastefulness of men. Groves of White Pine are sometimes seen where the ground is well stocked with thrifty trees of recent growth, from ten to thirty feet high. They have sprung up in the track of fires and maintained their place, and, if not interfered with, would in time form trunks of fair dimensions. The natural conditions are present for a Pine-forest from two to four miles wide, extending from the boundary of Indiana, eastward, into the state of Michigan. Most of this is now waste land, of little use for any produce that may be obtained from it. Once there were saw-mills in the tract cutting up Pines and Whitewood (Liriodendron), found in paying quantities.

Taking the coniferæ according to their abundance, the list is headed by *Pinus Banksiana*, the Gray Pine, or Jack Pine, as it is generally called at the west. It is limited to the close vicinity of the lake, a strip of land from half a mile to two miles wide embracing about all of it. An essentially pure wood of this species is found only on a narrow strip along the shore, where scarcely any trees except a few Red and White Cedars are mixed with it. The succession of woody plants is about as follows: Next to the beach is a fringe of Necklace Poplars (*Populus monilifera*), mostly stunted trees, often bearing fruit when only eight or ten feet high. Interspersed with these are Willows and Rose-bushes, Cornels, Grape-vines and the Sand Cherry (*Prunus pumila*). Then the Gray Pine comes in, dwarfed, and often shrub-like where much exposed, but forming trees with trunks six inches to a foot and a half through when away from the shore. Though it is usually a homely tree when standing alone, groves of it, where the ground is free from underbrush and covered with an abundance of fallen leaves or with a sparse herbaceous vegetation, possess attractive features.

Flattish reaches of this Pine convert the nearly barren sands into clean shady woods, almost equaling woods of Red Pine. They do not have the straight columnar trunk of this tree, covered with smooth reddish bark, the limbs high up and forming a close canopy, with thin, long and slender needles in brush-like tufts, but a short trunk with dark-colored, rough and flaky bark, the limbs low down and the branchlets studded on all sides with short, stiff, yellowish green leaves. They are most shapely when somewhat crowded, being spire-shaped when young and small, and when well grown making a roundish crown with their spreading limbs. As a shade-tree along a sandy road, they do well and may be quite shapely. Dr. Richardson considered Bank's Pine a handsome tree when growing in favorable situations.* Isolated upon the sand-hills, where it is buffeted by the winds, it may be only a straggling shrub or scraggy tree, standing firm till the sand is swept from off its roots and it is undermined and toppled over. Even in such localities it is frequently a picturesque object, winning respect for its sturdiness, though not admiration for its shape.

The Gray Pine in this section varies in height from a shrub, fruiting when but two or three feet above the ground, to a tree sixty feet high. Trees thirty or forty feet high are common in the denser woods away from the shore of the lake. I have measured some that had a girth of sixty inches, and those with a diameter of ten to twelve inches are frequent. The trunk varies but little in size up to the first branches when these are low, and scarcely any portion of the roots is visible above the surface of the ground, from which the tree rises like a post. It may be found producing cones when but half an inch in diameter at the ground and four feet high, bearing a few short branches at the top. But the trees are usually much more stocky than this when fruiting.

The crown of this tree is generally disfigured by the dark-

* Gordon, "The Pinetum," p. 231.

colored cones adhering to the branches. They are very persistent, and last for many years. It is doubtful whether they fall off naturally, though they may be broken from the limbs or drop off when the attachment rots away. They are more durable than the smaller branches to which they cling, for on fallen trees that have lain upon the ground a long time the cones remain till the branchlets decay, the thick and indurated scales being more lasting than the wood. They are closely sessile, and when a fresh cone is pulled off some of the wood of the supporting branch invariably comes away with it, a piece from half an inch to more than an inch in length, and often reaching to the centre of a small twig in depth, being torn out. No better proof of the growth of a flower-cluster from the wood could be desired. Even the old and dry cones do this to a less degree, or the branch breaks off before the cone can be detached. This persistence of the cones gives to an old tree the appearance of great fruitfulness, the fruit of many years being represented on it, though comparatively few cones are produced in any single year, the fresh ones often being quite scattered, or even scarce, upon the limbs. Hundreds of these old cones may be counted on a dead tree, the limbs being almost black with them, or they may look gray or grayish from the cones weathering on their exposed parts to the color of the nest of a paper-wasp. The old cones usually point downward from the limbs, and become top-shaped by the spreading of the scales, their diameter nearly equaling their depth, an inch or more across.

The newly ripened cones are from one to two inches long, conical, but usually a little curved at the end. They are of a light or yellowish brown color. The scales are thick and blunt, reddish brown within when they first open. Each ends in an oblique, somewhat four-sided, or rhomboidal plate. In the centre of the plate is a shallow pit, or eye, of a grayish color, from which many fine lines radiate to the margins. There is enough variety in their colors and markings to impart a fair degree of prettiness to them at this time. As they are often in pairs, and on opposite sides of a branch, pointing in the same direction as the branch, they have the appearance of stumpy horns scattered among the leaves.

Rudimentary cones are seen upon the branches in the winter, as they form the preceding season. These are from a fourth to a half inch in length and ellipsoidal in shape. Like the winter-buds, they are often coated with resin, which exudes freely whenever the wood is cut, and is also copious at the base of the twigs and branchlets. At these points it forms balls frequently half an inch in diameter, completely investing the branches. The resin is formed in connection with the persistent remnants of bud-scabs, encircling the twigs at their insertion, and hence accumulates there in balls. There are also seen upon the branches clusters of withered aments, which, though the tree sheds its pollen in May and June, remain till the following spring.

The seeds of the Gray Pine are small and dark-colored, with a relatively large pale-brown wing, so thin as to be transparent. Hence it is very light and may be carried far by the wind. The wing, shaped almost exactly like that of some insect, is striped along its inner edge with lines of darker brown. The seeds usually occur in pairs, and are eagerly sought for food by the White-bellied Nuthatch (*Sitta Carolinensis*). Small flocks of these birds, which become gregarious in winter, are seen flying about among the trees, searching the cones for seeds or pulling off bits of the bark under which insects or larvæ may be hidden. Their long and flattened bill is nicely fitted for this work, for the seed lies close to the scale, but the wing, dexterously snipped off and dropped, as it comes floating on the air, shows that they readily succeed in their efforts.

The position of the cones upon the branches is rather upright, which tends to keep the seeds from falling out. Though the cones mature in the fall they are slow to open, and continue to open throughout the winter, some being closed even up to spring. This prolongs the season of supply for these birds, which are quite abundant, and among the few to stay with us and make the woods more cheerful in the winter. The Gray Pine takes a wide range in its conditions of growth. Naturally a denizen of rocky ground and dry sands, it is not uncommon here in the wetter grounds. I have taken it from the scanty soil lodged in the fissures of rocks in Canada, and found it here in sphagnous swamps, growing amid clumps of Cassandra, with the Pitcher-plant at its base, its roots covered with Sphagnum and Cranberry Vines. In such wet positions it is short-lived, though it may grow to a shapely little tree, three or four inches in diameter. But in some swamps less wet it takes a place beside the Tamaracks, like this tree tall and slender when the growth is crowded, with a clean trunk devoid of limbs till near the top. Groups of such trees under these conditions are rather neat and attractive, in the winter the yellowish-green of the Pine offsetting the dense, rough spray of the Tamarack; in the summer mottling its soft foliage of lively green with a well-contrasted color.

Englewood, Chicago. *E. J. Hill.*

How We Renewed an Old Place.

IX.—PLANTING TREES ON A LAWN.

THE house at Overlea was begun in the summer of 1887, and completed in April, 1888, at which time the grading of the knoll was finished, and the lawn ready for planting and sowing.

Our first experiment, however, in moving good-sized trees was made in the month of January of the latter year, when we transplanted two large Norway Maples, given to us by a friend, on condition that we would take them away at that time, as otherwise they would be destroyed by some grading that was going on where they stood.

Fortunately, it was an open winter, with no frost in the ground, and there was no difficulty about digging. I personally conducted the procession, and insisted upon having the diggers begin at the outside and work in toward the trunk, so as to save all the little roots. It was slow and careful work, and it took all day to move two trees. They were too heavy to lift with a ball of earth, as we had no special appliances for the purpose, for the largest one measured six inches through, two feet from the ground, and had a lofty top.

After the trees were carefully uprooted their tops were cut off, until the main stems were only about eight feet high, and the branches that were left running up from them were also cut back to within a few feet of their union with the trunk. Could we have foreseen the mildness of the two succeeding winters we should have been tempted to prune them less severely. I am almost sure that it was unnecessary, but moving them at such an unusual season seemed to make it wise to give them more root than top. It will take about four years for them to get back their original stature after this severe treatment, but they perhaps have escaped risks of drawbacks by the way. Similar trees in this town, transplanted without topping, though they have lived, have shown signs of feebleness, and I am disposed to think that in the end ours will make the finer specimens.

The holes in which they were set were dug six feet in diameter and nearly five feet deep, and six or seven cart-loads of loam were put in them. A gentle rain was falling when the Maples were set; and when the roots were fairly covered and the ground trodden closely about them, water was put into the holes before they were finally filled up.

These two trees, planted on the south side of a gravelly slope, so that the moisture must run away from their roots more than is desirable, have made so heavy a growth in the last two years, that in the middle of summer we have been compelled to cut out many large branches to admit light, and to improve their shape. In addition to their density of growth, they have shot up fresh stems, between seven and eight feet long, in the two seasons they have been fairly growing, for the first summer they did not accomplish much beyond a good crop of leaves. By the end of July we look to see them grow four or five feet more, as they are fairly set, and in fine healthy condition. The ground about them has been kept open and cultivated, and is heavily enriched several times in the course of the summer.

They are so near the house that we use the broad space around them as beds for Geraniums and Heliotropes, which probably detracts a little from the growth of the trees, but at the same time improves their appearance and keeps the earth moist and well stirred up about their roots. When the season is dry they are very thoroughly watered at least twice a week, by leaving the hose to run on them from its open mouth for an hour or two at a time.

In April we moved in the same manner a Silver Maple, which has grown nine feet and ten inches, and a stocky White Willow, which has been put quite near the house to give us immediate shade, of which we are greatly in need, and which is to be cut down as soon as the Maples are big enough. This last tree has grown, in a very dry place, a dense head nine feet six inches in height, so that it is now a tree seventeen feet high.

These are the best we have to show, except a Catalpa, which has made a most luxuriant growth, for our Ash-leaved Maple, which was also disposed to make a record, has been moved twice, and so set back. But this growth on a gravel-bank,

where no one thought that trees could be made to live at all, is not to be despised. Some of the other trees have grown almost equally well, but were not so large to begin with, so they seem less important.

In that same April the generous friend who furnished us with the large Willow and Silver Maple, kindly sent us, in addition, a dozen moderate-sized trees which he was disposed to think would grow faster than the larger ones, and these were placed somewhat at random on the lawn, for they came unexpectedly, and had to be set without much reflection, so that some of them have had to be moved again.

And here we will honestly admit that the landscape-gardener would have been of great use to us, for the lack of experience gives one a feeling of uncertainty about the result of even his best-considered arrangement, which is often disquieting.

We know for one thing that we have too many trees too near together, because we never dreamed they would all make up their minds to live, and we discover that after taking great pains to make a tree grow, we cannot make up our minds to disturb it for fear it will be in the way in the future, and so we postpone the evil day. Possibly they will do better in their wind-swept situation for not being widely separated, and for the next generation, which will be unrestrained by our sentiments, we have provided some small Elms that ought to be good trees by the time the short-lived Maples are beginning to shuffle off their mortal coil. We know that the least enduring of them will outlive us, unless we emulate old Parr and the Countess of Desmond,

> Who lived to the age of a hundred and ten,
> And died by a fall from an Apple-tree then.

All we ask is that they will hurry to shelter us from the burning afternoon sun, to which our front is exposed, and when their task is done, the noble Elms, which are "a hundred years growing, a hundred years standing, a hundred years dying," shall be our monument when this house, like its ancient predecessor, shall have crumbled to ruin.

Impatient as we are to achieve miracles of growth, we might forget how much our little trees are doing were it not for a photograph taken in 1888, which shows them scudding under bare poles, that makes their present height quite imposing by contrast.

In the five years which we claimed of our critics in the beginning, we are now sure that all air of newness will have gone from the knoll, which, even the second summer, astonished the passers-by, who were most of them unused to the results that can be attained by unremitting exertions.

Against these trees we have no charges to make of either stubbornness or ingratitude; given the conditions, the results are all, and more than all, we had a right to expect. The only ones that have not been what we could wish are the Hemlocks, which object strenuously to the dry, windy situation, and only live under protest. In vain do we plant nursery trees with good roots, they dwindle and pine, and refuse to profit by their advantages. If Garden and Forest will give us any advice about treating them, we will gladly follow it. Out of over forty trees planted on the lawn and its slopes, they are the only ones that fail to give satisfaction, and we desire to get the better of them if possible.

No evergreen is so graceful and suggestive of wild woodland ways as this feathery denizen of the forest, that seems to shrink from the companionship of man. The perfume of its boughs reminds one of camps in the woods, of canoes, of Indian guides, and silent solitudes. For me it has ever a peculiar and elusive charm, and I cannot come in my wanderings upon some majestic old tree beside a granite boulder, as it loves to grow, without a thrill compounded of association and admiration. The Hemlock seems to possess every beauty that a tree can have: its form, whether it be symmetrical with youth, or gnarled and twisted by age, is always impressive and noble; the murmur of its boughs is tenderly musical, its fragrance exquisitely wild and aromatic; its very shyness has a charm that seems to breathe distinction, and, best of all, it is perennially green, so that its blue shadows on the snow give one of the loveliest tones in a winter landscape.

Why, then, since I woo it with such tender affection, such anxious care, does it refuse to grow for me? Possibly it is killed with kindness, and some wholesome neglect may be what its shy soul desires, for I notice that the little ones in the swale, half-smothered in grass, do not die, though left wholly to their own wayward devices, while the pampered specimens on the lawn lift bare and ragged branches to the sky, from out their luxurious beds of mulching, and are painfully disappointing and uncertain.

Hingham, Mass. *M. C. Robbins.*

Weevils in Leguminous Tree-seeds.

THE beetles known as weevils, belonging to the genus Bruchus, are known to live during their early stages in the seed of various plants, especially those of the *Leguminosæ* or Pea family. The Pea and the Bean-weevils are examples too well known to gardeners, grain-growers and dealers.

While many species of weevils attack the seeds of plants which are not at present of great economic value, their ravages in the seed of leguminous trees and shrubs in various regions must often be very considerable. Some of the arid, as well as the more fertile, parts of our south-western states and territories and of Mexico are characterized by several genera and species of leguminous trees, which comprise the principal arborescent vegetation over large areas. Aside from the uses to which the wood is put, the fruit of these trees is sometimes of much value to the native inhabitants of the region. This fruit is often seriously infested by weevils of several species, four of which Mr. C. E. Faxon has drawn for the accompanying illustration, together with several of the pods infested.

An idea of the abundance of these pests may be derived from the fact that out of hundreds of seeds Mr. Faxon sometimes found difficulty in getting a perfect one and its embryo for illustration in the "Silva of North America."

A better knowledge of the weevils affecting these trees will probably show other species besides those already known.

Although each is usually confined to one kind of food-plant, the same species of weevil sometimes attacks the fruit of leguminous trees belonging to different genera. These insects undergo all their transformations within the fruit, and, when mature, the beetles cut small round holes in the seed, or through seed and pod, and make their escape.

The pods and seeds of the screw bean (*Prosopis pubescens*) are ground into a sort of flour and used as food by the natives of Arizona and New Mexico. These pods often contain great numbers of the little grubs, which afterward develop into the small weevil named *Bruchus desertorum*,* or the Bruchus of the desert.

The color of this is ashy-red above and gray beneath. The wing-covers are splashed and dotted with yellowish red or darker markings, which vary extremely in different individuals, being almost entirely absent in some. It is about one-tenth of an inch long.

Perhaps, the presence of large numbers of these insects in the screw bean gives it an added richness and flavor when ground and cooked. The screw bean is also said to be infested by *Bruchus uniformis*, a large, ashy-reddish colored species much like the next.

The Mesquit (*Prosopis juliflora*), often a most characteristic tree of arid areas in Arizona and Mexico, has its pods infested by *Bruchus prosopis*, a grayish brown species, with dark markings above, and about a sixth of an inch long. The fruit of this plant, known also as *Prosopis* or *Algarobia glandulosa*, is eaten by Indians, and even by white men, but is chiefly valuable as food for horses, which eat both beans and pods.

From fruit of *Cercidium Torreyanum*, sent to the herbarium of the Arboretum, four quite different-looking species of weevils have been taken. *Bruchus amicus* came out of seed received from Texas. It is among the largest of the American species of the genus, sometimes measuring a fifth of an inch in length. This beetle is densely covered with a silky gray pubescence, which, when rubbed off, leaves the surface smooth and black, or reddish black. Seed of the same plant collected in Arizona was found to be infested by *Bruchus pruininus* and by great numbers of *B. limbatus*.

The first of these two is black, but is so covered by a fine silky pubescence that it has a bluish gray appearance. It is about two-thirds as large as *B. amicus*, to which it has some resemblance. It is said to occur on the "Ironwood-tree" of Arizona, which may mean the *Olneya Tesota*, but I have not yet found it in seed of this tree.

Bruchus limbatus is a small, stout, black species, with a broad red stripe on each wing-cover. This red stripe is variable in shape in different individuals, and it is usually more or less constricted in the middle. Large specimens are about one-eighth of an inch in length. A package of the beans of *Acacia Greggii*, sent from Arizona, proved to be utterly ruined by these beetles. Not a bean contained less than half a dozen of the insects, while twelve or fifteen was a common number, and each emerged by a separate hole.

---

*Technical descriptions and references to original descriptions will be found in a paper entitled, "A Revision of the *Bruchidæ* of the U. S.," by G. H. Horn, M.D. *Transactions of the American Entomological Society*, Philadelphia; vol. iv., pp. 311-342.

It may be of interest to note that this package of seed, containing thousands of weevils, had a distinctly warm feeling, a fact which has recently been brought to notice in regard to weevil-infested peas and cultivated beans.

The fourth species of weevil which came out of pods of *Cercidium Torreyanum* was *Bruchus Ulkei*, a beetle quite as large as *B. amicus* and densely covered with a whitish pubescence, except the outer half of each wing-cover, which is black.

extracted from the flowers, and it may be worth noting that the pods sent to Dr. Hagen were represented as being exceedingly rich in tannin.

Species of weevils also infest the seed of Gleditschia, Robinia, Cercis, Leucæna and other American leguminous trees; and the larva of a large Tineid moth has been found to live in pods and seed of Leucæna and Cercidium from Texas.

Dr. H. A. Hagen, of the Museum of Comparative Zoölogy at Cambridge, Massachusetts, has for many years had several of the foregoing species of beetles and specimens of their work in his biological collection. These were principally collected by Dr. G. Engelmann, Dr. E. Palmer and Professor F. W. Putnam in their various collecting and exploring expeditions.

In this biological collection there are pods of *Acacia Farnesiana*, which were received from Mexico and found to be much infested by *Bruchus protractus*, a weevil resembling *B. prosopis*, but rather more slender in shape and darker in color and with heavier markings on the wing-covers. *B. amicus* also came out of these pods.

Acacia Farnesiana is now naturalized in nearly all the tropical countries of the globe. It is well known that a perfume is

Foreign Correspondence.

The Temple Show.

THE fourth great plant exhibition held in the gardens of the Inner Temple, by the Royal Horticultural Society, on the twenty-eighth and twenty-ninth of May, eclipsed everything of the kind seen here before. There may have been larger exhibitions than this, and it is possible that some departments of horticulture may have been better represented at the famous shows held by this society thirty or more years ago than they were yesterday, but, taken as a whole, the verdict of all qualified judges is, that English horticulture had never before achieved anything like this Temple show. The chief attractions were supposed to be Orchids and Roses, and

these were indeed magnificently represented. But quite as much may be said of the herbaceous and alpine plants, the Ferns, Calceolarias, Begonias, Heaths, and the many other popular flowering plants, both tender and hardy, all of which were shown in marvelous form. In spite of one of the severest and most trying of winters, followed by a spring and early summer equally unfavorable to good gardening, the condition of almost every plant shown at this exhibition was perfect. As an indication of the strength of horticulture in England the show was a surprise, even to the well-informed who expected great things. There can be no question of the claim of Orchids to the first position among garden-plants; the exhibits proved it as strongly as the crowds of visitors who gave unrestrained expressions of delight at the wonderful specimens shown by both nurserymen and amateurs. "Orchids first, and the rest nowhere" was the comment of a companion who disliked the hustling and crush which prevailed almost the whole day through wherever Orchids were staged. Public taste is not quite so partial as this, however, appearances notwithstanding. The collections of Orchids contained so many remarkable examples that much time was needed to see them all. Even connoisseurs lingered about the Orchids, note-book in hand, while cultivators hung round and wondered "how it was done." For it is not every one who essays Orchid cultivation that can accomplish such things as are to be seen in the collections of Baron Schrœder, Sir Trevor Lawrence, the Baron Rothschild, Mr. Sander, Mr. Cypher, and others. Orchids are not easily killed, it is true, but they are only rarely grown to perfection. "It is all done by looking after them," declares a master of the art, while another will tell you that "no plants are so easy to grow as Orchids, when once you understand them," truisms which tantalize instead of helping one.

The collection of Orchids from the famous St. Albans nurseries was the largest and richest ever exhibited from any one garden; indeed, I doubt if any one but Mr. Sander could make such a display. The immense houses at St. Albans are packed with all the best and richest of Orchids from almost every part of the world, and most of the plants are possessed of all the rude health which is common to newly imported pieces. With so much of the best material to select from, together with exceptional cultural skill, Mr. Sander was certain to make a fine display. But it was much finer even than could have been anticipated. From one end to the other of a tent 130 feet long, Mr. Sander had arranged a collection comprising many hundreds of plants and disposed with excellent taste. First came a large group of huge specimens of *Cymbidium Lowianum*, mixed with Odontoglossums of every kind, some of them of great beauty and value. After these came a grand group of *Lælia purpurata* in variety, full of charm and variety, as also was a cloud of yellow insect-like flowers upon strong tall spikes of *Oncidium ampliatum*. Mass after mass of striking plants, such as *Cattleya Skinneri*, *C. Mendelii*, *C. Mossiæ*, *Dendrobium Dalhousieanum*, *Miltonia vexillaria* and *Odontoglossum crispum* varieties, and Masdevallias were rendered effective by being alternated with groups of miscellaneous plants of exceptional interest. Among these latter were *Grammatophyllum Measursianum*, the most interesting, and certainly the most beautiful, new Orchid exhibited; *Cypripedium Rothschildianum* and *C. Elliotianum*, the hybrid *Masdevallia Mundyana*, the result of a cross between *M. Veitchii* and *M. ignea*; *Odontoglossum excellens Sanderæ*, *O. excellens Schrœderi*, *O. crispum Amesianum*, with many others. A very prominent feature of this group consisted of a large number of beautifully flowered plants of *Odontoglossum citrosmum*, which were suspended among elegant Palms and Ferns, so that their spikes hung gracefully and with most charming effect. It is impossible to do justice to this, or, indeed, to any of the large groups of Orchids exhibited; one can only say what was said, after a thorough inspection of Mr. Sander's group: "A wonderful exhibit, and a great credit to those who made it."

Messrs. Low & Co.'s collection followed, and contained some beautiful plants of Dendrobiums, Cypripediums, Phalænopsis, Epidendrums, etc. Messrs. B. S. Williams & Son exhibited a fine group of a miscellaneous character, Cypripediums predominating. There were also several grand specimen baskets of the white-flowered *Utricularia montana*, each about two feet through, and as well bloomed as a Pansy. Grown so excellently, this plant is almost as effective as *Phalænopsis grandiflora*. Mr. Cypher, of Cheltenham, also showed a grand group of Cattleyas, Lælias, Odontoglossums, etc.

The amateurs' exhibits were in a tent separate from that containing the nurserymen's plants. As was to be expected, the collections from Baron Schrœder and Sir T. Lawrence were remarkable for the wealth of variety and excellence of culture they revealed. Some of the plants from the famous Dell collection were marvels of floral wealth and vigor. *Odontoglossum Piscatorei*, var. *Veitchii*, the highest-priced of all cool Orchids, was there with two very fine spikes of its large, beautifully marked flowers. *Masdevallia Courtauldiana*, the pretty hybrid from *M. rosea* and *M. Shuttleworthii*; the curious though scarcely beautiful hybrid, *Miltonia Bleuiana*, raised in France from *M. Vexillaria* and *M. Roezlii*; *C. Lawrencianum Hyeanum*, the pallid variety which is so highly prized by admirers of this genus; enormous plants of Lælia, Cattleya, Odontoglossum, Dendrobium, Vanda, Ærides, Masdevallias and others came also from the Dell.

Sir Trevor Lawrence always contributes most liberally to these exhibitions, and his plants are invariably of unusual interest to the Orchid connoisseur, for they are either nearly all rarities or extremely handsome varieties. *Spathoglottis aurea*, *Maxillaria Sanderiana*, *Ærides Savageanum*, *A. Houlletianum*, *Cypripedium grande*, var. *atratum*, and *C. Fraseri* were some of the most noteworthy.

Vanda teres was exhibited in splendid form from the gardens of Baron Rothschild at Gunnersbury Park—a group of about forty plants, each from two to three feet high, and each bearing one or two many-flowered racemes. These plants had been grown in a pine frame, where they get full sunshine all the year round, with a very high temperature. Many people know this plant, with its short, fleshy, terete leaves, but comparatively few have the pleasure of flowering it. At Gunnersbury it is grown in quantity to supply cut flowers for the table as though it were merely a Rose or Carnation.

The Duke of Marlborough sent a collection of grand Cattleyas and other Orchids from Blenheim, and Mr. Joseph Chamberlain exhibited a collection of the flowers of Masdevallias which were very tastefully arranged with Ferns. Numerous other collections were contributed by some of the best-known English amateurs, almost every group being a good exhibition in itself.

Roses.—Large and well-grown specimens of some of the best exhibition Roses were shown by Messrs. Paul & Son, Cheshunt; W. Paul & Son, Waltham Cross; Charles Turner, Slough, and W. Rumsey, Waltham Cross. Among the new kinds were Danmark, Crimson Queen, Spencer, Mrs. John Laing and Souvenir R. Gounod, which seem to possess all the characters of first-rate Roses. The large specimens were of the usual compressed bush form, the only exceptions being several pretty white single-flowered kinds, which were untrained, and which were, therefore, as elegant and artistic as Roses generally are when their natural habit of growth is not interfered with. Large Bamboos and purple-leaved Maples formed a charming background to some of the groups.

The Calceolarias were marvelously well grown—indeed, they were in some cases almost too fat with flowers to look artistic. Tuberous Begonias were shown by Messrs. Laing and Messrs. Cannell, the group of double-flowered kinds from the latter being exceptionally attractive. Wonderful though these double ones are, they are less beautiful than the single-flowered kinds. Among Mr. Cannell's plants were several with flowers six inches across each way, and a considerable number of salmon-pink and pale madder colors, which, Mr. Cannell informed me, are all the fashion now. Very large groups of Caladiums, Pæonies (both herbaceous and tree), Rhododendrons, Azaleas, Anthuriums, Ferns, Leschenaultias, Pelargoniums, Gloxineas, and many others helped to fill the four great marquees provided. Mr. Rivers sent a collection of pot specimens of Oranges, Peaches, Plums and Cherries in fruit. Pansies from Scotland, Lilacs from France and Eremurus from Cork were shown, and they indicate the comprehensive character of the exhibition.

London. *W. Watson.*

New or Little-known Plants.

Crinum Asiaticum.

THIS is the largest Crinum known. It forms a conspicuous object in the Palm-house at Kew, its huge evergreen leaves being decidedly effective among Palms, Cycads and such-like plants. Its flowers, too, are ornamental, and they are produced frequently, say half a dozen times a year, on full-grown plants; they are white, with crimson filaments, and they are fragrant. The plant from which the accompanying photograph was made is five feet high and eight feet through. The large bulb is buried in the soil, but its exposed stem-like neck is a foot long and

six inches in diameter. Each leaf is five feet in length by eight inches in breadth, channeled all along the midrib, and colored bright green, with darker reticulated veins. The peduncle measures two and a half feet in length, and the head is composed of about fifty flowers, each with a tube four inches long and spreading segments nearly as long.

C. Asiaticum belongs to the evergreen group of Crinums, all of which are easily cultivated, free-flowering and attractive. They require a rich soil, plenty of water both winter and summer, and a tropical temperature. Although not much grown nowadays, *C. Asiaticum* has been in cultivation over a century and a half. It is widely distributed in the tropics of Asia, and it varies somewhat in consequence. The following are now considered to be only varieties of it by Mr. Baker—namely, *C. declinatum*, Herb.; *C. sinicum*, Roxb.; *C. procerum*, Carey; *C. anomalum*, Herb. At Kew there is in cultivation a variety with leaves handsomely streaked with creamy white. Suckers are produced abundantly by large plants, and these, if removed in spring and treated liberally, will grow into large specimens in two years. The large, fleshy, tuber-like fruits of this species are also freely produced on cultivated plants.

Kew. *W. Watson.*

Cultural Department.

Points of Merit in Vegetables.

Snap Beans.—Since the general introduction of the wax-podded sorts people have come to judge of this vegetable almost entirely by its appearance, the longest, whitest, handsomest pods being considered the best; but a better observation will show one that the whitest pods in the basket are by no means the whitest when cooked. If we cook the clear white pods of the Ivory Pod and the yellow ones of the Golden Wax, we shall find the latter much the lighter and brighter colored; and if we go further and taste them, there will be no doubt as to which is of the better quality. The value of a snap bean rests in its fleshy pod, and in judging of the merits of different lots we should not only look at the external shape and color, but at the flesh. This should completely fill the pod so that there is little depression between the seeds, and on cutting the pod at these points there should be no cavity seen. The flesh, too, should be firm and solid. In some sorts it is very juicy, and even watery when the pod is young, but speedily becomes spongy or pithy. Last, but by no means least, the pod should he, as the Europeans say, "free from parchment"—that is, the inner lining of the pod should be thin and without fibre, a point which is often overlooked, the observer being satisfied if there is no "string" at the back.

Beets.—Most people are content if the root is smooth, shapely and of good color, but this is by no means all. The color should be one that will hold while cooking—should be "fast"; and, secondly, the top should be small and compact, and occupying as little as possible of the upper portion of the root, because it will always be found that the portion just below the base of the leaves is harder, rank-flavored, and lacking in sugar. This is so invariably true that the French and German sugar-makers always cut off and throw away this portion (often amounting to from three to five per cent.) of the root, saying they cannot make good sugar when it is taken.

Cabbage.—In a long and large-stemmed plant we shall find the leaves relatively far apart and with large, coarse midribs; and as a portion of the stem extends up into and becomes the objectionable core of the head, it carries with it the same character, and we have a large-cored and soft-hearted head, the base of the leaves being separated in the head in the same way as below it. Again, the shape of the leaf is important. A frequent fault is, that the blade does not extend to the very base, thus giving the leaf a distinct stem. The leaves of the head will be of the same character, and, consequently, the heart, made up of the bases of the leaves, will be loose and "stemmy" at the centre, even if hard and firm at the outside. The leaves should also be abundant in number, long, and should show a decided tendency either to enclose the centre or to be dish-shaped. If not, we have a head in which the leaves do not lap by each other, forming one with either an opening or a soft spot down through the centre, through which the seed-stalk will soon push its way, the head thus becoming worthless. Lastly, the leaves of all cabbages should be thick and brittle, rather than thin and fibrous.

Cauliflower.—The common opinion is that cauliflower-heads should be smooth and flat; but Long Island gardeners, who have given more attention to this vegetable than any one else in this country, declare that the head should be round rather than flat, and as knobby as possible. They claim, and we think with good reason, that the flat umbel-shaped head must of necessity have a much larger proportion of stem than one which is in general outline nearly globular, and in which each section is also globular, thus giving a rough or knobby, rather than a smooth, head. Certainly such heads are much heavier and more solid, and we think are of better quality.

Carrot.—Few people in this country know how palatable well-grown and properly cooked carrots are, but in order to fully appreciate them one must use the small and finer-grained garden varieties, and when they are in proper condition, which is when they are young and tender, not waiting until they are nearly full-grown, as is commonly done.

Celery.—Here, as in beans, too much weight has been given to whiteness; and flavorless and soft White Plume has ruled the market. It certainly is true that excessively blanched and white celery is always of inferior quality. Often it is actually worthless, being pithy and soft. Good quality is indicated by fine grain and solidity. A person should be able to snap a stem into three pieces by taking it in both hands and giving a quick jerk with each hand in opposite directions. The break should be square, showing brittle fibre, and as little "string" at the back as may be. The flesh should be firm, solid and fine-grained, and have a rich nutty flavor. Such celery is rarely seen in the market, because of the demand for the whiter and (to the novice) more attractive kinds; but no one knows better than the Kalamazoo growers how to produce it if it is called for.—*Professor W. W. Tracy, before the Michigan Horticultural Society.*

Notes from the St. Louis Botanical Gardens.

Tigridia violacea is an interesting member of this Mexican genus, and, this year at least, is the first to flower by several days. It bloomed on the last day of May at the Botanical Gardens here. It is about one foot high, bears, in succession, several violet-colored flowers with variegated centres an inch and three-fourths wide. Not quite as attractive as *T. buccifera*, though having larger flowers, it is a fitting companion to it, coming into bloom only a few days earlier.

Pentstemon pubescens, which is quite common in this part of the country, has been in flower for fully two weeks. It selects dry situations, clay banks, mostly in half-shaded places. Just before it flowers, or late in August, seems to be the most suitable season for transplanting this species, or at least it does much better than when set in spring.

Potentilla paradoxa, now in flower, is quite an interesting hardy perennial, about two feet high, bearing at the terminus of the branches numerous flat, pale yellow flowers, a little more than an inch wide, which come in long succession.

Cerastium tomentosum, a hardy perennial of eastern Europe, scarcely a foot high, with light downy foliage and pretty delicately white flowers, is a common garden-plant and a useful one for the open border. It is quite hardy and thrives in any ordinary garden-soil.

Houstonia purpurea, at this season, when there is a scarcity of wild flowers, is one of the most attractive. It usually grows less than a foot high, in fine round clumps, with nearly white or, sometimes, pale purple flowers. It seems to be suited to any soil or situation that is not too wet, and does well in sun or shade. If the plants are taken up from their natural home in full leaf, just before they flower, they will scarcely notice the change, and will bloom as freely, if not better, than when left to themselves.

A fine clump of *Ansonia Tabernæmontana* has been in bloom in the herbaceous grounds for some time. It is not a showy plant, but it forms a nice large clump of its thick, green foliage, four feet high by as many wide, and each of the many stalks terminates with a small panicled cyme of pale blue flowers. It will do fairly well in shade, but a clay soil and full sunlight suit it here.

Phlomis tuberosa, one of the Mint family from eastern Europe, much resembles some of our American Monardas. It attains a height of about four feet, is quite hardy and easy of culture.

Cypripedium acaule, *C. pubescens* and *C. parviflorum*, all of which have bloomed quite freely here, are now past flower, and even *C. spectabile*, the last one of our natives to flower, is nearly past. These native Orchids seem to do as well here, with a little extra care, as in more northern latitudes.

One of the best plants at the garden at this season is *Crinium longifolium*, a member of the Amaryllis family, a native of India. Some plants are more than three feet high and have three or more flowering stems. Fifteen large showy flowers are not uncommon on one stem, and they come in long succession. The flowers vary in color from pure white to rose-purple, are tubular in form, six or eight inches long, and about three inches wide at the opening. The plant is perfectly hardy here, and, with a little protecting, would probably survive any New England winter. The bulbs are very large.

St. Louis. *F. H. H.*

German Irises.

Iris Germanica has been true to its season, and now follow the hybrids, known to the trade as German Irises. As is well known, these are among the most satisfactory of hardy plants. Their creeping rhizomes are proof against the severest weather, and they increase rapidly. The flowers, though not very lasting, are usually very attractive, or, at least, among their countless forms, any taste may be gratified, as they range through so wide a scale of color and markings. *I. Germanica* is not in cultivation a seed-bearing plant, and so careful an observer as Professor M. Foster is convinced that the hybrid Irises are not of its progeny; these plants being hybrids of *I. pallida*, *I. variegata*, *I. sambucina*, *I. squalens*, *I. lurida*, *I. neglecta*, *I. amœna*, *I. plicata* and *I. Ewerti*, and possibly of *I. flavescens*.

The hybrids of *I. pallida* are easily recognized by the withery white spathe valves, which lose their greenness before the bud is swollen. They vary in color from nearly pale blue to a deep blue, some having a reddish tinge. Queen of May (rosy lilac) is a familiar example of this strain. The *I. variegata* blood is seen in forms like Louise, Lila and Jenny Lind, with golden standards and purple-brown falls. Among a collection of hybrid Irises will usually be found many smoky or bronze-tinted forms, as Diana, Magnet and Nemesis. These are from *I. sambucina*, *I. squalens* and *I. lurida*. *I. neglecta* is responsible for those which have standards and falls of white, marked with purple, such as Madame Chereau; and *I. amœna* for those with white standards and marked falls, such as Fairy Queen.

These conclusions reached by Professor Foster are readily verified by any one who cultivates the species and a collection of hybrids. It is one of the features of this section of the Iris family that they possess infinite variety, giving scope for much interesting study. Some of the hybrids are so much mixed in blood that their parentage is not so easily traced as those mentioned above, and these will be likely to furnish puzzling problems to the most skillful. In the mean time these are the beautiful flowers unfolding day by day to be enjoyed, and there are few more pleasing pictures in the hardy garden than good clumps of German Iris. With clean, attractive foliage and abundance

of gay flowers, they are well named "the hardy Orchids." The flowers individually are not very lasting, but strong plants produce many blooms, and the season extends over several weeks, with a daily unfolding of new beauties.

Elizabeth, N. J. *J. N. Gerard.*

Early Peas.—Another season's trial at this station satisfies us that the green-skinned extra Early Peas of the Kentish Invicta type are not only earlier, but more vigorous and productive than the common extra early varieties of the Daniel O'Rourke type. But neither type has high quality enough to make it the best stock to work upon for improvement. In the mere matter of earliness both excel, but we ought to develop an extra early of fine table quality, vigorous habit and productiveness. Market buyers in the cities get few peas which country people consider fit to eat, and growers could make money by offering peas of high quality for discriminating customers—at least those who sell their own peas to consumers could. For home use wrinkled peas can be had for every season, but the very earliest varieties of the Alpha type come hard after the Daniel O'Rourkes. What we need is the production of some well-flavored early sorts which will bear with sufficient abundance to be profitable market sorts and supersede the flavorless extra early peas which are now universally sold.

Raleigh, N. C. *W. F. Massey.*

Alstromeria pelegrina.—Last year I noted the beauty of the white form of this plant, which is also known as the Lily of the Incas, though, of course, not a Lily at all, but one of the *Amaryllidaceæ*. The white variety is beautiful certainly, but the typical form is proving itself equally good, and much more showy than its variety Alba. The color is a soft pink, with a shade of green, and red lines. A small root imported last fall has produced many flower-sprays, and they last well when cut. This Alstromeria is not to be recommended for out-door planting, but as an in-door pot-plant. It is easily raised from seed, as these germinate much more readily than those of other kinds, but I have a suspicion that it depends not so much on the species, whether the seeds germinate readily, as upon their being recently gathered, for I know that in the seeds of the same species in the hands of different persons there was a great difference in the period between sowing and germination.

South Lancaster, Mass. *E. O. Orpet.*

Grammattophyllum Measuresianum.—This plant is now flowering, for the first time in America, I think, in the collection of Mr. W. S. Kimball, of Rochester. It is a stately plant, with enormous pseudo-bulbs and handsome, broad foliage; it also is very free in its habit of growth, and requires little attention. On the plant at Rochester a spike, four feet high, carries forty-five finely marked and well-developed blossoms. They are light yellow, profusely spotted with chocolate. Basket culture, with very little compost about its roots, a good supply of air during its growing season, and a temperature of sixty-five degrees will suit its requirements. At the great Temple Show in London, held recently, this beautiful Orchid, exhibited by Sander & Co., was universally admired and ranked among the finest in the display.

New York. *A. Dimmock.*

Correspondence.

Fruit-trees on Lawns.

To the Editor of Garden and Forest:

Sir,—There has grown up a canon that condemns the use of fruit-trees on lawns, but there seems no sufficient reason why the useful and beautiful should be divorced. A lawn with fruit-trees alone may be made very attractive, although it would be better to combine fruit and nut-bearing trees. Apple-trees scattered about and grouped on lawns with Pear-trees, Walnut, Butternut and Chestnut-trees may produce fine effects. The lawn is too often a homeless place, lacking in the hearty welcome that fruit-trees give us. I have a group of Buffam Pears that stand thirty feet tall, and are much admired, besides yielding me twenty bushels of fine fruit yearly. Other Buffams stand about my lawn to relieve the uniformity of round-headed and conical trees. This Pear is one of the best of all upright-growing trees for lawns, giving not only novelty of form, but fine foliage and color. But there are other Pear-trees of singular grace and charm. The Anjou, for example, makes a noble head. The advantages of lawns of this sort are that many who cannot afford to assign ground for lawns with ornamental trees will do so for those that return a profit. The only serious disadvantage is the possibility that by fruit-gathering some damage may be done to the foliage or important limbs broken, but with proper care there need be no such danger.

Plums do not make good trees for the lawn, as a rule, because they are short-lived, and are liable to be misshapen by the necessary cutting that removes black knot. But there are few handsomer trees than Cherries, either Murillo or Heart. But my preference has been to grow them mostly in shrubberies or on the edge of the lawns. The Persimmon forms a good crown, and adds to the number of good lawn fruit-trees. It is hardy with me in central New York, although I do not know of any trees hereabout except my own.

I agree with Henry Ward Beecher that America furnishes no sight more beautiful in all its blossoming flora than an Apple-tree in full bloom. The variety in shade and in form of petals is remarkable. I have before my window a Kirkland Apple-tree and a York Pippin. The blossoms of the former are massed like a huge snowball. The petals are long and twisted and star-like; those of the latter are broad, and held up like a saucer. The Japanese worship the Plum and Cherry-blossoms, and in our shrubberies we have nothing finer than Wild Cherries, and Wild Plums and Crab-apples, in addition to our cultivated Cherries and Plums. The finest group that I have had this spring consists of Governor Wood Cherry-trees, bordered with Late Montmorencies.

Clinton, N. Y. *E. P. Powell.*

[We are not aware of the existence, in treatises of landscape design, of any such canon as that laid down by our correspondent, and if fruit-trees are seldom used in pleasure-grounds it is probably because there are some good reasons against the practice. There are cases in which these trees could be satisfactorily planted on grounds about houses—about a farm-house, for example, with surroundings of orchards and meadows and cultivated fields. The question is one of details and particulars, and no rule of universal application can be laid down. If by a lawn is to be understood a slightly undulating body of turf with foliage so disposed about it as to make the most pleasing sylvan composition, and especially to introduce an element of obscurity and indefiniteness in its outlines, we should select the trees best suited to produce that effect, and it is difficult to see why fruit and nut-trees should be preferred to other forms of foliage, or how they could be mixed with other forms of foliage with any gain in respect to harmony or agreeable contrast. Further than this, fruit-trees, as a rule, are apt to take a formal shape, especially if they are pruned and managed with reference to the production of the greatest amount of fruit. Again, nearly all of them are more subject to be injured in appearance by fungi or insects than are those trees usually preferred for lawns. The beauty of the bloom of a Cherry-tree is evanescent, and when not in bloom a mature tree is usually very stiff and unsympathetic in its form when mingled with other trees, or it suffers from some disfigurement. Its beauty during the short flowering period does not compensate for what would be lost in substituting a Cherry for some other tree which is more desirable throughout the year. Besides this, fruit-trees, as a rule, have little beauty in the autumn. The Cherry turns slightly, and so do some of the Pears which contain the blood of the Chinese Sand Pear, but, as a rule, fruit-trees lack the beauty of our native trees in autumn, and it is very desirable in lawn-planting to take advantage of the beauties of autumn coloring.—Ed.]

A Neglected Evening Primrose.

To the Editor of Garden and Forest:

Sir,—There is a glowing California field-flower that possesses many charms, and well deserves introduction to the garden. In its season this lovely Californian Œnothera, with its dwarf growth and its compact clusters of golden bloom, appears as distinct and as striking a feature of the landscape as the great flame-red Eschscholtzias. One can almost claim that, when the Wild Poppy became the state flower, the modest merits of this perennial Evening Primrose were sadly neglected.

The other day—it was May 10th—I walked up the long seaward slopes of Berkeley. Every vacant lot and the very streets were golden with little plats of shining blossoms. I began to

remember that for three or four months this brilliant display continues; I bent down and counted the flowers and yet unopened buds on the nearest plant of *Œnothera ovata*. The plant was nowise conspicuous among its fellows that dotted the slope; in fact, many showed far more flowers and covered a greater area. The sample plant, however, made a very respectable display. The circle of its outer leaves was about a foot in diameter; they rested upon the turf, hardly rising four inches above it at any point. Fifteen open flowers rose well above the foliage, and no less than thirty-six buds could be counted without pulling the crown apart and descending to the microscopic sizes. Each of the four-petaled flowers was fully as large as a fifty-cent piece; one almost covered a silver dollar. The rich clear yellow hue, and the regularity of the petals and stamens, with the golden ball of the erect pistil, formed a charming whole.

Botanists are interested in this little Œnothera on account of its peculiarly long calyx-tube, which is never less than one inch, and usually is from three to five inches long. The ovary is concealed in the very crown of the plant, and is thus protected from accident in as complete a manner as one could well imagine. There are not many flowers of this curious type, and none is better adapted for a garden-flower. *Œnothera ovata*, if planted on the lawn in a solid bed of, say, ten feet square, would surprise every beholder by its abundant bloom and its glowing color.

Niles, Cal. *Charles Howard Shinn.*

The American Association of Nurserymen.

Annual Meeting at Minneapolis.

THE sixteenth annual meeting of the American Association of Nurserymen was held during the first week of June in Minneapolis. President Emery called attention in his address to the strength of the organization, which now numbers more than four hundred members, with abundant money in the treasury and a history which proves that substantial benefits have been received from concerted action. In regard to the condition of the business the President said: "We have to congratulate ourselves upon the improved tone of the nursery business. Nursery stock is worth from twenty-five per cent. to forty per cent. more at wholesale than it was a year ago, but this is no good reason why indiscriminate planting should be indulged in, for the fact is that the past prevailing low prices have discouraged heavy settings, and the overplus has thus been reduced, and prices raised to a point where it pays the grower to produce stock."

Mr. Emery advocated among the improvements to be desired the official adoption of a general telegraphic code by which orders could be abbreviated, and time and expense saved; and on the subject of the World's Fair he said: "The fact is patent that California is determined to control the Horticultural Department. The work of the Classification Committee, of which a member from California is chairman, is pathetic in its ludicrousness. That they assign four classes to horticulture and fourteen to viticulture shows the animus. A chief of the Horticultural Department, a Californian, has been appointed; his appointment has not been confirmed—the principal opposition coming both from his own state and from the horticulturists of the country at large. Under his management and dictation we can expect the wines, brandies and citrus fruits of California to head the procession, and her dried fruits and flavorless orchard products to occupy space that rightfully should belong to the class of fruits that are the bone and sinew, so to speak, of the business. A vigorous protest against such folly is in order, and failing to secure the recognition that our suggestions, as the nurserymen of the United States, entitle us to, we ought to wash our hands of the entire matter."

The committee who made a report on the President's address also protested against the World's Fair classification, and resolved, "That we most earnestly protest against the appointment of Mr. Walter S. Maxwell, of California, as Chief of the Division of Horticulture of the World's Columbian Exposition, believing as we do that there should be a man at the head of this great work who, by taste, knowledge, experience and acquaintance, is in full touch and sympathy with every horticultural interest of this great country."

Wm. C. Barry, of New York, E. L. Watrous, of Iowa, N. H. Albaugh, of Ohio, and Charles W. Garfield, of Michigan, were appointed a committee to meet the Board of Directors of the World's Columbian Exposition in Chicago, to present to that body the action of the Association.

Among other resolutions adopted by the Association was one commending the work done for horticulture through the Eleventh Census, and tendering thanks to the superintendent and to Mr. J. H. Hale, the special agent, for the complete investigation which had been made of the nursery interests in the United States, and requesting the superintendent to issue a bulletin report of this work similar to the one on floriculture before the opening of the fall season.

It was decided to hold the next annual meeting at Atlanta, Georgia, and the following list of officers was elected: President, J. Van Lindley, North Carolina; Vice-President, W. J. Peters, Ohio; Secretary, C. A. Green, New York; Treasurer, G. A. Whiting, Dakota. Executive Committee—W. F. Heikes, Alabama; W. C. Barry, New York; G. J. Carpenter, Nebraska.

Extracts from some of the addresses delivered at the meeting are given below:

GROWING AND MANAGEMENT OF EVERGREENS FROM THE SEED.

This subject was treated by Charles F. Gardener, of Iowa, who said:

"In growing evergreens from seed the beds are prepared four feet wide, running east and west, and raised three to four inches. Stakes fourteen inches high are driven on the north side, and twelve inches high on the south side of the beds; on these stakes are nailed strips of boards two inches wide and one inch thick. The seed is sown broad-cast, at about the rate of four to the square inch, after the soil is well pulverized by raking, and a garden-roller is run over the bed, lengthwise, twice if necessary, to firm each seed in its place in the earth. The beds are then covered with evergreen leaves to the depth of two inches. As soon as the seeds sprout the leaves are raked into the alleys between the beds, and the beds covered with white sand from one-quarter to half an inch in depth.

"Shades are made of lath put together in frames four feet square, with the lath three-quarters of an inch apart; and the frames are put on the strips nailed to the top of the stakes, the lath crossing the bed north and south.

"When the evergreen leaves are taken off, the sand is put on as fast as the leaves are removed. The leaves must be slightly shuffled back and forth while being removed, to kill the weeds that have started, and the little trees will have a perfectly clean bed to make their appearance on. The lath-frames are put on as soon as the beds are covered with sand. We never water the beds, and if cracks appear more sand is put on.

"After the trees appear above the sand, and before the seed-shells have dropped off, dry sand is sprinkled over the beds in sufficient quantity to fill all little cracks and holes that may appear. The beds should be carefully hand-weeded the first season, and if a good stand is secured the first year the weeds will trouble but little the second year.

"We leave the lath-frames on until they are needed the next season to cover new beds. In damp, cloudy weather we raise them to an almost perpendicular position, thus giving the plants all the air and light possible; they should be replaced as soon as the sun comes out.

"Trees should not remain in the seed-beds longer than one or two years. Yearling trees should always be bedded out; two-year-old trees may be bedded or planted into double nursery rows; in either case they require no shade.

"The birds must be kept away from these beds, especially from White Pine beds, or they will take every tree as fast as it makes its appearance. The worst birds with us are the blue-jay and turtle-dove."

GEORGIA AS A FRUIT-GROWING STATE.

Major Gessner, general agent of the Central Railroad of Georgia, said:

"Five years ago little serious attention was given to fruit-growing for market in Georgia. Since that time, however, railroad facilities have been increased, so that we can supply fruits very early to northern markets and place them there in good condition. As a consequence we have realized perhaps the largest prices that were ever paid for peaches in the New York market, which was twenty dollars a bushel for the earliest Alberta peaches. Usually the first shipments of peaches are made about the 20th of May. They are expressed to Savannah, and thence to New York by steamer—something like two and a half or three days' journey. Year before last the Georgia peach crop brought better prices and had a better sale in the New York market than Delaware peaches. Grapes, too, are proving profitable, and we have been receiving, for our early ones, five cents a pound at the station.

"Within the past two years the capacities of our state for growing fruit has attracted much attention. Near the centre

of the state three companies, organized in Ohio, have purchased tracts of 1,300 acres, 1,250 acres and 600 acres respectively. Mr. J. H. Hale, of Connecticut, has purchased 800 acres, while fruit-growers from New York, Michigan and other states have bought large tracts. The Albaugh Company set out at one time last winter 70,000 Peach-trees on 400 acres. It will be seen from this that there is an opening in Georgia for nurserymen. After our large peach crop two years ago many people wished to embark in the fruit business, but there were not trees enough to supply the demand, and there are not enough to-day. In this fruit-growing part of Georgia, where there are little frost, and a soil peculiarly adapted to small fruits, peaches and grapes, there is promise of great fruit-production in the future."

ROCKY MOUNTAIN EVERGREENS.

Mr. C. S. Harrison spoke on this subject. He said:

"The problem of clothing the western plains with forests is an important one. Conifers by the million have been shipped over the Missouri River, and by the million they have failed. Near the one-hundredth meridian the White, Norway and Black Spruces and the Arbor-vitæ are failures. The Scotch Pine does well while young, but in time of trial it goes down before the drought. The Austrian Pine thrives while young, but the White Pine is uncertain always. Looking down from the foot-hills of the west, and belting northern Nebraska, there is a Pine, however, which is equal for the emergency. Six years ago I brought some from the mountains and planted them in the open ground without protection. I cultivated the first year, and after that left them to utter neglect. The ground was sometimes very dry, but none died after they were established, and they averaged about a foot a year in growth; taken from the mountains they are hard to transplant. One year with another I save fifty per cent. They grow readily from seedlings, and these transplant as well as any evergreens.

"I think this Pine (*P. ponderosa*) the best for our region. The leaves are glossy and of deep, rich green, and often eight and ten inches in length. The wood is heavy and the grain coarse, from rapid growth, but it takes a fine polish, and is used for grain finish in some of the finest houses in Colorado.

"The Douglas Spruce is the great timber tree of the Rockies and Sierras. I have recently visited many of the leading nurseries of the east, and find that in rapidity of growth it led all the conifers. This tree has an almost infinite variety of form and foliage. Some trees will have short leaves, others heavy and long. Some will be light green, and others almost blue, with a frosting of silver. The mountain seedlings transplant readily, planted in the open air.

"*Picea pungens* is king of the Spruces for the first thirty years of its growth, and its silver sheen is matchless. If anything tends to retard the growth, or when old age comes on, its color reverts to green. This is a rigid tree, with stiff shelf-like branches. Only about one tree in four, or perhaps one in ten, will have the exquisite silver color. It transplants very readily. The best way to secure the finest specimens is to go to the mountains and collect the small trees with colors already established.

"Almost equal in beauty, with more of grace and softer outlines, is *Picea Engelmanni*. This is the giant of the high altitudes. It grows in a belt reaching nearly 2,000 feet higher than *P. pungens*, shooting up well to timber-line. It transplants very easily. It will resist any degree of cold, and I believe with the Black Hills Spruce it will be one of the timber-trees for the great north-west. This tree has a sheen nearly as rich as that of the *P. pungens*, and is often of a graceful drooping habit.

"*Abies concolor* is queen of the Firs. No other tree has such a rich variety of color. The Blue Spruce is beautiful while young, but this Fir holds its color. One can often see a grove of these trees with their silver gleaming miles away. Some clusters have very deep color with plentiful frosting, so as fairly to sparkle. The new shoots are of light soft green; the older growth is nearly blue. On one tree the blossoms and cones will be purple, on another light green, The clear gum exuding from the cones flashes like pearls; and when a light breeze puts all this beauty in gentle motion, you have a scene worth a journey across the continent to see."

ONE WAY TO SELL NURSERY STOCK.

Mr. G. L. Grant suggested that if florists could be induced to plant ornamental shrubs of the most attractive varieties on their grounds their customers, when they saw these shrubs in flower, would be glad to place their orders there for delivery at the proper season if they could be assured of receiving plants of the same varieties. Improper planting has been the cause of much undeserved criticism of nurserymen, and so is the frequent long exposure of the stock in unexperienced hands after unpacking and before planting. If a florist had this stock on sale he could send a man who knew how to plant it properly. In other words, it is advisable for nurserymen to cultivate closer relations with florists throughout the country, and sell through them instead of traveling agents. These agents are often unknown, and buyers have become suspicious of them; but if they could deal with some one whom they could find again and whom they knew to be trustworthy, they would feel safer in ordering ornamental trees and shrubs; and inasmuch as they are buying of the local florist herbaceous and other ornamental plants, it would be very natural for them to extend their orders to one in whose judgment on horticultural matters they had confidence. The sample shrubs and trees which the florist could have would be an inducement and an assurance to purchasers who have been deluded with colored plates. Besides this, it is well known that trees and shrubs will thrive in one section better than in another. The local florist, being in the vicinity of the buyers, could soon determine which were the best kinds for that particular region, so that the most satisfactory selection would be made.

In the discussion which followed this essay, Mr. Albaugh thought that while the theory might be good, it would be found in practice that few florists could give sufficient attention to a retail tree business in addition to their own. One intelligent tree agent would sell more stock than a dozen florists in a county by careful canvassing among individuals who take no interest in flowers, and who care for nothing unless it is forced on their attention and unless they are convinced that there is money in it. Mr. Albaugh had found business men who, for a fair compensation, were willing to devote their entire time to canvassing for the nursery trade, and it was just as legitimate a business as any other. After thirty-six years' experience and trying five or six ways of disposing of his goods, and abandoning one after another, he had at last adopted this one. He employs energetic men, and makes himself responsible for what they do, giving them certificates that bind their principals legally for their acts.

Mr. Harris thought that the plan suggested might answer for the sale of ornamental shrubbery, but it would be of no value in selling fruit-trees. Mr. Hale said, that from what he had learned of florists in getting statistics for the census, nurserymen, in many cases, might do well to unite with them in the dissemination of certain specialties, because, in the first place, this would be simply an addition to the florist's business, and, in the second place, he had found the florists, as a class, unusually enterprising, and the enormous development of their business during the last fifteen or twenty years shows them to be in close touch with the people and the people's wants.

Mr. Hill had no doubt that an intelligent florist would make a good salesman if he could give time and attention to the matter, but the florist who has not enough business in his legitimate line to occupy him at the time when nursery stock should be sold had better retire. The busy seasons of both industries come at once, and a successful florist has all he can possibly do in his legitimate calling at just the time when shrubs and trees should be sold.

Notes.

Three hundred thousand tons of vegetables were brought into the city of Paris last year, and their value reached the amount of $25,000,000.

The bright purple and fragrant flowers of *Clematis crispa* are already opening, and since they will continue to appear until frost this must be considered among the valuable garden-plants which are native to this country. Besides the beautiful solitary flowers, the foliage is very graceful, and the plant, although it is found from North Carolina to Texas, is perfectly hardy in our northern states.

We have received from the Meehan nurseries, Germantown, a spray of *Benthamia Japonica* in bloom, and the flowers closely resemble those of the Flowering Dogwood, although the white satiny bracts are narrower and more sharply pointed. Blooming as it does after the bright green leaves have attained their full size, this is a promising addition to the showy flowering shrubs for the gardens of our northern states.

A German journal states that the "Fragrant Goose-foot" (*Chenopodium ambrosioides*) is the sixty-sixth plant which has been recommended by Mr. John R. Jackson, of Kew, as a substitute for tea and coffee. It is a native of South America, whence it was exported under the name of "Jesuit Tea," but has become naturalized in Mexico and the West Indies, at the

Cape of Good Hope and in certain isolated spots in Europe. The whole plant has a strong, penetrating and notably aromatic odor, and, as it acts temporarily on the nervous system and in subduing cramps, it is useful as a mild medicine and tonic.

The statue of Mr. James S. T. Stranahan, which had been placed near the main entrance of Prospect Park, was unveiled on the 6th of June. It is the work of Mr. W. Frederick M'Monnies, a young artist who was born in Brooklyn and has lived for some years in Paris, and is the gift of the citizens of Brooklyn. Statues to living men are not often erected, but the exceptional honor was, in this case, well deserved, and, of course, it was fitting that Mr. Stranahan's figure should be placed where it would typify the greatest of his many services to his native town—the leading part he played in the establishment of Prospect Park.

A figure is published in the issue of the *Gardeners' Chronicle* of May 3d of a hybrid Sweet-brier Rose, with bright crimson flowers. This interesting plant was raised by Lord Penzance, and was described by him in a paper on the hybridization of species of Rose published in the eleventh volume of the *Journal of the Royal Horticultural Society*. It was raised from the Austrian Brier, fertilized with the pollen of the Sweet-brier, and is said to be intermediate between the two parents, its foliage having the fragrance of the Sweet-brier, while the flower, which is two inches across, is pale crimson, flushed on the under-surface with fawn-colored tints.

Few people know, perhaps, that any article of food is imported into this country from Egypt, but, according to the New York *Tribune*, that country sends us large quantities of onions, as many as 50,000 bushels often arriving in a single week. The onions, which are shipped from Alexandria to Liverpool, and thence to New York, are small and yellow, and not so good as those grown in this country, while they naturally deteriorate somewhat during their long voyage; but they are readily sold, because the price asked in Egypt is so low that, after adding freight charges and a duty of forty cents per bushel, a bag, containing nearly two bushels, is sold here for two dollars or two dollars and a half.

We have received a copy of the "Flora of New Bedford and the Shores of Buzzard's Bay," which is a careful revision of "A Catalogue of Plants found in New Bedford and its Vicinity," published thirty years ago. The author, E. W. Hervey, has made corrections in the nomenclature, and has added to the earlier list of plants such as have since come to his notice. An important part of this work is the "Procession of the Flowers," the object of which is to show the precise time of the year when each plant begins to flower. In this list the more conspicuous of the cultivated trees, shrubs and vines are included, and the dates will be found to answer fairly well for Massachusetts, Rhode Island and Connecticut. Inasmuch as the flowers of the same locality bloom every year with surprising regularity as to time, if we except some variations in the season of early spring flowers, one in search of a particular flower, if informed as to the time of its appearance, does not make a fruitless search by going too early or too late.

The *Vossische Zeitung* recently gave an interesting account of a gardener named Adophe Vard, living at Aubevage, near Gaillon, in Normandy, to whom a decoration had just been awarded by the French Academy. It seems that for thirty years Vard was employed as an oiler at the railway station in Vernon, and devoted himself to gardening only after he had earned the right to retire on a pension. But during many previous years he had spent his leisure hours in self-instruction to such good purpose that, without a teacher, he learned to read Greek and Latin as well as gained an intimate acquaintance with the classic writers of France. Later in life he essayed poetical composition himself. His chief work is a charming story in rhyme, called "Le Rêve de Muguette," in which the taste which turned him toward gardening is clearly evinced. Vard was too poor to publish this work, but the cost was borne by one of his friends, a neighboring inn-keeper; and it is the success of "Le Rêve de Muguette" which has brought him the purple ribbon bestowed for distinguished accomplishment in letters or the arts.

A writer in *Gartenflora* declares that if the present love for Chrysanthemums, which, almost everywhere in the north of Europe, has become almost a craze, ever spreads through the extreme south, it will prove that there is nothing that Dame Fashion cannot accomplish, for, he says, in southern Italy the Chrysanthemum is the "Flower of Death," and is rarely grown except in graveyards, or near by, for the purpose of decorating graves at the feast of All Saints. If it is seen in a garden the place is pretty sure to belong to a foreigner; no native would stick a Chrysanthemum in his button-hole, and the writer doubts whether ladies will ever fill their vases with them, and declares that he has seen an Englishwoman stared at by a wondering crowd in the streets of Naples because she was carrying an armful of these "unlucky death-flowers." At All Saints, however, the cemeteries become perfect "seas of Chrysanthemum-blossoms," other flowers seldom being mingled with them, and they are profusely planted near graves and along the borders of the cemeteries. In no part of Europe, continues the author, could the Chrysanthemum be grown to better advantage than in southern Italy, for it is green all the year round, and blooms from July to January. It often occurs wild, even in good old varieties with double flowers, although these seem to ripen seeds only now and then, and one form is entirely naturalized—a single yellow-flowered form—which grows in a somewhat ragged way, but is well covered with pretty green leaves which retain their freshness even in times of great drought.

On Thursday evening, June 11th, the students of the College of Agriculture of Cornell University held a grand jubilee and banquet to celebrate the prosperity of the college, and in honor of the graduating class, which is the largest in the history of that department of the university. President Adams, of the university, Ex-president White, Hon. O. B. Potter, of New York, and other distinguished guests were present, and made admirable speeches on the history and aims of agricultural education. The elaborate banquet was quite unique, in that everything on the tables, except the sugar and spices, was supplied by the farm and gardens of the department of agriculture. The farm furnished a large variety of breads, meats, and dairy products; the horticultural grounds and forcing-houses, fruits and vegetables; while the conservatories of the botanical department, in addition to a splendid display of decorative plants, supplied some very beautiful specimens of tropical fruits, including bananas, oranges, lemons, and figs. In an adjoining room the various departments of the College of Agriculture had also contributed to a very attractive exhibition of implements, products and appliances for laboratory study. With strong men at the head of all its departments, the College of Agriculture now seems to be entering upon an era of great promise. Several of the highest honors of the university have this year been awarded to students of the college, and work is soon to be commenced upon a new building, which is to be equal to the best of those occupied by other departments of the university.

Walter Baker & Co., of Dorchester, Massachusetts, have issued a handsome volume, entitled "The Chocolate Plant and its Products," in which is given a full and very interesting outline of the early history of the Chocolate-plant, with a sketch of the primitive methods employed in cultivating it and in utilizing the seeds, with an account of the introduction of the beverage into Europe, to which are added a botanical description of the plant and its commercial relations, with microscopic and chemical characters of the seeds as they appear in commerce, an estimate of the value of chocolate as an article of food, with suggestions relative to the cooking of chocolate and cocoa and receipts for using it in different forms. The historical value of the publication is very much enhanced by the introduction of a number of fac-similes of engravings taken from early European works. The first of these, from a rare volume by Bontokoe, shows the Chocolate-plant bearing its large fruit from the main stem and growing under the shade of a larger tree. This is interesting, showing the fact, now generally recognized, that the Chocolate-plant can only be grown successfully in the shade was realized more than three centuries ago. Interesting, too, is the photograph of the flat mortar used by the natives of tropical America for grinding the seeds of the Chocolate. This was done by means of a roller, or short thick stone of cylindrical shape, which could be used with both hands in the same way that the common rolling-pin is used. A fact which will be surprising to most readers certainly is brought out in the history of the Chocolate-plant, that is, that chocolate was used as a beverage in Europe before either tea or coffee was employed anywhere in western Europe. The volume is avowedly an advertisement of the firm whose name appears on the title-page. As an advertisement, however, it is a model of its kind, beautifully printed and illustrated, and full of curious and interesting information which is not accessible to one person in a hundred thousand of those who use the seeds of the Chocolate-tree in some form or other nearly every day of their lives.

TABLE OF CONTENTS.

The Bermuda Juniper.

THE principal tree of the Bermuda flora is the Juniper, which covers the islands and makes the conspicuous feature of their vegetation. A few other trees grow naturally on these islands, and several others have been carried to them by man and have now become more or less firmly established. No tree but the Juniper, however, makes much show on the islands, which, from a distance, seem to be completely covered with it.

This Juniper has been growing on Bermuda for a long time. The wood, in the condition of lignite, was found at the depth of fifty feet below low-water mark during the dredging operations undertaken by the British Government in connection with the building of the Bermuda dry-dock. Subsidence of land is slow unless it is the result of some violent catastrophe, like an earthquake, and the fact that this Juniper grew on ground which is now far below the surface of the ocean is conclusive evidence that it has occupied these islands for a period so long that the mind of man, accustomed to measure time by years or by centuries, cannot form a clear notion of its immensity.

How did the Juniper first get to Bermuda? By what process did this tree, which is unlike other trees of its kind, first appear on these minute islands remote from all other land, and raised from the bed of the ocean by the patient toil of insects, long after the neighboring continent had assumed very nearly its present aspect? These are questions which present themselves to the student of nature as he sails into the harbor of Hamilton and sees the low islands about him everywhere clothed with this peculiar tree. It was not a case of separate creation, for the idea of the old philosophers, that plants and animals were created as they now appear in the different parts of the world where they occur, is no longer tenable. Man certainly did not bring the Juniper to Bermuda, for it is not quite four hundred years yet since man first saw these islands; and it is not improbable that trees are still standing which were growing when Juan Bermudez sighted the islands which Oviedo, the first naturalist to write on the New World, and a passenger with Bermudez on his ship "La Garza," described as "the most remote of all the islands yet found in the world."

Fifty years ago these questions would not have been easy to answer. Now the light which Darwin and Hooker and Wallace and other naturalists, working on the lines laid down by Darwin, have thrown on the origin of insular floras makes it easy to find a simple and, probably, a correct solution of the presence of the Juniper on the Bermuda Islands. There is a Juniper in North America growing in nearly all parts of the continent, from Canada to Florida, and from Cape Cod to Vancouver's Island; this is our so-called Red Cedar (*Juniperus Virginiana*), a tree which, in all important respects, is very similar to the Bermuda tree. It is a well-known fact that several of our birds are very fond of the berries of the Red Cedar and devour them in large quantities. To this is due the fact that this tree is so generally scattered and multiplied through the country, as birds void the hard stone-like seeds without injuring their vitality, and so spread them far and wide. There is evidence enough that our Red Cedar was growing on this continent long before Bermuda rose above the surface of the ocean; and a bird, with his crop full of Cedar-berries, may have been blown off from the mainland and found a resting-place on the then barren coral rocks, where the seeds he had brought found conditions which favored their germination. Our continental birds, in several species, now visit Bermuda every year in considerable numbers, and this habit must have had its origin in accident. The Red Cedar once established in Bermuda, it is easy to imagine that the climate and soil conditions of its new environment would gradually change its appearance, just as all plants are gradually modified by the influences of their surroundings; and that in time, after the lapse of countless years, that it would take on its present appearance and stand for what naturalists call a species, that is, a modified or differentiated form of some other form or species. And, after all, the differences which distinguish the continental Juniper from its insular descendant are not very great. The branches of the island tree have grown stouter and tougher through their long struggles against the ocean gales; the roots have learned the secret of holding on to bare rocks or of penetrating deep into their interstices. The foliage has lost its dark green tints and is now a pale blue-gray. The leaves are blunter and are furnished on the back with a gland or resin duct. The fruit is somewhat larger, and the heart-wood is not so bright a red and is rather less fragrant than that of the Red Cedar.

An interesting thing about the Bermuda Cedar is its ability to grow apparently equally well in very different situations. It flourishes on the dry porous limestone-hills and grows as freely on the brackish swamp-lands which occur in some parts of the islands. It is not unusual to find trees of a wide geographical range, and therefore subject to different climatic surroundings, which seek to adapt themselves to them by selecting situations which in one region are at the sea-level and in others are at the top of high mountains. Many conifers which grow at the north at the sea-level are found in the south only at considerable elevations above the ocean; and the Red Cedar itself, which grows at the north on high dry uplands, inhabits, in Florida, swamps which are inundated during a considerable part of the year, and in the dry climate of the western part of the continent occurs only at high elevations. But the Bermuda Cedar grows as well in one place as it does in another, although climatic conditions do not, of course, differ perceptibly in different parts of this small group of islands.

Large individuals are no longer common; the axe of the wood-cutter and the ship-builder long ago swept them away. Here and there a venerable trunk may still be found, but among the large trees still growing on the island

very few probably are much more than a century old or are large enough to possess any great commercial value. Formerly the wood was much used in ship-building; and it is interesting to note that Henry May, an English sailor, who was wrecked on the Bermuda Islands in 1593, and who afterward printed the first account of them, escaped with his companions to the banks of Newfoundland in a vessel which they were able to make from the Cedar-wood. This same wood, twenty-seven years later, furnished the material from which Admiral Sir George Somers, who the year before had been wrecked while in command of the "Sea Adventure" on the islands, constructed the vessel which carried him to the relief of the infant colony of Virginia, and in which his body was afterward borne back to his native land. Beautiful and very lasting furniture, too, was once made on the islands from the Cedar-wood, and old cedar chests and cabinets 200 years old and more are still held as heirlooms by the descendants of some old Bermuda families who still live in houses finished with this wood, which grows with age rich and dark in color like old mahogany.

Two portraits of Bermuda Cedars are printed in this issue. That on page 274 represents the stem of a very old tree standing in the Devonshire churchyard close by the ivy-covered parish church, which resembles in architecture and surroundings one of the little churches of the older Devonshire. The tree, which recalls one of those venerable Yews of England, hoary with age, and familiar inhabitants of many an English churchyard, probably led to the selection of this particular spot as a place of worship. The tree must have been a very old and large one when the little church was built; it may well have been standing when human eyes rested on these islands for the first time, and probably it has changed very little in the last 200 years. The diameter of the trunk is now fifty-nine inches, and the height of the tree is some forty feet. Only two larger specimens are now known to exist.

The second view represents the tree as it grows in the moist black soil of the Devonshire marshes, a large tract of ground covered with Cedars of large size and springing from a dense undergrowth of Wax Myrtle, or Myrica, identical with the species so common on our Atlantic sea-board, and of Baccharis, similar to, although distinct from, our sea-board species. Tall specimens of the Bermuda Palm which, next to the Juniper, is the most interesting plant of the islands, appear here and there among the Cedars, and the ground beneath the shrubs is covered with a luxuriant growth of Ferns—with the Bracken (*Pteris aquilina*) with fronds four or five feet tall, with numerous clusters of the great Marsh Fern (*Acrosticum aureum*), and with the rare and local Devonshire Marsh Fern (*Aspidium Capense*). These marshes and their inhabitants are very beautiful, more beautiful, certainly, than any other part of the islands, and as the sunlight plays through their open glades on the pale trunks of the great trees, they offer contrasts of color and afford effects of light and shade which our picture does not convey and which words cannot paint.

The Lynn Public Forest.

AN interesting sketch, published in a recent issue of the *Lynn Transcript*, contains much information relating to the early traditions and uses of the public woods which now form a unique pleasure-ground to that city. One of the things which surprise people visiting the Lynn woods for the first time is the rude stone walls which cross them from Wyoma and Saugus, extending in straight lines for many miles through swamps and over hills. They were built by the Puritan founders of Lynn to protect the live stock of the young settlement. To properly understand the motives which induced the great expenditure of time and labor needed in constructing these walls one must consider "the admirable economic system of land tenure which shaped the early towns. The church was the nucleus about which the planters grouped their dwellings. That the houses might be within a convenient distance from the church and from each other, and, at the same time, to foster that spirit of loyalty and independence which springs from the ownership of the soil, the Puritans threw away utterly the last traces of feudal holding of lands for services, and distributed home-lots in fee-simple. The Pilgrims at Plymouth tried at first a pure community of lands and of goods; the Puritans of Massachusetts Bay made no such mistake. They decreed every man's house as his castle in a truer sense than Englishmen had known in the Old World. Thus they established convenience to attend church and nearness to each other for safety, and the home became a sacred holding. The Puritans, however, tried the experiment of herding the stock of individuals upon commons held by the towns. This custom grew out of the Puritan reverence for that other chosen people—the children of Israel. Herding in common, but retaining individual ownership in the stock, besides being a labor-saving device, made the settlers neighborly. The early colonial ordinances teem with regulations concerning cattle, corn-fields, fences, tolling and banding of cattle, trespass by cattle and swine, damage to cattle by wolves. Cow-herds and shepherds and swine-herds became classes."

The long walls were built by the common labor of the men for the protection of their stock. The cow-pastures were nearest to the settlements because the cows had to be driven home twice every day to be milked. The horses were carefully watched, and the General Court as early as 1668 passed an ordinance directing the selectmen of towns to attend to their improvement. The Lynn horse-pasture was north of the present Pine Grove Cemetery, and was well watered by a never-failing spring, which flows as freely to-day as it did two hundred and fifty years ago. The pasture used by the early settlers for their oxen was beyond what is now Glen Louis Pond. Being farthest from the settlement, it was exposed to the ravages of wolves, which abounded in those days, and necessitated the construction of the wolf-pits, which still remain, a striking example to the ingenuity of the early settlers. The Puritans' dread of wolves was only second to their fear of witches, and in 1645 the General Court passed a law by which it was provided that the sum of ten shillings should be paid out of the county treasury "to any person, English or Indian, who shall kill a wolf within ten miles of any plantation."

The writer in the *Lynn Transcript* points out that the "Lynn woods have had three periods of usefulness. Down to 1706 they furnished pasturage and timber and shelter to the village. In their second period, covering the life of the town shifting from the pastoral to mechanical pursuits, they were still useful, although restricted to furnishing fuel to the inhabitants. As time went on, and cheap coal came in with the ever-advancing density of population, it seemed as if the slaughtering brick-maker and the fire-fiend would render the woods a desolation, a desert and a menace to our fair town."

But a period of greater usefulness has come. The inhabitants of cities require pure water, and the people of Lynn have wisely determined to protect and preserve the abundant supply which still flows from the springs which watered the cattle of the Puritans, and these woods now perform their noblest duty in furnishing the great city with water, oxygen and sylvan beauty for the repose of its inhabitants.

"The fathers, with their Aryan ways, their patient oxen and their demon wolves, have gone; the woods which were used first in common, then in severalty, the walls which testified to their energy, and the wolf-pits which note their skill in masonry, are being restored to the common inheritance of their children's children."

Bristol Pond Bog.

TO most people the word bog does not suggest anything very inviting. On the contrary, it is considered nothing but a miry piece of ground where no one would venture, unless obliged to, and where nothing attractive can be found. This is, no doubt, a correct impression of some bogs, but we have, in New England, bogs and swamps that are as attractive, at certain seasons, in their display of natural scenery as any of the mountain forests.

In the town of Bristol, Vermont, is what is called Bristol Pond, a small sheet of water fed by mountain brooks and springs, and from which flows a lively little creek. The pond is almost surrounded by bog lands, of which there are several hundred acres, and on the east side, bordering the bog, is Hog's Back, a large foot-hill of the Green Mountains, which extends north and south for a distance of about nine miles. The pond is about a mile long by a third or half as wide, varying, of course, at different points, and very irregular in outline. The depth of the water varies from a few inches to six or ten feet, but under this lies an unfathomed body of thin, soft, peaty mud, about as thick as porridge at its surface, but probably

thicker at lower depths. The water is quite clear when not disturbed by winds, but there is a constant bubbling in warm weather from the escaping gases of the mud.

Water-lilies flourish here in the little bays, where severe winds do not disturb them; and around the margin, where the bog often projects out over the water, may be seen fine large clumps of the Swamp Loosetrife (*Nesæa verticillata*), its gracefully drooping branches resting and rooting on the surface of the water. Not only are the rose-purple flowers of this plant attractive, but its leafy recurving stems are pretty the whole season, and, for artificial bogs or the margins of ponds and streams, planted in a peaty soil, it has no substitute. Here also may be seen, flowering in its season, the Swamp or Water Rose (*Rosa Carolina*), which grows in such localities, with various other water-loving shrubs. For quite a distance back from the margin of the pond is an open bog upon which few or no trees grow, but there are low shrubs on a part of it, while other portions have only Rushes, Sedges, Pitcher-plants, and Cotton Grass. Of the latter there are three or four species. The Twig Rush (*Cladium mariscoides*) is everywhere on this open bog, and one or two species of the Beak Rush (Rhynchospora). *Dulichium spathaceum*, another queer and striking bog Sedge, also abounds, as well as other small plants that would interest the botanist. Not far back from the margin of the pond are clumps of Arrow Arum (*Peltandra Virginica*), and, scattered all over this open space, as well as back among the timbered portions of the bog, grows very abundantly the Side-saddle Flower, or Pitcher-plant (*Sarracenia purpurea*), of which the specimens here, in the full sunlight, have beautifully variegated and colored leaves, and much darker purple flowers than those in the shade. Acres of this plant in full bloom make an attractive scene. Going back from the margin of the pond upon the open bog we find, on slightly elevated portions, now and then clumps of trees—low Tamarack, Spruce and Arbor-vitæ; and clustered about them, as if planted there for a purpose, are such shrubs as the Chokeberry (*Pyrus nigra*), Swamp Fly Honeysuckle (*Lonicera oblongifolia*), Mountain Holly (*Nemopanthes Canadensis*), the Myrtle and Hoary Willows (*Salix myrtiloides* and *S. candida*), Sweet Gale (*Myrica Gale*) and many more. Sphagnum Moss, which is not found on the wetter portions of the bog, usually grows about these trees and shrubs, and in it are such low shrubby plants as the Leather Leaf (*Cassandra calyculata*), *Andromeda polifolia* and the Pale Laurel (*Kalmia glauca*). The small Moss Cranberry (*Vaccinium Oxycoccus*) often forms, with the Sphagnum, a pretty carpet, and when covered with its abundant small white or pale pink flowers in early summer, or in autumn with its speckled fruit, is very attractive. The Large or American Cranberry (*V. macrocarpon*), though it grows here also, is nowhere so abundant. The Creeping Snowberry (*Chiogenes hispidula*), where it can find a little shade, is also abundant, and forms thick mats of its creeping stems and small dark evergreen leaves. Large overgrown clumps of the Stemless Lady's-slipper (*Cypripedium acaule*) are sometimes found here growing in the Sphagnum.

As we go farther back into the timbered portion we come among more Tamarack, Arbor-vitæ and Spruce, so that, though they do not completely cover the bog, they have hidden the pond from our view. Here in the half-open spaces, where the ground is higher, and is completely covered with moss, may be found in their seasons a wealth of flowers. *Arethusa bulbosa* is so abundant in certain localities that one might sit in the soft moss and gather a score of plants without moving. It varies in height from the little dwarf which rises an inch or two above the moss to the strong plants fifteen or twenty inches high. The Bog Shinleaf (*Pyrola rotundifolia*, var. *uliginosa*), which grows and blooms with the Arethusa, is a charming companion to it, has roundish shiny leaves and handsome purple or flesh-colored flowers. The Sarracenia and Stemless Lady's-slipper are also here, and one of the white-flowered Rein Orchis (*Habenaria dilatata*), with handsome spikes of fragrant pearly white flowers. *Calopogon pulchellus* is scattered about everywhere, as is also, though not quite so abundant, *Pogonia ophioglossoides*. Other less showy Orchids are growing in scattered groups not far away, such as *Habenaria hyperborea*, *H. tridenta*, *Listera cordata* and *Microstylis ophioglossoides*. The Bog Bean (*Menyanthes trifoliata*) is quite common in places, and the handsome racemes of its dainty white flowers are among the earliest of the bog. *Smilacina stellata* and *S. trifolia* are both common here, and add much to the floral display. The little Ram's-head Lady's-slipper (*Cypripedium arietinum*) also grows a little farther back in more favored situations; and in other places the small yellow Lady's-slipper (*Cypripedium parviflorum*) is quite abundant, and not rarely in clumps of a dozen stalks. At each step we sink ankle-deep in the cool soft Sphagnum, and as we turn back and see our footprints they reproach us as if we had ventured on sacred ground.

Walking at random, and with no definite course, through this botanical paradise, new attractions greet us at every turn. Farther back out of the locality of Sphagnum we find large patches of the Twin-flower (*Linnæa borealis*), which is one of our most attractive little vines when in flower. The Water Arum, or Wild Calla (*Calla palustris*), is also found here, and, though not abundant, the showy Lady's-slipper (*Cypripedium spectabile*) is frequently seen. Under some of the large thick clumps of Arbor-vitæ, where only a thin sifting of sunlight ever reaches it, is one of our most delicate and charming little Orchids, *Orchis rotundifolia*, with pale rose-purple flowers. Even the *Calypso borealis* is not a stranger to this bog, for it has been found here in the drier portions under the largest specimens of Arbor-vitæ. Around some portions of the bog's margin the Black Ash extends into the bog or peaty ground for some distance. Other portions are thickly covered with low trees or tall shrubs. Still others have such a dense growth of Arbor-vitæ that nothing can live under them. But in some places, where the evergreens are scattered with wide spaces of Sphagnum Moss between, may be found some sylvan scenes as rich as any our forests afford.

Botanical Garden, St. Louis, Mo. *F. H. Horsford.*

How We Renewed an Old Place.

X.—A STRUGGLE WITH THE WEB-WORM.

AMONG the difficulties of reclaiming a place, one cannot ignore the necessary hand-to-hand conflict with the various animal and vegetable enemies which lie in wait to destroy plants and trees. Eternal vigilance is the price of vegetation as well as of liberty, and the cultivator who dreams that he can for a moment take his ease in his inn, reckons without his guests of the insect-world, who take short naps, and require as much nourishment as Falstaff. I shall have more to say upon this subject at a later date, but I am now fresh from a conflict with the Web-worm, and find a treatise upon his manners and customs apropos. As an example of pertinacity, Bruce's spider beside him pales her ineffectual fires; as an evidence of the apathetic stupidity of man he is unrivaled, and as a menace of future untold horrors he may well be used to point a moral of grewsome interest.

Some philosopher has said that "the real end of the world will come when man ceases to be able to cope with the insects." When his time comes the worm is the master of us all, but there is no reason while we are yet stirring about this earthly ball that we need submit to be devoured by him before our day. And yet, when you come to think of it, that is what the brute is after. Too cowardly to attack man openly, he begins by eating up his provender. Man, being on the whole an easy-going animal, at first pays not much attention; but he only multiplies moderately, and the insect enormously. Where a man will leave a half-dozen descendants in a life-time a worm will leave one hundred and twenty-five thousand in a season; judge then if this can be allowed to go on indefinitely and man survive!

Where the inane apathy of the human being comes in is in not crushing his enemy while yet insignificant; forever penny wise and pound foolish, man tolerates a moderate evil until it becomes inordinate, and then wastes a fortune which might well have been saved, in doing ineffectual battle with his foe. It is the fable of Epimetheus forever renewed, and the appeal I would now make is to have this Pandora's box closed before the rest of the Web-worms escape to plague the world, and help make an end of the race.

It is idle to scoff at this idea as that of an alarmist. A few years ago the spring Web-worm was an unimportant factor in our orchards. The fall worm gave some trouble, but he was not impossible to cope with. Now, not only do we have to fight for every apple we possess in the autumn, but all through the months of April and May, when work presses, when every moment is precious, it takes not only all the hands on a farm to fight caterpillars, but also all the eyes of the family to detect their lurking-places; and this not as one job, but as a perpetually recurring duty for weeks at a time, and all on account of the crying neglect by land-owners of their premises, and by town authorities of the webs on their own highways, which have been allowed to accumulate, until the country roads have lost their beauty, lined as they are with trees shrouded from root to summit in ghostly webs, under which myriads of loathsome black worms writhe and crawl, and eat their fill, to the shuddering disgust of the wayfarer.

Far and near, not only are the wild Cherry-trees, already infested with the odious black knot, left to spread a second plague among the fruit-trees, but whole orchards are allowed to bear, unmolested, swarms of caterpillars, their owners preferring to sacrifice their apples rather than take the trouble to clean their trees of the webs.

If the state of Massachusetts has taken the Gypsy Moth in hand, why should not communities take charge of their own worms and enforce the destruction of the webs by each landowner, under penalty of a fine, while the street commissioners be made to attend to the trees bordering the highway?

The farmers who neglect this rapidly increasing nuisance seem to me like the Turk who sits under a crumbling wall, murmuring, "God is great! if it falls it falls!" and takes no pains to get out of the way.

So far as our own little farm is concerned, some tall wild Cherry-trees that we depend on for a screen give us timely notice of the arrival of the pest, and bring us all out promptly to do battle. The worms are fought with fire on the end of a pole, with a tall clipping knife, and with a wire brush attached to the end of a long bamboo rod which reaches to the very top of the tallest trees, where, being judiciously twisted, it brings down a crop of crawlers for more positive destruction below. The clipping is the most thorough method, for, if done late in the evening, the nest, with all its occupants, can be secured and its contents burned or trampled to death. In this way all the insects can be destroyed, but, of course, it is only possible where the web is on the end of a small branch. Where it lies in the great crotches the torch or the wire brush must be applied, but the former lets some escape, and I am told that when the nests are burned, the fire shrivels the outside of the crawling mass, which falls with the web to the ground, but the caterpillars in the heart of the living ball escape, to crawl up the tree again and start afresh upon their depredations.

It is of no use to think that you have accomplished your purpose because, after heroic labor, there seems not a vestige of a nest remaining. No sooner do you feel that you have routed the last encampment of the enemy than, presto, his tents are once more like those of the Assyrian for multitude, and in a day or two you must resume your round to find the enemy bigger and brisker than ever. About three months of the season have to be given up to the two campaigns, spring and fall, till finally a person of imagination begins to feel that the philosopher's prediction is about to be fulfilled, and that the worm has come to stay.

"Of what use are the Cherry-trees?" say the wise; "the worm, after all, is not so bad as the black knot, and compared to the canker-worm he is harmless"; but the terror of his multiplication is upon me, and I live in fear of the day when, having ruined all the fruit-trees, and having failed to find the shade-trees to his liking, the worm may take a fancy to investigate within-doors to find a more tempting meal.

A vision of opening the front door in the morning to find the house encased in an enormous web, under which the worms are feeding on the shingles, and glaring at you from under their silken canopy, besets the imagination. You seize your hat, a brisk young family drops out of it; your coat—there are a score of creeping things inside the sleeves. The breakfast-table is invaded by a squirming throng; others hang from the draperies and wander across the ceilings. Why may not the Web-worms become as great a pest to us as the Termites prove to the South African, if the apathetic public does not awake in time to the necessity of destroying them while they are yet in the minority?

Here in this town, where the neglect of certain farmers adds so greatly to the labors of their more thrifty neighbors, we have seen these loathsome creatures multiply in a few years to an alarming extent, and it seems as if the time had come to render it a penal offense to neglect to destroy the webs as fast as they appear. Unquestionably, the day is coming when some destructive measures will have to be adopted, and the sooner the matter is taken in hand the easier it will be for all concerned to get rid of the evil, and I should be glad if some more powerful pen than mine could be used to hurry this good end.

An evil, trifling in itself, becomes a menace if neglected, and the comparatively inoffensive character of this little brute seems to blind the public to the way in which he is multiplying. A committee to find out how much harm he does might serve as a preliminary to more strenuous measures, but if it were only in the interest of those lovely rustic roads, in which Garden and Forest takes so much delight, it would be worth while to clear away so obtrusive an eyesore as these loathsome webs from the way-sides, otherwise so beautiful with their wild vines and tangle of bushes.

Moreover, for the pedestrian the multiplication of caterpillars is a distress yearly more and more appalling. After the worm has eaten his fill he sets forth upon his peregrinations, to find a sheltered spot where he can become a hermit in a cell, until such time as his resurrection as a moth is in order, and you are obliged to meet him on his winding way at every turn in your path. Country sidewalks swarm with the wretches; verandas are their especial delight; you gather a flower, a caterpillar is crawling up the stem; examine your trees of all sorts, the brutes are making of their trunks a public promenade, up which they hurry at top speed to make a cocoon in the branches; would you rest yourself upon a bench, the caterpillar is there before you; if you wear a thin gown, you may have the pleasure of viewing through its meshes the wriggling, hairy form of your enemy, just where you cannot get at him. He makes himself at home amid the flowers of your bonnet, he swings down upon a silken thread within an inch of your nose. He arouses in the gentlest breast a desire to slay this future parent of thousands; he undermines the character by stirring up sentiments of virulent hostility in otherwise peaceable souls; he becomes a menace not only to existence, but to Christian character, by developing the savage instincts of our nature; and, therefore, on every ground, both physical and moral, he is an enemy of the public peace who should be taken in hand by the authorities and be doomed to extermination.

Hingham, Mass. *M. C. Robbins.*

Note.—The editor of this periodical requests me to provide my enemy with a more precise name than Web-worm. Not being learned in entomology, the only term I dare to vouch for is *Nasticrechia Krorluppia* (to be pronounced English fashion).

To this family I am entirely sure he belongs, but one of the reports of the Department of Agriculture has a good deal to say about a certain *Hyphantria cunea*, which seems to correspond to him in most particulars, and the same report furnishes for him ten more synonymous names that apparently can be used if necessary. From this abundance I have selected the above as the most euphonious and descriptive, for nothing could be more appropriate than the term Shameless Weaver, which, I am told, is the translation of these polysyllables. Should my particular Web-worm require a more formal introduction to the public, it is to be hoped that some entomologist will kindly supply us with his real designation.

New or Little-known Plants.

New Orchids.

Cirrhopetalum elegantulum, Rolfe, is an elegant and floriferous little species, native of the Coorg Hills, south India, which was sent to Kew by Mr. J. O'Brien, of Harrow. It is allied to *C. pumilio*, Hook., f., a native of Burma. The lateral sepals are yellow, except in their basal portion, which, like the rest of the flower, is striped with maroon-purple on a pale ground.—*Gardeners' Chronicle*, May 2d, p. 332.

Masdevallia × falcata, O'Brien, is a showy garden-hybrid raised by Mr. D. O. Drewett, of Riding Mill-on-Tyne, from *M. Lindeni*, crossed with the pollen of *M. Veitchii*, to which latter it bears a considerable resemblance, especially in color. It may be compared to *M.* × *Chelsoni* in its general characters.—*Gardeners' Chronicle*, May 2d, p. 332.

Epidendrum × dellense, O'Brien, is a pretty hybrid raised in the celebrated collection of Baron Schröder, of The Dell, Egham, between *E. xanthinum* and *E. radicans*, the latter being the pollen parent. It bears a considerable resemblance to the mother plant, except in color, which is a shade of orange approaching vermilion. The flowers, however, are larger, and there is a slight curvature in the column which bespeaks the influence of *E. radicans*.—*Gardeners' Chronicle*, May 9th, p. 584.

Sobralia macrantha delicata, O'Brien, is a pale, nearly white, variety, with a tinge of lavender on the sepals and petals, and lilac on the margin of the lip, and without any yellow on the throat. It flowered with F. A. Bevan, Esq., of New Barnet, from an importation of Messrs. F. Sander & Co., of St. Albans.—*Gardeners' Chronicle*, May 9th, p. 585.

Cirrhopetalum Wendlandianum, Kränzlin, is a remarkable species, native of British Burma, which flowered in the collection of Herr Wendland, of Herrenhausen, near Hanover. It bears an umbel of three to six flowers, colored in the way of the old *C. auratum*. The sepals are ovate, with long hairs on the margin, and with five or six fluttering serrulate leaflets at the top, almost as long as the sepals, and deep

claret-red in color. The petals are ovate at the base, protracted into tails from six to seven inches in length, longer than the pedicel itself. They are yellow, striped with purple in color, as also are the sepals, while the lip and column are purplish, with deep red spots. It is a very remarkable species.—*Gardeners' Chronicle*, May 16th, p. 612.

Cirrhopetalum Collettii, Hemsley, is a beautiful species, originally described from dried specimens, but now flowering, for the first time in Europe, in the Kew collection. It is nearly allied to *C. ornatissimum*, but has larger flowers, and is probably the finest species in the genus. It grows on the Shan Hills, in eastern Burma, at an altitude of 6,000 feet. The flowers are striped with reddish purple on a lighter ground. The upper sepal is adorned with numerous linear appendages on the margin, and the apex of the petals with several slender leaf-like bodies, which flutter in a singular manner with the slightest breath of wind, and probably serve to attract insects for the fertilization of the flowers.—*Gardeners' Chronicle*, May 16th, p. 614.

Kew. *R. A. Rolfe.*

Foreign Correspondence.

Some New Plants in England.

Primula Poissoni, Franchet.—This is a beautiful plant, for which we are indebted in the first instance to L'Abbé Delavay, who discovered it along with many other good garden-plants in Yun-nan, and forwarded seeds to the Jardin des Plantes, Paris, to which establishment we are indebted for several of the seedlings which are now in flower at Kew. In stature and general appearance *P. Poissoni* is similar to the popular *P. Japonica*, but it differs from that species in the smaller, more fleshy, glaucous, smooth character of its foliage, and in the color and several minor details of its flowers. The plant forms a dense tuft of leaves, each of which is six inches long by from one and a half to two inches wide, and the scape is erect, stout, as in *P. Japonica*, with the flowers in whorls and opening in succession. Each flower is as large as those of the best forms of *P. Japonica*, and colored bright rosy mauve, with a conspicuous eye-like ring of yellow around the apex of the tube of the corolla. The segments are obovate and notched, and in the Kew plants every flower has either six or seven segments. A description of this species occurs along with others in the *Bulletin de la Société Botanique de France* for 1887, which contains a paper by Franchet on the Primulas of China and Tibet.

P. imperialis, Jungh.—This is the giant Primrose of the high mountains of Java, which De Vriese described as a new genus under the name of *Cankrienia chrysantha*, and which Wallace mentions in his delightful book, "The Malay Archipelago."

In 1884 Sir Joseph Hooker referred this plant to the Himalayan *P. prolifera*, a smaller, and in every way much inferior, plant from the point of view of the horticulturist. The two may be specifically identical, but there is a great difference between the Himalayan form as represented in the *Botanical Magazine*, t. 6732, and the Javanese giant as represented by a batch of plants now in bloom in a cold frame at Kew. Picture a plant like *P. Japonica* in habit, but with leaves fifteen inches long by five inches in width, and a scape as thick as a man's little finger, bearing whorls of deep yellow flowers almost as large as those of *P. Japonica*. The scapes on the Kew plants are already two feet high, although only the first whorl of flowers has expanded, and there are five or six to come in all. As the largest Primula known, this species, or rather the Java form, has a special interest, but it also possesses beauty in its deep yellow flowers, while looking at it as the probable progenitor of a race of garden-plants—for it may be considered to have all the capabilities of its ally, *P. Japonica*—it must have a decided value for the breeder and cultivator. It has crossed freely with *P. Japonica;* at any rate, there are some plump, promising-looking pods of hybrid seeds on some plants at Kew.

The following plants were among those which obtained certificates at the exhibition held in the Temple Gardens last week:

Eremurus Himalaicus.—Several flower-spikes of this plant were exhibited from a garden in Ireland, where apparently these stately Indian Asphodels find congenial quarters. Mr. Gumbleton, of Cork, I believe, was the first to flower the above-named species, having raised it from seeds collected in the Punjaub, where it is said to produce flower-spikes eight feet high. Mr. Gumbleton's plants were five feet high. How high those exhibited had been I could not ascertain, but only the flower-bearing portion of the spike was sent, and this was exceedingly beautiful, being a compact tall pyramid, two feet high, of pure white flowers with golden stamens. The cultivation of these plants requires some care. They prefer a well-drained soil and a sunny position. The crowns, too, should stand a few inches above the level ground. *E. robustus* is another tall and handsome species which is sometimes to be seen in English gardens.

Cocos Pynærti.—This is a seedling variety of *C. Weddelliana* which came up among a batch of seedlings of the latter in the nursery of Monsieur Pynaert Van Gurt, of Ghent, after whom it has been named by Mr. Sander, who obtained a first-class certificate for it from the Royal Horticultural Society. A figure and description of it will be found in *Revue de l'Horticulture Belge* for April last (p. 91), where it is named *C. minima pulchra*, a name, by the way, so far accepted as to have obtained the notice and certificate of the Horticultural Society of Ghent. The plant is very elegant, owing to the narrowness of the pinnæ, which are scarcely half as wide as those of the ordinary *C. Weddelliana*. The Sanderian specimen is unique, so far as I can learn, and, as the plant cannot be propagated, it must necessarily remain so.

Grammatophyllum Measuresianum.—This was the most interesting Orchid at the exhibition. It was introduced from the Philippines by Mr. Sander about two years ago, and distributed under the above provisional name. A description of it will be found in Garden and Forest (ii., 524). The first plant to bloom was that exhibited by Mr. Sander, and, as a matter of course, it was awarded a first-class certificate. Whether it differs from *G. Fenzlianum* or not I am not at present able to decide; but, whatever its correct name may be, it must take rank among the best of tropical garden Orchids. Apparently, it has the same shy flowering character which is the only drawback to the popularity of the other two species in cultivation, namely, *G. Ellisii* and *G. speciosum*. The plant certificated was a grand mass, bearing four erect spikes about five feet long, branched and clothed with numerous flowers, each three inches across; the sepals and petals equal, wavy, half an inch wide, spreading, the tips recurved; lip small, with the sides overlapping and enfolding the column, the tip of which was revealed by the bending down of the tongue-like middle lobe. The color of the whole flower was greenish yellow spotted with reddish brown, the central lobe of the lip being white lined with crimson, the lateral lobes lined with brown.

Cattleya Prince of Wales.—This is a new hybrid raised by Mr. Sander from *C. Mossiæ*, var. and *C. elegans*, or some such combination. It is in the way of the last named, but smaller, with waxy-white sepals and petals, the lips also white, with rosy veins and a wavy margin.

C. Lowryana, from the last-named exhibitor, is supposed to be the result of crossing *C. intermedia* and *C. Forbesii*. It resembles the former in the size and shape of its flowers, which are white, with a purple or mauve tint on the front lobe of the labellum.

Masdevallia Mundyana is the handsomest hybrid Masdevallia hitherto raised. It is the result of crossing *M. Veitchii* and *Mignea aurantiaca*, combining the chief characteristics of the two in a peculiarly pleasing manner. The flowers are almost as large as those of *M. Veitchii*, their color being orange, changing to scarlet toward the lower part of the sepals. It obtained a first-class certificate.

Ærides Savageanum, as shown in several of the groups, was quite worthy of the first-class certificate awarded it. There are, however, many plants of it in cultivation which are a long way inferior, in the size and color of the flowers, to those shown. Mr. Sander thinks this species has not yet been seen at its best. It has elegant loose racemes of rather small but bright crimson-colored flowers.

Oncidium loxense.—This distinct and noble species was named by Lindley about forty years ago from a specimen collected by Hartweg on the Cordillera, near Loxa, in Peru, where it is said to produce "flower-panicles nine feet long, the flowers as in *O. falcipetalum*." In 1884 Reichenbach notices it in the *Gardeners' Chronicle*, in consequence of Mr. Sander having forwarded to him specimens and a drawing, but living flowers of it do not appear to have been seen in England until they were shown on a plant at the Temple last week. This plant has oblong compressed pseudo-bulbs, broad, somewhat rigid, leaves, and a spike five feet long bearing numerous flowers as large as those of *O. macranthum*, but differing from all other plants of the Microchila section in the size and form of its labellum, which resembles the lip of the African *Lissochilus Krebsii* in form and color. The sepals and petals are brown, with irregular blotches of yellowish green, and the lip is deep yellow. A batch of plants of this species was sold by auction in London in 1884.

Fig. 51.—Old Cedar in Devonshire Churchyard, Bermuda.—See page 289.

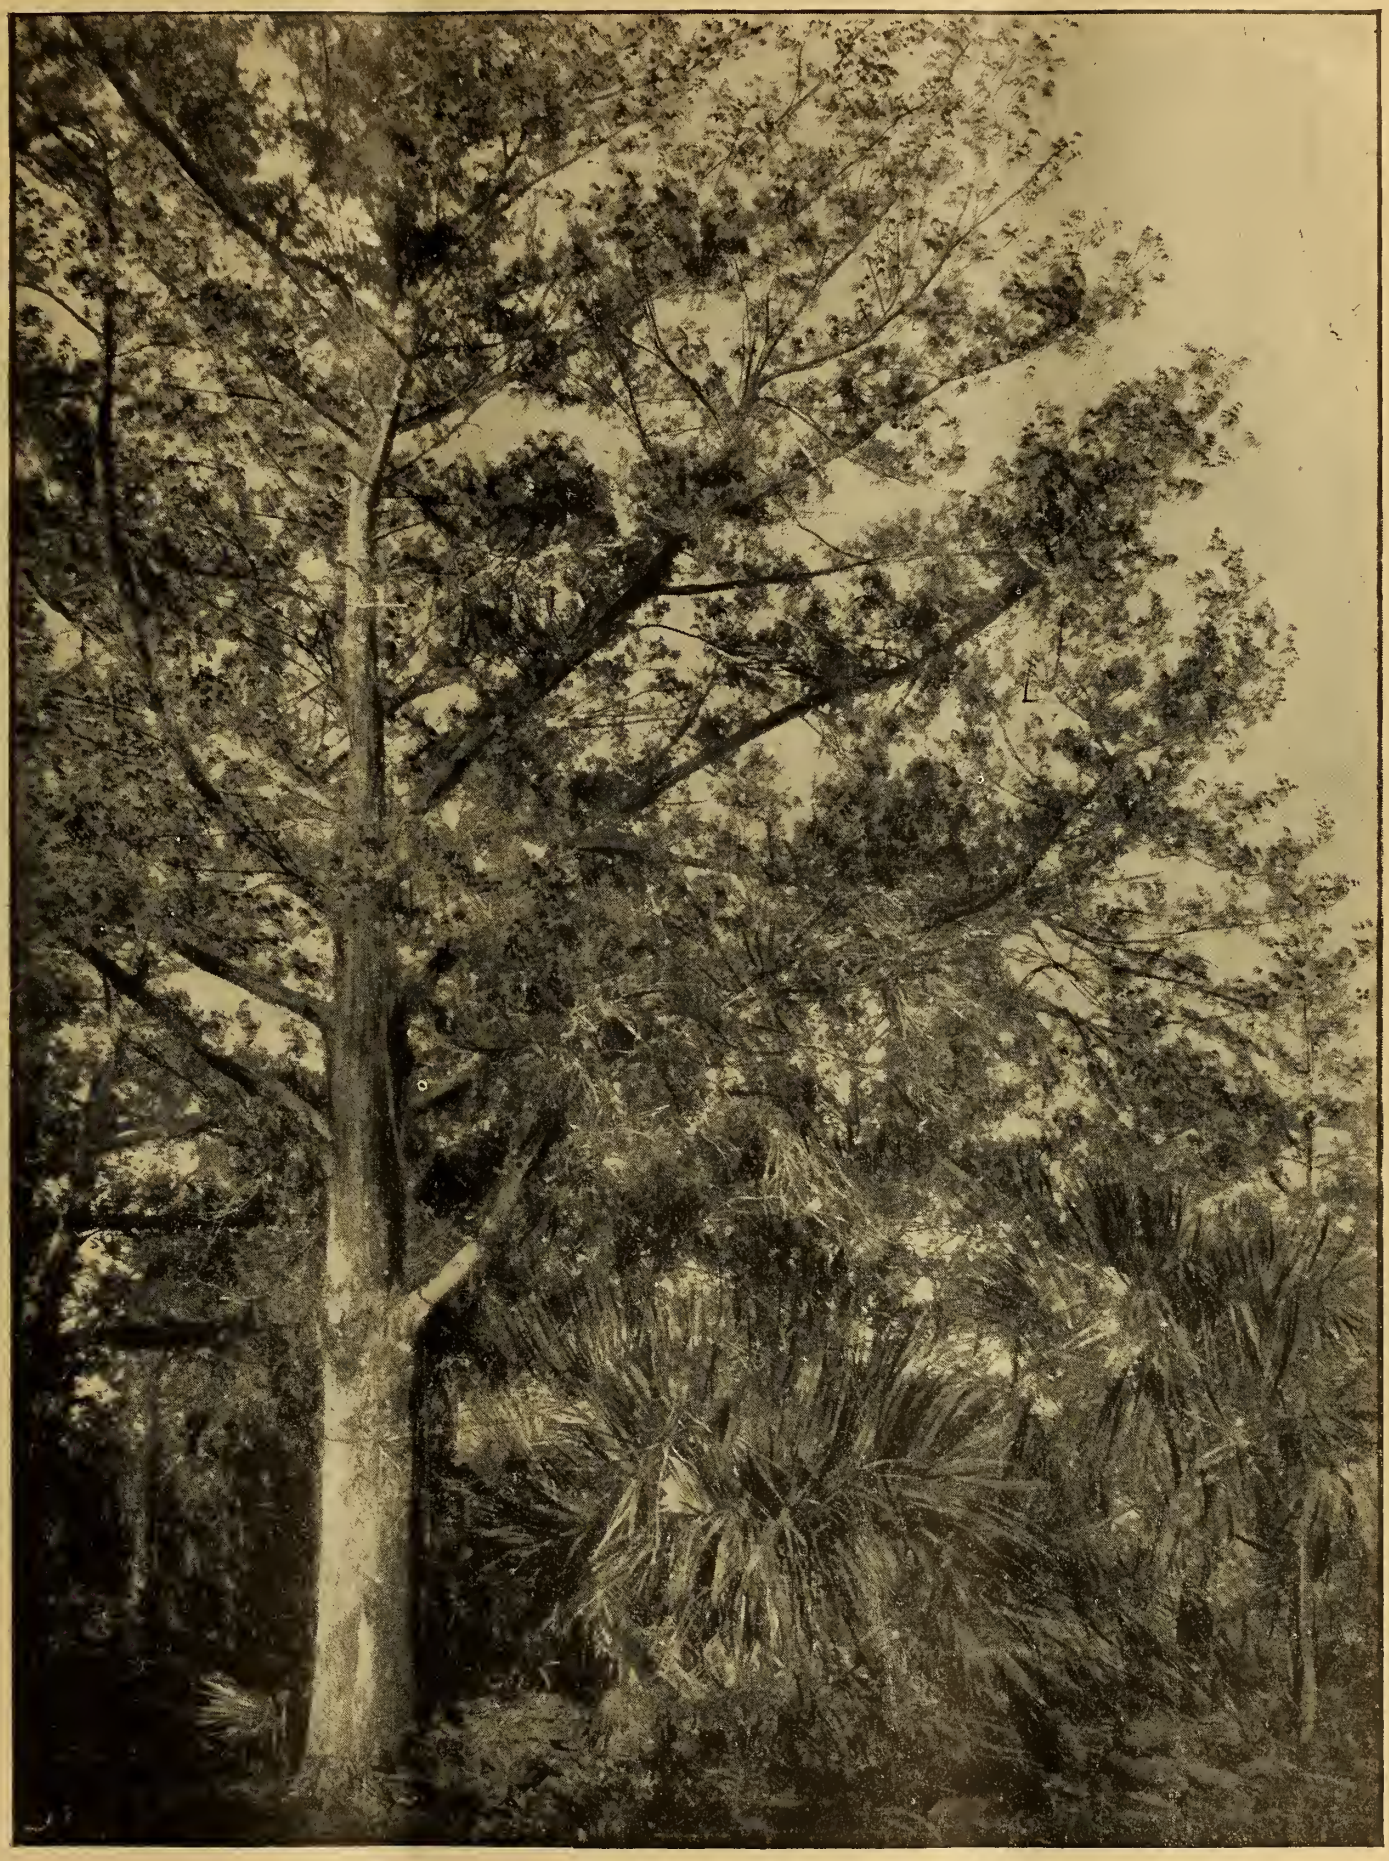

Fig. 52.—Juniperus Bermudiana in the Devonshire Marshes, Bermuda.—See page 289.

Other Orchids which were especially recognized by the Society were *Lælia elegans Statteriana*, white, with a large labellum veined with crimson, on a creamy-white ground; *Cypripedium Stonei magnificum; Dendrobium Parishii albens*, a variety with pale lilac flowers; *Masdevallia Harryana luteo-oculata*, large richly colored flowers with a distinct yellow eye; *Odontoglossum elegans Sanderæ*, which is a most beautifully and heavily marked variety of one of the very finest Odontoglossums; *O. Amesianum;* and several hybrid Cypripediums.

Cultural Department.

Stray Notes from the Arnold Arboretum.

MANY of the plants which will be mentioned in these notes have already been noticed in the columns of Garden and Forest, and several of them have been figured and described in detail. A longer test in this severe climate, however, brings out the good qualities and emphasizes the value of plants known in cultivation for a few years only or shows their weaknesses or bad qualities, and a few additional facts relating to them may be useful to planters.

Too much cannot be said, certainly, in praise of the native shrubs of eastern America for the decoration of the gardens and shrubberies of the region which they inhabit naturally. Our native Viburnums and Cornels are all plants of beauty and value. The natural shrubberies made several years ago in the Arboretum with these plants show their beauty and value where shrub-planting on a large scale is desirable. Many of the species are not less valuable as single specimens than when grouped in broad masses on the borders of natural woods or of wood-drives. The example set by the Arboretum in utilizing our native plants and in developing their beauties is beginning to bear good fruit, and there is now a demand for plants of this class which none of the nurserymen are enterprising enough to be able to fill at all satisfactorily. There is no difficulty, however, in getting up a stock of any of our native plants; they can, of course, all be raised from seed, and the seed is not difficult to procure in large quantities if any one knowing the plants will take the trouble to go out into the woods and gather it. Young seedling plants, too, can generally be found in abundance in the woods, and, with proper care, these can soon be grown into good specimens. But people do not always take proper care in such cases; and purchasers are apt to think that because plants grow naturally in the woods that they ought not to cost anything but the trouble of digging them. The result has been that nurserymen who have attempted to fill large orders for these plants have generally been forced to offer them at prices which do not allow them to supply proper plants.

The only way to be sure of succeeding with shrubs or trees dug from the woods is to select only small thrifty specimens—those which are only a few inches high are the best—then to plant them in nursery rows in good soil and to cultivate them for one and perhaps for two years. Plants treated in this way become stout and stocky and are supplied with abundant roots, and, transplanted to their permanent places, are certain to succeed and to grow rapidly as soon as transplanted. Such plants are worth at least four times as much money as the native plants usually sold and planted. These are generally dug in the autumn, the largest plants possible being selected, so as to make a good show and satisfy the purchaser who habitually wants "something big to make a show at once, as life is too short to plant little sticks"; the plants are then roughly heeled-in over winter and delivered in the spring with scanty roots and big tops, and usually more dead than alive. Of course, more than three-quarters of such plants die, and the purchaser is discouraged and believes that it is no use trying to make wild plants grow, and goes back to the conventional nursery-grown Golden Spiræas and Golden Elders, purple-leaved Plums, and all the other so-called novelties with which the tree-peddler beguiles the unwary. It costs just as much money and labor to prepare the ground for a bad plant as it does for a good one, and just as much to plant it. It is wretched economy, therefore, to plant cheap trees or cheap shrubs; they need not be large—generally the smaller they are when planted the better—but they should be provided with an abundant supply of active healthy roots. Good soil and good cultivation are needed to produce good roots and make plants which can be transplanted without risk of loss.

But to return to our native Viburnums and Cornels. The largest of the Viburnums, which grow in New England, and one of the handsomest of the whole genus, is the so-called Sheep-berry (*Viburnum Lentago*). This sometimes attains the size of a small tree, but is more often only a shrub. If it is planted by itself in good soil as a specimen on the lawn it will grow into a large round bush perhaps fifteen feet high and ten or fifteen feet through the branches, which will rest on the grass. The leaves are large and beautifully shining and lustrous, and the large flat clusters of small creamy white flowers are produced during the first days of June in the greatest profusion, and in autumn are followed by bunches of handsome blue-black oblong edible fruit. A well-grown and symmetrical specimen of this plant is an object of great beauty; there is hardly another shrub which can be grown into a more perfect specimen; and if the Sheep-berry came from Tibet or Yun-nan, or from the summit of an equatorial African mountain, and cost fifty pounds an inch, rich Americans would soon exhaust the supply. Now the sight of it only fills most people with surprise and a profound disbelief that such a handsome plant can grow by the roadsides and in the coppices of every New England village, for it is this species which is the chief ornament of our roadsides in early summer. *Viburnum Lentago* has been largely planted in the Arboretum, and has proved valuable in all the situations where it has been tried. It flourishes in the shade and in the full sunlight, and requires strong, rich soil and abundant space if it is to be allowed to spread to its full dimensions.

The nearest species botanically to *Viburnum Lentago* is the so-called Black Haw (*Viburnum prunifolium*). This plant does not grow in New England, although it is hardy here. It is very common in the middle and southern states, and abounds in Central Park, in New York, where there are many fine specimens in the wilder wooded parts, which are made beautiful by them in early May, when the plants are in flower. This species grows to be a larger tree than *Viburnum Lentago*, and the flowers, which are more nearly white than those of that species, are decidedly handsomer; the fruit, too, is more showy. The leaves, however, are narrower and less lustrous, and, on the whole, except when it is in flower, the southern plant is less beautiful than its northern relative.

Viburnum dentatum, or Arrow-wood, is as beautiful almost as either. It is a shrub ten or fifteen feet high, which grows in rather moist soil near streams and swamps all over the northern states, and has broad lustrous leaves with large sharp teeth and very prominent veins, and produces large flat clusters of nearly white flowers. The fruit, which ripens in the early autumn, is bright blue and very ornamental. This is an excellent plant in cultivation; planted in deep well-manured soil it grows with a vigor unknown to the wild plant and produces larger and richer-colored leaves and larger and more abundant clusters of flowers. Few plants better repay good cultivation, and there are very few shrubs of any country which are more ornamental in cultivation or better worth a conspicuous place in the shrubbery.

Viburnum pubescens is a smaller plant than *Viburnum dentatum*. The leaves are smaller, narrower and more sharply pointed, and the flower-clusters are much smaller. It rarely grows more than three or four feet high by as much broad. The flowers, which appear rather earlier than those of *Viburnum dentatum*, or during the first days of June, are produced in the greatest profusion, and quite cover the plants when they are grown in good soil and allowed an abundance of light and air. This is one of the best shrubs to plant on the outer margin of a large shrubbery, and it is particularly beautiful in the autumn, when the leaves turn a rich dark purple color like that of some old Spanish leather, a most unusual color among our plants. This adds greatly to the value of *Viburnum pubescens* as an ornamental plant, and makes its cultivation particularly desirable.

Delightful, too, is *Viburnum acerifolium*, the familiar Arrow-wood of eastern woods. This is a small plant with slender stems, which rarely rise to a greater height than three or four feet, and Maple-shaped leaves, which in the autumn turn a most beautiful scarlet color. The flower-clusters are not broad, but they stand up well on the ends of the branches, and the individual flowers when they expand are bright pink, and later become creamy white. The showy black fruit remains on the branches through the winter. This is naturally a shade-loving plant, and thrives when planted under shrubs and other trees; it bears the sun, however, and apparently grows as well when fully exposed to it as it does in its native glades.

Our two native Viburnums, with nearly entire bright green leaves with obscure veins and long-stalked flower-clusters, are plants for the garden. These are *Viburnum cassinoides* and *Viburnum nudum*. No one seeing these plants cultivated for the first time can be made to believe they are common native plants. In their swamps they grow up tall and spindling, but, transplanted to good soil, and given sufficient space to spread,

they form broad, round masses of large, handsome foliage, larger, and almost as beautiful as that of the Camellia, and, in June, cover themselves with great broad clusters of creamy white flowers. Naturally they inhabit swamps, but they seem to grow better in good, well-drained soil. *Viburnum cassinoides* is a more northern plant, and flowers rather earlier than *Viburnum nudum*, a native of the region from New Jersey to Florida. Both are equally hardy here, and there is little to choose between them as garden ornaments, although the leaves of the southern species are thicker and rather more lustrous than those of its northern relative. No one will make a mistake in planting either of them or in giving them a conspicuous place in any garden, however carefully selected its contents may be.

The Cranberry-tree (*Viburnum Opulus*), the wild form of the familiar Snowball-bush, is now so well known and so commonly planted that another notice of it does not seem necessary. It occurs in all the three northern hemispheres; and it is, perhaps, worth recording that there are now growing in the Arboretum plants raised from seed sent from northern China, which are much more ornamental in flower than either the North American or the European forms; the sterile ray flowers, being twice as large, and rather more than an inch across, while the anthers, instead of being green, are bright purple. The plants are perfectly hardy, and this variety should be better known and generally planted.

But the most beautiful of all the American Viburnums, so far as concerns the flowers, is the Hobble-bush (*V. lantanoides*), figured in Garden and Forest (Vol. ii., p. 535, f. 141). It produces, like *Viburnum Opulus*, neutral ray flowers around the outside of the cymes, and these are very large and pure white. The leaves are broad and thick, and, in the autumn, turn to a brilliant scarlet color. Naturally this plant grows under the dense shade of trees in the northern forests, which it cheers in early spring with its great clusters of flowers, and again in autumn with the bright colors of its leaves. It is a difficult plant to cultivate, and we have heard of a single instance only where, brought into the garden from the woods, it has been made to grow successfully. Mr. Dawson has found that, grafted on the European *Viburnum Lantana*, it grows stronger and more vigorously than it does on its own roots, and his stock of grafted plants now gives promise of ultimate success. It is such a beautiful plant, and one so well suited to flourish under the shade of trees, that serious efforts to get it established are well worth making.

Arnold Arboretum. *P. C.*

Some Early Spiræas.

From several causes the Spiræas have not done so well at the Arboretum this season as usual. Some were injured in winter, but the most damage was done by frosts in the first week of May and again about the 18th or 19th, when a great many buds were very much hurt. This frost apparently affected the buds of the hardiest as well as the more tender of the early-flowering species.

Spiræa pubescens, of which an illustration appeared on page 331 of the first volume of Garden and Forest, proved something of a disappointment this season. In a series of perhaps a dozen plants the blossoms were uniformly straggling and few, and the numerous naked stems and branches plainly showed that the plants were either all equally injured during the past winter, although planted in different exposures, or it may be that they are short-lived and degenerate after a certain period. The plants under notice were raised from seed collected by Dr. E. Bretschneider in the mountains near Pekin, China, and sown at the Arboretum in the beginning of the year 1883. Whatever may have been the cause of its present unsatisfactory condition, *S. pubescens* is well worth cultivation and frequent propagation on account of the earliness of its blossoms. These resemble the more common species known as *S. trilobata*, or the improved form known in gardens as *S. Van Houttei*, but they are of especial value because they appear two or three weeks before the flowers of the others. The blossoms are of about the same size, and are borne in similar clusters as in the two already mentioned. The foliage is of a light green color, and the young shoots and the under sides of the leaves are quite densely pubescent or downy.

As already stated, this is one of the earliest-flowering species, but it is not so early as *S. Thunbergii*, which ranks as the very earliest of the hardy species in cultivation here. Its value lies not so much in the abundant white, early spring flowers, by which its branchlets are covered, as in the fact that the fine soft foliage makes the plant a pleasing and ornamental object throughout the season, and in the brilliancy of its foliage in late autumn it is not equaled by any other species in the genus. It is scarcely surpassed by any other hardy shrub in its autumn coloring, and it has the great merit of holding its leaves until very late in the season.

The old-fashioned double-flowered *S. prunifolia* closely follows *S. Thunbergii* in its blossoming. Like many others, the plants of this species have a bare and straggling appearance as they grow tall and old. They grow easily and rapidly, and better results in bloom will be obtained if old stocks are occasionally removed and new shoots put in their place. *S. prunifolia* is usually fairly hardy here, although the tips of the branches are often winter-killed. What has been called the single-flowered type of this plant was received at the Arboretum several years ago, but it has been so much injured every winter that it has not been possible to get any idea of its normal growth and appearance. The few blossoms which have developed in early spring, through careful winter protection, have shown much likeness to those of *S. Thunbergii*.

In small gardens, where only a limited number of plants can be grown, there is probably no Spiræa which gives such general satisfaction as the form known as *S. Van Houttei*, which is generally considered to have been derived from the Asiatic *S. trilobata*, which is smaller and not so beautiful or graceful as a flowering shrub. *S. Van Houttei* is perfectly hardy, even in such a rigorous winter climate as that at Montreal, in Canada. Besides the beauty of its long sprays of white blossoms, which appear early in June, the plant has the merit of having clean, dark green foliage throughout the remainder of the season. It usually falls, however, without assuming any striking colors in the autumn.

More beautiful and striking in its individual blossoms than any of the preceding kinds are the flowers of *S. Cantoniensis*, which is very frequently found in catalogues and gardens under the name of *S. Reevesiana*. The blossoms are much larger than any of those mentioned, in larger corymbs, and of the purest white color. But, unfortunately, in New England this plant cannot be considered sufficiently hardy to be recommended for general planting. In well-drained, sheltered situations it sometimes thrives fairly well and produces a good show of blossoms, but, under most circumstances, the stems and branches become so much injured in winter that comparatively few blossoms appear in early June, the regular flowering period.

The double-flowered form of this species is quite handsome when well grown, but it suffers equally with the type from lack of hardiness. In a little less rigorous climate *S. Cantoniensis* is one of the most beautiful species which can be grown.

Arnold Arboretum. *J. G. Jack.*

Hardy Flower Garden.

At no season of the year does the garden present a prettier appearance than at this season; the gorgeous Oriental Poppies, and the Iceland Poppies too, are at their best, with Pæonies, German Iris, *Dictamnus Fraxinella*, with its flash-light in the evening when fire is applied to it. The Pyrethrums, double and single, are also now showing their full beauty, and the recent exhibits at the meeting of the Massachusetts Horticultural Society indicate plainly that they are fast growing in favor. It is often stated that double Pyrethrums cannot be raised from seed, and this may be true of some seed, but last fall I sowed two packets of seed and the plants were grown on in pots. They are now all in flower, and fifty per cent. are double, the rest being single, and many are as good as imported named kinds. The seeds cost about twenty-five cents and were obtained from Germany. For cutting purposes these "Painted Daisies" are valuable; they last a long time, and, when mixed with sprays of such plants as *Gillenia trifoliata*, have a pretty effect. *Dodecatheon Meadia* is blooming finely, and these American Cowslips are well worth growing, even in the most select borders, but care should be taken to secure bright-colored forms, as those of a pale, undecided pink are not worth the space they occupy. In some localities this Dodecatheon can be obtained of a bright rose color, and this is worth growing. Much can be done, however, toward improving the color of the flowers by applying burnt soil or refuse.

Helianthus divaricatus, *Artemisia Pontica* and some other plants which dealers persist in advertising spread rapidly and crowd their way among their neighbors, and are most difficult to get rid of. *Heliopsis lævis* is another weedy subject which seeds abundantly in fall and appears everywhere the following summer. Dealers in hardy plants should never disseminate such subjects without a full explanation of their

habits. Stocking a garden with persistent weeds is rather worse than selling us hardy plants altogether unfitted for outdoor cultivation, a practice not altogether unknown.

Of Aquilegias there is not one prettier than the Rocky Mountain Columbine, *A. cærulea*. It is a pity that it is not a better perennial, for, with the best of care, it does not live long in gardens. If good seed could be obtained fresh from its native localities there would be plenty of purchasers both here and in Europe, as seed of this species is dearer than any other of the older kinds, and it often germinates badly or turns out to be not true to name. After *A. Canadensis*, *A. cærulea* was the first to flower with us, and it is still very beautiful.

S. Lancaster, Mass. *O. O.*

Hardy Plants for Edging a Border.

STRAIGHT lines, as "the shortest distances between two points," are entitled to some consideration, but we usually have too many of them in our small gardens. In most of the well-kept suburban gardens one can start at the front gate and follow rectilinear paths all through the garden without finding a curve or relief to the trim formality. The lawn is trimmed at the border to the straightest line, and not a twig is allowed to encroach on its smooth surface. The borders following the straight paths are usually edged with grass in narrow lines, a source of constant care, and the whole effect is very prim and formal and sometimes distressing. In our small places we cannot often change the paths, and straight ones are often more in character than curved ones, which in limited grounds seem often in bad taste. But, given such a long path bordered by a flower-bed, why not discard the grass edging and grow plants, which are not only attractive and interesting, but which from their habit of growth will form irregular lines and break the formality? There are innumerable low hardy plants suitable for such a situation, and a border of this kind may be made one of the most interesting features of the garden, if one is willing to give its planting some little study.

To prepare such a border, the ground should be well broken up to a good depth and enriched with manure. The border should be raised about six inches above the path and edged on either side with rough stones. This does not seem an attractive picture, but it will be seen that such a border will exactly suit a large number of plants which require good drainage about their crowns, and, as they are mostly deep-rooting kinds, they will find moisture. On this border should be established dwarf plants, and especially those with procumbent, or creeping, habit. These latter will soon cover the nakedness of the stones, and, as they spread into the path, will form little areas of verdure and bloom, projecting into the desert walk and softening the stiff border-line into gentle undulations. Some of these plants, in time, make spreading clumps several feet in diameter, but while they are reaching this state there will be room to grow on the edging numerous small dwarf alpines and other plants. To mention a few suitable plants among the profusion which might be named, here might grow *Arabis alpina*, *A. albida* and *A. arenosa;* the hardy Alyssums—*A. saxatile*, *A. spinosum* and *A. Montanum* (the latter now in bloom, being a charming plant, with attractive light yellow flowers); *Iberis Gibraltarica*, more hardy on the raised border than it often proves when not in a well-drained situation. Aubrietias find a congenial home in such a border, too, as do the small Sedums—and there is a wealth of dainty beauty in this family. Achilleas, *A. tomentosa*, *A. argentea*, etc., *Thymus montanus*, and many more will occur to those who are familiar with hardy plants. If one were in a hurry and plants were scarce, the Moneywort (*Lysimachia Nummularia*) would soon cover all bare spots, and at this season is very attractive, although a very common plant.

To a lover of small plants such a border is invaluable as a substitute for a rockery and safe location for those which might be lost in an ordinary border.

Elizabeth, N. J. *J. N. Gerard.*

The Vegetable Garden.—The Chelsea Pea is an improvement on American Wonder in growing slightly taller and being rather more productive. It was also as early as any of the so-called extra earlies, this season. Its quality is inferior.

Profusion is a promising late pea, and so is the Mayor. Admiral is weak and delicate in growth, too tall, and not productive. The Don is also entirely too rampant in growth. At this date, June 10th, it is still running up, and where it may stop is not yet fully apparent.

The Sandwich Radish we like very much. It is much quicker in growth than most of the white Radishes we have grown. The backward season has retarded the ripening of tomatoes, and we have noted little in regard to any varieties yet. Last year Early Ruby was ripe on the 25th of May; this year it is still green, though in advance of most others. Atlantic Prize seems ahead this season.

Devon Market Lettuce may be different in some respects from the old Curled Simpson, but I have not been able to see it. Golden Beauty Lettuce shows no particular merit above other smooth-leaved Lettuces. Trianon is doing better than we expected of a Cos Lettuce out-of-doors. It will be valuable here if sown earlier than ours was this year.

Raleigh, N. C. *W. F. Massey.*

The American Association of Nurserymen.

Annual Meeting at Minneapolis.—II.

OUR report of the Nurserymen's Meeting at Minneapolis, which was begun last week, is continued below, with some additional extracts from the papers read on that occasion and the discussions which followed.

THE NORTH-WEST AS A FIELD FOR NURSERY EXTENSION.

Professor Charles A. Keffer, of the South Dakota Agricultural College, read an essay with this title. He said that Iowa, Minnesota, Nebraska and the Dakotas had been planted thickly with orchards and fruit-gardens because they were settled by men who were home-makers as well as farmers, and who wished to reproduce on the prairies the surrounding of their homes in the east and in Europe. The failures have been countless and the successes few. The farmers are prone to attribute their loss in fruit-culture to the false representation of the tree-seller, while the nurserymen feel that a large share of the failure is due to ignorance, to an unfortunate choice of varieties, or to needless haste, that is, to planting fruit-trees before the soil and shelter were ready for them. The climatic conditions here are so trying that some means for modifying them must be devised. It is useless to hope for success with fruit-trees on the prairies until the winds are conquered by groves and forest-belts. A forest-tree can thrive in untoward conditions where a fruit-tree would perish, and the wind-break must be the precursor of the orchard. Grove-planting must be the pioneer work in horticulture, and the farmer of the north-west cannot expect a profitable orchard until he has provided a sheltered location for it. Now that the Government has withdrawn the slight encouragement it once gave to tree-planting it is a matter of vital importance to the north-west that all the persons interested in agriculture and horticulture should unite to promote what may be called prairie-forestry. It seems, then, that the first duty and the first interest of the nurseryman is to push the sale of forest-trees in the treeless west, and, when these are established, there will be abundant demand for other stock.

The Plum is the pioneer fruit of the north-western states, and we are fortunate in having a native species from which many varieties of good quality are being secured. It would certainly promote the interest of the trade if such sorts as the Miner, and all of the Chickasaw family, were discarded, north of central Iowa. Of the more hardy type the Desoto Plum is our standard variety, although in the greater part of Dakota it is too late to be relied upon, for we must have fruits in which early maturity is united with extreme hardiness. The Plum-tree, being found along the streams of western Nebraska, eastern Colorado and both the Dakotas, is presumably hardy, but many varieties are caught by the frost before the fruit ripens. Two years ago I received specimens of fruit that was ripe on the 15th of August, small native red plums of excellent cooking quality. There are now being tested on the grounds of the South Dakota Experiment Station forty varieties, and from some of these we have hopes of securing the two great essentials of hardiness and earliness.

The Apple presents a still more serious problem. The north-west cares little about an Apple-tree's genealogy, whether it is Russian or American, but we want one that will live through the winter and one that has leaves and bark to withstand intense heat and sunshine; and these requisites secured, for the immediate future we will be content with a moderate quantity of fruit of only a moderate quality. Professor Keffer said that he once thought there was no virtue in the fruit of the Crab-apple, but that was before he had moved to South Dakota. He was not prepared to discuss the relative merits of the Russian and other varieties, but only knew that good fruit of Wealthy and Fameuse is grown in the southern counties of his state in peculiarly favorable locations on the borders of the Missouri River bottom-lands.

As to the relative methods of budding and grafting trees he had no question as to the superiority of the latter. Root-grafts

with long cions make the best trees for the north-west. Nurserymen should not send a budded tree into the north-west, for it is always sure to be deficient either in the hardiness of the stock or in the union of the stock and bud. In the development of horticulture in this region nurserymen must educate the people. They must realize that wind and frost and burning heat are to be the portion of every tree that is planted, so that it is idle to sell anything there but the very hardiest stock.

NOTES ON MINNESOTA HORTICULTURE.

The extracts which follow are from an address by Samuel B. Green:

Previous to 1884 Minnesota was generally looked upon by eastern and southern growers as hardly adapted to a rational system of farming, not to speak of anything in the line of fruit-production. In that year she surprised the country by the prizes won and the show of fruit made at the New Orleans Exposition; and the fine exhibition made last year at the State Fair seemed to indicate that there was a possibility that she might do as well at the Columbia Exposition in 1893.

Apples.—Most of the well-known eastern varieties of Apples have been tried here and found greatly wanting; even the popular, prolific and handsome Ben Davis was discarded years ago as being too tender for this climate, while the Baldwin, Yellow Bell-flower, Roman Stem, Golden Russet, Winesap and a host of other favorites have been repeatedly tried and rejected. In many parts of the state the Wealthy is largely grown and bears early and heavily.

We can grow Crab-apples in great quantities, and our markets are well supplied with this home-grown fruit each season. The most generally esteemed are Transcendent, Orange, Whitney, Early Strawberry, Virginia and Hyslop. Where the old standard varieties of Apples can be grown the Russians may not be welcomed, but in this state they are very promising. Take away from us to-day the Russian Apples and their seedlings, and we would have almost nothing left in a well-tried Apple of large size that can be grown at a profit. The Duchess of Oldenburg and Tetofsky have been long and favorably known here, and our markets are liberally supplied with them each year. Minnesota orchardists who carefully cultivate the Duchess get remunerative returns. Among other Russians of promise that have been quite extensively tried are the Hibernal, Autumn Streaked, Ostrokoff, Glass, White Pigeon, Charlamoff, Green Streaked, Yellow Annis, and we hope and expect that out of the many other varieties now on trial in the state and from seedlings of those Russians to get varieties better adapted for our own use than any now known.

I believe the time is coming when Minnesota will raise enough apples to supply her own wants. It has been found by those having the largest experience that our own home-grown nursery stock stands the rigors of our trying climate much better than Eastern and Southern grown stock.

Plums.—We cannot raise the varieties of Plums of the *Prunus domestica* type without giving them winter protection, neither do varieties originating from *P. Chicasa* do well here, but all varieties of *P. Americana* yield abundantly each year, and we think there is a great future for this hardy class of Plums. Each year notes the introduction of new varieties of merit. The best well-tried kind of this class of Plums is the De Soto, but the Forest Garden and Weaver are favorably known, and the Rollingstone, Cheney and New Ulm are new kinds of great promise.

Small Fruits.—All the small fruits grow here and yield abundantly. Strawberries take the front rank in value of the product, but we also raise large crops of raspberries, currants, gooseberries and blackberries. It is generally considered profitable to cover all small-fruit plants in winter, but some growers do not go to the expense of this even with Raspberries. Cranberries can be raised at a profit, and the wild bogs produce in abundance. The fruit raised in Minnesota is of high color, flavor and aroma, and finds a ready market in the large cities and towns of the state.

Horticultural Progress.—Minnesota established the first purely horticultural experiment station in this country, in 1880, and the State Horticultural Society has to-day, besides the department of horticulture in the central experiment station, one experiment station and eight horticultural trial stations, the most of which are devoted to special lines of work. We believe that by systematic selection and crossing of many fruit-plants now grown, that their value for this climate may be greatly increased, and we also believe that several of our native fruits, notably the Sand Cherry (*Prunus pumila*), the Wild Plum (*Prunus Americana*) and the Buffalo Berry (*Shepherdea argentea*), which are very prolific in their wild state, will well repay careful cultivation. We also look with favor upon the newly introduced Russian Cherries and Pears, and the growing of Peaches, by protecting them in the winter, is attracting some attention.

Alluding to Mr. Green's commendation of the Russian Apples Mr. William C. Barry said that eastern nurserymen were very desirous to ascertain which of these varieties has an established value. Many years ago Russian Apple-trees were imported by eastern fruit-growers, but none of them had been found equal to the Duchess of Oldenburg, and, after taking much pains and trouble with these varieties, they had become discouraged. It would therefore be of advantage if the nurserymen of the north-west who had made experiments would inform eastern nurserymen which Russian Apples ought to be catalogued and disseminated. Mr. Barry had attended a great many exhibitions of fruit in different parts of the country, and he had never seen these apples on the tables, nor had he seen accurate descriptions of them, and he said that it would much more than pay him for his journey to Minneapolis if he could secure one, two, three or more varieties which were as valuable, or nearly as valuable, as the Duchess. If western nurserymen have such varieties he assured them that there was a ready market for them in the east.

Mr. Albaugh added, that in Ohio no Russian Apples, except the Duchess, had proved of real value. Out of thirty-seven grafts obtained from the Iowa Experiment Station only one variety, the Longfield, made a healthy tree at three years old. Every other one was injured by winters which have not hurt the Ben Davis nor affected Yellow Bell.

Recent Publications.

We have received advance-sheets of a Census Bulletin on the Lumber-mills, Saw-mills and Timber-products of the states of Michigan, Wisconsin and Minnesota. These states embrace the great White Pine area of the north-west, which has been so important in the development of the central portion of the continent. Of course, the returns in this bulletin are of very great interest, but they would be still more valuable if the White Pine had been treated separately as a forest product, since the exhaustion of our Pine supply is a matter of national importance and interest. But it would have been very difficult, and perhaps impossible, to divide the product of the mills so as to show at once the quantity of White Pine and of hardwood manufactured. In the Forestry Report of the Tenth Census, Professor Sargent said: "The value of the lumber product of Michigan, Wisconsin and Minnesota exceeds one-third of the total value of all the lumber manufactured in the United States. This enormous development of the lumber business is due to the excellence of the forests of the Lake region, to the natural advantages of the country for manufacturing lumber, and to the easy communication between these forests and the treeless agricultural region west of the Mississippi River. The country between the Mississippi River and the Rocky Mountains, now largely supplied with lumber from the Lake region, must soon depend more upon the remote Pine forests of the Gulf region or of those of the Pacific coast. But the great north-western pineries are not yet exhausted, and they may be expected to increase the volume of their product for a few years longer to meet the demands of the population fast covering the mid-continental plateau." This prediction is justified in the report before us, which shows an increase of mill products amounting to nearly thirty per cent. in quantity and seventy-six per cent. in value. The increase of the number of hands employed is 138 per cent., and the increase of the total amount of wages paid is 141 per cent. The disproportion between the increase of quantity of the product and its value is due to the fact that the business of finishing and remanufacturing at the point of original production has been developed largely, and this augments the gross value of the product. The increase in the output is probably due, in a large measure, to the increased use of hardwood which, in late years, has been manufactured extensively, especially in the northern peninsula of Michigan.

Minneapolis now stands at the head of the lumber-producing cities of this region, the value of the output here having reached during the census year $6,584,456. In 1880 the value of the output at the same city was $2,740,848, an output exceeded at that time both by that of Bay City and of Muskegon. The increase in this product of Minneapolis is due largely to the opening up of the northern part of Minnesota, a region which ten years ago was worked comparatively little. Of course, this bulletin cannot show the quality of the Pine-timber manufactured, but it may be that while the output is larger, it consists,

to a great extent, of small trees which ten or twenty years ago would have been passed over as of too little value to saw. During the last ten years there has been a sort of clearing up of the forests going on in these states, so that while they make a fair showing in the general output, the area of good Pine-forest is now, beyond question, "dangerously small in proportion to the consumption of White Pine lumber."

The predicted exhaustion of these forests within a comparatively short time seems assured by returns from individual manufacturers. Their present holdings of standing timber in this group of states are only sufficient to supply them for about five years at the present rate of consumption. The quantity in reserve is believed to be principally comprehended by what is standing on lands owned by the federal and state governments. This quantity, however, is unknown. The federal government supplies no information on this subject, but the holdings of public lands reported by state governments indicate that no considerable area of timbered lands is owned by the state of Michigan.

The total area of land held by the state of Wisconsin on September 30th, 1890, is reported at 671,633 acres. Most of this land is located in the northern counties, and about one-half is said to be timbered. The state of Minnesota reports ownership of 13,000,000 acres of timbered land, containing twenty billion feet of standing timber, mostly Pine, valued at $60,000,000.

Notes.

One of the most attractive shrubs now in bloom is *Philadelphus nivalis*.

Just now the beautiful old Ascension Lily, *L. candidum*, is blooming in unusual abundance in gardens near this city, the disease which has for many years affected this plant having apparently run its course.

An English authority remarks that the growths of the Asparagus which are made this season lay the foundation for the next year's crop, and that, therefore, the stronger the growth of the shoots and roots this year the better prospects for a crop next season. This is true, and it follows that it is not too late still to cover Asparagus-beds with dressings of commercial fertilizers and of well-rotted manure in order to feed the plants and strengthen the growth.

Dr. Riley, of the United States Department of Agriculture, has published a bulletin on some of the more injurious locusts of the United States, together with the means of destroying them. It contains no technical matter, and any farmer will be able to recognize the different species from the figures. The most interesting part of the work is the illustrations of the machines which have been used for the destructions of these pests. Most of the matter is to be found scattered among former reports, but the description of the method used for trapping locusts in Cyprus is new, and so is an account of the method of poisoning them with bran and arsenic, which has been used with success in California.

Among the Columbines nothing is better than *Aquilegia cærulea*. Its white variety, Alba, has been distributed as a variety of *A. chrysantha*, and is one of the best of the white Columbines as we saw it growing recently on the grounds of H. Meyer, Passaic, New Jersey. A striking plant in flower there was *Centauria Ruthenica*, a tall thistle-like plant, three to four feet high, with heads of yellow flowers an inch and a half in diameter and deeply cut leaves. *Scabiosa Caucasica*, one of the best of hardy plants, neat in habit, and with flowers of the richest blue, was also in bloom. *Heuchera sanguinea* seems to have established its reputation for hardiness, although it comes from Arizona, for it was here in perfect health and opening its deep red flowers, although it had been in an exposed situation all winter.

At a late meeting of the Royal Horticultural Society, Mr. Barron, as reported in *The Garden* of May 30th, exhibited several small flowering branches of Apple-trees to show the variations in the size and tint of their blossoms. The largest and showiest blossom was that of the Royal Codlin, the flowers being deeply tinted with dark rose. Lord Derby, rather smaller, had very showy blossoms, and Gravenstein was almost pure white. It would be interesting to make a comparison of the blossoms of varieties which are well known in cultivation in this country, and such a collection would add interest to our spring flower shows. A study of the blossoms, too, as hinted at in *The Garden*, would not be unprofitable in answering such questions as those which follow, and very many more: Are large blossoms usually followed by large-sized fruit? Is there any connection between the color of the blossom and the color of the ripe apple?

Dr. John Dougall, of St. Mungo's College, Glasgow, has a letter in a recent issue of the Glasgow *Herald* on the banana, in which he quotes from Stanley's "In Darkest Africa" to show that "for infants, persons of delicate digestion, dyspeptics, and those suffering from temporary derangements of the stomach, the flour, properly prepared, would be of universal demand." During Stanley's two attacks of gastritis a slight gruel of this flour, mixed with milk, was the only material that could be digested. It is odd, also, as pointed out in Stanley's book, that in most Banana lands—Cuba, Brazil, West Indies—the valuable properties of this fruit as an easily digested and nourishing food have been much overlooked. Dr. Dougall has made some experiments in making banana flour. He concludes that it should be made from the ripe fruit at its place of production. In trying to make it from bananas purchased in Glasgow, he obtained on drying the pulp a tough sweet mass like toasted figs, an appearance probably due to the conversion of starch into sugar. Bananas contain only about fifty per cent. of pulp, and of this about seventy-five per cent. is water. They would yield, therefore, only one-eighth part of flour.

That even Frenchmen of the seventeenth century did not always approve of strictly formal gardens is shown by the following passage, which occurs in an essay by Pierre Huet, a well-known French critic of that time, called "Of the Gardens in Fashion." The author says: "I have no more approval for the gardens in fashion than for sky-lights. I mean those open gardens, composed of large, broad, sand-strewn alleys, of trellises, parterres, adorned only with a few delicate beds, defined by strips of box and edged with a few flowers and a few stunted trees, and in which you can scarce distinguish summer from winter. M. le Nostre, who is quoted as the author of this sort of garden, which, it is asserted, he brought back from Italy, did, it is true, adapt it to the King's Gardens, but he did not adapt it alone, for he added covered alleys, shaped woods, trees of lofty trunk, palisades, and green shades. The majority of private persons, possessing neither sufficient ground nor sufficient means to give their gardens all these ornaments and keep them up, have only adopted its parterres, which require little time and expense, but in which walking is out of the question throughout the day, and in which ladies, regardful of their complexion, would only venture to appear after sunset."

In an article called the "Evolution of Patent Medicine," published in the *Popular Science Monthly* for May, Mr. Lee J. Vance traces the belief in the efficacy of such nostrums back to those ancient times when no distinction was drawn between the physician and the magician, and when all remedies were looked upon as charms—a condition which prevails, of course, among savage and half-civilized tribes in our own times. The names of plants, Mr. Vance explains, shows how general was the belief in their inexplicable virtues. "Some plants have animal prefixes, as, Dog-elder, Dog-rose, Cat's-tail, Cow-bane, etc. Other plants derive their names from religious sources. Thus they are associated with the Virgin Mary, Saint John the Baptist, Saint James. Likewise the Latter-day Saints have particular plants dedicated to their memory. Most of the plants with mystic names were supposed to have magical virtues, and so they were largely used in folk-medicine. The weird associations clustering around many roots and herbs were enough to invest them with great repute," and in folk-medicine, even at the present day, "herbs are used not so much for their inherent medical properties as for their reputed magical virtues. . . . Another stage in the evolution of patent medicine is typified in the therapeutics of medieval mystics and alchemists. The great plant in their pharmacopœia was the Mandrake. Why? Simply because the roots of this plant were shaped like the human body. . . . The magical element in patent medicines actually won scientific repute in the 'doctrine of signatures'—a doctrine which held that plants and minerals, by their external character, indicated the particular disease for which Nature had intended them as remedies. Thus the Euphrasia, or Eyebright, was good for the eyes; the Wood-sorrel, being shaped like a heart, for the heart; the Liverwort for the liver, and so on. Pettigrew, in his history of medical superstition, says that this fanciful and magical notion 'led to serious errors in practice' and often to fatal results. Observe that at this stage of its evolution patent medicine is herb medicine, and so it remained for a long time. The materials of the healing art were all vegetable. The patent-medicine man was a dealer in herbs."

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by . . . . . Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, JULY 1, 1891.

TABLE OF CONTENTS.

The President and the Public Forests.

WE have more than once alluded to a section in the act repealing the timber-culture laws, which was approved on the last day of the last session of Congress, and which authorizes the President of the United States, from time to time, to set apart public lands bearing forests or in part covered with timber or undergrowth as public reservations. The final clause of the section reads as follows: "And the President shall by public proclamation declare the establishment of such reservations and the limits thereof." This section has been interpreted as having a more than permissive force. Commissioner Carter, of the General Land Office, has issued a circular to special agents, in which it is held that, for the purpose of carrying into effect the provisions of the act, it is important to reserve all public lands which bear forests or which are covered with timber or undergrowth on which the timber is not absolutely required for the legitimate use and necessities of the residents of the territory or state in which these lands are situated, or for the promotion of settlement or for the development of the natural resources of the region in the immediate vicinity of the forest-lands in question.

The circular goes on to instruct the agents that it is of the first importance to reserve all public lands in mountainous and other regions which are covered with timber or undergrowth, at the head-waters of rivers and along the banks of streams, where such forests are the natural agents for absorbing moisture, checking mountain torrents and preventing the sudden melting of the snow and the floods which follow. Special agents are directed to make a personal examination of such forest-lands, and to acquaint themselves in every possible way with the facts as to the value of these lands for all purposes, and such investigations are to be reported to the Land Office. Furthermore, they are to submit a report, with a recommendation in each case, as to whether the lands examined should be set apart as a reservation, together with the reasons for this recommendation. This recommendation and the reasons therefor, with the full description of the lands under investigation, are to be published in the land offices and in the newspapers of the vicinity, and it must be stated that the object of such publication is to give timely notice of the proposed reservation, so that all persons who have any interest, either in favor of or in opposition to its establishment, may have an opportunity to petition or remonstrate. This must be done in time to have these views considered before final action is taken in regard to the establishment of a reservation. Wherever there seems to be any imminent danger to the timber of any particular tract which has been considered as a proper one for reservation, the agent is to report this danger at once and state his reasons for believing that there is necessity for immediate action.

All this is done in order to lay before the President such information as will enable him to take intelligent action thereon. Of course, there are other means of acquiring information which the President can make use of, and it is altogether proper that any one who has any special knowledge in this direction shall place it at his service. The American Forestry Association, we are glad to see, is taking steps to examine certain forest-areas in order to ascertain whether they should be reserved from settlement. There is very little danger that the Chief Executive of the nation will include too large a fraction of the public domain in these reservations; and even if lands which are more valuable for agriculture than for their forests should be included, it would be very easy afterward to turn them over to settlers. Indeed, we have urged that all forest-lands should be withheld from entry until the data which special agents of the Land Office are now instructed to collect could be ascertained by a commission of scientific men. The present action, however, is much better than no action at all; but what protection is there thrown around these reservations even after the President has made his proclamation to set them apart? So far as we are aware, no legal provision is made for guarding them against depredation or protecting them from fire. It has been our opinion that the United States army was the proper force to use in guarding the forests on the national domain, and we have urged that these forest-lands withdrawn from entry should be placed under the charge of the army. This has been done to some extent in the case of the Yellowstone reservation and the great Sequoia reservations of California. If it is practicable to place such reservations as are declared by the President under this same guardianship, we shall feel that something has been done for our forests which promises to have practical value, and the brief section which was attached to an act relating to quite another matter may prove an important piece of legislation in the history of the forests of the nation.

Do New Englanders Love Flowers?

MR. HAMILTON AIDÉ, in his article in the *Nineteenth Century*, on "Social Aspects of American Life," ventures the remark that "the true love of flowers, the patient, careful love—not the cupidity for cut roses at two dollars apiece—does not seem to be inherent in the national character," and alludes to Miss Wilkins' stories to show that "flowers are an accident, not a daily interest, in village life" in New England.

This might pass as a snap-judgment on the part of a foreign traveler, but how shall we excuse the critic in the *Boston Transcript*, who declares that he "cannot deny the truth of what Mr. Aidé says." He who takes this ground can scarcely be familiar with the old country towns of that section to which one must look for the typical aspects of New England life. Like all the sentiments of its people, the love of flowers is there, not paraded, but profoundly cherished; and if there is no gaudy display in the door-yard, there is sure to be found a corner behind the house,

easily accessible to the kitchen, where old-fashioned plants bloom gayly, and are cherished often from some tender association with the past. Any country doctor in one of the older New England villages can tell these critics that there are almost no houses so homely, but he finds in them, in winter, a few plants in the window, and in summer some bright flowers in a tiny garden, cultivated and watered often by feeble and tired hands. Hard and dreary as are many of the poor little lives of New England villagers, this one touch of color and perfume is there almost invariably, to show that the thirst for beauty is unquenched.

If, with its ungrateful soil and tormenting climate, New England cannot rival Old England in the gay surroundings of its cottage doors, the same love of flowers is there, finding such expression as it may under the cruel conditions of a sterile earth, and burning summer heats and dryness, alternated with sharp east winds, which make a labor as well as a pleasure of a garden.

The Bermuda Palmetto.

WE published last week two views of the Bermuda Cedar (*Juniperus Bermudiana*). On page 307 of the present issue there is reproduced a photograph of the Bermuda Palmetto (*Sabal Blackburniana*) as it appears growing in its native marshes, a species endemic to the islands, and the most interesting plant of their flora after the Cedar. Botanically this Bermuda Palm closely resembles the Palmetto of the coast of Carolina and Florida (*S. Palmetto*), and there is little doubt that, like the Cedar, it was first brought by birds from the mainland, and afterward gradually underwent the slight modifications which serve to distinguish it from its remote ancestor. So very near alike are the two plants that it is only in recent years that the insular Palm has been recognized as a distinct species. It is a curious fact, moreover, that this Palm, although so recently understood, has been cultivated in England a long time without the origin of the cultivated plants being known. The wild specimens sent to Kew for determination, Mr. Hemsley tells us in his botanical report on "The Scientific Results of the Voyage of H. M. S. Challenger," "proved to belong to a species of Palm of which there is evidence that it has been cultivated in England for at least one hundred and fifty years, and of which, besides numerous small ones, there is a magnificent example in the Palm-house at Kew which flowers and bears fruit continuously. The origin of the cultivated Palm was involved in obscurity. In 1737 a small plant of it was presented by Lord Petre to the grandfather of the Mr. Blackburn for whom it was named. The earliest record of its flowering in this country that we have found is in 1818."

S. Blackburniana grows in Bermuda to the height of forty or fifty feet, with a trunk diameter of from twelve to sixteen inches, and produces leaves six or eight feet across, borne on stout stems seven or eight feet in length. At the base of the leaf-blade there is a broad yellow spot which surrounds the end of the stalk and serves to distinguish the Bermuda Palm at a glance from its continental relative. The fruit of the insular plant is considerably larger, too, and was once held in much esteem as an article of food. Jourdan, in his "Discovery of the Bahmudas, otherwise called the Isle of Divels, by Sir Thomas Gates, Sir George Somers and Captain Newport, with divers others," states that "there is a tree called a Palmito-tree which hath a very sweete berrie, upon which the hogs doe most feede; but our men finding the sweetnesse of them did willingly share with the hogs for them, they being very pleasant and wholesome, which made them carelesse almost of any bread with their meate; which occasioned us to carry in a manner all that store of flour we could save for Virginia. The head of the Palmito-tree is very good meate either raw or sodden. It yeeldeth a head which weigheth about twenty pounds, and is farre better meate than any cabbige."

The Palmetto is frequently mentioned in the early annals of the islands, and laws were passed for its preservation. An intoxicating beverage, known as "bibey," was distilled from it, and the leaves have always been used for thatch and for baskets, fans and various fancy articles; and all the vegetables exported from the islands were until a few years ago sent away in the small oblong baskets plaited from Palmetto-leaves. These baskets, now replaced by boxes made of cheap American pine, have almost entirely disappeared, and are only to be found in the shops devoted to supplying the tourist with natural curiosities and other mementos of a visit to the Insulæ æstivarum.

Kew and its Work.

THE following extract is from an article in a recent issue of the *Gardeners' Chronicle*, and it is the preface to some account of the successful journey of Mr. Morris, the Assistant Director of the Royal Gardens, to the West Indies in the interest of economic botany. Now that a movement is on foot for the establishment of a botanic garden in this city it is proper that the people at large should be informed of the possibilities of such an institution, and of what would be expected from it and from its management:

When, in 1841, Sir William Hooker undertook the direction of the Royal Gardens, Kew, that foreseeing botanist laid down a triple course of action. Kew was to be the botanical centre of the empire in a threefold capacity—as a great scientific institution, the headquarters of economic botany, and as a pleasure-ground for the public; each department was to be made as perfect in itself as possible, each was to co-operate with the others for the common benefit. How successfully the idea has been carried out by successive directors is known to all our readers. Kew, as a scientific institution, is absolutely indispensable, and is the acknowledged head of all similar bodies, at home or abroad. In the "gardens," where "collection" was once the dominant aim, selection now prevails. The best and the most suitable plants for particular purposes are grown in masses, so that their qualifications can the better be estimated, while each individual is so cultivated as to display to the fullest advantage its botanical and ornamental characters. Of course, while demonstrations (we use the word in its educational sense) of this character are given for the benefit of the gardener and the delectation of the public, the equally or, so far as Kew is concerned, the much more important functions of experimental cultivation are not neglected. This may not be very attractive to the casual visitor, but it is of the utmost importance to botany and horticulture, and, of course, it furnishes the basis for those more decorative "demonstrations" of which mention has been made. While a certain amount of mere decorative gardening, according to conventional pattern, cannot be dispensed with in a great pleasure-resort like Kew, competition with ordinary gardens and parks in these respects is hardly to be desired. We look to Kew to set the fashion, not to follow it. We depend on it to furnish us with new materials, new illustrations, new developments, new combinations. The educational and instructional element should, without being offensively obtrusive, permeate the whole garden, so that the visitor, delighted with what he sees before him, may, at the same time, and it may be imperceptibly, receive impressions which will serve to expand and refine his taste, and augment his intelligence in the future.

But, in addition to the purely scientific and æsthetic functions which this great garden performs, Kew is the centre of economic botany. The phraseology is somewhat pedantic, but we do not know how to mend it, for the term "applied botany" is hardly more familiar. A visit to either of the Kew museums (there are three) shows, however, at a glance, what is meant, and is calculated to conciliate any gradgrinds who might be disposed to grumble at the expenditure of public moneys for purposes they do not appreciate. These museums furnish the best available concrete reply to the question, which, even in these days of scientific progress and its resultant advantage, some people still put, "Cui bono?" ("What is the use?") From the very first the energies of directors and curators have been turned strongly in this direction, museums have been formed, libraries accumulated, and floras written at Kew expressly with this object. The residents in the colonies have been furnished not only with information

as to the plants to be grown with the greatest advantage commercially, but with the plants themselves. We need not do more than incidentally mention the great part that Kew has taken in the diffusion of such plants as Cinchona, Coffee, Caoutchouc and many others.

Who can estimate the value of the labors which have been carried on in those quiet-looking propagating-houses at Kew for the last half century?

How We Renewed an Old Place.

XI.—RECLAIMING A SALT-MEADOW.

THE fable of Metius Curtius plunging on horseback into the morass which had opened in the Roman Forum, because the oracle had declared that only the best thing in Rome would be of avail to close it up, seems simply to show that the Romans, great engineers as they were, fully recognized that filling up a marsh was a well-nigh endless job, which would require the sacrifice of the best blood and treasure of the state before it was accomplished.

In spite of the illustrious warning given by M. Curtius, there lives not a man with soul so dead as not to be fired with ambition to make dry ground out of his meadow, if he is so unlucky as to own one; and he always starts in with figures on paper to show what a fine income of hay is to result from a comparatively small investment of labor and gravel. But the work goes on, then more work and more gravel, till finally the account of this part of the business gets mislaid, so that by the time the far-distant hay-crop begins to materialize, a page has settled over the amount of capital (literally) sunk, and only the hay returns are brought prominently to the front.

When we first surveyed the half acre or so of salt-grass which had been left over on our side of the fence when the road was built across the meadow, it did not seem of much importance, one way or the other. The English grass grew luxuriantly down to the edge of it, and the soft, fine, salt-hay was excellent for bedding, the only objection being that it was so palatable that the horses ate up their mattress before breakfast every morning.

After the causeway was constructed across the wet ground behind the stable to Winter Street, there did not seem very much reason for meddling further with the marsh, but given a gravel-bank at one end of a farm, and a swamp at the other, and you may depend upon it there will be a marriage between them at no very distant date.

The intercourse between the two of our acquaintance, once begun, was seldom interrupted, the more the meadow saw of the hill the more it wanted to see, and, with a perversity only to be found in meadows, the more it was given the more it wanted of the same kind.

At first it seemed as if a few cart-loads of stones dumped in the lowest parts, where the water stood longest, would be all-sufficient, but the amount of material that this anaconda of a marsh can stow away is, to use the slang of the day, phenomenal.

Piles of stones, rubbish, sand, boughs of trees, old crockery, ashes, the débris of our own and other people's places, it "swallows them all without any remorse," till the top of the fence along the road has nearly disappeared from view, and still it calls for more, and continues to subside.

Across the street our neighbors have tried the experiment before us, so that we are aware that it is unsafe to put soil on this gravel until after it has had a chance to settle for a year or two, otherwise a high tide is liable to come and wash away all the loam out to sea.

As the surface rises the fresh water runs off less easily, so that the enterprise gains in magnitude as it goes along, and the space covered promises to turn out a whole acre instead of half a one, before the job is fairly completed.

Still, time and the hill will fill even this capacious maw, and, though at present in a sketchy condition, the meadow gives promise of a beautiful grass field, which, it is to be hoped, will repay all the labor of its construction.

The tradition goes that the building of the street behind us across his meadow-lot was too much for the gentleman who owned the place at the time it was made, and that he never recovered from the shock of having his estate thus divided and his house-lot spoiled. The enterprise was a formidable one, for it involved the construction of a great stone arch across the stream that drains the meadow, and the laying down of heavy plank rafts for the piers of the stone bridge to stand upon. For years and years the road would be built up to a good height every summer, and then would subside under the influence of the high tides in the autumn and spring, till it seemed as if it would never hold its own, and keep its head above water all the year round.

But constant renewals of the layers of gravel have at length made of it so substantial a causeway that nothing but the very highest of spring-tides prevails against it, and such water as finds itself on our side, forces itself rather under than over it.

Those of our neighbors who have reclaimed land from the main meadow on the other side of the road, have done so by first building a kind of rough dam of stones and clay, and then gradually filling in behind this dam with rubbish, and stones, and sand until they reach the level of the street. When properly covered with loam, after having had plenty of time to settle, this well-watered foundation affords excellent soil for grass, which grows upon it with great luxuriance.

As the road acts still further for a dam between us and the meadow, our task becomes simpler, and we can reclaim our piece of land with far less trouble than our neighbors have had with theirs, and we are encouraged to look for equally good results.

But it is distressing to see the surface of the hill, which we would fain see rolling in graceful slopes to the swale, waving with the forest of our imagination, still vexed by the presence of carts and horses, and torn by the torturing spade.

He who undertakes to change the face of Nature must needs have patience. Monarchs like Nebuchadnezzar may hang gardens in the air in a few months, or a Louis Fourteenth may construct a pleasure-ground like Versailles, by the aid of forty millions and the genius of Le Nôtre, in a few years; but one who has not the resources of an empire at command must imitate more closely Nature's own deliberate and tortuous methods, often seeing the labor of years destroyed in a moment by an unforeseen freak of the old dame, who resents being interfered with, or finding to his dismay that his own scheme has been a mistaken one, and must be revised.

An illustrious townsman of ours started out like ourselves with a bit of salt-meadow, in which he laboriously constructed a pond, spending his hours of ease from the cares of state in building a wall about it, to make a neat and appropriate curb. But after this was accomplished, with much trouble, it proved not to be at all what he wanted, so that there was nothing for it but to fill the hole, and with months of labor bring the meadow into a smoothly turfed field.

Our day of repentance has not yet dawned, but we have a fear that it lurks somewhere behind the horizon. Some modern Metius Curtius may yet have to be found to help fill up the marsh with a horse and wagon, for that Charybdis has already taken toll more than once from a dump-cart, though she has not yet succeeded in swallowing it up in spite of various malicious efforts. She has designs upon the cow, only frustrated by careful watchfulness, and to her deep treachery there is no end. The family purse she long ago put in her pocket, and her mouth yawns for all the future revenues that may accrue for her benefit. She has eaten up a large part of a neighbor's hill, besides taking most unbecoming bites out of our own, and if ever future generations weave a legend about the ancient dragon of Overlea, which demanded a victim every summer, it will be traced by the unraveler of myths of the period, to the unremitting appetite of this hungry meadow.

But who, looking out, on some sweet spring day, upon that beguiling distance, could believe ill of anything so softly lovely as the picturesque marsh of which ours is the fag-end. In the foreground, the richest tones of green are gently blending in the grass; in the middle distance a point runs out toward the stream, laden with fruit-trees in snowy bloom; the Willows near and far are putting on their gray-green coats, making a tender shimmer around their swaying branches and graceful twigs. The little river winds blue and full, here and there amid the grassy stretches, and the distant hills are full of opalescent hues of emerald and pearl, with red of tree-stems, and faintest green hints of foliage, such as Monet would love to paint. The houses of the port, not yet quite veiled by leaves, make spots of white and yellow and red against the deepening background of Elms and Maples. A streak of blue still indicates the harbor; by to-morrow it will have disappeared, for the vision changes like a kaleidoscope—the white of Pear-blossoms passing like a cloud, to be succeeded by the rosy blush of Apple-buds. Each day some well-known feature of the winter landscape grows fainter as the leaves expand, till of a sudden you look for it and it has gone, and in its stead are the full-robed trees. Over all domes a blue sky streaked with faint white cirrus clouds, only the azure reflected in the placid stream below.

An impressionist alone could catch this fleeting beauty of early May—to-day one thing, to-morrow another—and fix it

eternally upon his canvas. The tender grace of early spring, and the glowing glory of autumn are alike evanescent and wonderful expressions on this smiling meadow face. Like a dream, this hint of ineffable beauty melts away, and the impression gives place to a reality of vivid green field, and dark blue water, which will make but a pleasant inland landscape until the August sun burnishes it into ruby and gold, and makes it once more a vision for a painter.

The exquisite must perforce be evanescent, that no touch of commonness may mar its distinction.

The tender grace of a day that is dead

haunts many a spot, otherwise tame enough, with a memory and a knowledge of its capabilities, that make it forever dear and beautiful to him who has seen it under that enchanting glamour lent by a season, or an hour, which imprints upon the brain a picture that can never be forgotten. And when at other times of year I look upon this far reach of often-changing meadow, there abides with it always a memory of the soft and tender charm of early spring, that no reality of November-brown, or winter-snow can wholly drive away.

Hingham, Mass. *M. C. Robbins.*

Winter Studies of the Pine Barren Flora of Lake Michigan.—VI.

NEXT in abundance among the conifers is the White Pine (*P. Strobus*), either in moister and richer ground or mingled with the Gray Pine and Oaks upon the ridges. The trees are mostly small, none more than a couple of feet in diameter. The bright green soft and slender leaves, two to four inches long and in bundles of five, are somewhat tufted at the ends of the branches, giving to this Pine a grace too little appreciated by those in search of trees for ornamental planting. There is a feathery softness in the foliage of the White Pine which is lacking in that of the Scotch and the Austrian Pine, so often seen in parks or in private grounds. The foreign trees appear stiff and rugged beside it. The branches of the older trees are nearly horizontal, and rather slender near the end, and, when the leafage is heavy, may curve or droop a little on this account, and when moved by the wind wave to and fro with a graceful motion. But the wind generally gives them a broken, choppy motion, like a subsiding water-surface on which the storm has spent its force. This is more apparent when their tops can be looked down upon from some commanding height. For use in parks, particularly if the soil is light or sandy, this Pine is admirably adapted. I once came into a pure wood of this tree near Michigan City, Indiana, which had evidently been cared for by the proprietor. The trees were young, the trunks from six inches to a foot in diameter, and not crowded for standards of such dimensions. As a result, the limbs were lower down, and the crowns rounder and more spreading than when pressed upon by others in the thick forest. The sandy ground, well covered by fallen leaves, was completely shaded, and the cool, refreshing grove showed the possibilities of this Pine for park purposes, either when available as a natural wood or planted in harmony with its natural conditions.

Another conifer is the White Cedar, or American Arbor-vitæ (*Thuya occidentalis*). The small trees, from ten to twenty feet in height, either border the sloughs or form small groves in the moist grounds, but are nowhere abundant. Though its foliage resembles that of the Gray Pine in color, in other respects it is quite in contrast with it. This is shown by the form and arrangement of its scale-like leaves, its flat, fan-shaped spray, its numerous branches, the smaller drooping and twisted so as to point various ways, and its bole covered with light-colored shreddy bark. The Red Cedar (*Juniperus Virginiana*) is sparingly found either in company with the White Cedar, or oftener in drier ground. It is scarcely taller, the trunks being rarely more than six or eight inches through. Nearly all are beautiful trees, almost perfect spires, though somewhat grim in habit. The spray is dense, beginning near the ground, and the branches shorten so gradually as to make a conical mass of foliage. The leaves are rusty green and but slightly glossy, and in the winter change to a tanny brown and other shades, which impart to the crown a purplish hue. By means of its different tints it is readily distinguished from the White Cedars, even at a distance, and charmingly varies the effect when grouped with them, its purples and browns mingled with their light, and, in the winter, somewhat faded green. The ordinary, or more typical, leaves of the Red Cedar are blunt and scale-like, but near the ends of the more vigorously growing branches they are stiff and prickly pointed, like those of the common Juniper, though considerably smaller. The youngest trees, till they reach the height of a man, have leaves almost wholly of this character, and entire branches on older trees may be found that look as if a branch from a different species had been fastened to it. I have taken from the same tree three forms of spray—that with ordinary leaves, that with the pointed, awl-shaped leaves, and that with the two commingled.

The common Juniper (*Juniperus communis*) is often met with, especially near the shore of the lake, though clumps of it occur throughout the sand region, so that it is the most widely diffused of the conifers here. Some of the shrubs attain a large size, the prostrate limbs from three to six inches in diameter. Clumps are found more than thirty feet across in their longer diameter, their general shape being oval or circular. Those, from a single root, sometimes measure twenty-five feet, and those from ten to fifteen feet are not unusual. The color of the bushes is considerably variegated in the winter. The smaller branches are brownish or purplish near the end, the leaves changing somewhat in color. Lower down, or nearer the ground, they preserve their look of glossy green. The lower surface of the leaves shows more in the cold weather than in the summer. The spray is flattish, but the ultimate branches tend to rise into a vertical position, or twist upon their support, thus interfering with their flatness, and exposing the glaucous under sides of the leaves, so that the ends of the branches seem to be covered with hoar-frost. The appearance is so deceptive that upon a day suitable for frost actual touch may be needed to convince one of his error. This varies their color still more. The green or bluish green berries are commonly abundant, and this also gives variety to their general appearance. These do not assume their dark blue color till the season following the time of flowering, the fruit ripening the second year.

There are occasional groves of Tamarack (*Larix laricina*), or some trees may be found by the edges of sphagnous swamps. The largest areas comprise but a few acres, and on the whole the tree is scarce. It is of low stature and bushy-branched, the limbs usually coming low down upon the trunk. The recent shoots are brownish or reddish gray, but the ground color of the mass of the spray in the winter season is very dark, the bark on many limbs, either from its own decay or from some fungoid growth, being coated with a sooty substance, which may be rubbed off like a black dust. The branches are nearly horizontal, and divide into numerous short, straight and very slender branchlets, on which rest the round or cylindrical buds, often wider than the twigs themselves. The prominence of these buds when the limbs are bare of leaves gives to the spray of the Tamarack a peculiarly roughened appearance, as if covered with wart-like bodies.

Plant Notes.

Some Recent Portraits.

The June issue of the *Botanical Magazine* contains figures of the new *Lilium Henryi* (t. 7177), one of the interesting plants discovered by Dr. Augustine Henry in western China. From Dr. Henry's notes it appears that "it occurs in two situations, both near the town of Ichang, in the Hupeh province, on the grassy slopes of precipices at an altitude of 200 to 2,000 feet above the sea-level. A few specimens occur on the eastern side of the dome, a mass of conglomerate, which rises to about 1,800 feet, and which lies ten miles south of Ichang. The plant is very plentiful on the right bank of the Ichang gorge, between the villages of Ping-shan-pa and Shih-pi-shan, and on the grassy slopes of the limestone cliffs inland from the last-named village, from which the path leads up to the Taout monastery, named Yang-tai-kuan." *Lilium Henryi* flowered at Kew in August, 1889. It is a species with bright yellow flowers two or three inches long with lanceolate segments reflexing when expanded from near the base and furnished with numerous red-brown spots, and toward the base with a green keel and a few large clavate bright yellow papillæ; *Cypripedium Klotzschianum* (t. 7178), a showy species discovered in British Guiana during Sir Robert Schomburgk's second exploring expedition in that country. With regard to the affinities of this species, it is stated in Veitch's Manual of Orchidaceous Plants that, "though when not in flower, it is scarcely distinguishable from *C. caricinum*, the nearest affinity is undoubtedly with *C. Lindleyanum*"; *Aphelandra Blanchetiana* (t. 7179), a showy acanthaceous plant and a native of Brazil; *Edgeworthia Gardnerii* (t. 7180), a native of the Himalayas, extending eastward into China and Japan, in which last country it is also extensively cultivated, as it furnishes a valuable

material for making the best kind of paper. The genus contains this species only, and differs from Daphne only in its longer style and stigma. It makes, in Europe, a handsome greenhouse plant when well grown, and formerly was much more frequently cultivated than at present; *Colchicum Sibthorpii* (t. 7181); this is said by Mr. Baker to be the finest of all the Colchicums in cultivation. It is a native of the mountains of Greece and of Macedonia, ascending to an elevation of 5,000 feet above the level of the sea. In its distinctly tessellated flowers it agrees with *C. variegatum* and *C. Parkinsoni*, although the segments of the perianth are much broader than in those species, and the leaves, like those of *C. autumnale*, are suberect, obtuse, and not at all undulate. It has only been introduced lately into cultivation, the corms cultivated at Kew having been sent to the Royal Gardens by Max Leichtlin in August, 1890; the flowers are produced in the autumn and are bright mauve-lilac, and are borne in from one to five-flowered clusters. The perianth has a stout white tube from three to four inches long, with a campanulate limb, oblong-obtuse segments two inches long and distinctly tessellated on the inner surface. The stamens, which are about half the length of the perianth-segments, bear large linear yellow anthers.

Foreign Correspondence.

London Letter.

Orchids.—*Disa Veitchii* is the result of crossing *D. grandiflora* with *D. racemosa*, and is another addition to the many first-rate hybrid Orchids raised in the establishment of Messrs. J. Veitch & Sons, Chelsea. The late Dr. Moore proved at Glasnevin, many years ago, that *D. grandiflora* could be propagated from seeds almost as easily as Gloxinias; Messrs. James Backhouse & Sons, of York, also have raised large quantities of this plant from seeds. The habit and general characters of the comparatively new *D. racemosa* are very similar to those of *D. grandiflora*, while its behavior under cultivation, so far, has been uniformly good, which is more than can be said of the Table Mountain plant. A cross between these two, therefore, was almost certain to prove good in a garden sense, and Messrs. Veitch lost no time in putting it to the test, for *D. racemosa* did not flower in England until 1888, when it bloomed at Kew, yet a plant of the hybrid was exhibited in bloom at the last meeting of the Royal Horticultural Society, although only twenty-one months old. No doubt, the hybrid will be much finer even in a year or two than now, but it is a really first-rate Orchid as it is. In habit and foliage it resembles both its parents, but the flower is like that of *D. grandiflora* in size and form, while in its bright rose-mauve color it resembles *D. racemosa*. The chief merit of this plant lies in its being within the reach of every one, either by repeating the cross or by means of offsets, which are produced freely by both parents, and, no doubt, will be by the hybrid. *D. racemosa* is now represented by about twenty spikes of flowers in the Kew collection. As I have said several times already, it is a beautiful Orchid, and as easy to cultivate as *Odontoglossum crispum*. *D. tripetaloides* is also in bloom here; it has racemes a foot long, each bearing about a dozen white flowers spotted with rose.

Lælia Arnoldiana.—Messrs. Sander & Co. have just flowered a most beautiful hybrid, which they have named in compliment to Mr. Hicks Arnold, of New York. It is the result of crossing *L. purpurata* with *Cattleya labiata*. The plant has the general appearance of *L. purpurata*, and so has the flower, but it differs in having a large labellum, fully two inches across the front lobe, which is colored deep amethyst-purple, darkening to maroon in the throat, where there are a few veins of a golden-yellow color. The sepals and petals are of good substance, and colored a soft rosy mauve.

Sobralia macrantha Keinastiana is a pure white form of the well-known *S. macrantha*. It was shown in flower by Baron Schrœder, and obtained a first-class certificate. It is the best of all the colorless varieties of *S. macrantha* hitherto seen, the sepals and petals being snow-white, the only color being a blotch of golden yellow in the throat of the labellum.

Hæmanthus Katherinæ is a very handsome stove bulb which is so easy to manage, and blooms so freely, that it deserves a place in every collection of stove plants. It was introduced to Kew in 1877, and figured in the *Botanical Magazine*, t. 6778. Since then it has seeded in various gardens, and some of the seedling varieties are much superior to the type. The best is known as Alice Barr, or Superbus, and has very large heads of bloom, one which I saw from Mr. Gumbleton last year being nine inches in diameter and colored rich scarlet. This species does not require to be dried off at any time.

Bauhinia Galpini.—This is a promising garden-plant, and, therefore, an exception to almost every one of the many species of Bauhinia which have been tried in the garden at one time and another. It has lately been introduced to Kew by means of seeds sent from the Transvaal by Mr. E. Galpin, who describes it as "a handsome bush, about five feet high, with large red flowers, and certainly the plant of plants so far as the De Kaap vegetation is concerned." Mr. Galpin sent flowering specimens which bore out his statements with regard to the beauty of this species, and the behavior of the plants in cultivation at Kew is all that could be desired, as they grow freely and form shapely elegant pot-shrubs. As yet they are too young to flower, but Mr. N. E. Brown, of the Kew Herbarium, has drawn up a description of the plant, which is published this week in the *Gardeners' Chronicle*. The leaves are of the usual two-lobed form which characterizes all the plants of this genus, and the flowers are in axillary racemes which, in wild specimens, are extremely abundant upon every branch. Being found at an elevation of about 2,000 feet, or not far from the home of *Clematis Stanleyi*, this species is certain to thrive in a geenhouse. Like all Bauhinias, it revels in sunshine and a moderate allowance of moisture. We have plants a yard high which promise well for flowering shortly.

The only other species of Bauhinia which have proved worthy the notice of horticulturists are *B. corymbosa*, from China, and *B. Natalensis*. There are over a score species in cultivation at Kew, and while some, such as *B. Vahlii*, are handsome foliage plants, deserving a place in large stoves, they rarely produce blossoms, notwithstanding their well-known free-flowering behavior in a wild state.

Celmisia spectabilis.—The Celmisias are peculiar to New Zealand, where they grow at high elevations, and are known as Mountain Daisies. Twenty-five species have been described, and almost every one is of such a character as would find favor in the garden. Unfortunately, however, they are exceedingly difficult to introduce, either by means of plants or seeds, and, notwithstanding the repeated efforts made by the Kew authorities and others, they remain still almost unknown in English horticulture. We possess two, however, namely, *C. Lindsayi*, which has been at Kew ten years, and of which a figure was published in the *Botanical Magazine*, t. 7134, and *B. spectabilis*, of which Messrs. J. Veitch & Sons exhibited a small plant in flower at the last meeting of the Royal Horticultural Society, where it obtained a first-class certificate. This plant was six inches high, the leaves lanceolate, rather rigid, thickly felted beneath with silky wool and silvery upon the surface. The flowers were daisy-like, erect, about two inches across, the disk golden yellow and the ray-florets pure white. There is a very fine example of this species at Kew, but it has not yet flowered. It thrives in a cold pit, where it receives protection from frost in winter and exposure to sunlight in summer. It is a striking and interesting plant even when not in flower. Last year we succeeded in getting from New Zealand to Kew no less than nine species of Celmisia, which arrived alive, but every one failed to grow. If we can only hit upon the right way to import these plants, our gardens will be considerably enriched thereby.

London. *W. Watson.*

Cultural Department.

Memoranda from the Strawberry-field.

After an examination of my rows I am once more of the opinion that we have no berry as yet to surpass Bubach No. 5 for general culture. The season here has been and beyond all precedent, and most berries are severely dried up. All are injured, but Bubach No. 5 gives us good berries and in large quantities. It is a solid and finely flavored fruit, and never badly shaped; the color a deep red. I shall make it my staple berry in fall-planted grounds. It is pistillate, and that is its only drawback. The size is very uniform, the foliage ample, the growth rapid, and the roots strong.

Sharpless must still hold its place as one of the first for quality, size and productiveness; at least on my soil, which is strong clay, it is very productive. I have planted Ontario largely, and it is possible it is not the same as Sharpless; but they are so closely similar that it is not worth while to keep them apart.

Cumberland, for a very early berry, is yet unsurpassed by any I have tried. I am growing fifty sorts, and, year by year, this old acquaintance turns up so fine that it loses no marks of

high standing. The berry is roundish, large and very sweet. It is light red and handsome. There is very little waste from small berries, and never any waste from ill-shaped ones. It not only does well in all parts of the country, but in all localities—in the shade nearly as well as in the sun. I have them growing under my Grape-vines, and even there the fruit is smooth and handsome. Both Cumberland and Sharpless are bisexual.

Haverland has this year failed to give me its usual large berries; but it stands in matted rows. I think this berry, to do its best, must have either hill-culture or be grown in very narrow rows. It is a rampant grower and feeder, and needs room for each plant. It bears enormously, and, at its best, very large long berries. In flavor it is not up to the highest rank. It is pistillate, and not suitable for distant shipment.

Jessie I shall drop out. It needs petting to bring out its best qualities, and is never a heavy cropper. The plant is vigorous and the flower perfect. The quality is also excellent. It has, in fact, enough good points to make it available as a fertilizer for pistillate sorts.

Warfield No. 2 I have tested thoroughly in different fields, and, while it bears good crops, I want no more of it. The berry much resembles Wilson, is quite as sour, and not of standard flavor. The berries hang down close to the ground, and are not as large, on the average, as those of the Wilson. The fruit is solid, and bears shipment well; the blossom is pistillate.

Mrs. Cleveland is not of the best flavor, but it is a superb bearer, and the quality is at least good. The size is very large, and the form not quite regular, but in no way distorted. I do not think any one will make a mistake in planting this berry freely. The flower is pistillate.

A companion berry, sent out by Mr. Townsend, of Ohio, is the Eureka. This pleases me in growth, in berry, in crop and in foliage. The fruit is very large and of fine quality, not equal, however, to Sharpless or Cumberland. The growth is a trifle less luxuriant than that of Mrs. Cleveland, but they both make runners very fast. Both grow well in hill or matted rows. Some varieties, when matted, make so close growth as to stifle each other, which is not the case with either Eureka or Mrs. Cleveland.

Among the not quite new but still scarce sorts I select, as two exceedingly fine ones, Pearl and Florence. Pearl is a truly good berry every way. It stands up well on strong stalks, its form is regular and conical, with a slight neck. It grows rapidly, vigorously, and bears splendid crops. I like the looks of it, both in the row and the basket. The quality is fine. Florence has also a tall stalk, bears freely a conical berry, bright red and handsome. Mark these as attractive berries, and both of them good to win buyers. Florence, with me, makes the largest stools, but Pearl makes the most rapid growth. They can both be planted with confidence. Pearl has a perfect flower and produces pollen freely.

Michel's Early, if I have the real plant, is a disappointment. It is not as early as Crystal City, and not very much larger. It is a rampant grower, a good bearer, and the fruit stands up well. When dead-ripe the flavor is good, but peculiar. It bears considerable resemblance to Crystal City in style of growth and fruit.

Belmont is not a success in my grounds. I think it will be profitable only under a system of highest culture. I am even compelled to drop out that delicious berry, the Prince of Berries, a handsome and excellent fruit, but slow grower and impracticable every way.

Among those that I admire is Summit, and until this year have insisted on growing it. I cannot hold one of the berries in my hand without thinking of a small pear. It is as large as some Seckels, and most delicious; but it is a very poor grower, as well as so slow in ripening, as to make it another of the impracticables.

Gypsey is delicious, early, handsome, medium in size. It is also a moderately good grower, but the quantity of fruit does not warrant large plantings, while the foliage is not strong nor abundant.

One berry I have replanted and am satisfied I did not do it justice by the first test—that is Lida. It bears abundantly large berries of good quality, and has many claims as a first-rate fruit.

Of strawberries, even more than of other fruits, one must speak with much caution, because different varieties require different soil. My own fall-planting will include (1) Bubach, (2) Sharpless, (3) Cumberland, (4) Eureka, (5) Mrs. Cleveland, (6) Pearl, (7) Haverland, and there will be further test of Thompson's No. 51, as well as Tippecanoe, Saunders, Middlefield, Parker Earle and Edgar Queen.

The extraordinary dryness of the present season has taught me the absolute need of irrigation. I shall adopt the easy plan of having my Strawberry-garden below my barn, so that I can carry water to it in pipes from a well. This many can do.

Clinton, N. Y. *E. P. Powell.*

Stray Notes from the Arnold Arboretum.—II.

SOMETHING was said last week in these notes of the beauty of our native Viburnums, and of their great value for planting in gardens, and on the wilder parts of city parks and of large private estates.

Equally valuable, certainly, for such purposes, are many of our native Cornels, several of which are more graceful in habit than any of the Viburnums, and which, although usually not quite as ornamental in their flowers, produce generally more highly colored and showier fruits. The bark of the branches of some of the species is bright colored, and, in winter, when the plants are stripped of their leaves they make a brave show and offer bright bits of color which are invaluable in the winter landscape.

The most beautiful of all the Cornels which grow spontaneously in this part of the world is the so-called Flowering Dogwood, *Cornus florida;* and here, in parentheses, it may be affirmed that this plant is not poisonous. Many people think so because a so-called Dogwood, like the Poison Ivy, has acrid juices which are extremely poisonous to most persons, but here is a case which illustrates the confusion which often follows the promiscuous use of vernacular names for plants instead of the precise and exact names imposed on them by science, and which, in nine cases out of ten, are not more difficult to learn and to remember than English names. "The Poison Dogwood" is not a Dogwood at all, but a sort of Sumach, or Rhus; and the Poison Ivy is not an Ivy or anything like an Ivy, except that it sometimes climbs by the aid of rootlets produced from the stems; and none of the Dogwoods are at all poisonous. Here, then, are three popular errors about three of our most common and best-known plants which have all come from the unfortunate coining of popular names which are now so firmly fixed that they will probably be used as long as the English language is spoken on this continent. It may be a small matter in speaking of a Rhus to call it an Ivy, but it is rather unfortunate when this looseness in the use of language casts a suspicion on one of the most beautiful of all trees. For the Flowering Dogwood, or *C. florida* as people ought to learn to call it, is not excelled in beauty by many other trees.

It has all the qualities which make plants valuable from the ornamental point of view. In habit it is a low, round-headed tree, sometimes at the south forty feet high, but at the north rarely growing to half that height. The flowers, to be sure, are small and not at all conspicuous, but the clusters are surrounded by large snowy white floral bracts or leaves, which, when they are fully grown, make what look from a little distance like white four-petaled flowers, each two or three inches across. These floral leaves, and the flowers themselves, develop before the appearance of the true leaves, so that when the plant is in flower it looks as if it had been covered with a white sheet.

The illustration which was published on page 431, vol. iii., of Garden and Forest shows what a beautiful object this tree is in early spring. The foliage is abundant, ample in size, and of cheerful and pleasant colors, yellow green on the upper surface and pale on the lower. Very few of our trees, perhaps not a single one, are more beautiful in the autumn than *C. florida*. It is worth growing for the autumn effect which the foliage affords, quite apart from its beauty as a flowering tree. Here, in New England, toward the end of October the leaves take on their autumn coloring, a deep and intense red, which makes the trees conspicuous from as far as they can be seen. The color of the leaves changes only on the upper surface, while the lower surface retains its pale color, so that when the wind plays through the branches charming contrasts of color are produced between the upper and lower sides of the leaves. The beauty of the tree in autumn is increased, too, by the abundant fruit which is produced in heads or clusters, each fruit being rather less than an inch long and bright scarlet. Birds are fond of the fruit, and often strip the trees as soon as it ripens, but when it escapes their attention it serves to heighten by contrast the color of the foliage, and gives to the tree a warm, cheerful look which is not easy to explain by words.

C. florida is one of the best of all the small trees to plant in this country as a specimen on a small lawn or in a garden. It needs good soil, and in eastern New England rather a shel-

Fig. 53.—The Bermuda Palmetto *(Sabal Blackburniana)* in the Devonshire Marshes.—See page 302.

tered situation, for we are close to the northern limit of its range, and, although it is found here and there growing wild in the woods, it is a comparatively rare tree, while in the middle and southern states it is one of the most common of all the smaller inhabitants of the forest. The best place, however, in which to plant *C. florida* is on the borders of natural woods—that is, in those situations which it selects itself—on the margins of clumps of larger trees, in woodland glades, and in all the places where an attempt is made to produce by planting natural effects. It can be introduced with advantage much more freely than it has been before into our large parks, in which sufficient attention is rarely paid to making the margins of the plantation as beautiful as it is possible to make them by the use of the material which is ready to the hand of the American planter. It is only in recent years that nurserymen have begun to learn what a valuable and useful plant *C. florida* is, and it can now be purchased in considerable quantities in a few of our nurseries. We should probably have seen more of it in American gardens if it had been a favorite plant in England, upon which country we still depend more than we should for horticultural ideas, and from which we formerly obtained nearly all our ornamental plants. But *C. florida* needs the hot sun of our long summers to thoroughly ripen its wood and to make it flower freely; and not finding in England the proper conditions, it has rarely shown there its real beauty.

Abnormal forms, whether of habit or of flower, rarely equal natural types in beauty, and, as a rule, are not to be commended. There is a variety of *C. florida*, however, in cultivation with pink, instead of white, flower-bracts, which is really a handsome plant, although considerable prejudice has been created against it by the absurd overcoloring of the bracts as they appear in illustrations in the sale-lists of nurserymen who are seeking to make a market for it. The bracts are really delicate pure pink, and trees of this variety planted with those of the common form ought to produce very charming color-effects. There is a variety, too, in which all the branches are more or less pendulous. This is not, however, a very handsome or desirable plant, as the round top and rather formal outline this tree assumes naturally is one of its great attractions.

The forests of North America produce a Cornel which is even more beautiful than *Cornus florida*. This is *C. Nuttallii* of the Pacific coast, which may be described as a giant *C. florida*. It is often a tree sixty feet high or more, with large leaves and immense floral bracts, which sometimes form heads six inches across. For some reason or other this tree does not take kindly to cultivation, and although efforts have been made for years to induce it to grow, they have so far been unsuccessful. Other trees of the region where it grows flourish in Europe, and a few of them, like the Vine Maple, do well here; but *C. Nuttallii* cannot be persuaded to live in cultivation for more than a year or two. The seeds germinate freely enough, but the seedlings go off before they are a foot high. If these notes are read by any one who has succeeded in cultivating this tree he will confer a favor on the readers of Garden and Forest if he will give them the benefit of his experiences with it.

The Asiatic representatives of this peculiar group of Cornus with large flower-bracts, which, although they are really Cornels, are generally spoken of as Benthamias, are less showy in flower than *C. florida*, although the Himalayan species (*C. capitata*) produces much larger and finer heads of fruit; this is a beautiful tree, which ought to be planted in the south, where, in some regions like central Georgia, it would doubtless succeed. The Japanese plant of this section (*C. Kousa*) was introduced into our gardens many years ago, and now flowers in the neighborhood of New York every year. Here it is not very hardy, and, as an ornamental plant, has nothing to recommend it over *C. florida*, for a poor form of which it might well be mistaken.

The eastern states produce a number of shrubby Cornels and one arborescent species besides *Cornus florida*. This is *C. alternifolia*, so named because the branchlets and the leaves, instead of being placed opposite to each other on the branches, as is the case with most of the Cornels, are alternate. This plant, like some of the Viburnums, is a surprise to most persons who see it well cultivated for the first time and who are unwilling to believe that this common road-side shrub, or small tree, can become such a wonderful object when it is set in rich soil and allowed to develop its peculiar method of growth. This peculiarity consists in the whorl-like arrangement of the branches, which leave the main stems at right angles and form flat stages one above the other, the whole making a regular pyramid from the ground upward. In old age the lower branches usually disappear; the upper branches lengthen out and form a low flat top which is very characteristic of the species as it appears in its native state, growing in broad coppices on rich hill-sides, or by the borders of country roads, where it is often very common, or near the margins of swamps. The branchlets of *C. alternifolia* are bright green and more or less streaked with white. The leaves, which taper at the two ends, are not more than three or four inches long and are clustered near the ends of the branchlets; they are light green in color, with yellow shades, and very bright and cheerful, but in autumn do not assume a brilliant color before falling. The flower-clusters, which stand up all over the top of the flat branches and so make a great show, are not individually very large, and the flowers of which they are composed are small and pale yellow; and it is the arrangement of the flower-clusters and their great number which make this such a conspicuous plant in the middle of June and not the individual beauty of the flowers. The fruit, which is deep blue when it is ripe, is very beautiful, however, its appearance being heightened by the contrast it makes with the bright red stems on which it is borne.

C. alternifolia has been very largely planted in the Arboretum in many situations, and has proved satisfactory in all of them. It is, perhaps, most ornamental as it stands near the margins of the roads and has been given sufficient space in which to send out its wide-spreading branches. It is not to be surpassed, however, as a specimen plant for the lawn, and it is surprising that its beauty for such a use was not recognized long ago; or it would be surprising in any country except this, where the almost entire neglect of native plants is one of the remarkable and unfortunate features of the recent development of American horticulture.

In another issue of these notes the claims of some of the shrubby Cornels of our wood-sides for ornamental planting will be considered, and something will perhaps be added concerning a few foreign species.

Arnold Arboretum. *P. C.*

A Few Irises.

THE Japanese Irises are at present the most attractive flowers in the hardy garden, and their wonderful blooms will continue for several weeks to make the principal display of the season. Among the countless Irises, *I. lævigata* is unique for entire distinctness of flower both in form and coloring. The petals or falls, while having a tendency to flatness, show all manner of graceful curves and wavings as they expand, and are free from all stiffness and coarseness so usual in large flowers. Their colorings are as singular as their forms, the most attractive, to my taste, being the pure white ones and those with violet veinings. Among them are deep dull reds and purples, nearly black, not without attraction. With flowers gracefully poised over the tall rush-like leaves, and swaying to every breath of wind, there are few more attractive plants of any season than Kæmpfer's Irises.

A few Irises loosely arranged in a tall vase make a striking floral arrangement. Their flowers are not very lasting if plucked when fully expanded, but if cut before they commence to unfold they retain their freshness several days. Like many of the flowers which ripen their pollen rapidly and are self-fertilizing—Poppies and single Dahlias, for instance—cutting at an early stage gives them a check, the pollen matures more slowly, and they retain their petals much longer than if plucked later.

A writer in Garden and Forest some time since expressed a fear that some one would double the Iris. As these Irises are the only species possessing double flowers, perhaps I may be permitted to say here that it seems a hypercritical taste which would object to them. The number of petals is simply doubled, making a flower with a somewhat full outline. Among the numerous forms of Japanese Irises it is doubtful if any are finer than the kinds originally imported by Mr. Thomas Hogg, which were the first seen here. One can secure, however, an endless variety, and as they cross readily and have a tendency to sport, it is interesting to grow seedlings. They seed freely, and strong plants may be had from these the third year. In any position the flowers are large enough to please the average grower, but where very large flowers are desired it is usual to grow the plants where they can have large supplies of water. It will not do, however, to plant them in standing water, for they are not aquatic—at least they do not grow for me with roots submerged.

In my limited experience I find it difficult to believe that any of the Irises are properly classed as aquatic. Of course, I am aware that a number of varieties are found in standing water, and live and grow under this condition, but I do not

know any variety which does not grow better in a less wet position. Remove an *I. versicolor* from the marsh, where it is often found, and plant it in a damp border, or even a moderately dry one, and it will be found to grow much more vigorously, with taller foliage and abundant flowers. Perhaps nature does not make a mistake exactly in planting them in marshes, but their usual location there is probably due to the fact that their abundant seeds find in such a place the necessary moisture for their germination.

In writing plant notes one usually hesitates to recommend plants for general culture, but in the case of Japanese Irises there can be no hesitation in saying that they are plants for everybody and every garden, large or small, grand or humble. They are not continuous bloomers, but, when not furnished with flowers, the tall rush-like foliage is persistent and attractive through the season.

I. juncea and *I. Pavonia*, just out of flower, are two bulbous Irises which cannot be so strongly recommended for general culture, but they are plants of great beauty, if of somewhat less pronounced a type, and are well worth the necessary attention. *I. juncea*, the rush-leaved Algerian Iris, proves hardy here in a warm border. The foliage is very narrow, about a foot high. The flowers are large, of a clear, deep, golden yellow, and are about the most attractive Iris flowers of this color. *I. Pavonia*, the Peacock Iris, is (or was) botanically known as a Moræa, and is a Cape bulb, and, as such, is usually treated like the Ixias in a frame or cold house, where they come into bloom in May or June. Their flowers are very attractive, with white falls distinctly blotched at the base with a peacock eye. The flowers are small, and their beauty is of a dainty order. These bulbs, I find, are fairly hardy, as they flowered a few days since in a very exposed border where they were planted in October. Such a position, however, is scarcely suitable, and possibly the experiment might not be often so successful.

Elizabeth, N. J. *J. N. Gerard.*

Notes on American Wild Flowers.

Lilium Grayi is one of our best native plants. It is not only a very attractive species when in bloom, but it seems to be as easy to grow as the common Meadow Lily or the Swamp Lily. It is about the same height as the *L. Canadense*, and the color is a mixture of red and yellow, as with some varieties of that species; but the petals of the long funnel-shaped flower are not reflexed, as in most of our species, and this distinction is its most prominent feature. It is among the first to flower, coming into bloom about with *L. Parryi* and a little later than *L. Columbianum*. A rare local species, inhabiting certain portions of the southern Alleghanies, *L. Grayi* has not until quite recently been easy to obtain.

The purple Corn-flower (*Echinacea purpurea*), which flowers early in June, is a striking member of the composite family, about three feet high, bearing one to three, or sometimes more, large rose-purple flowers with a brownish purple centre. If the petals stood out horizontally the flowers would be from three to five inches wide, but they generally have a half-drooping habit, which not only lessens the width of the flower, but it gives them a peculiar appearance. It ought to be a useful plant in cultivation. Its odd shape and color and time of flowering are all in its favor.

Coreopsis palmata is a more erect plant in habit than *C. lanceolata*, which is so generally cultivated. Its flowers, though not so large and showy, much resemble those of *C. lanceolata*. It seems to be a little later in flowering, so that it would afford cut blooms after *C. lanceolata* had passed. It is quite as hardy as the other, and needs the same soil and sunny exposure.

Asclepias purpurescens (Purple Milk-weed), which grows on dry banks and borders of woods, comes into flower early in June, and is one of the most showy species. To me it is quite as attractive a plant as the Butterfly-weed (*A. tuberosa*), which has been in cultivation for some time, and blooms earlier. It is frequently seen in the shade, but the richest flowers are found in full sunlight. It transplants well, and needs no special treatment.

Monarda Bradburyana is our earliest species, growing in dry half-shaded places, only about fifteen inches high, and bearing a terminal whorled head of pale purple flowers. A useful plant for a dry partly shaded place, remaining a long time in flower. Its near relative, *Blephelia ciliata*, flowers only a few days later, and has slightly darker flowers.

Nemastylis Brunnea, Watson, is a new species which Mr. Pringle found in Mexico in the summer of 1889. Its flowers are open, bell-shaped, nearly an inch wide, light purple outside, and yellow-purple and white within. It has a long grass-like leaf much like some of the smaller species of Tigridia, and needs the same treatment. The flowers seem to be a little more durable than are some of this genus.

Pentstemon lævigatus, var. *digitalis*, bears large showy heads of white flowers. The heads or panicles are often four inches or more in length, well filled with the large flowers, which are an inch or more long. It likes a moist, but not wet, clay soil, either in the full sunlight or in partly sheltered situations.

Botanical Garden, St. Louis, Mo. *F. H. H.*

Rogiera gratissima.—This beautiful greenhouse-plant resembles a Laurustinus in growth and general habit, and, like it, produces flowers in large terminal trusses. A native of the highlands of Central America, it does well in a cool greenhouse, with the same treatment given to Camellias. It is best to plant it out, as it likes root-room. The fragrant flowers are produced several times each year. The foliage is bold and of a rich dark green. It is a very free bloomer, and when young should have some of the flower-buds pinched out as they appear, or the plant will be weakened by over-blooming. It is easily propagated from cuttings taken from half-ripened wood, and placed in a gentle bottom heat.

Maywood, N. J. *James P. Taplin.*

An Orchid Anthracnose.—Several complaints have reached us from Orchid growers of a decay which, in its worst form, destroys entire plants. The trouble is first noticed by a discoloration of the stem, which rapidly turns brown, and almost black, the succulent interior becoming a mass of decay. Following this, upon the smooth exterior, small pimples appear, which finally develop into the spore-bearing spots of the fungus—a species of Glœosporium. It does not appear to be the *G. cinctum*, B. & C., of the Orchid, as its spores are twice as large, and straight instead of curved. However, the main point to insist on is, that the trouble can readily spread through an Orchid-house if the keeper neglects to collect and burn all decaying stems or leaves in their early stages of decay before the fungus has time to mature its crop of rapidly germinating spores.

Rutgers College. *Byron D. Halsted.*

Correspondence.

The Cultivation of Acacia Farnesiana, or Cassie, in Europe.

To the Editor of Garden and Forest:

Sir,—These notes on the cultivation of a North American tree in Europe may interest some of your readers. The *Acacia Farnesiana*, commonly called in France Cassie or Cassier, is a large shrubby tree in cultivation here, eighteen to thirty feet high, according to the fertility of the soil where it grows, with spiny branches, compound leaves, and orange or yellow fragrant flowers collected in small globular axillary heads on the branches of the year. It is cultivated in various parts of Provence for its flowers, used in the manufacture of perfumes, especially in the neighborhood of the town of Grasse, which is the centre of this industry.

A sandy soil is preferred for Cassie, and situations on the southern slopes of hills open to the sun and protected from the cold north winds. The plant is destroyed, or the branches, at least, are killed back if the thermometer falls below six degrees centigrade below zero, a rare occurrence in the regions where it is cultivated. *Acacia Farnesiana* succeeds equally well on limestone soil and grows to a larger size than it does on granite; it flowers, however, later, and this is a serious objection, as the flowers which appear late in the season are much less fragrant than those developed earlier. The plant is propagated by seeds, and their germination can be hastened by soaking them in water for thirty or forty hours in order to soften the outer coat.

The seed is sown in March and April in beds of carefully prepared soil, exposed to the south, and these beds are frequently watered to hasten the germination of the seed and the growth of the young plants. The following year these are transplanted to the ground where they are to stand permanently, and are set six feet apart each way in order that they may have sufficient room for the development of their branches, and to allow the cultivation of the soil between them with the plow, or, as is usually the case, by hand. The ground should be kept clean between the plants, and it is usually thoroughly cultivated every spring, and enriched from time to time with a good coating of manure. As the flowers

are gathered by women and children it is necessary to prevent the plants from growing to their full height. To accomplish this it is customary to stop the main stem of the young plant at about two feet from the ground. This causes it to form several main branches, and these are cut every year in such a manner as to give to the plant the form of a vase, this being the shape best suited to produce the largest quantity of flowers near the ground, the plants being kept down to a height of five or six feet. The plants continue to produce flowers from the middle of summer to the middle of autumn, and a few flowers continue to appear until frost, that is, until the middle of November or the commencement of December. The first flowers, however, those which open during hot weather, are much more valuable than those produced late in the season. For this reason cultivators use every effort to advance the flowering period.

The flowers are always gathered in the morning and are turned over at once to the manufacturers. It is estimated that a fully grown plant in good condition will produce a kilogram of flowers during the season worth from five to seven francs, according as the supply is more or less abundant. A hectare (about two and a half acres) produces, on an average, eleven thousand pounds of flowers.

The flowers are never distilled, the only process used to extract the perfume being that known as "enfleurage." The essence of Cassie is used in the preparation of pomades, to perfume oils or to make extracts of different species, the preparation of which is more or less the secret of the perfumers of Grasse. The process of "enfleurage" consists in spreading flowers over glass plates covered with a layer of pure grease three or four millimetres thick. This is turned over two or three times a week, or until it is impregnated with the perfume—a process which usually requires a period of twenty-five or thirty days. The impregnated grease is then distilled in order to obtain the pure essence, a kilogram of flowers producing three or four grams of the essence. The process of "enfleurage" is also performed with hot oil. Olive oil of the best quality is poured into large heated kettles, into which are put the Cassie-flowers. The oil is then heated to the boiling point, or almost to the boiling point. Workmen provided with large wooden spoons keep turning the flowers to prevent them from falling to the bottom of the kettle, where they would burn. When this operation has been continued long enough the whole of the contents of the kettle, flowers and oil, is poured into little sacks, which are compressed under an hydraulic press. In this way the perfumed oil of Cassie is obtained. It is not easy to explain these processes, and they cannot be thoroughly understood unless they can be seen in operation.

In addition to the typical *Acacia Farnesiana* a remarkable variety, discovered about fifteen years ago, is now cultivated. This is the *Acacia Farnesiana sempervirens*. It is said to be much more valuable than the ancient form, and is a larger, more robust and productive plant. It requires, however, more room. Plants of this variety ought not to be set less than fifteen feet apart, and need abundant watering and manuring during the summer. This variety is hardier than the type, and it grows more rapidly. Its principal advantage over the ordinary *Acacia Farnesiana* is found in the fact that it produces two crops of flowers in a year—the first at the end of the summer, the other in the spring. It is now largely and profitably cultivated in the neighborhood of Grasse.

Antibes, France. *Charles Naudin.*

Forest Fires.

To the Editor of Garden and Forest:

Sir,—During the month of May the papers were filled with accounts of forest-fires, but only a fraction of the cases where serious damage is done is ever reported in the press. Where one acre of valuable Pine is destroyed, there are 80 or 100 acres burned over of what would be a forest in the future. Whole townships were literally devastated, and a cloud of smoke more or less dense hung over the whole of northern Wisconsin and the upper peninsula of Michigan, as well as the northern part of the lower peninsula of Michigan. From a private source I learned of one lumberman losing 50,000,000 feet of standing pine in primeval forests. Numberless camps, with all their outfit, including even the horses in some cases, have been destroyed, with vast quantities of lumber and logs, and dams used for driving logs; in short, everything which fire can consume is swept away by these conflagrations. They cannot be stopped or checked. Spread over a large area, the induced currents of air become fierce gales, the heat becomes so intense that men cannot bear it; the sand becomes red-hot, and turf and mold and roots of trees—everything burns. Sparks and flaming brands are carried long distances beyond the line where the fire is raging, starting blazes in new places; rivers and swamps offer no obstructions. Even rain is but a temporary check, and when the next dry time comes, from smoldering embers in decayed trees or from the depth of some body of turf, the flames break out afresh. Smothered fires may keep alive in such places until a heavy mantle of snow finally puts them all out. How are our Pine-woods to have insurance against fire under such conditions? Generally speaking, our hard-wood forests are proof against fires to the extent, at least, that old forests do not easily suffer. This is not always so, however, and in severe fires like those of the present year mile upon mile of hard-wood timber may be destroyed.

The lumbermen are careful in all their operations not to allow fire to escape them. Farmers, in clearing the land by burning, and hunters and fishermen are usually the culprits, and timber-owners are helpless to prevent it. "What are we going to do about it?"

Milwaukee, Wis. *Charles L. Mann.*

Old Fort Erie.

To the Editor of Garden and Forest:

Sir,—There is a historic spot in plain view from this city that is curiously favored by nature, and yet but for the near neighborhood of an excursion steamer's landing it would be rarely visited. Old Fort Erie is now nothing but a bewildering labyrinth of tumble-down walls and grass-grown embankments, a simple pasture-field, with no habitation near, but it has a breezy situation and a wonderfully varied outlook. The soft outline of Lake Erie, and the steady, quiet flow of the Niagara as it leaves the lake, have no suggestions of war, and one is delighted to find the whole slope on which the fort lies sown, as it were, with that old favorite of all lovers of sweet-scented flowers, the thorny Sweet-brier, or Eglantine (*Rosa rubiginosa*). The heavy turf and unprotected field seems not at all suited to this shrub, yet it is here in profusion on every side of the fort, and when the bright pink blossoms are out, here about the last of June, the air is loaded with fragrance.

I find Sweet-brier stems close under the remaining walls of the fort at least an inch and a half through, though sheep-pasturage has kept most of the plants small. New shoots are now coming up of an almost scarlet hue in their luxuriance, and, as they are simple at first, like the Bramble, they are very striking. But for the pasturing the field is subjected to, it would be a wilderness of Sweet-brier, for the moat no longer holds water, except here and there, where the shallow depths are given up to Water Plantain, crawfish and snails.

As if the Eglantine alone were not considered striking enough for the spot, there are scattered over it two species of Thorn (*Cratægus coccinea* and *C. tomentosa*), the former of which is (June 6th) in full blossom, and the latter just beginning to show bloom. These masses of white flowers, soon to be replaced by the delicate pink of the Sweet-brier, seem a sort of mild reproach to the nations who within the century made war on each other in this now most peaceful and restful spot.

Along the river opposite the old fort at this season only two or three wild plants are conspicuous. *Cynoglossum officinale*, or Hound's-tongue, grows with especial vigor, and the shaggy Henbane (*Hyoscyamus niger*) is now in blossom. Later on *Datura Stramonium* forms thickets on the bank close to the water.

Buffalo, N. Y. *J. C.*

Recent Publications.

The Second Annual Report of the Missouri Botanical Garden, St. Louis, 1891, has reached us. It contains the report of the officers of the Board, the second annual report of the director, an account of the proceedings at the first annual banquet given by the trustees to gardeners, florists and nurserymen, which was held in December of last year at the rooms of the Mercantile Club, and finally Professor Trelease's revision of the "North American Species of Epilobium," which is accompanied with forty-eight lithographed plates. The volume is further illustrated with views, taken in the greenhouses of the garden, of a neglected and of a well-pruned Apple-tree, and of some bunches of Delaware grapes, showing the good results obtained by bagging. Professor Trelease, in his report, shows that solid work is being done in the garden, which is better equipped financially than any similar establishment of its kind in the world, the total receipts of income from September 1st, 1889, to December 31st, 1890, having amounted to no less than

$120,841.93, an income which ought to enable the managers to develop in time the most important botanical establishment in the world.

Professor Trelease has, very wisely we think, devoted much attention to building up a great library and to placing the herbarium on a good working basis. These two are always the important departments in a garden of this nature. Without them a scientific garden cannot be maintained or operated, and its fame and usefulness will be great or small in proportion as these departments are largely or imperfectly developed. The garden is fortunate in possessing the herbarium which was formed by the late Dr. Engelmann, and which is especially rich in those families of plants which he studied specially, such as the *Cactaceæ*, the Conifers, the Oaks, the Gentians, etc. It contains the types of many species, and must always be consulted by persons who desire to learn everything that there is to be known about these plants.

The library, it appears, has received constant additions during the year, no less than $6,000 having been expended for the purchase of books. Numerous donations, all mainly in the form of pamphlets, have been made to it. Little attention has been paid to the purchase of recent works, the available funds being used in securing rare old works and in completing the necessary sets of serials. This is as it should be, for the older books on botany are every year becoming scarcer and more expensive, and good judges of such matters believe that at the end of another fifteen or twenty years many standard works will have entirely disappeared from the market, many public libraries now buying them, not only in the United States, but in Australia and other English-speaking colonies.

We venture to congratulate Professor Trelease on the substantial progress he is making in building up an institution which Mr. Shaw's liberality has made possible. That his success is real, and that he is working on the right lines, this handsome volume abundantly indicates.

The Forest-trees of North America. By Asa Gray. Plates prepared between the years 1849–1859. Smithsonian Institution, Washington, 1891.

When the Smithsonian Institution was established, the first secretary, the late Professor Joseph Henry, proposed to publish a series of contributions to knowledge consisting of memoirs on different branches of sciences, as well as a series of reports on the progress of knowledge to be of a more popular nature and intended for wider distribution than the contributions. The second of the latter series undertaken by the Institution was announced in the secretary's report of 1848, and was to consist of a report on the forest-trees of North America, by Dr. Asa Gray. It was intended in the work to give figures from original drawings of the flowers, leaves, fruit, etc., of each principal species in the United States proper, for the most part of the size of nature, and so executed as to furnish colored or uncolored copies, the first being intended to give an adequate idea of the species, and the second for greater cheapness and for general diffusion. It was proposed to accompany this report with an introductory dissertation giving the present state of the knowledge of the subject, divested as much as possible of all unnecessary technical terms, of the anatomy, morphology and physiology of the tree, tracing its growth from the embryo to its full development and reproduction by the formation of the fruit and seed. A number of plates of this work were made, but Dr. Gray's absence in Europe, and the many calls made upon his time while at home, prevented him from ever preparing any text to accompany them. The work was found to be an expensive undertaking, and after about ten years had been devoted to preparing a number of plates it was finally suspended, and the whole matter was allowed to rest until some more favorable opportunity should present itself for carrying it on. This time never came, and the stones engraved from beautifully colored drawings by Isaac Sprague, with a number of imprints from them, remained in Dr. Gray's custody at Cambridge until after his death, which occurred three years ago. They were then sent to Washington, and the present secretary of the Smithsonian Institution, Professor Langley, has determined to distribute them to the principal botanists and museums of the world "as mementos of the distinguished man who gave so much of his life and labors to this department of knowledge." They are now issued in pamphlet form. The species which are illustrated are *Magnolia grandiflora, M. glauca, M. Fraseri* (which to our mind is the most attractive picture of the series), *Liriodendron Tulipifera, Tilia Americana, Acer rubrum, A. spicatum, Æsculus glabra, Æ. discolor* (that is, *Æ. octandra hybrida* of the new Silva of North America), *Æ. parviflora* (which can hardly be considered a tree), *Robinia Pseudacacia, R. viscosa, Cercis Canadensis, Gymnocladus Canadensis* (the staminate flowers only being shown), *Gleditschia triacanthos, Prunus Americana, P. Chicasa, Cerasus Pennsylvanica, C. Virginiana, C. serotina, Pyrus coronaria* and *Cornus alternifolia.*

Exhibitions.

The Massachusetts Horticultural Show.

THE Rose and Strawberry Show of the Massachusetts Horticultural Society, held in Boston on Tuesday, Wednesday and Thursday of last week, fell far behind similar exhibitions in late years, both in the number and quality of the exhibits. This was due to the unprecedented weather of the previous month. A dry spring with late frosts was followed in early June by a period of exceptional drought, with three or four days of intense heat, followed in the week preceding the show by a cold rain-storm of several days' duration. Nothing could be much worse for the production of good Roses, as the exhibition showed.

The local exhibitors made a poor show, and if it had not been for the large collections of flowers sent by Mr. Joseph S. Fay, of Wood's Holl, Massachusetts, there would hardly have been a Rose show at all. The effect of climate was clearly shown in Mr. Fay's flowers, which have been subjected to less trying conditions than those grown in the eastern part of the state. Mr. Fay took no less than eight first prizes for Roses, besides making a good show of vegetables, for which he took also several prizes. Among individual Roses shown none, perhaps, were better than the pure white Gloria Lyonaise, a rather tender Rose usually, but this year seen in unusual perfection. Very fine, too, were Prince de Portia and Thomas Mills. Unusually good specimens of Her Majesty, a very miffy subject usually, were shown by William Patterson, of Quincy. The special prize for the Ulrich Brunner Rose, offered by Dixon & Sons, of Belfast, brought out some good examples of this fine Rose—Joseph S. Fay being awarded the first and John L. Gardner the second prizes.

Mr. E. W. Gilmore, of North Easton, staged a collection of small, well-grown and well-flowered Orchids, taking the first prize for six, the second going to John L. Gardner. The prize for the best specimen Orchid was also awarded to Mr. Gilmore for an excellent plant of *Phalænopsis grandiflora.* A remarkable specimen of *Ouviranda fenestralis* was shown by R. Gardner, gardener to Cornelius Vanderbilt, Esq., of Newport. This is a curious aquatic plant from Madagascar known as the Lace-leaf, or Lattice-leaf-plant, with long narrow leaves composed of a net-work of vascular tissue resembling lace or a window covered with lattice-work. It has to be grown in water in a high temperature. Mr. Gardner's plant was admirably grown, and was shown in a large tub of water placed immediately under an electric light, so that visitors in the evening could see and enjoy the peculiar structure of the foliage. Benjamin Gray, of Malden, showed a tub with a flowering plant of the always attractive and interesting Japanese Nelumbium, and the Hon. Robert C. Winthrop sent pots of Gloxinias and of tuberous Begonias, besides a large collection of Gloxinia-flowers of an excellent strain.

The Strawberries, like the Roses, showed the effects of the dry season. The first prize was taken by Mr. Joseph S. Cowles, the gardener of Fairman Rogers, Esq., of Newport, for Sharpless. The second and third prizes were taken by Belmont, now a great favorite in eastern Massachusetts, as judged by the number of exhibits of this variety. Among newer kinds, the Haverland seemed to be the most deserving.

Mr. Fay showed specimens of Blonde Blockhead Lettuce of enormous size, surpassing, it is said, anything ever seen before in Massachusetts, although inferior to the Deacon Lettuce, sent by the same contributor, and which took the first prize.

Notes.

The third and final part of the "Provisional Host-Index of the Fungi of the United States," by William G. Farlow and A. B. Seymour, has appeared.

Mr. H. W. S. Cleveland, of Minneapolis, has associated with him, as an active partner in the professional work of landscape-gardening, his son, Mr. Ralph D. Cleveland.

Our correspondent, Mr. George Dawson, the assistant director of the Geological Survey of Canada, has been appointed a commissioner on the part of Great Britain to settle the Behring Sea controversy.

In reply to an inquiry from a correspondent, whose address has been mislaid, we would say that the parts of Hooker's "Icones Plantarum" cost four shillings each, and can be obtained from Williams & Nordgate, 14 Henrietta Street, Covent Garden, London.

The *Los Gatos* (California) *Mail* is authority for the statement that the manufacture of perfumes has begun in that town. One woman has a Rose-plantation of some sixteen acres in extent, besides Orange-trees, Acacias, Rose Geraniums and other plants bearing sweet-scented flowers.

The Hazel is not regarded in this country as a very valuable nut-bearing tree, and we doubt whether it is cultivated to any great extent. But it is more esteemed in Germany, as is shown by a pamphlet recently published at Berlin, in which the best methods of cultivating the Hazel are explained and a list of "eighteen chief varieties" is given.

An idea of the beauty and value of the new Japanese Lilac, *Syringa Japonica*, can be obtained from the fact that there is now a specimen in Mr. William B. Bacon's garden in Jamaica Plains, a suburb of Boston, only fourteen feet high, bearing one hundred and thirty clusters of flowers, many of them being from two to three feet long and eighteen inches or two feet broad.

The officer appointed by the State Board of Horticulture of California has seized 375,000 Orange-trees, just imported from Tahiti, because they are infested with different varieties of scale insects. They were intended for San Bernardino County, and if permitted to enter without being properly fumigated these insects would have spread throughout the choicest orange district in southern California.

The June issue of *Le Journal des Orchidées* contains an interesting and sympathetic notice of the late Paul Emile de Puydt, the distinguished Belgian writer upon horticulture, who died on the 20th of May last. He was a constant contributor to the horticultural press, and in 1860 published his *Traité de la Culture de Plantes de Serre Froide*. This was followed six years later by *Les Plantes de Serre*, and in 1880 by *Les Orchidées*, a work full of valuable information.

Among the newly introduced or still unfamiliar American plants recommended in the May number of the *Illustrirte Gartenzeitung* of Vienna are a brilliant orange-colored Coleus, Prince of Orange, which is declared to be the most splendid open-air sort yet grown; Nott's Excelsior Pea; the Remotant Pink American Flag; *Rhododendron occidentale*, from the Sierra Nevada Mountains; *R. Vaseyi*, of the Alleghenys, and the smaller and rarer *R. macrophyllum*, which is more commonly called, in Germany, *R. Washingtoni; Wistaria Chinensis floro albo*, a Chinese plant, but introduced into Germany by an American firm; four new Roses, Souvenir of Beauvoir House, Miss Winnie Davis, Miss Mildred Lee and Flor-Field (?); *Hibiscus Californicus*, and the Idaho Pear.

Monsieur Franchet describes and figures in the mid-June issue of the *Revue Horticole* his *Jasminum polyanthum*, discovered in 1883 by the Abbé Delavay growing in hedges in the neighborhood of Tarpin-tzé, a small town of Yun-nan, in China. This beautiful species, which Monsieur Franchet suggests will flourish in southern France, and possibly in regions of severer climates, is related to the well-known *Jasminum grandiflorum*. Its leaves, however, are much larger than those of that species, and of a different form, and the calyx-teeth are longer. It is remarkable in the great quantity of flowers which it produces in its native country, for the plant is not yet known in cultivation. The flowers are of a bright rosy flesh-color on the exterior and snowy white on the interior, and are possessed of the delightful perfume found in many species of the genus.

In his "Flora of New Bedford and the Shores of Buzzard's Bay," Mr. E. W. Harvey remarks that the favorite color of nature in that region is yellow in its different tints and combinations. In a number of species there are as many of a white or whitish color, but these are for the most part diminutive and inconspicuous. The various shades of yellow are more noticeable in spring, owing to the size and abundance of the flowers of a few common species, such as Buttercups, Dandelions, Potentillas, Calthas, etc., but there are really as many white-flowered species, though the flowers are smaller. Reds are not abundant at any time, but more common in the summer months. Purples are most frequent in August and September, when they rank next to the yellows, while the blues are more rare than any other color, and flowers of this hue are small in size, with the exception of the Iris, Lupine, Chicory, Aster, Pontederia and Gentian. The percentage of each color, computed by the number of species, is as follows: White, 33; yellow, including orange, 33; red and blue purples, 15; red, including crimson, scarlet and rose, 12; blue, 7.

Mr. E. S. Carman observed, on one of our recent hot days, that the Rose-bugs invariably sought the shade. Several of the beetles were then caught and placed in a paper box exposed to the sun. The thermometer in the box rose to 110 degrees and the insects died. Hot water was then tried, and it was found that the beetles were killed by water at a temperature of 125 degrees. The experiment was then made of heating water to 170 degrees and then spraying it upon some Magnolia flowers which were covered with the Rose-bugs. By the time the spray reached the insects it had been reduced to a temperature of 120 degrees, and it killed them without injuring the foliage or the flower. This experiment indicates that we may have a cheap and practicable check upon the ravages of this dreaded pest. It is plain that the nozzles which divide the water into mist are not the best for this purpose since the spray will hardly retain enough heat to kill the insects. A nozzle which emits coarser streams would be more effective, and it could be used at a greater distance. It is hoped that a trial will be made of this simple remedy wherever an opportunity offers.

We have received from Mr. Samuel C. Moon, of the Morrisville Nursery in Morrisville, Bucks County, Pennsylvania, flowering specimens of *Magnolia Kobus*, a Japanese species, which produces flowers before the appearance of the leaves, in early spring. Mr. Moon informs us that his specimen, which is now twenty feet high, with a straight trunk, about six inches in diameter, flowered for the first time in 1889, which is probably the first time that this species has ever flowered in the United States. It was planted by the late Mahlon Moon about twenty years ago, and was obtained it is supposed from Hovey & Co., of Boston, who had undoubtedly received it from Thomas Hogg, who, about that time, introduced many Japanese plants into the United States. The flowers of *M. Kobus* are smaller than those of *M. conspicua*, but they are pure white and very fragrant, and if the tree, with age, develops a free-blooming habit, it will prove a desirable addition to our gardens, as it is one of the hardiest of all Magnolias, perhaps the hardiest in eastern Massachusetts, where there are now several specimens of this tree raised from seed sent some years ago to the Arnold Arboretum from the northern island of Japan. None of these plants, which are now twelve or fifteen feet high, have yet flowered. *M. Kobus* was distributed in this country under the name *Magnolia Thurberi*, an unpublished nurseryman's name.

In view of the fact that the Hop plant-louse has appeared in alarming numbers in New York, Oregon and Washington, Professor Riley has prepared a bulletin which explains the main facts in its life-history and the remedies best known against its ravages. Since it was discovered a few years ago that the eggs of this insect were laid in the autumn on different varieties and species of the Plum, both wild and cultivated; that from these eggs were hatched in early spring stem-mothers of a dozen generations, and that the third generation of lice being winged desert the Plum-trees entirely and settle upon the Hops for their summer's work, it has become possible to devise an intelligent plan of attack. It is found: (1) That it will pay to spray the Plum-trees with some preventive application either in the spring, before the lice migrate to the Hops, or in the fall, after the lice have returned from the Hop to the Plum and are making preparations to lay winter eggs. The latter time is preferred, because in the fall the Plum-trees will be less susceptible to the action of poison, and stronger solutions can be applied without damage to the trees. (2) That all wild Plum-trees about the woods through the Hop-growing country should be destroyed. (3) That Hop-vines should be burned or drenched with a kerosene emulsion as soon after the crop is harvested as possible in order to kill the males. It is too late for preventive work of this sort this season, and the only thing now to be done is to spray the vines with some insecticide to kill the lice already there. Fortunately, the individual Hop-grower can be assured that his work cannot be thwarted by the carelessness of his neighbors, because the summer lice are wingless, and can only migrate by crawling from one yard to another. The bulletin goes on to state that the best insecticides for *Phorodon Humuli*, so far as known, are kerosene emulsions and fish-oil soaps. The proper method of preparing these mixtures, and the description of the best spraying apparatuses, have often been published, and they are repeated, with illustrations, in this bulletin.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by . . . . . Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, JULY 8, 1891.

TABLE OF CONTENTS.

The Value of Rural Beauty.

A RECENT number of *The Press*, published at Ridgefield, Connecticut, contains an account of the settlement of West Mountain, and the narrative carries a lesson which could be profitably studied in many rural communities. The West Mountain district lies a few miles west of Ridgefield. It is a region of wooded heights and deep valleys, and, therefore, of sparkling rivulets and placid lakes, with many picturesque glens and sweeping views of diversified scenery. No doubt, the people who have lived within sight of West Mountain have always enjoyed its beauty, but it was a visitor from the city who was so profoundly impressed with the native charms of the place that he decided to make for himself a summer home in the midst of these sylvan surroundings. The first settler was followed by another and another, and now a single purchaser has secured a large tract with the intention of perpetually preserving it, so that the beauty of these natural hills and woods and lakes can be enjoyed forever. Now, it is a sordid view which estimates rural beauty solely by its money value, but it is worth while to remind the owners of real estate in the country that, even if rural scenery fails to make any moving appeal to their own sense of beauty, there are other people who do prize it. No doubt the purchase of this West Mountain land, which has been idle and practically valueless, will prove a substantial pecuniary advantage to all that neighborhood. Not only will it bring visitors and consumers of home products, but it will enhance the value of all the neighboring real estate, and every landholder thereabout will be the richer because of the discovery and development of this natural beauty, and of the assurance that it is likely to be preserved.

It is encouraging to know that in many other places there is a growing tendency to purchase so-called waste lands and to hold them for the enjoyment of the people. We call to mind another region in Connecticut where the villagers are united in their interest to preserve all the rural charms of the neighborhood. Miles of highway have been purchased with no other purpose than to allow Nature to frolic in her own free way by the road-side. Forests have been bought that they might be held for public enjoyment, and the feeling of the community is strong for the preservation of all wild spots which will help to satisfy the desire for beauty and repose. The state of New Hampshire has considered it worth while to recognize officially the value of its mountain-passes and ravines, its lakes and cascades, and to provide roads and paths for the purpose of making them accessible. All this indicates that every year there are more people who find pleasure and rest in the contemplation of natural beauty, and therefore there is reason for more earnest protest against the wanton marring of that beauty.

Of course, it is not meant that the axe should be kept out of every wood-lot or that every roadside should be left to wild vines and shrubbery. There is a beauty of cultivated fields and road-borders of trimmed turf, as every one will recognize who drives, for example, through the rich farm-lands of Lancaster County, in Pennsylvania. But no community lives up to its duty or highest privilege when it fails in solicitous care for the preservation and enhancement of the natural beauty which is its heritage. The destruction of a few venerable trees may turn a delightful piece of road into a dreary one; a railroad excavation may so gash a mountain-side as to destroy an entrancing prospect, and very often communities have no redress against such inflictions. But, where an alert public sentiment has been cultivated, a community is less likely to suffer in this way, for when it is known that rural beauty is prized as a public possession no one cares to fall under popular disapprobation for defacing it.

But sometimes more than a mere protection against damage ought to be possible. If it is a worthy purpose to conserve, so far as possible, and consistent with the demands of every-day business life, the beauties of a country, the endeavor to multiply and enhance these beauties is equally commendable. There is an art which doth mend nature, and if in all the planning and planting, as well as in all the clearing and general improvement throughout the country, the effect of what is done upon the surrounding scenery is studied—that is, if every proprietor of land should take constant thought about the landscape he is helping to make—the country would steadily grow in attractiveness. If every town possessed a man of taste whose counsel was listened to, village and farm-land, forest and orchard, might gradually shape themselves into pictures upon which the eye would delight to linger. Some one has said that society will not be regenerated by the landscape-gardener; but since a love for natural beauty seems to be an original instinct of the human soul, it certainly is wise to gratify this universal longing and cherish the beauty which lies about us rather than destroy it.

AT the recent meeting of nurserymen at Minneapolis, Mr. C. L. Watrous, of Des Moines, Iowa, took occasion to state a fact which is too often neglected in estimating the adaptability of trees in different regions of the country. What is known as "hardiness" means much more than ability to withstand a certain lowness of temperature. A tree, to be valuable in any situation, must be able not only to endure the cold of its winter, but the heat of its summer, and to endure these extremes for long periods. Besides this, the dryness or dampness of the atmosphere are to be considered as well as the liability to sudden changes in the way of moisture and temperature, with many more climatic complexities. Therefore it is often found that a tree which does fairly well in one situation may perish but a few miles away, and the only safe course is for every section of the country, and no very large section at that, to make its own trials, and find by

actual experience what trees can be planted with hope of success.

The fruit-growers of Iowa began to plant orchards years ago, and their work was full of promise; but disastrous seasons came and the orchards perished. Again they planted hopefully and largely of fruits imported from eastern Europe, where the climate was said to resemble that of our north-west. But here, too, there has been much disappointment, and many persons now believe that profitable orchards in the north-west are not to be found in importations from any different climate.

Some years ago, at a pomological meeting in Boston, there was an exhibition of fruit from every state in the Union, and a member of the Pomological Society from Iowa called attention to the fact that his experience at former exhibitions had been repeated at this one, and he ventured to say that it was always safe to expect that the premium specimens of any variety of fruit would come from a region near by the place of its origin. This statement was not altogether novel, but it impressed Mr. Watrous with the belief that the true way to provide fruits suitable to the north-west was to produce them from seedlings of the native sorts which had already proved themselves adapted to the peculiarities of the north-western climate. This belief is shared by many fruit-growers, and the work of producing native seedling fruits is now carried on with persistence and system in several of the north-western states. Mr. Watrous stated that in Iowa the State Horticultural Society had appropriated $2,500 each year and established twenty experiment stations, where fruits deemed worthy of trial are put under proper tests. Besides this, skilled men are employed to cross-fertilize fruits of various kinds. During the present year many hundreds of crosses have been made upon native Crab-apple trees, some of which already bear fair-sized fruit. The pollen is usually taken from such apples as Jonathan, Grimes, Northern Spy, Baldwin and other large apples of good flavor, late-keeping qualities, and preferably a red color. In the same way pollen is taken from European varieties of the Plum and used upon our native plants. The Sand Hill Cherry from the Dakotas has been planted, and is to be crossed with the best varieties of the European Cherry. The same is done upon our native Currants.

We are not aware that systematic attempts at improving fruits and adapting them to given conditions by cross-breeding has ever been tried on so large a scale in any other part of the world. It is certainly an experiment which all pomologists will look upon with interest. If we can ascertain some of the laws which govern the transmission of the specific qualities of given seed-parents, this would be a marked advance in the science and art of horticulture.

The idea of self-denial for the sake of posterity, of practicing present economy for the sake of debtors yet unborn, of planting forests that our descendants may live under their shade, or of raising cities for future nations to inhabit, never, I suppose, efficiently takes place among publicly recognized motives of exertion. Yet these are not less our duties; nor is our part fitly sustained upon the earth, unless the range of our intended and deliberate usefulness includes, not only the companions but the successors of our pilgrimage. God has lent us the earth for our life; it is a great entail. It belongs as much to those who are to come after us, and whose names are already written in the book of creation, as to us; and we have no right, by anything that we do or neglect, to involve them in unnecessary penalties, or deprive them of benefits which it was in our power to bequeath. And this the more, because it is one of the appointed conditions of the labor of men that, in proportion to the time between the seed-sowing and the harvest, is the fullness of the fruit; and that generally, therefore, the farther off we place our aim, and the less we desire to be ourselves the witnesses of what we have labored for, the more wide and rich will be the measure of our success. Men cannot benefit those that are with them as they can benefit those who come after them; and of all the pulpits from which human voice is ever sent forth, there is none from which it reaches so far as from the grave.—*John Ruskin, The Seven Lamps of Architecture.*

Bronx Park.

FEW people of New York know that within their city limits lies one of the most picturesque spots to be found this side the Adirondacks. Bronx Park is situated beyond the Harlem River, between Williamsbridge and West Farms, in Westchester County, and is about twenty minutes distant from the Grand Central Station. It consists of a strip some two miles long and half a mile wide, mostly wooded, on both banks of the little Bronx River. Altogether it comprises between 600 and 700 acres. In some places the river is a narrow stony brook, and in others widens out into placid sheets of water, surrounded with grassy knolls, shaded by tall, handsome trees. Very peaceful is the scenery, and the visitor finds no suggestion of a neighboring city beyond an occasional glimpse of a gray-coated park watchman and the shrill echoes of frequent steam-whistles.

The park is a portion of the outlying district annexed to New York in 1873, and, beyond taking down most of the old buildings scattered through the tract, nothing has been done toward improving or laying it out. Two or three highways cross it and a few pathways wind along the stream; the rest is left to the care of nature.

The native trees of this region are well represented through the park—Elms, Maples, Beeches, Birches and Chestnuts abound, five or six species of Oak, and, what is most surprising, quite a large grove of sturdy, healthy Hemlocks. Perhaps there are none of very great age, but many are good-sized trees, and what is most encouraging for the future, is the abundance of young ones. The Hemlock grove is the most picturesque part of the park, for there the Bronx winds through a narrow ravine, on the steep rocky sides of which the geologist will invariably point out some astonishing pot-holes. The botanist will not find himself alone in studying the banks of the Bronx; the artist will see many scenes worthy of his pencil, and even the archæologist will find there happy hunting-grounds, for an Indian grave-yard is close at hand.

In the beginning of May the fields and swamps were bright with spring blossoms. Violets were everywhere, white ones and blue ones, the latter going into astonishing vagaries as to color. On the marshy ground the common Blue Violet (*Viola cucullata*) was lilac with a slightly darker spot on the lateral petals; in the woods it was a nearly uniform blue-purple, and on the dry river-banks it was a deep red-purple, very large and handsome. Delicate little lance-leaved Violets (*V. lanceolata*) grow on the edge of the Hemlock-woods with dainty Wind Flowers, which we are now to call *Anemone quinquefolia!* Graceful Uvularias and the sturdy Jack-in-the-Pulpit, the green and the purple-striped form, growing side by side along the marsh and all through the woods, while higher up, in a secluded spot, the bright-green Indian Poke (*Veratrum viride*) is occasionally seen.

On the border of the marsh at Williamsbridge a row of Pin Oaks (*Quercus palustris*), covered with golden-brown tassels, presented a beautiful appearance. The lower branches of the trees almost touched the ground, and, at the water's edge, Sagittarias and their kin were just emerging from their winter sleep.

The pretty little lilac-flowered *Aphyllon uniflorum* was in bloom under the Hemlocks, and along the sandy stretches near the old Lorillard snuff works the curious wild Ginger (*Asarum Canadense*) covered the ground with its blue-green leaves. Witch Hazel grows along the mill-race of the old factory, and the graceful drooping clusters of the Bladder Nut (*Staphylea trifolia*) were reflected in a big pool overshadowed by lofty Hemlocks. The most striking bit of bloom was on the rocky bank near the Fordham road, where rose-colored Pinxter-flowers (*Rhododendron nudiflorum*), Black Haw (*Viburnum prunifolium*) and high, straggling Dogwoods were flowering. The Azalea was abundant and very luxuriant. Among the stones all about it was the pretty Columbine (*Aquilegia Canadensis*) and the wild Pink (*Silene Pennsylvanica*). Of Laurel there were only a few stunted shrubs, which bear the marks of very rough handling.

In 1639 one Jonas Bronck, a Swede, with his wife Antonia, a Dutchwoman, their servants and cattle, sailed from Amsterdam in the "Fire of Troy," and, on his arrival here, "purchased from the Indian sachem, Tackamack, and his associates the large tract of land called by them *Ranachqua*, lying between the Great Kill and the River *Ah-qua-hung*, now the Bronx . . . and since included in the Manor of Morrisania."* There "Seignior Bronck," as he was styled, built a stone house, tobacco-house, etc., and there died in 1643. After his death his estate passed through several hands till, in 1668, one

* "Harlem: Its Origin and Early Annals," by James Riker. New York, 1881.

Samuel Edsall conveyed it to "Colonel Lewis Morris, of the Island of Barbadoes, Merchant." At the death of the latter, in 1691, the whole estate, embracing 1920 acres, fell to his nephew, Lewis Morris, and was, in 1697, erected into the Manor of Morrisania.

Less than a century later, in September, 1776, General Washington established his headquarters, first at the country-seat of Roger Morris, and then at White Plains, his army being entrenched along the Bronx. It was on Chatterton's Hill, writes Washington Irving, that, by his skill displayed in the construction of earth-works, Alexander Hamilton, then a young captain of artillery, first attracted General Washington's notice. Of the battles of those days, along the Bronx, only tradition remains, and as the city extends the old landmarks quickly vanish. Even their names are forgotten in our fashion of neglecting points of historic interest in the nomenclature of city streets and squares.

Bronx Park has been selected as the site of the Botanic Garden which it is hoped the city will one day possess, and a more appropriate site could hardly be imagined. The river furnishes abundant water, and the varied soil and surface offers a rare opportunity for a fair piece of landscape-work.

The accompanying view on Bronx River is from a photograph taken by Mr. Charles G. Wood, junior, at a point below the Hemlock Grove.

New York. *Anna Murray Vail.*

How We Renewed an Old Place.

XII.—TERRACES AND SHRUBS.

THOUGH we have no especial preference for terraces, which used to form a feature of many old-fashioned homes, the conditions of our house-lot have forced them upon us on three sides. As I have before stated, the flat top of the knoll is very limited in extent, so that, even in building, we were forced to cut our coat according to our cloth, and support the rear of the house with a high basement to serve for laundry, dairy, and other offices, instead of adding the more usual L, or wing.

The width of the lot at this point would not allow of more than ninety feet between us and the highway, even by setting the building as far back as possible, and, when this was done, leaving a gentle slope from the front door to the road, the ground on the north and south sides of the house fell with such abruptness from the foundations that no room was left even for a passage-way.

This lack was remedied on the north of the house by constructing a terrace sufficiently wide on top for a tree or two, and some shrubbery to mask the foundations, with plenty of space for climbing things to grow over the veranda. This bank, supported on the east by the heavy wing-wall of the house, slopes to a driveway below, which leads to the stable behind. It is high and steep, but well sodded, and rather adds to the commanding effect of the house, besides serving to break the height of the building at the back. A flight of steps at the rear of the veranda leads to the drive below, and some good-sized Pines have been planted there to still further hide the basement.

The main approach was not planned with sufficient consideration for anything but convenience, and consists of a semi-circular driveway to make the house easily accessible from both ends of the town, but it is our plan to alter it before long, so that the front door will only be accessible from the north to carriages, which will give us an unbroken stretch of grass on the east and south, whereas now there is a half-moon of greensward in front, enclosed between the driveway and the street, thickly planted with trees destined soon to form an effectual screen between us and the dusty road.

South of the house, near the highway, the ground slopes gently into the swale, which, with its groups of trees, forms a side lawn of uneven surface, bounded at the rear by the hill, with its rising tiers of little Pines. Near the dwelling, however, in order to get any greensward or shade at all, we were forced to construct, of stones and gravel, a terrace some twenty-five feet in width at its narrowest part, to support which about two hundred feet or more of massive wall were constructed. This wall is low in front, and buries itself in the grassy slope, but where it curves around the knoll at the rear, it is six feet high, and makes a warm background for Grape-vines, and the hot-beds, which are placed below the vines, fronting the south. A steep bank, thickly sodded, descends from the level of the lawn to the top of the wall, which is also covered with turf. This sunny south terrace is the very spot for the old-fashioned Rose-bushes which we have transplanted hither from the other parts of the place, and here, too, is a bed for more delicate specimens, which can be protected by a glass frame in the winter-time, as well as a tree to shade the south windows from the heat.

The wall was quite an important construction, and I am afraid to say how many tons of stone went into it, for the largest portion of it is underground, the results being very solid and substantial.

Behind the house, on the basement-level, is still another curved terrace, from which a grassy cart-path leads down to the swale and the hot-beds, and here the various walls are utilized to protect rows of Currant-bushes above, and Raspberry-bushes below, which are easy of access from the kitchen-door.

To cover all this expanse of gravel foundation required untold quantities of loam, so much, indeed, that we thought ourselves fortunate if we could allow an average of four inches over the whole surface of the lawn, but this meagre allowance seems to afford sufficient hold for the grass-roots, and heavy annual dressings of compost add continually to its depth. It is rather a curious study to watch the formation of soil, and the gradual way in which the sand below is transformed by the roots—first into yellow, and then into black loam. How long, we wonder, will it take before a foot of soil is obtained over a surface treated as this lawn is treated, the fine grass dropped from the lawn-mower being left upon it without raking, and the drainage from the heavily enriched trees always helping it along, in addition to its own annual dressings?

The shrubs on the knoll, at first scattered about rather promiscuously, as they increase in size we are struggling to group properly, according to the lights thrown upon this subject by Garden and Forest, but the articles we have so carefully studied on this topic presuppose a great number of bushes of one kind to begin with, and where you have perhaps three Golden Spiræas, and a half-dozen Lilac-bushes, and a hardy Hydrangea or two, and a few Deutzias, and Weigelias, and other heterogeneous things in variety, the question is to set them so that they will produce the effect of twenty-five of each. We have managed it so that really the shrubbery appears rather crowded, but it has been done in a manner to horrify the authorities.

We have treated our landscape very much as a painter would his canvas. We dab in a shrub where we think it will produce the effect of half a dozen, and if, after a few months, the picture seems to require its removal, out it is scratched and dabbed into another spot, and thus, in true amateur fashion, we feel our way toward a final result, for we find things never look when they are little as they do when they are fairly grown, —the usual experience of amateur gardeners.

The best that can be said for this method is, that the results are unconventional. I have discovered that a landscape-gardener gets a style, a mannerism, like a poet or a draftsman, and that, after some experience, you can detect the professional manufacturer of a garden by the receipts on which he works. Twenty-five Spiræas here, twenty Deutzias there, Viburnums one dozen, Lilacs in variety, Forsythias eight, a bushel or two of golden Evergreens mixed with Juniper and Arbor-vitæ, at such a point, a hedge here, curves on this side, straight lines on that, etc., etc.—it is all reduced to a system, and the results, if repeated in the same town, are monotonous.

We are bound, having gone in for it, to defend the natural method. If the results of the artificial are more satisfactory, the execution is not half the fun.

Can there be, I ask you, the same enjoyment in sitting down to watch the growth of a border of shrubs that somebody has set out for you, that there is in dragging the few you have planted yourself, out of their holes and transporting them to a more becoming place, as you would a flower on a bonnet?

Anybody can put in a tree or a shrub and let it alone, but it takes nerve to wheel it about like a baby in a go-cart.

We have neighbors who employ the conventional methods with dazzling results, but, on the whole, we doubt if their vast and imposing plantations give them as much enjoyment as our more personal intercourse with our little family of growing things. We are quite sure that each scrubby little Pine on the hill is dearer to us than a thicket of well-fed trees planted by a nurseryman.

"You will know my children," said the Owl to the Fox, with whom she had made a compact to spare them, "by their being the most beautiful little darlings in the whole world." But when the Fox came to the nest full of big-eyed, long-billed, unfledged frights, he failed to recognize the description, and ate them all up under a misapprehension. *De nobis fabula.*

We are afraid that most people would pronounce in favor of the upholstering of the professional, rather than of our private efforts at lawn-furnishing, but we can recommend our

method on the ground of economy, both of material and of amusement, for there is no reason why this play should not go on forever, like a Wagner opera. It has its surprises too, in the way of some happy effect that you had not imagined, and again, you are horrified at the outcome of some arrangement that seemed felicitous. We have got our own shrubs so beautifully trained now, that they do not mind moving on the first of May, any more than an old New York citizen. Up they come, blossoms and all, and never drop a petal, but go on blooming serenely in their new home as if they had always been there. This spring we had a present from a kind friend of a box of rare and beautiful little shrubs, the very names of which it took a day to look up. We knew they were coming, but not what they were to be, so a bed was prepared for them within easy reach of the hose, and, when they came, they were set out carefully, in the midst of an April snow-storm, and a cold wind, which nipped their poor little half-opened leaves most cruelly.

After they were all arranged, and the weather had moderated sufficiently for one to study the labels, we found that the arrangement would have driven a gardener wild, future trees, a hundred feet high, having been set side by side with burly little shrubs, which at present look much more important than their (to be) stately neighbors. What with snow one day, and burning heat the next, combined with steady dry weather, those shrubs have had a struggle for existence, in which they have been sturdily abetted by their natural protectors. The hose one minute, and newspapers and branches of trees the next, have been called upon to supply the deficiencies of Nature, who has been more than ever capricious during this extraordinary season, and if at the end of the summer they are all well and firmly established, it will prove what care will do to defy the inclemencies of the season. After a year or two they will have acquired the customs of the place sufficiently to be moved where they will make the best show, but before they reach their final resting-place it is possible that they may have several halts by the way. With a ball of earth attached to the roots, traveling does not seem to hurt them much, though no doubt it retards their growth somewhat, which is all the better if they are to be kept in proper proportion to the place, which is not adapted to anything very gigantic.

Of one thing I have become certain in this limited experience of landscape-gardening, and that is, that the pleasure is in the doing, in the vision of the mind, in the ever-expanding hope for the future. When the trees have grown too large to move, and the shrubs are irrevocably rooted, we shall surely be no happier than now, when they are viewed in a halo of imagination.

Hingham, Mass. *M. C. Robbins.*

The Weeds of California—I.

IT might be unnecessary to begin a treatise on Weeds with a definition of the meaning of the word were it not that usage attaches to it two really distinct ideas, having in common only that of a hardy plant that is of no particular use. A weed in one sense bears the reproach of being a persistent invader of the husbandman's realm, difficult to repel; while in another it means simply a hardy plant thriving under difficulties which discourage more useful growths, and therefore obtruding its presence on road-sides and other waste places. It will hardly do to go so far as to attach the opprobrious term to any plant that habitually appears in a place where it is not wanted, despite the analogy of the "dirt" on the goldsmith's apron and the "pay dirt" of the placer miner.

It has not uncommonly been noted, as a matter of surprise, that the troublesome weeds of any country are rarely aborigines thereof. In reality this is probably but one of the phases of the survival of the fittest under natural conditions; for neither road-sides and waste places on the one hand, nor cultivated ground on the other, can be classed among such conditions. In order to become a weed a plant must be placed under unnaturally favorable conditions, unlike those which have naturally concurred toward the secular co-adaptation of plants, soils and climates. We see the converse process in the complete disappearance of native plants that have formed the predominant growth, as, for example, that of the Buffalo Grass (Buchlöë) from the plains of Nebraska and Colorado, not as the result of displacement, but of unsuitable conditions; while the Thistle on the Pampas, and the Guava on the Hawaiian group, are examples of almost complete displacement of native growth by foreign invaders. In California the progress of the invasion by some of the most common weeds can be currently traced as yet in the more remote regions; and the influence of climate in modifying the "weed nature" of a number of well-known plants forms an interesting study.

The broad fact in the premises that first strikes the newcomer in California is that a number of plants that are the subjects of careful culture east of the Rocky Mountains, as well as in Europe, and which quickly succumb when deprived of artificial protection there, are here found among the most persistent and obnoxious weeds; while very many of those that are specially abundant and troublesome in the Atlantic region are conspicuously absent on the Pacific side. Foremost among the former class are the two "Mustards," *Brasica Rapa* and *B. nigra*, respectively known as White Mustard (or Wild Turnip) and Black Mustard; and next to these the common Radish (*Raphanus sativus*, not *R. Raphanistrum* of the European fields). The first-named is most abundant on the borders of the Bay of San Francisco, and occupies not only abandoned fields, but disputes the ground with the cereals to such an extent that it is often difficult to believe that it has not been planted on purpose; and were rapeseed oil as much sought after as of yore California could doubtless lead the world in growing the plant which yields it. The Black Mustard is of more extended prevalence, and both in the coast region and in the great valley takes possession of neglected fields to the exclusion of everything else, growing so tall in rich soils as to hide horse and rider, and forming impenetrable thickets that, like the Thistle of the Pampas, serve as a place of refuge for wild animals. In the Santa Barbara region such Mustard patches are often cut for their seed, which is extremely pungent; but the crop often fails in consequence of the overwhelming attacks of an aphide upon the peduncles and forming pods. Apart from this latter drawback, California could probably also defy competition in Mustard-culture.

The Radish is not quite so overwhelming in its attacks upon cultivated ground; but large patches of its rose-colored flowers often contrast very prettily with the prevailing yellow of the two Brassicas; and the extirpation of its roots, equally tenacious in texture and life, and enduring several years, is no small problem in badly infested fields. Its habit would seem to indicate its derivation from some one of the long varieties of the cultivated plant.

Of cruciferous weeds the Hedge Mustard (*Erysimum officinale*) is somewhat troublesome at times, and the Shepherd's Purse is well acclimated, but hardly obnoxious. Of native crucifers the only one that maintains its place among cultivated crops with some tenacity is the *Tropidocarpum gracile*, which finds improved conditions of existence in the irrigated districts of the upper San Joaquin Valley. Of other cultivated plants that maintain themselves by road-sides and elsewhere in the open country in suitable ground the Celery, Carrot and Fennel are conspicuous. The tall and dense bushes formed by the last-named plant, even on well-trodden road-sides, recall the mention of Fennel-thickets, dreaded as the lurking-places of wild beasts, by travelers in the coast region of Asia Minor. The Fullers Teasel, likewise, has escaped from cultivation, and forms a serious pest in some places.

Of weeds conspicuous on the Atlantic side and almost unknown as such in California, the entire series of Polygonums is perhaps the most striking example, excepting only *P. aviculare*, which is probably more troublesome here than anywhere else, the rainless summers being nowise against its full enjoyment of life, and, in the prevailing absence of summer cultivation, enabling it to develop into gigantic wheel-shaped specimens, as much superior in size to their eastern brethren as are the proverbial California pumpkins. It is, however, a more or less acceptable pasture-plant for cattle during the dry season. By ditches and in meadows a few scattering plants of *Polygonum lapathifolium*, *P. Pennsylvanicum* and a few others are occasionally seen; but they do not maintain themselves and do not spread into the cultivated fields.

Of their near relatives, the Docks, however, there are several that count among the more troublesome invaders. While *Rumex sanguineus* and *R. obtusifolius* are hardly more often seen than are the Polygonums, three others—*R. crispus*, *R. pulcher* and *R. Acetosella*—are common and extremely tenacious of life, sprouting up from their roots, cut by the last cultivation in May, at any time during the dry season, and seeding quickly and abundantly.

Of Amaranths it may in general be said that they flourish in the fields of California as well, or even better, than on the Atlantic side, although somewhat changed in habit. *A. retroflexus*, as troublesome in California vineyards as among the Corn and Potatoes of the prairie states, forms here mostly a flat, wheel-shaped mass, from which the ground-squirrel, stooping down, gathers its winter hoard. *A. albus* maintains very nearly its eastern aspect.

Of Chenopodiums, *C. album* and *C. Bonus-Henricus* are almost, if not quite, as familiar as in the east and in

Europe; *C. vulvaria* likewise is found, but less generally diffused.

Portulaca oleracea, so common and troublesome in eastern and European gardens and fields, has appeared in a few localities, but, although doing well, has made no headway as a troublesome weed. The altered aspect of its fleshy leaves, which become much reduced in size, and almost terete, under conditions of extreme drouth, so that the thick red stems resemble a group of stout, radially disposed worms, suggests a marked adaptation to environments.

The native *Claytonia perfoliata*, although somewhat persistent among the grass in moister ground in spring, hardly maintains itself against regular cultivation, but its pretty relative, the *Calandrinia Menziesii*, does not give up so readily, and may be seen covering the ground in orchards and vineyards in the coast region, forming a beautiful carpet of purple that attracts attention from afar. Its vegetative duration is too short, and its root system too light, to render it troublesome, but the multitude of its shining black seeds render it difficult of extirpation.

University of California. *E. W. Hilgard.*

New or Little-known Plants.

Arbutus Arizonica.

THE Arizona Arbutus has long been a puzzle to the botanists, not many in number, who have seen it growing. Dried specimens, as they appear in herbaria, do not afford characters, except in their narrow leaves, by which to distinguish them readily. Indeed, except in the form of their leaves, several of the American species, in all of which the flowers and fruit are very similar, are not easy to separate in herbaria. The resemblance between the three species which are found in the territory of the United States is so great that Professor Gray at one time considered the Texas tree a mere form of the Pacific coast *A. Menziesii*, from which he did not distinguish our Arizona plant at all ("Syn. Fl. N. A.," ii., i., 27). Afterward he considered the Texas tree to be a variety of the Mexican *A. Xalapensis*, which he called var. *Texana*, and the Arizona tree another form, calling it var. *Arizonica* ("Syn. Fl. N. A.," ed. 2, ii., i., Suppl., 396). The Texas tree, which I have seen growing in several places in western Texas, including Buckley's original station, does not, however, appear distinct in any way from *A. Xalapensis*, as I understand that species after having seen it growing on the mountains near Monterey in Mexico, and in the series of specimens preserved in the herbarium of the Royal Gardens at Kew. As I know it, it is a low, wide-branching tree, with a stout trunk separating near the ground into a number of large, upright-growing stems. Near the ground only the trunk is covered with thick dark brown or nearly black deeply-furrowed bark, the surface of the ridges separating gradually into thin scales. The remainder of the trunk and the branches are covered with the thin, smooth, bright red bark peculiar to all the plants of the genus. The leaves are oval or ovate or rarely lanceolate-oblong, two or three inches long, rather thick and coriaceous, dark green above and sometimes pale on the lower surface. The ovary is pubescent.

The Arizona tree differs from the other species of the genus, as I know them, in the mature bark which covers the trunk and the lower parts of the principal branches, and which is as white as that of our White Oak and deeply furrowed, the ridges being broken by cross-fissures into thick square plates. The leaves are paler and much narrower than those of the Texas tree, although much reliance cannot be placed on the shape of the leaves of Arbutus, as they vary strikingly on the same plant, and even on the same branch. The character of the bark, which was the same on all the trees seen by Dr. Engelmann and myself on the Santa Rita Mountains, and the habit of the tree, which is that of a small Oak, appear sufficient, however, to distinguish this species which, if my views upon it are correct, will have to be called *Arbutus Arizonica*. It is apparently confined to the mountain ranges of southern Arizona; at least, Mr. Pringle has found nothing like it in northern Mexico, although he has been on the lookout there now for several years for all forms of Arbutus.

Arbutus Arizonica (see Fig. 54) is a tree forty or fifty feet in height, with a tall trunk eighteen inches to two feet in diameter, covered with white bark, stout spreading branches forming a rather compact round head, and stout tortuous red branchlets. The leaves are pale, lanceolate, or rarely oblong, two to three inches long and a third to nearly an inch broad, with entire or minutely denticulate margins, and are rounded or gradually contracted at the base into slender-grooved petioles sometimes an inch long. These, like the young shoots, are slightly puberulous when they first appear. The inflorescence is two and a half to three inches long, tomentose, with conspicuous scarious bracts. The flowers are rather smaller than those of *A. Xalapensis*, but otherwise not distinguishable from those of that species, except in their pubescent ovary. The fruit ripens in October, and is a quarter of an inch broad.

Arbutus Arizonica is found on dry gravelly benches and ridges between six thousand and eight thousand feet over the level of the sea, growing with *Quercus grisea*, *Q. Emoryi*, *Q. chrysolepis* and *Pinus ponderosa*, just above the region of *Pinus Chihuahuana* and below that occupied by *Pinus Arizonica*. It appears to have been first noticed by the late Dr. Thurber at the time of the Mexican Boundary Survey. Much later it was collected by Rothrock, Lemmon, Sargent and Engelmann, who first called attention to the character of the bark, Pringle, and Mayr. It grows in a region which is almost unsurpassed on this continent in the variety and interest of the trees which compose its forests—a region which will well repay more detailed study at the hands of botanists than it has yet received.

Cultural Department.

Stray Notes from the Arnold Arboretum.—III.

SOMETHING was said in the last issue of these notes of the horticultural value of the two arborescent Cornels of eastern America, and now there is something to say in the same connection of some of the shrubby species, among which are to be found at least three or four excellent garden-plants, and possibly more, but nothing is known yet of the behavior of the California species in cultivation.

By far the most beautiful of our shrubby Cornels is *Cornus circinata*. This is a plant of northern woods, in which it grows in rich and in sandy soil or on rocky banks and hill-sides from Nova Scotia to Dakota, and through the hilly and higher parts of the northern states and along the mountains to Virginia. It is not a large plant, and produces rather rigid erect stems rarely reaching the height of ten feet and covered with smooth dotted bark, which is at first pale green and later becomes light brown or purple. The leaves are perhaps the most beautiful thing about this plant; they are large for the leaves of a Cornel—four or five inches long and three inches or more broad—elliptical and long-pointed. The color of the upper surface is yellow-green, while below they are bluish white or steel colored and covered with short soft hairs. The coloring of the leaves of few shrubs is more striking and beautiful. The flowers appear rather early among those of the Cornels and at the very beginning of June; they are produced in rather small, flat cymes, like the flowers of most of our species, and are small and yellowish white. The fruit is more beautiful than the flowers. It is spherical, as large as a pea, bright blue, and very conspicuous for the size of the clusters. It ripens early in the summer. This has always been a favorite plant in the Arboretum, and has been used in considerable numbers through the shrubberies and along the drives. A few years ago it was only the botanists who knew or cared anything about our Cornels and many other native shrubs, but now landscape-gardeners and nurserymen are beginning to find out their value, and Cornels and Viburnums appear in this vicinity not only in public gardens and parks but in small villa gardens as well—a hopeful thing, perhaps, as indicating that garden fashions in this country are working out of the old ruts and that the popular knowledge and appreciation of plants is broadening.

Ten years ago, in this neighborhood at least, the list of shrubs one found in the majority of villa gardens, was a very

short one indeed, all the horticultural efforts of such establishments being devoted to securing during a couple of months in summer a glaring display of tender bedding plants. Now many of these gardens contain large collections of shrubs often tastefully grouped and arranged, while the use of hardy perennials has also increased. It is interesting to trace the influence of the Arboretum in this increase in the popular knowledge of hardy plants and to find that some of the most popular shrubs in the gardens of the northern states were first raised and cultivated in this country by Mr. Dawson a very few years ago.

surface; they are yellow-green above and pale on the lower surface. The flowers make their appearance late in May or in the early days of June, and are produced in rather small, flat and few-flowered clusters. The fruit, which grows rapidly, ripens in July, and is white or lead color, but not very showy or handsome, as the color is dull, and only a few fruits ripen in the clusters. The color of the branches in winter is the most ornamental thing about this shrub. They are bright red purple, especially the portion produced during the previous summer, and make this plant a conspicuous and interesting object. At the season of the year it is stripped of its foliage, and

Fig. 54.—Arbutus Arizonica.—See page 317.

But the remembrance that the Cornels, like so many other native shrubs, were first cultivated in the Arboretum on a large scale has carried us too far away from the consideration of the individual value of the species. Another of the early-flowering Cornels is the so-called Red Osier Dogwood, *Cornus stolonifera*, so named on account of its habit of spreading and multiplying freely by prostrate or subterraneous shoots. By these, if the plant happens to find itself in the deep, rich, wet soil it delights in, it soon forms great broad clusters of graceful branches, six or eight feet tall. The leaves are lanceolate or ovate, and vary considerably in size and shape on different plants, and in the amount of pubescence which clothes their

interest and variety in the composition of gardens and shrubberies is often lacking, a plant of this Cornel lights up a whole shrubbery, and makes, when seen against a background of snow, a bright spot upon which the eye delights to rest. No other plant is so well suited to produce this sort of effect, with the exception of an Old World Cornel, closely related to *C. stolonifera*, which shall be mentioned a little later, when we come to speak of the foreign species. *C. stolonifera* is a northern plant, and loves a cold climate and moist soil. It grows in the east, from New Brunswick as far south as the Potomac, and extends along the shores of the Great Lakes far into British America and

ranges southward, on high mountains, to Arizona and New Mexico.

The panicled Cornel is another species which has been planted in the Arboretum in large numbers and with good effect. This, in most works on botany, appears as *C. paniculata*, but Humphrey Marshall's name, *candidissima*, is older, and has been adopted by Professor Coulter in his recent monograph of our Cornels, and it is by this name that the panicled Cornel should be known. It is a good name, as botanical names go, for the flowers, although they are certainly not pure white, are whiter than those of the most of the species. The clusters are loose and convex and often panicled, and are produced in the greatest profusion along the branches, making this the most beautiful of our shrubbery Cornels at the time when it is in flower. The flowers open here about the middle of June, and, late in the summer, are followed by rather showy clusters of white fruit. *C. candidissima* is sometimes almost tree-like in habit and in the height to which it grows. The branches are erect, slender, very numerous, and sometimes nearly twenty feet tall, and are covered with smooth, gray bark and abundantly supplied with narrow, not very large, pointed pale leaves, sometimes green on the two surfaces and sometimes pale below. This plant grows on the banks of streams and in moist situations, where it often forms extensive thickets; it is one of the most common and widely distributed of all our Cornels, being found from Nova Scotia and Florida to Minnesota and Texas. It abounds in the south, where it replaces *C. stolonifera*, and, in some parts of the country, is one of the most common and conspicuous roadside plants where roads cross streams or low wet places. It will thrive, however, in any good garden-soil, and adapts itself to new conditions to which plants in the gardens often have to submit.

The Silky Cornell (*C. sericea*) is the last of our species which has been grown in the Arboretum in large numbers. This is a variable plant in general appearance and in the size and coloring of its leaves, and it is not at all improbable that two or more distinct species can be made out from what has been usually considered *C. sericea*. This plant has the merit of flowering at the very end of June and in the early days of July, that is when most shrubs have passed their time of blooming, and the best effects in the shrubberies at the Arboretum at this time are produced by the great masses of this Cornell, which have been used along the drive-ways. The flower-clusters are not large, and the flowers are yellow rather than white; they are produced, however, in the greatest profusion, while the habit of the plant is excellent with its long graceful branches, which, when it is given sufficient room in which to grow, spread out over the ground and form great masses of foliage fifteen feet or more across. The foliage is almost orange-colored in some forms and pale in others, and the leaves, like the slender, graceful purple branchlets, are covered with soft silky hairs. *C. sericea* likes moist soil, and shows its greatest beauty when planted in such a position that it can hang its long graceful branches over a brook or decorate the margins of a pool. It flourishes, too, if it happens to be planted in dry soil, although, unless the conditions favor it, it will not show its greatest beauty.

C. asperifolia, another native species peculiar to the central and southern parts of the country, is grown in the Arboretum, but not in large numbers, and enough is not known about this plant in cultivation to make it desirable to say much about it as a garden-plant. It is a tall, erect-growing and rather distinct-looking shrub, with reddish brown branchlets, narrow leaves, small flowers and showy white fruit produced in red-stemmed clusters. It is a hardy plant, but not distinct enough to be very valuable probably in the garden, except as a curiosity, or worth planting on a large scale if the other and better-known species can be obtained.

These notes have reached the limit the editor has set for their length, and the consideration of some exotic Cornels must be postponed for another issue of the series.

Arnold Arboretum. *P. C.*

Notes from the Harvard Botanic Garden.

Anemone sylvestris.—The "Wood Anemone," or "Snowdrop Windflower" (the latter name given on account of the drooping habit of the flower-buds and flowers), is one of the most useful and beautiful of the spring-flowering Anemones. It is a native of continental Europe, and has long been cultivated in British gardens. The shining green, ternate leaves are borne on slender petioles, which proceed from the root and are from five to seven inches in length. The divisions of the leaves are cleft and serrate. The pure white flowers, one and a half inches across, with broadly elliptical petals slightly incurved, and a cushion of greenish white pistils encircled by a showy band of bright yellow stamens, are borne singly at the top of a slender, but erect, stem, which often exceeds a foot in height. The leaves of the involucre are borne on stout stems from one to two inches in length, and, although smaller, they bear a strong resemblance to the root-leaves. The plant blooms very freely in May and June, and the flowers are effective, and, for Anemones, last well when cut. It is an excellent plant for the herbaceous border, but is seen to the greatest advantage when planted in clumps on the outskirts of shrubberies or naturalized in irregular patches in shady groves or "wilderness gardens." It will grow in any ordinary soil, but does best in rich loam. The roots are easily divided in autumn, and the plant can be propagated in this way. Seeds ripen freely in this climate, and they are ready for gathering about the latter part of June or early in July, and may be sown immediately with advantage.

Clematis recta.—Among hardy plants, this herbaceous species ranks with the best for garden decoration. It is native in various districts of south Europe, and was first introduced to English gardens from Austria in 1597. A variety peculiar to Spain, *C. recta*, var. *Hispanica*, differs but little from the type, and was introduced in 1800. The species is a plant from four to five feet high, forming a compact mass of growth, the stems terminating with a large, much-branched cluster of small creamy-white flowers, fragrant and packed together in close order. Large, established plants are very effective at the back of an herbaceous border among such things as the Oriental Poppy, *Thermopsis Caroliniana*, *Baptisia tinctoria*, the tall-growing Delphiniums and *Achillea filipendula*, var. *filicifolia*, throughout the month of June. *C. recta* seems to thrive better and flower more freely in a soil of medium fertility. It will live in partially shaded situations, but the most luxuriant plants are found in full sunshine. Old plants should not be disturbed so long as they remain in a healthy condition; and while propagation may be effected by dividing them, it will be found more satisfactory, if a trifle slower, to increase the stock by seed, which is borne abundantly.

Corydalis nobilis.—This is a charming plant for shady positions in the rock-garden and mixed border. The erect, angular stems grow to a height of twelve or eighteen inches, and are furnished with glaucous, bipinnate leaves, which have a very elegant appearance. The flowers are clustered in a dense terminal raceme, and an acute green bract appears at the base of each pedicel. The two outer petals gape, and are of a showy yellow color at the tip, while the other two are smaller, tipped deep brown, and united so as to form a covering for the reproductive organs. The petals terminate at the base with a hollow spur of greenish white. It is to this spur that the generic name refers. The plant is a member of the Fumitory family, and Corydalis is derived from the Greek name for the lark. The spur of the flower, it was imagined, bore some resemblance to that of the lark. This plant flowers profusely in May, and it delights in a free rich loam. When planting in the rock-garden avoid dry positions; they are dangerous, and not infrequently the cause of death. *C. nobilis* is a native of Siberia, and was introduced by a Mr. John Græfer in 1783. Propagated chiefly by division, but it may also be readily increased from seeds when they are obtainable.

Heuchera sanguinea.—A little tuft of this "Alum Root," which was risked to all the rigors of the late winter, is now in full bloom. This fact, taken with the notes of other cultivators in various parts of the north-east, proves that this excellent plant is, beyond all doubt, hardy as far north as Boston at least. Few plants of recent introduction have attracted such wide-spread attention, and the number of those as well worthy of cultivation is still smaller. It was introduced from Mexico about ten years ago, and the exertions of propagators were rewarded by rapid distribution in Europe. The demand for the plant is still strong across the ocean, and it now finds a ready sale in this country. The uncertainty as to its hardiness was the principal cause of the neglect which it has hitherto suffered from American growers of hardy plants, but it is likely to receive ample attention in future. The plant forms a close mass of pale green lobed leaves, the entire cluster of foliage being about eight or nine inches high. The erect, loose panicles of bright salmon-red flowers attain a height of from eighteen to twenty-four inches, and are produced in large quantity. When in bloom, in established masses, the plant is a never-failing source of gratification. There are, at the present time, many more striking hardy plants in bloom, but certainly none more pleasing. This Heuchera thrives best in a

light and moderately rich soil. The best situation is one where the roots will be moderately dry in winter, and which affords moisture and partial shade in summer. Propagate by dividing the plants early in the season before growth commences.

Ranunculus aconitifolius.—This is a native of Europe, and was introduced in 1596. It is a hardy herbaceous perennial, from twelve to eighteen inches high, and of profuse branching habit. The flowers are small, white and single, but they appear in great abundance. It is seldom found in gardens, but the variety known as *R. aconitifolius flore pleno* is a popular plant. This was introduced about the same time as the species, according to Loudon, but Gerard informs us that it was not known to be wild anywhere in his time. At all events, it has long been a favorite among hardy border plants, and is invariably met with in those rare old-fashioned gardens kept by really old-fashioned people in parts of England and Ireland. They would hardly know it by such a name as *R. aconitifolius*, however, being satisfied with such simple names as "Bachelors' Buttons" and "Fair Maids of France."

Fig. 55.—A View in Bronx Park, New York.—See page 314.

Masses, about a yard across, intermixed with similar masses of other plants, are more effective than those of larger dimensions. Occasional clumps on the verge of a shrubbery have a pleasing effect, and the flowers are among the best that can be used for cutting.

Cambridge, Mass. *M. Barker.*

Carnivorous Plants.

Cephalotus follicularis.—This new Holland Pitcher-plant, though by no means new, is infrequently seen. It is perhaps the oddest member of the Saxifrage family, because it produces leaves of two very different forms on the same plant, some being simply elliptical and flat, while the others consist of tiny pitchers very similar in shape to those borne by some of the Nepenthes. The pitcher-leaves are usually from one to two inches in length and are produced on short stout stems, the color, which varies widely in different plants, being green, much marked and shaded with brownish red or chocolate. The total height of the leaves is seldom more than three inches, although the flower-spike, if permitted to develop, is a few inches higher. The flowers, however, possess comparatively little beauty, and their development is not recommended, because they weaken the growth of the plant, and the pitchers, its chief beauty, are therefore apt to be smaller.

Cephalotus follicularis is the only species of the genus, and is a cool-house plant which delights in moderate shade and abundant moisture. It grows well in a soil of rough peat, sand and living sphagnum, and the pitchers nestle in the moss. A moist atmosphere is so congenial to it that it will thrive under a bell-glass. The propagation of Cephalotus is effected by division of the crowns, by seeds, and also by means of root-cuttings, the latter being probably the most satisfactory method, providing proper care be taken of the cuttings. This plant was introduced from Australia some seventy years ago.

Dionæa muscipula.—As a companion plant to the Cephalotus, the Venus Fly-trap, or Dionæa, is very interesting, and the two plants will give an opportunity, in a small space, for the study of so-called carnivorous plants, and both are charming little plants, without taking into consideration their digestive possibilities. The Dionæa will flourish under the treatment recommended for the Cephalotus, and, like the latter, it is benefited by the removal of the flower-stems before they are fully developed. Dionæa is also a monotypic genus, and is found in swampy ground in a few localities near the Atlantic coast, in North and South Carolina.

Further interest may be added to the collection by the addition of some of the Sundews (Droseras), to which Dionæa is allied. Among the native species *D. rotundifolia* and *D. filiformis* are the prettiest, while, among the many species of foreign origin, *D. binata* and *D. spathulata* are notably good, and deserving of cultivation.

All of these plants may be grown in quite small pots—a good plan being to plunge several pots in a pan of moss or sand, by which means it is easier to keep them moist during hot weather.

Holmesburg, Pa. *W. H. Taplin.*

Garden Edgings.—Four days before Mr. Gerard's article on this subject appeared in Garden and Forest (page 298), the *Gardeners'* (London) *Magazine* contained the following note: "Many kinds of edgings may be put down in gardens to divide beds or margin walks, although the man who only uses tiles and brickbats thinks that plants should not come into consideration. The perpetual use of Box, clipped into painful regularity, is almost as tiresome as glazed tiles; but I allow of none of these in my own case. One long walk is edged with Gentianella, which has formed a perfect mat-like growth, enriched with the profound blue flowers; another formed of Saxifrage, and the others of Stonecrop, Arabis, or lovely herbs of dwarf growth. One of the principal walks is margined with soft stones, having Stonecrop, Saxifrage, etc., planted between delightful rock things that soon cover the stone with a velvety carpet, studded in spring by flowers. The Armeria deserves a special note. It is one of the best edging plants that may be used, growing luxuriantly, and presenting at this season a surface of rosy flowers, rising up with great regularity. The Thrift, or Armeria, remains green throughout the year, but needs attention about once in two years, when the whole should be lifted, the tufts divided, and replanted in light loamy soil, well mixed with silver sand. Visitors here think the edgings of Thrift worth a journey to see, and I send this note in the hope that those who have not tried it, or the other kinds of edging mentioned, will do so."

Spiræa gigantea, said to be a variety of *Spiræa Kamtschatica*, is a plant of noble port, with very large palmate leaves on stout erect stems. The flowers, which are produced freely in large racemes, are attractive and, on first opening, of a creamy tint, changing to a pure white. In rich, deep, wet soil it is said to grow seven or eight feet high, but on the border of my tank, in somewhat heavy soil, it flowered about the middle of June when five feet high. It promises to be a good plant to establish on the margin of water where a bold effect is desired, since it is distinct and larger in all its parts than our common Meadowsweet. Like most of the herbaceous Spiræas it soon turns rusty after flowering, so that it is not a desirable plant for a small garden or prominent location.

Correspondence.

The Naturalization of Exotic Forest-trees in Prussia.

To the Editor of Garden and Forest:

Sir,—Ten years have now passed since the Prussian Government undertook the cultivation, on a large scale, of a considerable number of exotic forest-trees, principally American, with a few also from Japan. This period, although a short one in comparison with the life of individual trees, seems to have satisfied the authorities, in a certain degree at least, as to the feasibility of the undertaking. There is nothing novel in this experiment, because similar ones were made here during the last century; but in our age more persistency and method are used in carrying out such trials. Americans who take a friendly interest in their vegetable compatriots in a foreign country will be glad to hear, perhaps, of some of the results which have been obtained with them in this country. It is safe to say in general terms that this new departure in German sylviculture has been successful. The success is due principally to Mr. Lucius de Ballhausen, late Minister of the Interior, seconded by Forest-master Danckelman, of the Academy of Neustadt Eberswalde.

The list of species tried at first was large, but has now been greatly reduced, and only includes those trees which seem to be the most promising, the forest-administration being determined to confine itself to testing thoroughly only the most valuable trees which up to the present time have proved themselves best suited to flourish in the climate of northern Germany; and in the future these species only will be cultivated on a large scale. The purpose of this note is to give some information with regard to these trees gathered from recent publications of the Forest Academy, the most important of these being a pamphlet from the pen of Professor A. Schwappach, entitled, "Denkschrift betreffend die Ergebnisse der in den Jahren 1881-90 in den Preussischen Staatsforsten ausgeführten Anbauversuche mit fremdländischen Holzarten."

The department, between 1881 and 1890, distributed an immense quantity of the seeds of trees furnished almost entirely by our distinguished countryman, Mr. John Booth, formerly proprietor of the celebrated nurseries at Flottbeck. The appropriation for the purchase of seeds being now exhausted, efforts will be confined for the present to a study of the growing plantations. These are considerable, and occupy in the forests of the state alone a surface of ten or twelve hundred acres. Experiments have been made with twenty-two American and six Japanese species, as well as with *Pinus Laricio* of Corsica and Nordmann's Fir of the Caucasus. The experiments will be continued on a large scale in future with the following selected species only: *Pseudotsuga taxifolia, Picea Sitchensis, Chamæcyparis Lawsoniana, Thuya gigantea, Quercus rubra, Juglans nigra, Hicoria ovata, Hicoria minima.*

A second class, composed of trees which promise only a partial success, is reserved for less extended trials. It is composed of the following: *Pinus rigida, Juniperus Virginiana, Abies Nordmanniana, Pinus Laricio, Acer barbatum, Betula lenta, Hicoria alba, Hicoria porcina.* The following trees have been rejected entirely: *Pinus Jeffreyi* and *P. ponderosa, Acer saccharinum* (*dasycarpum*), *A. macrophyllum, Hicoria sulcata, Fraxinus pubescens.* In place of the last it is now proposed to try *Fraxinus Americana.*

Of all the new introductions which, as you have noticed, consist principally of conifers, the Douglas Spruce appears destined to occupy the first place. Nothing but praise is heard for it. The seed of none of the other exotic trees has been distributed so generally and so profusely in all parts of the country, from the north to the south, and none of the others has given such brilliant results. Immense quantities of the seed of this tree are now planted in all parts of Germany, and the supply is not commensurate with the demand. This splendid tree, therefore, has the best chance, if not of replacing our indigenous conifers, at least of placing itself on a par with them in the composition of our forests. Its success seems to be assured in all parts of the kingdom, even in the provinces of the north-east, where the cold is extreme. Not particular as

to soil, it thrives everywhere except in low peaty swamps and on the moving sands of our maritime provinces. The Douglas Fir is one of the best presents which have been made by the New World to Europe. The publication to which I have referred devotes itself especially to discussing the differences between the so-called Red and Yellow Firs, races which seem to mingle in this country in the general success of the species.

The Douglas Fir has for a close second the Sitka Spruce, which is also very promising, although it grows less rapidly than the Fir; and we expect to see this tree of the Pacific coast occupying some day or other immense tracts of the German forests, especially in those peaty soils where the Douglas Fir refuses to flourish.

Lawson's Cypress, that ornament of gardens, is valued for the solidity of its wood and for the ease with which it adapts itself to soils of the most variable character. What I think will surprise you is the hardiness of *Thuya gigantea* in the extreme north, even to the very confines of that eastern Prussia which at Berlin has come to be considered the vestibule of Siberia. It is needless to say that, as it flourishes in that inhospitable region, the parks and gardens of Brandebourg, in a more temperate climate, are now enriched with the tall stems of this superb plant, which passes uninjured our most severe winters. Even this last one of abnormal severity and length has not affected it in the least.

Pinus Jeffreyi and *P. ponderosa* have been struck out from the list of trees available for planting in the neighborhood of Berlin, although there is still some hope that *Pinus rigida* may succeed here, this being the species which was believed to furnish the pitch pine of commerce, which is, however, probably produced by *Pinus mitis* or by *P. palustris*. That this communication may not be too long, I must not speak in detail of all the species which have been tried. The Black Walnut and the Hickories rarely find here soil suited to their needs, while the Red Oak succeeds admirably. This last, however, has been naturalized here for a long time, its introduction dating from 1740. Up to the present time, however, it has been grown as an ornament of gardens, and not as an inhabitant of forests.

I cannot leave this subject without expressing my thanks to Mr. Schwappach for his admirable essay upon the results of these forest-experiments. I shall take an early occasion to speak of the results of the experiments with Japanese trees in Prussian forest-planting.

Berlin. *C. Bolle.*

Irish Daffodils versus Dutch in the New Country.

To the Editor of Garden and Forest:

Sir,—I was pleased to see what is said about the successful cultivation of Daffodils in Garden and Forest. I should add, as a European and one who grows bulbs by the thousand, do not depend for bloom on rich, over-fed bulbs that look plump and heavy. Rather select smaller bulbs that are properly ripened, with flower-buds well set in them. Where there is a lot of green unripe wood on a plant, it means a lack of flowers. Where there is a lot of dense foliage on a Daffodil-bulb produced by over-feeding, the same rule holds good. The overfed bulb never gets properly ripened. It keeps growing, making leaves instead of bloom, and when it settles down to rest is too often dug from necessity in a thoroughly green state. This applies to Daffodils such as Trumpet Major, Trumpet Maximus, Spurius; with Bicolor Horsfieldi, Emperor, Empress, Sir Watkin, etc., that produce large broad leaves, the larger the bulbs and better fed they are the better. But with all the Spurius class, Princess, Trumpet Major, Von Sion, etc., the hard, dry, well-matured bulbs, grown without stimulants of any sort, are best. For experiment I procured four bulbs of Princess from Holland, which were beautiful to look at. In fact, they were originally Irish bulbs, grown three years in Holland. I planted them side by side with small bulbs of the same stock grown in Ireland. The result was one flower each on the fat Irish bulbs, pampered by a Dutch expert for three years, and two and three blooms each on smaller-looking stuff kept and grown on in their native soil. Holland can grow Tulips, Hyacinths, Crocus, Anemones and Ranunculus better than any nation in Europe; it never can grow ordinary Daffodils with the south of England or Ireland. It has not the soil. Sand answers well. But to grow Daffodils to perfection you must have the command of good hazel loam and ample drainage during the resting period.

The crop of bloom does not come in Holland until April. In the south of Ireland the flowering season is late February and March. If bulbs flower early under good conditions they ripen early, can be planted early, and will bloom early.

Cork, Ireland. *John Quill.*

Recent Publications.

A Manual of Forestry, Volume II. *Formation and Tending of Woods, or Practical Sylviculture.* By William Schlich. London: Bradbury, Agnew & Co., 1891.

The first volume of this manual appeared in the autumn of 1889 and was reviewed at length in these columns by Sir Dietrich Brandis, the former head of the Indian Forestry Department. That volume dealt with the question of the general utility of forests, and, in part, with the fundamental principles of sylviculture. The present volume describes the practical application of those principles, with a description of various trees, with special reference to their adaptability and value for cultivation in Great Britain. Practical sylviculture, as Mr. Schlich defines it, is the production of woods or forests —that is, all the operations connected with the formation and care of woods until the trees which compose them are ripe for the axe. The principles which guide the forester in this business were explained in the first volume of this manual, and all that is left for the author to accomplish in the present installment of this important work is to explain the practical application. The subject he divides into their following chapters:

Preliminary Works, under which head Dr. Schlich treats of the choice of species, the question of fencing, and the preparation and reclamation of the soil. In his second chapter he treats of the formation of woods either by artificial or natural means. The third chapter is devoted to the care of the woods after they are planted, while in his fourth chapter the author sketches in the form of notes the economic value of various forest-trees.

Mr. Schlich very properly points out that the success of all forestry operations depends primarily upon the judicious selection of the species of tree which is to be grown under a given set of conditions; and this, we may remark, applies not only to forests planted primarily for the production of timber, but to all plantations for whatever purpose they may be made. Mistakes made in the selection of species to be planted can be rectified only after a considerable lapse of time. Many species, as we know to our cost in this country, where we are only just beginning to learn that the Norway Spruce and the Scotch and Austrian Pines are worthless here, thrive well for a series of years, and only commence to fail after twenty, thirty, or even after a longer period. The entire success of any species in any given locality is dependent on many things besides hardiness. A species possesses greater or less value in proportion as it can be adapted to desired systems of sylviculture, as it may possess, in a greater or less degree, power to preserve or improve the fertility of soil and capacity to resist damage from external causes. Not only must the value of the products of any species have its proper weight in causing the selection of trees to be planted on a large scale, but the matter of the improvement of the soil through planting is one of vital importance which cannot safely be overlooked, as in it lies the germ of the whole theory of profitable sylviculture. Unless land which is covered with trees improves from year to year and from century to century by the action of these trees, some mistake has been made in their selection, and any system of sylviculture which does not improve the condition of the soil has not been wisely selected and developed.

In the chapter on the formation of woods, directions are given for sowing, for selecting and testing seeds, for the formation and management of germinating or seed beds, for methods of sowing, whether broadcast or in patches, or in trenches or pits. The section which treats of the quality of the plants we are glad to reproduce entire, because there is no department of planting in which planters in this country so often fail as they do in this particular.

"The success of planting operations," the author tells us, "is governed by the quality of the plants which are used, just as the success of direct sowings depends on the quality of the seeds. Hence only healthy vigorous plants should be used, which are likely to bear well the interruption of growth involved in the transfer from one locality to another under circumstances admitting only of a limited amount of attention being paid to each plant. The vigor or growing power of a plant is indicated by a normal shape and a healthy appearance.

"The development of each part must be in due proportion to the rest; the plants should be neither tall and thin, nor too short and stout; nor should the stem be crooked, especially in the case of coniferous plants; the root system should be ample, with a fully developed system of rootlets; the crown should have a healthy green appearance and possess numerous well-developed buds. These are the general characteristics of good healthy plants."

These sentences may well be read by many persons in this country who have charge of planting our public parks, in which it often happens that crooked, distorted and half-dead trees and worthless shrubs are set. Such plants never produce desirable results. The cheapest and best thing to do with such plants is to put them on a brush pile. It is certainly a waste of money to plant and cultivate them. There is no branch of American horticulture which now needs reform so much as in the quality of nursery-grown ornamental trees and shrubs as usually offered for sale. Nurserymen, of course, will continue to sell poorly grown plants as long as purchasers can be found for them, and a reform in this direction will not come until purchasers know what a good plant is, and what it is worth. When this time comes they will be willing to pay what it costs to produce a well-grown, well-rooted and well-pruned shapely plant. The character of the material which is being planted in some of our cities under the direction of park commissioners and landscape-gardeners is not a credit to the existing knowledge of tree-planting in this country, and we are glad of the support of so eminent an author as Dr. Schlich on this subject, which is one of very considerable importance, as a bad tree, once planted, will, unless it has the good fortune to die, continue bad until the end of its life and remain a daily proof of bad methods.

We are glad to quote, too, the sentence that, "as a general rule, young plants are best because the operation of planting is cheaper. The plants survive more easily the interruption of growth involved in the change, and they adapt themselves more readily to new conditions." These are sound arguments against the prevailing notion that it is better to plant large plants than small ones.

Persons who desire to plant on a large scale will find in this work a detailed account of all the methods necessary to follow in planting forest-trees in the most economical manner, with descriptions of the tools used, and such other information as will enable them to carry out sylvicultural operations successfully. They will find, too, a clear account of the systems employed in Europe in renewing woods by the natural process, with suggestions for the application of these rules in particular cases. We should be glad to describe these methods more in detail, but the want of space compels us to refer the reader interested in such subjects to the book itself, which has the exceeding merit of being written in plain and simple English, and in a style which makes it perfectly easy to understand some of the rather complicated operations of which it treats.

Sylvicultural notes on British forest-trees, which occupies the fourth and concluding chapter, is devoted to an account of the native trees of Great Britain, with a description of the material they produce, their distribution, with notes on the climates and soils in which they flourish, together with an account of the best systems for cultivating them profitably; and, in convenient form, much useful information upon the diseases and other dangers which threaten them. The only foreign tree included in the list is the Douglas Fir of western North America, a tree of which numerous experimental plantations have been established in Great Britain and Germany, some of them upward of thirty years old.

The last *Bulletin of the Cornell Experiment Station* is devoted to the winter forcing of Tomatoes, which has become a prosperous business in the vicinity of our large cities. The most essential points in cultural practice may be summarized as follows: A Tomato-house should be very light and warm, and the roof should be at least five feet above the beds or benches. An abundance of sunlight is essential, and the temperature should be about sixty to sixty-five degrees at night and seventy to eighty degrees during the day, or higher in full sunshine. House-Tomatoes demand a rich soil and a liberal supply of fertilizers, and they will bear when four to five months old. They like brisk bottom heat and may be grown in large boxes or upon benches; eighteen-inch square boxes, placed a foot apart, and containing four plants to the box, afford one of the neatest and best means of growing Tomatoes. Winter Tomatoes must be trained. From one to three stems, depending upon the distance apart of the plants, are allowed to grow from each. These are trained upon perpendicular or ascending cords, and they must be pruned as fast as new shoots appear. The heaviest clusters should be supported. Water may be used more freely early in the growth of the plant than later. Wet the soil thoroughly at each watering rather than water often. When the fruit begins to set, keep the atmosphere dry, especially during the middle of the day.

House-Tomatoes in this latitude yield about two pounds to the square foot. The amount of the first crop does not appear to influence the amount of yield in the second crop from the same plant. Lorillard, Ignotum, Volunteer, Ithaca, Golden Queen and Beauty have been found good winter varieties. Insect pests are kept in check by fumigating with tobacco, and the spotted mite by Hughes' fir-tree oil. Fungi are controlled by ammoniacal carbonate of copper and Bordeaux mixture.

The most interesting passage in the bulletin is that which relates to the necessity of aiding nature in the work of pollination. Some account of experiments on this point was given in Garden and Forest while they were being carried on, but the subject is of sufficient importance to be referred to again. When the flowers appear, the atmosphere is kept dry during the brighter part of the day, when the pollen is discharged most profusely, but in the short, dull days of midwinter the flowers must be helped, or the fruit will not set. The common practice of tapping the plants in the middle of the day with a padded stick may be better than nothing at all, although some tests of the value of this operation showed indifferent results. The most expeditious and satisfactory method which has been used is to knock the pollen from the flowers, catch it in a spoon or other receptacle, and then dip the stigmas of the same or other flowers into it. There is a proper time in the life of a flower when the pollen falls out readily if the atmosphere is dry enough. This is when the flower is fully expanded and somewhat past its prime. If the flower is then tapped lightly with a lead-pencil the yellow powder falls out freely.

But there is additional reason for hand pollination. In-door Tomatoes are smaller than those grown out-of-doors, and midwinter fruits are smaller usually than those produced in late spring. There is also a tendency in house-grown Tomatoes to be one-sided, and Professor Bailey concluded that, although the lack of sunlight had something to do with inferior size, this lack of symmetry, and perhaps the smallness, too, were due to irregular and insufficient pollination. As an experiment two fruits upon one cluster were pollinated from the same source. In one case very little pollen was used, and it was applied to one side of the stigma only, while the other flowers received abundant pollen over the whole stigmatic surface. A picture of the fruits which resulted shows that the freely pollinated fruit was large and symmetrical, while the other was small and one-sided. In the large fruit, too, all the cells developed and bore seeds, while the smaller one had seeds on one side only. This experiment was repeated several times with substantially the same result. From these tests it appears that one-sidedness is due to the greater development of seeds upon the large side; that this increased development of seeds is due to the fact that the greater part of the pollen has been applied on that side; that abundant pollen placed over the entire surface increases the number of seeds and the size of the fruit; and that perhaps the pollen, either directly or indirectly, stimulates the growth of the fruit beyond the mere influence of the number of seeds.

Another interesting section relates to the second crop. The yield from the trained shoots of Tomatoes under glass does not exhaust the vitality of the plant, and, therefore, when the crop is well advanced, one or two new shoots may be trained from near the base to produce a second crop. If the plant is carrying fruit while these shoots are trained, liquid manure should be given once or twice a week, and a fresh mulch of manure may be added. In the dark days of midwinter there is not light enough to make strong shoots, where the planting is close, and it is better, therefore, to delay starting them until the fruit of the first crop is nearly all grown. But late in February or in March the new shoots may be allowed to grow three or four feet long before the old ones are cut away. The stocky shoots, from six inches to a foot long, give fruits as early as weak and slender ones, three or four feet long, and they make better plants. The second crop can be made to follow the first with an interval of from only four to six weeks, although this may be difficult when the planting is close. Another method of obtaining the second crop is to bury the old plants, after the fruit is off, until only a foot or so of the tips projects. The soil which was removed to make a hole into which the plant is coiled down is then filled in and the tip grows the same as a young plant. By this method the yield has not proved quite so heavy as from single shoots, although it is abundant and quite as early. The operation is laborious, and some of the stiffer plants will crack in handling. A third way of obtaining a second crop is by seedling plants which are started from seeds two or three months beforehand, and transplanted two or three times into pots. At the final removing they are taken from four or five inch pots when they are eighteen inches or two feet high and ready to be tied up. Seedlings will bear about the same time as sprouts of equal length to begin with, and the preference, therefore, will

be for sprouts, as the previous labor of sowing and handling is avoided, and, besides this, the seedlings take up valuable room while growing.

Notes.

The double Potentillas, which are now profusely blooming in all shades of orange and red, are showy plants. The flowers last a long time after they are cut as well as on the plants.

Four factories have filed applications in California for bounties on sugar production from beets. One of these, known as the China beet factory, has 4,000 acres planted in beets, and it is expected that the sugar yield will be 5,000,000 pounds.

Mr. Edwin Lonsdale writes to the *American Florist* of a new Rose, a sport from American Beauty, which differs in color from its parent, being a much lighter and more lively pink. The flower becomes lighter with age, but does not show a tendency to the purple shade so often assumed by an off-colored American Beauty. The sport originated with Mr. John Burton, of Philadelphia, and he has just planted a house with the stock for winter-flowering.

One of the most beautiful of climbers is the so-called Prairie Rose (*Rosa setigera*), which is now covered with flowers after the general Rose display is over. This plant is much more beautiful than the double varieties. It is a free grower, and will cover easily a hundred square feet of trellis with its bold, healthy foliage, which is as clean and free from fungi and insects as that of *Rosa rugosa*. The large rose-colored flowers, with conspicuous clusters of yellow stamens, come in corymbs and keep opening one after another for several days.

Monsieur Pasteur long ago expressed the opinion that the bouquet and special qualities of certain wines are due to their particular ferment. This view is supported by Monsieur Jacquemin, who reports some experiments in which he endeavored to impart flavor to barley wine by making it from wort leavened with special ferments of wines of delicate flavor, and found that the sugar-water, in which the ferment was kept, obtained the exact flavor of the various wines used, such as Champagne or Burgundy. He also imparted the flavor of apples and pears by using their ferment in barley wort. The cultivation of particular microbes to furnish any given bouquet to fermented liquors is now in order. It may be, in the future of wine-making, that the quality of the ferment will be considered of more consequence than the quality of the grape.

Agricultural Science contains an account of some European experiments which seem to show that the copper salts so generally used against fungal diseases of the Grape and other plants may be hurtful to vegetation. Certain cereal Grains and Grasses planted in pots were watered with pure water and with water containing copper salts in different proportions, and the dry matter in the harvested plants decreased regularly as the copper salts increased. It was found that the lime and potash in the soil, where copper sulphate was used, formed soluble sulphates, which were washed into the subsoil, while the copper oxide remained at the surface to poison the roots of the plants. The addition of lime to the Bordeaux mixture, of course, lessens the danger of such deterioration. If it is true, as now stated, that weaker solutions of copper salts than those now used are effective as fungicides, the strength should be reduced for other reasons than that of economy.

At the Convention of Nurserymen recently held at Minneapolis, Mr. J. V. Cotta said that the breeding of a race of Apple-trees from seeds gathered from the hardiest known varieties to the manner born was possible, but it would require a generation before these hardy trees, which yielded late-keeping fruit of good quality, could be produced. He had practiced another method. Under this system varieties too tender for the northwest, when grown by root-grafting or budding, could be produced so that they would endure climatic adversities two or three hundred miles farther north than their profitable range under the old method. This way is to top-graft them, standard-high, on perfectly hardy, free-growing, congenial stocks which have been previously grown by root-grafting; or, in other words, the plan is to double-work the trees. He has practiced this for nine years with entire satisfaction. Of course, double-working means double expense, and often more, but with his present experience he would no more think of planting an orchard of root-grafted or of budded trees of a less hardy strain than the Duchess, even in northern Illinois, than he would of attempting to grow Figs or Oranges there as a commercial venture. In the spring of 1883 he found his root-grafted trees, with a few exceptions, such as the Duchess and some Crab-apples, almost ruined, while top-grafted and double-worked trees of the same sort came out sound to the tip.

A private letter from our correspondent, Monsieur Charles Naudin, written at Antibes, informs us that the beautiful *Sophora secundiflora*, a small tree of western Texas and northern Mexico, introduced into Europe a few years ago through the Arnold Arboretum, has flowered this year for the first time (probably in Europe) in the gardens of the Villa Thuret, and is now ripening its fruit. Among other recent introductions from North America now flourishing in these gardens are *Isomeris arborea*, introduced in 1881, and now flowering and producing fruit abundantly every year; *Pinus cembroides*, *Hicoria myristiciformis*, *Juglans Californica*, *Prosopis juliflora*, *P. pubescens*, *Bumelia lycioides*, introduced in 1880, and now flowering and fruiting every year, *Dasylirion quadrangulare*, *Lupinus arboreus*, *Leucœna pulverulenta*. This last, if it succeeds as well as it does on the banks of the lower Rio Grande, promises to be one of the best shade and ornamental trees that have been planted in southern Europe. Curiously enough, as we learn from our correspondent, *Olneya Tseota*, the beautiful leguminous tree from Arizona and Sonora, cannot be induced to grow, although the seeds germinate freely enough at Antibes; the seedlings soon become sickly and perish. The same is true of *Pinckneya pubens*, which has been tried on several different occasions at Antibes without success. Three large plants of *Yucca filifera* (see Garden and Forest, vol. i., pp. 78 and 79) were flowering at Antibes on the 20th of June, and had produced panicles more than forty inches long. This, Monsieur Naudin writes, is certainly one of the most important ornamental plants which have been introduced into Europe during the present century.

The Formosa camphor of commerce is obtained from *Laurus Camphora*, of which immense forests cover many of the lower ranges of hills in the island, extending up the lower slopes of the mountains. Many of these forests have not been invaded, and the statement that the camphor supplies in the southern part of the island are becoming exhausted applies only to those districts which are purely Chinese. The supply from other parts of the island is said to be practically inexhaustible; and, even in the districts inhabited by the Chinese, it is only in certain places that the supply is falling off in consequence of the reckless manner in which the trees have been destroyed, partly for the sake of their timber and for camphor, and partly, probably, to clear the ground for cultivation. It has been stated that the method of obtaining crude camphor in Formosa was by steeping the chopped branches in water and then by boiling them until the camphor begins to adhere to the stick used in stirring, when the liquor is strained and the camphor is allowed to harden. By this method it is not necessary to destroy the tree. It may have prevailed formerly, although it certainly does not at present, the yield of camphor from the branches being too small to repay the cost of extraction. A recent British consular report gives some details of the method now in general use. A tree is selected by an expert, who scrapes into the trunk in different places with an instrument resembling a rake, for the purpose of ascertaining if it contains sufficient camphor to repay the cost of extraction. Trees less than fifty years old do not produce camphor in paying quantities, and the yield varies considerably in individual trees. Sometimes one side only of a tree contains sufficient camphor to make extraction profitable, and, in this case, that side alone is attacked. The trunk is scraped as high as the workman can conveniently reach, and the scrapings are pounded and boiled with water in an iron vessel, over which an earthenware jar, made especially for the purpose, is inverted. The camphor condenses on the inner surface of the jar, and is removed from time to time. The root of the tree and the trunk, for some eight feet up, contain the greatest quantity of camphor. If the scrapings obtained from the trunk yield well, the chipping is continued until the tree falls. The roots are then grubbed up and the camphor from them extracted. If the scrapings are not sufficiently productive, the tree is abandoned and work is commenced on another. No effort is made to extract the camphor from the fallen trunk or from the branches. In some cases the trunk, however, is sawed into lumber, but this depends on the locality where the tree is growing. In many districts, owing to the want of roads, the timber would not pay the cost of its transport. It is impossible to imagine a more wasteful method, and it is fortunate that these camphor forests extend over a large part of the islands. Ten of the iron pots in their accompanying jars make up what is called a "set," and are worked by four men. One set will produce about sixty-five pounds in ten days, but this yield is reached only under the most favorable conditions.

NEW YORK, WEDNESDAY, JULY 15, 1891.

TABLE OF CONTENTS.

The Planting of Home Grounds.

"THE union—a happy marriage it should be—between the house beautiful and the ground near it," says a writer in a recent number of *The Garden*, "is worthy of more thought than it has had in the past, and the best ways of effecting that union artistically should interest men more and more as our cities grow larger and our lovely English landscape shrinks back from them." This writer, we may divine from the initials signed to the article, is Mr. William Robinson, whose essays and books have already had an excellent influence upon contemporary gardening art in England. We are not surprised, therefore, to find that, in speaking of the ground near a country house, he should advocate treating it in a manner which will harmoniously unite it with the landscape beyond, thus making a beautiful whole of the near and distant surroundings of the house. This ground he calls "the garden," although this term is more generally understood as meaning something in the nature of an enclosure, where plants are grown without any thought for harmony of general effect, or for the proper connection between all the spaces which the eye can compass in a single view. Taking "garden" to mean all the grounds close to the house—the "home-grounds," as is sometimes said—he explains that there are situations, as on the hillsides of Italy, where the nature of the spot prescribes a formal, semi-artificial garden. But, he continues, "the lawn is the heart of the true English garden, and as essential as the terrace is to the gardens on the steep hills"; and, in general, these words are true for America as well. There is less need in America than in England to protest against formal gardens where such lawns, with appropriate framings and backgrounds of foliage, should exist. In this country we are not very fond of designing "geometrical gardens," even in those occasional cases where some natural or architectural peculiarity would sanction their existence; and it would be difficult to discover American homes where "on level ground the terrace walls cut off the view of the landscape from the house, and, on the other hand, the house from the landscape." Nevertheless, there are other errors in garden design into which we are as apt as the English to fall, and we should be doubly anxious to avoid them, as our architects seem to be succeeding better than the English in creating that "house beautiful" which must be the centre of the complex ultimate picture. That is, if Mr. Robinson's taste in such matters can be trusted, "most of the houses built in our time," in England, "are so bad that even the best garden could not save them from contempt"; but, though we often build bad houses too, and though our average efforts are less ambitious than those of Englishmen, many of our country homes are so good architecturally that one thinks, with a pang, how much more beautiful they would be were their "home-grounds" properly arranged and planted.

How to plan and plant such gardens as these is the problem to be considered. We will suppose that the house has been advantageously placed, that it looks out upon a beautiful landscape, and that the intervening space is of such an extent and character that it can be made an harmonious link between the house and the landscape, giving the house a fitting environment when seen from a distance, and the landscape a fitting foreground when seen from the house. The two questions then are, How to plant, and What to plant.

As regards the manner of planting in such cases much has already been said in these columns, and it may suffice briefly to repeat that there should, if possible, be a wide extent of lawn or lawns to give repose and unity to the picture, with surrounding plantations, varied in mass and sky-line, to enframe the lawns and connect them with the landscape; that open outlooks should be left to reveal the most beautiful portions of the distance, while disagreeable objects are masked from view; and that roads and walks should be as few and as inconspicuous as convenience will permit. If a good landscape-gardener is employed, these arrangements will be planned and their preliminary portions will be executed without much trouble to the owner. But in settling the question what to plant in completing them the landscape-gardener, in America as in England, often seems in need of guidance as well as the owner, and when his views are just, the owner too often interferes with their development or adds inharmonious details of his own as the years go by.

Mr. Robinson is partially right when he says that most people who care for gardens (still taking the word in the wider sense he gives it) suppose that they are made for plants, and that "if a garden has any use it is to treasure for us beautiful flowers, trees and shrubs." Yet this idea of a garden's function is too narrow, and devotion to it often deforms even small gardens which have no purpose except to surround the house agreeably, still more often deforms larger ones which serve as a foreground for a beautiful prospect. A garden is, beyond question, a place where beautiful plants are to be fostered; but it is also an entity which should be beautiful as a whole and in harmony with its surroundings. And, however well planned, its beauty may be spoiled, and a look of painful artificiality may be given it if its contents are injudiciously selected. Therefore we must dissent from Mr. Robinson when he says, "The true use and first reason of a garden is to keep and grow for us plants *not* in our woods, and mostly from other countries than our own." The true use of a garden is to grow for us beautiful plants of such a kind that their association will form a beautiful whole, beautifully in keeping with the house and the surrounding landscape. In fitting it for this use we are at liberty to get our trees, shrubs and flowers where we will, provided we introduce none which, by a discordant note, will mar the general effect, which must be determined by the character of the local landscape. To be harmonious, and therefore beautiful, a garden, over which we see the Berkshire hills or the valley of the Hudson, must be evidently an American gar-

den, just as one in the valley of the Thames must be English, and on the southern shore of France must have the mixed, semi-tropical character peculiar to the Mediterranean coast. To secure this proper local character, local plants are almost essential for the groundwork; and then, to give variety, interest and a true garden-like air and charm, exotics should be mingled with them. But these exotics should never be chosen for their rarity or novelty alone, or even for their intrinsic beauty, and still less, as is too commonly the case, for their mere conspicuousness. First of all they should harmonize with the other plants about them, and the novice may well hesitate before dipping deeply into those stores of foreign plants which are now so vast and varied and accessible. His choice will not be narrow, if, in addition to native plants, he selects such as have come from lands with climate akin to our own. In using these last he will be following Nature's own example. Here in America she does not confine herself to growing plants which were originally American. She takes up vegetable immigrants as hospitably as our civilization takes in human immigrants, and assimilates them as quickly and naturally. Who would suspect the White Willow in New England, or the Pawlonia in the woods of Maryland to be an exotic? And who sees anything inharmonious or strange in the aspect of the Ailanthus-trees which, mingling with the native Elms, shade the rustic streets of Nantucket? Nature chooses which exotics she will grow for what we may call scientific reasons, but the artistic effect of her results is invariably good. And man should learn from her how to make a similar choice, taking a wider liberty, of course, when he is planting a garden than when he is planting a forest, but never forgetting that, in a garden such as we are now describing, he should grow together only such plants as will look well together. There are exotic flowers which look as natural, as appropriate, in a garden as the Marguerite of Europe looks in our meadows. But there are others which seem entirely out of place as parts of an American garden which has any design—any character at all.

This is not meant to disparage the cultivation of rare or novel or conspicuous plants, whether native or exotic. Many refined persons take the keenest delight in individual flowers and collections of plants for their own sake, and without any reference to their relation with the surrounding scenery. But in grounds like those now under consideration, there will be ample space to grow them in locations specially set apart for them where they will not injure the main picture formed by the general environment of the house and the encircling landscape. As regards the grounds, the "garden" in its wider sense, it will assuredly be most beautiful, interesting and enjoyable when both native and foreign plants have been used in tasteful combination. But if confined to one of these classes we should probably lose as much by adopting Mr. Robinson's idea, that the first reason for this sort of a garden is "to grow for us plants *not* in our woods and mostly from countries other than our own," as we should if we adhered exclusively to the plants of our own country. Using these alone the planter will miss a thousand chances for securing beauty and variety, but he will not run the risk of the greater misfortune of producing a garden full of beautiful plants, but not a beautiful garden, after all, nor an appropriate environment for his house, nor a suitable foreground for the landscape beyond.

From a note on another page of this issue it will be seen that the Trustees of Public Reservations, the body incorporated under an act of the last Legislature of Massachusetts, for preserving beautiful and historical tracts of land within that commonwealth, has been organized, and is ready for work. Our readers need not be told that we heartily commend the objects of this association, for it has been one of the steady purposes of Garden and Forest since its foundation to aid in forming public taste and guiding public sentiment in this direction. The plan adopted seems business-like and feasible, and now that the machinery is in competent hands and fairly under way, it is a proper time to say that the success of the enterprise in its early stages is due very largely to the energy and intelligence of Mr. Charles Eliot, the secretary, who really assumed the burden of carrying the measure through. It ought to be said also that the successful inauguration of such a movement in a community is an indication of a high order of enlightenment. The people of Massachusetts have reason to be proud of it, and they should encourage and promote it in every reasonable way. It is to be hoped that public-spirited men and women in other states will be prompt to organize similar corporations until it becomes a settled policy throughout the country to preserve the natural beauty which we have inherited, and to protect from defacement and ruin, and for the inspiration and enjoyment of our children's children, all places about which patriotic and historic memories cluster.

Mr. John Robinson, in his interesting and valuable series of papers on the "Trees of Salem," now being published in *The Salem Gazette*, suggests, in speaking of our two poisonous species of Rhus, the only poisonous plants of our northern flora, a few simple rules which can be easily remembered, and which will aid persons in recognizing these plants, and at the same time prevent a needless fear of the many beautiful flowers and berries of the woods and meadows. These are his rules:

Never put any portion of any plant in the mouth unless it is certainly known to be wholesome.

Have no hesitation in handling any plant that has beautiful or attractive flowers, berries or fruit of any kind, for the two poisonous native plants have inconspicuous greenish flowers, mostly under the leaves, and later small bluish white berries close to the branches or hanging from them.

Beware of gorgeous red and yellow autumnal leaves on shrubs and climbing plants which are not known to be harmless. Our two poisonous native plants display the most brilliant autumnal colors of any species in our woods and by-ways.

The poisonous Sumach resembles a group of young Ash-trees.

The poisonous Ivy resembles the harmless Woodbine. Its leaves, however, have but three leaflets, while those of the Woodbine have five.

Dijon.—I.

THE city of Dijon lies in a charming valley at the foot of the hills of the Côte-d'Or in one of the most fertile and beautiful regions of France. It is said to have been founded in the early days of the Roman empire. Upon its history, however, I have no purpose to dwell, nor yet upon its buildings, which, despite the generally modern look of the place, still make it interesting to the artist and the antiquary. Its parks are less famous, but well deserve the notice even of those travelers who come in great numbers during the summer, but, intent on reaching Switzerland as quickly as possible, usually do no more than sleep a night in the huge hostelry, called the *Cloche d'Or*, which, in its unlikeness to the inns of most French provincial towns, seems a prophecy of the tourist-ridden land toward which they yearn.

It is only a short walk from the hotel, and only a step from the railway station, to the gardens called *L'Arquebuse*, which formerly served the local Society of Arquebusiers as their place of exercise. We are not told when they were first established, but it is known that, in the year 1591, Henri IV. here joined in the sports of the Dijonais musket-men. Their disposition seems to have been the result of chance rather than design, and although they contain some symmetrical features, they give, as a whole, a naturalistic impression and form a pleasant, verdurous, shady and not unpicturesque resort.

Close to *L'Arquebuse*, and separated from it only by a little stream, lies the Botanical Garden, founded by Legouz de Gerland in 1772. It covers a wide area, and, in addition to the regular beds where the smaller plants are grown—among them being 300 varieties of the Vine—it contains a park-like space through which flows the little stream, forming in one spot a miniature lake, the general design suggesting the fact

that at the end of the last century "English gardens" were becoming popular in France. Some fine cut-leaved Alders grew by the bank of the stream, and on the edge of the pond large Taxodiums were throwing up their "knees," as they do in the Florida swamps. Many other beautiful specimen trees attracted the eye; and though Weeping Willows can hardly be called beautiful, historical sentiment was stirred at the sight of a large example which had grown from a twig brought many years ago by Montholon from St. Helena.

Their plants, not their design, give these two gardens their interest; but the one which forms the central feature of the newer part of the town is as charming an example of the artistic treatment of a small urban pleasure-ground as I remember to have seen. The intersecting streets here leave a long and rather narrow isoceles triangle. The point of this triangle is occupied by the Place Darcy, but the greater part is filled by the park. At its broader end the ground lies high above the surrounding streets. Here a wide space has been laid out with a music pavilion in the centre and with a graveled surface that may be covered by chairs upon occasion, but closely shaded by many regular rows of fine Plane-trees, concentrically arranged near the pavilion and in rectangular lines at a greater distance. From this space the ground descends steeply toward the street on three sides, turfed, planted with graceful groups of low trees and shrubs, and everywhere encircled by a gilded railing of good design. On the fourth side, however, which faces the Place Darcy in the point of the triangle, the rapid descent of the ground is utilized to form a fine series of marble terraces with cascades rushing out beneath them and falling into rectangular basins set with aquatic plants, flights of steps flanking the cascade on either side and being flanked themselves by the lateral slopes of turf, which in this part end at gravel walks running near the outer railing, well shaded and furnished with comfortable seats. The level of the street is reached before we get to the limits of the park at its narrower end, and here we find the usual arrangements of paths, grass-plats and seats very charmingly managed; and hence, as we look out on the Place Darcy, we find that even its open space has been brought into the general scheme, an oval of grass and shrubbery lying at a little distance from the borders of the park, then at a greater distance a tiny triangular plantation, fitted to the shape of the contracting triangle, and finally, closing the long converging perspective, a triumphal arch, which stands across the entrance of the Rue de la Liberté.

The view of this lower portion of the park and of the Place Darcy, seen over the cascades from the terraces above, is extremely impressive, considering the small scale of the whole; and a word should also be given to the arrangement of the shrubberies on the lateral slopes of the park. Whether seen from above or seen from the street outside, one cannot but admire the skill with which they have been disposed; now running outward till they reach the railing with their luxuriant masses of drooping foliage, and now curving inward to leave a wide stretch of grass next the street, or, here and there, room for a little path, a graveled spot and a big marble bench whence the lively panorama of the street may be viewed at once. The harmonizing of the formal upper portions of the park (which, by the way, is properly called the *Promenade du Château d'Eau*) seemed to me very skillful, and, taken as a whole, this pleasure-ground would, I think, convince any observer that formal and naturalistic elements may be happily joined, and that, in a small urban park, the presence of formal features is extremely desirable. No wholly naturalistic design could have given this park so great a serviceableness or so much dignity, or could have harmonized it so well with the surrounding rows of buildings; of course, its designers were lucky in having a piece of ground so varied in surface to work upon, but had they not been artists they would not have profited by their opportunity. It was easy, but not pleasant, to fancy what the place might have been in the hands of an unskillful designer.

New York. *M. G. Van Rensselaer.*

How We Renewed an Old Place.

XIII.—EVERGREENS IN SPRING.

I KNOW few things more depressing than the sight of conifers in May, when every deciduous tree is putting its best foot foremost and giving promise of a fine crop of leaves. The Pines and Spruces and Firs which have gladdened our eyes all winter, with their fine green masses relieved against the snow, or standing up bravely from the brown grass, in rich contrast to the barrenness around, now begin to show the sere and yellow leaf. The March sun and winds have burned and browned their tips, the winter storms have buffeted their branches and torn great gaps in their outline. Their new shoots are all hidden under a little tight white or yellow, or brown nightcap that looks dried and wizened, as if no promise of life lurked underneath.

When the snow melts sufficiently for one to walk abroad among his plantations, he views them with a feeling akin to despair, so unlikely do they seem to recover themselves. Some branches are entirely dead, the tops of others are winter-killed, a few have turned copper-color from root to crown, and beside the bright green of bursting buds and springing grass, the best of them look worn and dingy by contrast.

Not until the middle of May do they pluck up their spirits, pull off their bonnets, and show that their apparent deadness resulted from the fact that they take their season differently from their gayer neighbors, and wear their winter furs, however rusty and inappropriate, far into spring, while all the others have come out in their new clothes of brightest hue. Some years June will be here before they condescend to put out the green tassels which are their first adornment, but through the month of roses they do their prettiest, and hang out their banners with the best.

Some of the authorities recommend the month of June as the most desirable for transplanting evergreens, but my experience would lead me to the conclusion that with them, as well as with hard-wood trees, the period before the bursting of the buds is more satisfactory than the time when they have already begun to swell. Seasons vary so decidedly that a few warm days may hasten the new shoots, and they may be three inches long before you think of going for trees, so that they droop discouragingly after transplanting, and sometimes never brace up again. This is particularly the case with Pines, which have a way of drooping their little brown heads despairingly, and refusing to stiffen, in which case, if they cannot be freely watered, they are sure to die.

This year the warm days in April so quickened all vegetable life, that, when we set forth in the middle of May in search of new trees for the hill, we found to our surprise that the green tassels on some of the trees were as long as one's finger, which gave us a pang lest we were already too late for the best satisfaction.

However, as there had been already some six weeks of unprecedented dry weather, and there were signs of rain in the atmosphere, it seemed that if there was any chance at all, now was our time. We accordingly arranged for a morning among the Pines, and, accompanied by a big farm-wagon to bring them home in, we wended our way along the winding country roads, until we came to where the young trees abounded, and we could select our specimens.

There is little doubt that the stocky, bushy trees of close, heavy foliage, not more than two or three feet high, are the most likely to live and do well, but there are days when one's ambition outruns one's discretion, and, revolting at the slowness of the growth of the little ones, he desires to realize his forest immediately, if only for one summer, and so, like a child who plants his sand-garden with blooming flowers, ventures on a load of trees five or six feet high, in hopes that, after making a brave show for a few months, they will be aided by some happy freak of nature to take root in earnest.

But planting Pines on a dry hillside is like investing in a lottery—the success of the enterprise depends wholly on the sort of weather that immediately follows, and who can reckon with that? Talk of the vicissitudes in the life of a broker—what are his uncertain and incalculable quantities compared to those with which the farmer and gardener have to deal? A broker can abstain from buying bonds and stocks if he will, but the farmer has to plant when the time comes, and take his chances, and for surprises the weather can give points to Wall Street any day. With the largest experience and judgment you can no more reckon securely on the coming down of rain than of Bell Telephone, or Calumet and Hecla.

No sooner are one's trees planted than he becomes a bear upon the weather market, but this summer old Probabilities has made a corner with the bulls, and kept rain up persistently, so that the wisest calculations have gone agley; and if Paul plants, and Apollos declines to water, what then?

To return to our expedition. There was an easterly tang in the air, a smell of rain that promised well for the morrow, though in the shelter of the trees all was warmth and sunshine, and bursting buds. Upon the rocks the Lady's-slipper was waving its rosy blossoms, tempting us to add a few roots of it to our shady garden, where it has thriven well. The Beeches and Birches were full of crumpled leaflets, Anemones were blooming by the wayside, the Oak-tops were reddened with the flush of early leaf-buds, the forest was astir. Along the fences

ran the busy chipmunks, saucily chattering with their bushy tails trailing behind them. The wood robins were singing in the thickets, and the thrushes challenging us from wayside bushes. In northern Maine one hears always in summer the tender song of the Peabody bird in such places, but here it occurs but seldom, and I missed it from the woodland sounds, of which the air was full. The Witch-hazel stared at us with its wicked-looking eyes, and the Hemlocks hid themselves behind the Alders.

When at last we came to the clearing, we found Pines in plenty, but, unfortunately, the soil was rocky, and the trees were hard to dislodge, and did not come up with as good a ball of earth as in the sandy hill where we had found them before; but we packed them well away in the cart, with moss about their roots, and a rubber blanket to keep off the sun, and pretty soon the wagon was nodding with trees four or five feet high, closely jammed together, and Birnam Wood was on the march for Dunsinane.

The hill had been dug the day before, and some two score holes prepared for the new-comers, so that by noon-time those of the first load were all firmly wedged into their beds, to be staked and tied later, to prevent their rocking with the wind, which gives them at present quite the air of a paddock of frisky young colts, carefully hitched to prevent their getting away.

That night there was a brisk and most encouraging shower, and the next day, after the rest of the holes had been filled with a second load of Pines, there came down quite a respectable rain, so that we greatly plumed ourselves upon our foresight in having got in our trees in the nick of time, just as the drought "broke."

But, alas, for the prescience of man, and for our corner in Pines! We mulched them all well with sea-weed, to keep in what moisture we might, and waited confidently for more rain; but no rain came! Two weeks more of dry weather ensued, many of the green tassels hung sadly down, a cold, dry wind blew, twisting and turning them in every direction, and mercilessly whipped the branches about, giving the poor things a cruel foretaste of what they are likely to encounter as time goes on. If the new trees look about upon their well-rooted neighbors they must be struck with the havoc made upon them by the north-west wind. It is always the north-west side of a tree that is brownest and thinnest, and which shows the most broken branches, and the greatest number of withered, copper-colored spines.

Not until May 29th did the rain come down in earnest, too late for any but the most healthy of the Pines to reap the benefit of its invigorating freshness, and they still have a long hot summer before them.

To show the importance of moisture to a Pine, I will add that among the trees brought, there were about a dozen that had no ball of earth attached to them, and reached here with perfectly bare roots. Knowing it was useless to set them on the hill in this condition, they were all planted in a very wet place at the foot of it, which is kept as a nursery for decrepit and rootless trees. If from anywhere we receive a tree poorly provided with roots, or of drooping and unhappy aspect, or if we bring one home that looks unpromising, into that moist spot it goes, and never a tree has perished there yet, no matter how forlorn a specimen it was when it went into the ground. This nursery is called the Tree Hospital, and we find a year in it is a cure for most of the ailments that roots are heir to.

In this last experiment, the ten trees planted there, though quite the worst of the lot, never have shown a sign of wilting through all the dry weather. Their tassels stand up straight and stiff, of a clean bright green, and, though so unpromising to start with, will probably in the end leave the others far behind. Even the Hemlocks, so troublesome on the lawn, thrive in this low and sheltered spot, where we have finally sent the worst of them for repairs. I have been told by one who knows, that what the Hemlock cannot abide is the March sun, which does mischief, while the blaze of summer is harmless to it.

I was shown one day at the Arnold Arboretum, near Boston, the north side of a hill, steep and rocky, but clothed with giant Hemlocks from its lofty summit to the burbling beck at its base. No nobler sight can be imagined. I entered this forest at twilight, and I found it a temple, solemn and silent. The majestic trunks rose from their rocky base at wide intervals, climbing one above the other to the crest of the lofty eminence they crowned. Their close-knit branches, far overhead, formed a dense canopy through which the failing light came dimly, as befits a temple. So wild, so sylvan a spot, within the limits of a great city, can be found in no European park, however magnificent. It is unique and singularly imposing. On the southern slope of that hill no Hemlock grows, showing that what this noble tree demands for full development is shade and coolness, and shelter from summer winds, which burn and blight. That glimpse of ancient woodland, ages old, will always linger in my memory as a link between the bustling present and the silent past. The busy city presses around it, the hum of traffic is near. You step aside from the highway, pass a gate, cross a tiny brook that tumbles as carelessly at the foot of the hill as if it were racing through the wilds of Colorado, and you enter a domain apparently as remote, venerable and silent, as when the Indian was the sole occupant of Shawmut, and found his way through the trackless forest to his hunting-grounds. A little path worn by the foot strays along beside the laughing stream; other paths may lead over the hill, but in the dimness I failed to see them, and the solitude seemed unbroken. Night was falling, the air was chill, the murmur of the leaves far above was barely audible, the impression was indescribably solemn and church-like, as if the aisles of some great cathedral were there stretching away into the shadowy distance, full of mystery.

Stately and strong the old trees stood, as if they might be as eternal as the rocks and hill, and beautiful they were in their silent majesty, uplifting their venerable heads to the gray evening sky which had domed over them for centuries.

On an opposite hill a grove of young evergreens was springing up.

"That, too, will be fine in a hundred years," said the Director, as we passed out of the great gate; and, with a thought of my baby-forest at home which, perhaps, in a century or two, may be worth while, I went away grave but rejoicing, for I had seen a noble sight.

Hingham, Mass. *M. C. Robbins.*

The Weeds of California.—II.

AFTER the general sketch already given, the more important weeds of California may be discussed in detail, under their respective orders, in the usual sequence.

Of the *Caryophyllaceæ*, the most universally diffused and troublesome member is *Silene Gallica*, which seems able to withstand the most severe aridity attained in the lowlands of California, at least in the central portions of the state. *Stellaria media* is among the most persistent of summer weeds in cultivated vineyards and orchards; while in spring, *Spergula arvensis* takes possession of the moister grounds in the Coast range as well as in the great valley. *Mollugo verticillata* is seen sporadically, but is not as troublesome as in eastern corn-fields.

Of the *Papaveraceæ*, the *Eschscholtzia Californica* maintains itself somewhat tenaciously in pastures, but hardly in regularly cultivated ground. Yet, in grain-fields, where its spring bloom has been prevented by cultivation, it will very commonly recoup itself by a copious autumn flowering, and thus it forms large areas of flaming orange on the outskirts of growing towns, where the ground has ceased to be cultivated with regularity.

Of the *Malvaceæ*, almost the only member that is really a weed is the *Malva parviflora*, although a few others are locally complained of. This, the "Malva" par excellence, regarding the extirpation of which many newspaper articles are written. It is at home in the heavy black clay or "adobe" soils of the Coast range, where it will grow to four and five feet in height, under favorable conditions; but on roads it will form decumbent, wheel-like masses, resembling those of its eastern congener, the *M. rotundifolia*. Its seeds, borne in the greatest profusion, will germinate with the most surprising readiness, even when the plant is killed quite green; the seedlings will be found coming to the surface from the depths of the soil-cracks in midsummer, and mature an abundance of seed under the most discouraging conditions, It is one of the most persistent weeds the California farmer has to fight, and its extirpation from ground once well stocked with it seems almost hopeless. Some have recommended it as a forage plant, but few cows will touch it so long as anything else is in sight.

The *Geraniaceæ* are prominently represented by the *Erodium cicutarium* and *E. moschatum*, both commonly known as alfileria or alfilerilla, and both widely diffused. The first-named, however, the one that has been carried even to the remotest districts of the state, is distinctively the species possessing value as a forage plant. The *E. moschatum* is so distinctly of musky flavor that, like Anthoxanthum among the grasses, it is eaten only in limited quantity by any animal, as a flavoring; an alfilerilla pasture once overrun with the musky species ceases to have much value; and in heavy, rich

soils the more valuable kind is often completely run out by the other. In light, sandy soils the *E. cicutarium* is more likely to hold its own. Its long, red tap-root will then descend for moisture to the depth of several feet, and its leaves will keep green when everything else that is of value as forage is dried up. The rosettes formed by its radical leaves lie close to the ground in winter, and resist even heavy frosts without injury. Both plants are regarded as marks of a rich soil; and in such soils the task of keeping them in check is indeed a serious one, for the seeds will continue to germinate in the driest and hottest times of midsummer, after the land is "laid by"; and the costly operation of hoeing alone can master it at that season. The propagation of the alfilerilla as a pasture plant is rendered difficult by the nature of the seeds, with their long, spirally coiled awns (styles); and in certain sandy soils of south California its spread is sometimes arrested by the red ant, which gathers the seeds in its burrows, leaving conspicuous piles of the awns outside, around its hills.

Oxalis corniculata is locally a very persistent weed, resisting the summer's drought to an extraordinary degree; but it is not generally distributed, though more common in southern than in northern California.

Fig. 56.—Populus Monticola.—See page 330.

The western Poison Oak, or Sumac (*Rhus diversiloba*), is a very persistent invader of pastures on which it formed part of the original growth, and keeps sprouting up from fragments of root-stocks remaining alive in the soil for years. In company with the Brake Fern (*Pteris aquilina*) it is usually the last of the native vegetation to be subdued by cultivation, both in the Coast range and in the foot-hills of the Sierra Nevada.

University of California. *E. W. Hilgard.*

New or Little-known Plants.

Drymophlæus olivæformis.

THIS is one of about a dozen species of Arecoid Palms peculiar to tropical Australia, New Guinea and several small islands adjacent. The genus is closely related to the true Ptychospirmas and Pinangas, and it resembles them in having unarmed, thin, elegant stems, which often flower in cultivation when only a few feet in height, and continue to flower annually. Drymophlæus is scarcely known in cultivation outside botanical collections, although most of the species, the one here figured in particular, are ornamental and of convenient size for pot-culture in ordinary stoves.

D. olivæformis, Mart., is a native of the Moluccas, where it forms a slender stem from fifteen to twenty feet in height, with a spreading head of pinnate leaves. The Kew plant, from which the accompanying photograph (see page 331) was made, is about fourteen years old, and at present its stem is three feet high, its leaves three feet long, and the wedge-shaped pinnæ are about five inches wide at the apex, the upper margin being jagged like a fish's tail. The texture of the leaves is soft and fleshy for a Palm. An inflorescence is produced annually, and the plant is about six months in maturing its fruit. The flowers are small, white monoicous, and the fruits are egg-shaped, an inch long, and colored rich scarlet. At the time when the photograph was made the fruits were at their best, and were as attractive as the brightest of flowers. Like all the Palms of this section of the order, Drymophlæus requires a tropical moist house and plenty of water at all times.

London. *W. Watson.*

Populus Monticola.

WE are able to publish a figure (p. 329) this week, made from material with which the discoverer has supplied us, of the interesting and very distinct Poplar found in Lower California in January of last year by Mr. T. S. Brandegee.

*Populus Monticola** is a tree which grows sometimes to the height of eighty or ninety feet, with a stout trunk three feet through, covered with rough ash-colored bark and with ascending branches and slender terete branchlets, which are covered when they first appear with thick white tomentum, and during the first year at least with pale silky pubescence. The bark of the trees, until they are about thirty feet high, is described as smooth and light-colored, resembling that of the Aspen, and it only becomes rough on large trunks. The bud-scales, which appear to persist until the leaves are nearly half-grown, are ovate, rounded at the apex, ciliate on the margins and coated with silky white pubescence. The leaves are broadly ovate, coarsely and sinuately dentate, often acute or sometimes rounded at the apex, and wedge-shaped or nearly truncate at the base. They are conspicuously reticulate-veined, three inches long by as much broad, or often somewhat smaller, and are three-nerved from the base, the middle nerve being furnished with two or three pairs of principal veins. The leaves are silky pubescent on the two surfaces, especially on the broad nerves, and are borne on slender terete petioles two inches long and covered with thick white tomentum. The stipules are linear, chartaceous and early deciduous. The fruiting ament is an inch long and a third of an inch broad. The capsules are ovate, thickly coated with white silky tomentum, and two to three-valved. There are usually two styles united at the base; the disk is small and nearly flat; the scales are rounded, slightly sinuate-dentate, ciliate on the margin, but otherwise almost glabrous. The male flowers have not been collected.

"*Populus Monticola* inhabits," Mr. Brandegee informs us, "the high mountains of the interior of the cape region of Lower California, growing along the streams and following them into the cañons well down toward the warm lowlands. At high elevations (5,000 feet), and growing in cool, rocky gulches, it is not more than twenty feet high. At lower altitudes it becomes a large tree, nearly 100 feet high, and is a favorite support for the wild Grape-vines. The wood is of a light reddish color, and is used for making furniture.

"This Cottonwood is known by the name of Guerigo to the inhabitants, who distinguish it from the common one of the fields and gardens, called by them Alamo. The leaves and flowers appear in February, and in October all are fallen, a season of growth usual in California, but very different from the ordinary habit of the plants of the cape region of Lower California, where most of the vegetation comes forward with the summer and fall rains at the time when the Cottonwoods are losing their leaves, and appear to be preparing for the winter, which, however, never comes. The contrast between a flora dying and a flora coming into life, at the same time and in the same place, is strange and interesting. Associated with the Cottonwood in locality, and in its habit of coming forward with the new year, are the Arbutus, Rubus, Ribes, Prunus, Heteromeles, Vitis, etc., although plants belonging to northern genera do not always have flowers that bloom in the spring." *C. S. S.*

* *Populus Monticola*, Brandegee, *Zoe*, i., 274.

Cultural Department.

Stray Notes from the Arnold Arboretum.—IV.

AMONG exotic Cornels, as at present represented in the Arboretum, there are only two which possess ornamental qualities of a different character from those found in our native species, and which will repay cultivation in this country. There are some east Asian species, which are not introduced, and a few others only imperfectly known, so that there is a chance that the number of good garden Cornels may still be enlarged.

The two foreign species which can well be added to our shrubberies are the White-fruited Dogwood, *Cornus alba*, and the so-called Male Dogwood or Cornelian Cherry, *C. Mas*. The first is a spreading shrub which, in good soil, grows to the height of six or ten feet and produces slender, recurved branches covered with bright red bark. In habit and in the general appearance of the foliage and flowers, and in the color of the fruit, it bears a strong resemblance to our native red-stemmed Dogwood (*C. sericea*), and the only advantage it possesses over that species is in the brighter color of its branches in winter. In this particular it is far superior to the American plant and should replace it where the attempt is made to produce a bright effect in the shrubbery during the winter months. There is a variety of this plant occasionally met with in nurseries under the name of *C. Sibirica*, which has deeper-colored and brighter branches than any other plant which is hardy in this climate; and this, rather than the more common form, should be planted. Of the origin of this variety not very much is known; it may have been brought from Siberia or it may have appeared in some European nursery. The earliest mention of it is to be found in the catalogue for the year 1836 of the Loddiges, fifty years ago famous London nurserymen who maintained a large and very rich arboretum in connection with their business.

C. alba is widely distributed and very common in Siberia and through northern Asia, and in this country is perfectly hardy. It is, like all the Cornels of this class, easily raised from seed or from cuttings made in the summer; it grows as rapidly as any of the native species, and can be mingled with them without danger of offending the most sensitive taste or shocking the susceptibilities of those critical designers of natural landscape who sometimes find the most beautiful garden-plant out of place in the picture of silvan beauty and quietness they would create, unless from harmony of outline and of character acquired by natural selection and long association it happens to accord with its surroundings.

The Cornelian Cherry is a small tree, reaching sometimes the height of twenty feet, with slender, rigid branches forming a head of rather formal outline. It is one of the plants which cover themselves with flowers in early spring, before any of its leaves appear. The flowers are small and bright yellow; they are arranged, however, in compact, many-flowered clusters, and these, being scattered along the whole length of the branches, give to the plant, in the early days of April, a very striking and beautiful appearance. Here it is the first of the shrubs with showy flowers to blossom, the flowers appearing

almost a week earlier than those of the native Benzoin-bush, which the Cornelian Cherry resembles in general appearance at that period; that is, the two plants cover themselves with yellow flowers before any of their leaves unfold. The Cornel is, however, a more showy plant; it grows to a larger size and the flowers are of a brighter yellow. There is not much to say, however, of this Dogwood, once its flowers are fallen. The fruit, which is half an inch long, or rather more, is elliptical and bright red, and, individually, is as handsome as a cherry or a small plum. But, in this country at least, it is not produced in very great abundance, and the leaves so completely hide it that, practically, it makes no show at all, and there is nothing striking or remarkable about the foliage. One passes the plant without noticing it much, except in early spring, and its appearance leaves no lasting impression on the mind. But this, after all, is perhaps a merit, for plants without striking individuality are sometimes the most valuable, as they are available for many purposes and combinations where more distinct subjects might prove disturbing elements in a composition. The Cornelian Cherry is, therefore, a good plant to use in a garden or a shrubbery where a bright show of flowers would be agreeable in the very earliest days of spring, and where, for the rest of the season, a mass of pleasant, objectionable foliage would not destroy any of those natural and restful conditions of scenery a good garden should be made to afford.

C. Mas. is a native of central and southern Europe, and is one of the hardiest and most satisfactory of the trees of that continent which have been introduced into America. The wood has in all ages been celebrated for its strength, hardness and density, and it is from this peculiarity that the Cornels get their name of Cornus, derived from the Latin word meaning a horn. The origin of the English name of Dogwood is not so apparent. John Parkinson, who wrote voluminously and learnedly about plants in England two hundred years ago, says that the name came from the fact that the fruit of the English species (*C. sanguinea*) was so bad that it was not fit to give to the dogs. In his time the English Cornel had been called Hound's

Fig. 57.—A Fruiting Specimen of Drymophlæus olivæformis.—See page 330.

berry-tree also, and Hound's-tree and Dogberry-tree, so, for some reason or other, its canine affinities seem to have been firmly settled in the popular mind.

The fruit of *C. Mas.* is at least more valuable than that of the other species, although it appears to have been one of the coarse fruits which Circe threw with acorns and Beech-mast to the companions of Ulysses after their transformation. When it is thoroughly ripe the flavor is sweet, and not entirely disagreeable, and in Germany and other European countries it is used in making preserves, robs and liquors. It is not probable that it will ever find much favor in this country, or that the Dogwood will be planted for its wood, which by the ancients was much esteemed for the shafts of javelins, and in later days for the cogs of wheels and butchers' skewers.

There is a variety in gardens with light-colored fruit, and others with brightly variegated leaves. These last, however, are feeble and ugly plants of no merit whatever, except in the eyes of those persons who delight in vegetable monstrosities and like to see a garden filled with "freaks" and converted into a vegetable dime museum, useful enough, perhaps, to physiologists, but abhorrent to the lover of the beautiful.

Among the native shrubs which are not well known to gardeners there is a southern species of Viburnum which deserves a place in the garden. This is *Viburnum molle*, a plant which is widely scattered through the southern states, and which just reaches New England on the Massachusetts islands of Nantucket and Naushon. In habit and in general appearance, in the shape of the leaves, in the flowers and in the fruit it bears a strong likeness to the Arrow-wood (*V. dentatum*). It is not a handsomer or in any way a better plant than that familiar species, and its value lies in the fact that it flowers two weeks or more later than the other Viburnums. It serves, therefore, to prolong the flowering period of one of the most useful and beautiful of the groups of hardy shrubs, and Mr. Dawson is preparing to get together a large supply of young plants, with a view of introducing them on a considerable scale in some parts of the Arboretum.

A word about *V. dilatatum*, described and figured in Garden and Forest (vol. iv., page 150) a few months ago, will not, perhaps, be out of order here. The plants have passed safely another winter, and have flowered more profusely than ever before. There can be little doubt that this is a perfectly hardy plant in this climate and that it has the capacity of adapting itself to its new surroundings. It will only be planted by people who desire to make their gardens beautiful in the late autumn and early winter; in habit and in foliage it is not better, and, indeed, not as good as our native *V. dentatum* or the species which has just been mentioned. The flowers, although abundant enough, are much smaller, and they fall almost as soon as they open; and this Japanese species has really little to recommend it as a flowering-plant. But the fruit is splendid, brilliant, abundant and long-hanging. There is no shrub of recent introduction that equals it in the beauty of its fruit, and there is hardly one among the innumerable varieties found in this collection which surpasses it. This certainly is one of the plants which need to be known only to become one of the most popular garden-plants of the country.

In another issue of these notes something will be said of the new species of Lilacs as they appear in the Arboretum, where most of them have now been successfully cultivated for several years.

Arnold Arboretum. *P. C.*

Hardy Plants.

It is, perhaps, true that no doubt now remains as to the hardiness of *Heuchera sanguinea*, but it ought to be known that there appear to be varieties in cultivation that are scarcely worth planting, being but poor in comparison to the better form that every garden should possess. If any reader is disappointed with his plants it is quite possible these are poor varieties, and, as seed is produced so freely, there is considerable variation in the seedlings, both in foliage and flowers, and some plants have been raised of exceptional merit.

One of the prettiest Campanulas we know is *C. punctata*, which has been in bloom several weeks; its flowers are large, on stems eighteen inches high, and are prettily spotted within; it is a nice companion plant for *C. macrantha*, with large, deep, blue flowers, and *C. Van Houttei*, with flowers of a paler blue. These three Bell-flowers are all in bloom together, are hardy and good perennials. *C. Van Houttei* does not seed, as it is said to be a hybrid, and must always be propagated by division.

A charming little Pea is *Lathyrus tuberosus*. It is now flowering abundantly, and the clusters of deep red flowers are very pretty. I am indebted to an English correspondent for my plants, and they seem perfectly contented and may prove hardy. The roots are tuberous, and much resemble those of the Ground Nut, *Apios tuberosa*. *L. tuberosus* appears to prefer to trail rather than climb; it is at present not more than eighteen inches high, and covered with flowers and buds.

We read much of hardy Gladiolus, but there are few indeed that are quite trustworthy in this respect. I have found *G. Saundersii* to be hardy and to come up and flower year after year when established. This, I believe, is well known, but we have had, during the past month, a pretty clump of *G. Byzantinus* in flower from bulbs that were planted in a border last fall and not protected in any way. The flowers of *G. Byzantinus* are very pretty and showy, and always early; in fact, the plants resemble *G. Colvillei* in every way excepting the color of the flowers, which is crimson, with white stripes on the lower part of the flower. Bulbs can easily be obtained in the fall from dealers, and, when once planted, need no further attention.

Nice clumps of the pretty Himalayan Primrose, *P. rosea*, were sent here last fall, and one of these was risked in the open ground in moist soil, and I fully expected this would be the end of it; but in May, after the potted plants had been past several weeks, the little rose-colored flowers began to peep above the ground, as is their way before the leaves grow, and our entire stock will be left out another year alongside of a little colony of *P. denticulata nivalis*, for which I am indebted to Herr Max Leichtlin, who sent me seeds last fall. Many of these plants are now in flower, which are pure white. The typical plant is well known to be hardy in Massachusetts, and is also of Himalayan origin, and we therefore have reason to hope that the variety will prove to be useful.

Achillea serrata plena, The Pearl, which gave promise last year of being a desirable border-plant and of great use for florists' work, has this season usurped more than a square yard of space to itself and will certainly have to be removed, for at its present rate of increase one can hardly contemplate its progress for another year without alarm. The danger is more threatening when we remember that last year each plant bore about three flower-stems, while now there are at least fifty to each clump, and this without any special cultivation or attention. It is a plant that must be placed where it cannot elbow its feebler neighbors out of their rightful places.

South Lancaster, Mass. *E. O. Orpet.*

Currants.

A careful re-examination of my Currants shows that the crop will be a moderate one, but it is profitable even when it does not exceed one-third of what the bushes ought to yield. For the best crop the ground must be in good tillage and kept well fed. It is absolutely essential to have good drainage. In wet soil the bushes heave in winters, and are not healthy, yet the Currant must have moisture. It is well to give them mulching after a second hoeing. Many of mine grow in a vineyard, between rows of Grapes, from which they get partial shade. These bushes do well.

In pruning I do no more than cut out weak new shoots and old wood that begins to be disbudded or decayed. I have never pinched back bearing shoots. I prefer to have high bushes, removing very low limbs, which often bend down with fruit and soil it. The top should be only reasonably opened to the sun.

Of the red varieties I place Versailles and Fay together at the head. The Versailles grows stronger and taller, and bears with me more profusely than Fay. In quality I find no difference. In size the Cherry is about identical; but the stems are inclined to be very short; the fruit in bunches, and not, therefore, nearly as profitable as the others.

Red Dutch, Prince Albert and Victoria do not differ very greatly in quality, but the real Red Dutch is much the smallest Currant. Prince Albert and Victoria are late and profitable. But the demand is almost universal for "Cherry" currants—a name that in market covers Fay and Versailles. For family use some of the later sorts are valuable.

The best in quality of all currants is White Grape; for the table it is delicious. Next to it I place Versailles and Fay. White Dutch is very rich, but smaller and more seedy. Its distinctive feature is its transparency, and a golden hue instead of white. For family use the White Grape should be planted largely.

The market demand for white currants is increasing steadily. It is a curious fact that, if scalded before pressing, the whites make a rich red jelly, not as dark as that from red currants, but very handsome. Those who make jelly should call for

white currants. Those who eat currants will soon learn to prefer the whites.

Black currants I have mostly discarded as unprofitable for market. One grower, with an acre, can supply the demand of a whole county. Lee's Prolific was heralded as a great advance on Black Naples; it is but little better. Crandall, a native fruit, is a sprawling grower. It is possible that we shall yet get from this stock, or by crossing, an improvement, but the Crandall, as I know it, can make no claim to superiority.

The currant-worm this year came in constant succession from May 12th to July 1st. Its feeding capacity is enormous. It is possible to kill vast numbers by examining the leaves for eggs before they hatch. The after-remedy is the well-known hellebore, sprayed or sprinkled on as soon as the worms begin. As many as four applications are often needed to keep down the pests. Guinea-hens eat the worms, and the currants too. If the bushes are defoliated one year the buds for the next year are debilitated, and a short crop will be produced.

The demand for currants has steadily increased with the demand for all other small fruits. After the cherry it is the most wholesome fruit for dyspeptics. It ships well, and it may remain long on the bushes. Unlike the strawberry, and especially the raspberry, it never hurries us. The opening price in market is from eight to ten cents a pound, wholesale. It seldom drops below five. I have this year given up baskets and sent all my currants out in crates. It will become the only method shortly. In the small boxes they are not crushed, and if picked wet they get dry, while in large baskets they mold.

Clinton, N. Y. *E. P. Powell.*

Notes from the Harvard Botanic Garden.

Utricularia montana.—This charming little "Bladderwort," first introduced to British gardens through a Mr. Ortgies in 1871, occurs freely in South America and the West Indian islands, being epiphytic on the mossy trunks of trees in the mountainous regions. In cultivation it is usually associated with Orchids, and this fact, with the peculiar structure of the flowers, leads many of the uninitiated to consider it a member of that family. It belongs, however, to quite a different order, *Lentibulaceæ*, and, although lacking the brilliant colors found in many Orchids, it is still pretty and interesting. The roots consist of numerous greenish tubers, with fine thread-like white rootlets. The pale green, petiolate, oblong-lanceolate leaves proceed from a cluster of these tubers, and are about six inches long. The scape, almost twice their length, is slender, erect, bearing from three to five flowers two inches in diameter, with a calyx of two triangular, cordate lobes, pale green, and corolla two-lipped, the upper one white and semicircular, the lower white in front and of oval outline, raised and blotched with yellow at the base, with an incurved spur, tapering to a fine point, beneath. The plant blooms at various periods of the year, but most freely during the early summer months. It thrives luxuriantly when suspended from the roof of a stove, close to the glass, in a basket containing crocks, peat and sphagnum in equal mixture, a quantity of the latter being added by way of surface-dressing. Water should be given freely at all seasons, and propagation is readily effected by division of the roots.

Hymenocallis speciosa and H. ovata.—When seen apart it is rather difficult to state in what particulars one of these plants differs from the other. Both bloomed together at this place recently, giving the opportunity of comparing their characters and merits. The latter plant may always be distinguished from *H. speciosa* by its leaves; these are from twelve to eighteen inches in length, oblong, broadly lanceolate, tapering to a petiole-like base one-third of their entire length, somewhat leathery, and of a pale, glaucous-green color. Those of the former, on the other hand, are fully six inches longer, oblong, obtuse, the stalk-like base one-half their length, dark green and succulent. The flowers, however, afford the safest means of identification. Those of *H. ovata* are pedicillate, while those of *H. speciosa* are as distinctly sessile. *H. ovata* flowers the most freely, and should be given the preference on this account. These plants require stove-treatment, but they should not be dried off as severely as most other bulbous rooted plants. They like rich soil, and, in summer, abundance of water, which may be varied occasionally with advantage by the application of liquid manure.

Cambridge, Mass. *M. Barker.*

Cucumbers.—Whether for pickles or slicing, if triangular in general shape of cross-section, as most of them are, the sides should be concave outward, instead of convex, the latter shape always indicating a hard and often bitter strip along the centre of each side where the seeds are attached. The fruit should also be nearly the same size throughout its entire length, any depression or seedless neck being indicative of hardness and bitterness of flesh at that point. In pickling cucumbers, the color is a very important point. It should be as deep, and extend as uniformly over the fruit, as possible. Contrary to the usual opinion, we do not think that coarse spines or prickles indicate crispness of flesh, as the most crisp and brittle sort we know of is the Parisian Pickling, in which the spines are exceedingly small.

Lettuces should be divided into two classes, according to the method of use. If to be served with oil or similar dressing, the leaf should be thick, brittle and crisp rather than tender, and should have a decided flavor—may even have, when first picked, a decided bitter taste, this disappearing when served. Most lettuces of this class form distinct heads. In the second class, the lettuce is cut up with vinegar, sugar, etc., and here tenderness is the great consideration and outweighs all others. No bitterness is admissible, and, as a rule, there is but little flavor. It is a disadvantage for lettuces of this class to form a distinct cabbage-like head, as the thin tender leaves lose all their crispness and beauty of color when crowded into a dense head. A cluster of large leaves is much more desirable.—*Professor W. W. Tracy, before the Michigan Horticultural Society.*

Correspondence.

The Red-flowered Dogwood.

To the Editor of Garden and Forest:

Sir,—A correspondent says (page 308): "There is a variety (of *Cornus florida*) in cultivation with pink, instead of white, flower-bracts, which is really a handsome plant, although considerable prejudice has been created against it by the absurd overcoloring of the bracts, as they appear in illustrations in the sale-lists of nurserymen who are seeking to make a market for it."

As our firm is responsible for these colored plates, permit us to say that when we received the proofs from Rochester, after our strict caution that nothing should be overwrought, we ourselves imagined they were overcolored. We cut some of the drawings, so that only the colored portions of the flowers should remain, and put them on the plants beside the real flowers, and no one could tell which was the painted flower and which was the genuine. This test will hold good to this time.

In justice to your correspondent, however, it may be said that the tint on transplanted plants, or plants not in vigorous health, is lighter than that on vigorous established specimens, and that, after a flower has been opened a few days, the bracts lose color. We are satisfied that he has seen them much paler than the colored plates represent, but if he will call on us when the plants are in blossom we shall be glad to have him test the pictures with the colors on our plants, and are sure he will acquit us of "absurd overcoloring" afterward.

Germantown, Pa. *Thomas Meehan & Sons.*

The Destruction of the Pines.

To the Editor of Garden and Forest:

Sir,—As one reared under the shadow of the eternal Pines, and loving them as only the objects familiar to our childhood are ever loved, as well as one of the great American people who are being defrauded of their birthright, I desire to protest against the wholesale destruction of the Pine-forests now going on all over the country, and particularly in my own state of Georgia. In traveling the other day from Macon to Brunswick I passed through the heart of what was once the great Pine region of the state, and, notwithstanding a long and sad experience of the ways of that most destructive of animals, "the great American developer," I was amazed and appalled at the work, not of destruction merely, but of utter annihilation and extinction that has been accomplished within the last twenty years. During the whole distance traversed of nearly 200 miles there is not left standing on either side of the railroad, as far as the eye can reach, a single stick of Pine fit for timber; and not only this, but Nature's generous and patient efforts to repair the waste are thwarted by the greed of the turpentine distiller, who comes along and destroys what the axe of the lumberman has left. I saw thousands of acres of saplings, some of them less than five inches in diameter,

stripped for turpentine, and thus practically destroyed. The Pine is a forgiving victim, and does its best to protect its destroyer from the effects of his own folly, for at the very feet of the dying parents a new generation of young conifers springs up that would, in time, repair the havoc made by the saw-mill and the turpentine-still, but their greedy enemy will not suffer it. Relentless as Herod, he slays the infant Pines by wholesale, and, like the stupid woman in the fable, who destroyed the goose that laid her golden eggs, he converts his God-given wealth of noble forest into a barren waste of sand and Palmetto scrub.

And thus, from Georgia to Maine—nay, to far-off Nova Scotia—the work of desolation goes on; from Georgia to Maine the mouldering, blackened stumps tell their mute tale of havoc and ruin. I have seen the Kennebec, from Augusta to Bath, so covered with logs that you could hardly see the water; poor, little, scrubby, spindling logs they were, too, that told their own sad tale of the slaughter of the innocents of the forest.

In most of the states there are game-laws for the protection of useful animals, and if these are compatible with democratic institutions, then, why not forest-laws as well? We have in Georgia a closed season for shad and partridges, during which it is unlawful to destroy or molest them, and the Legislature ought, at its very next session, to enact a law making it a misdemeanor, under heavy penalties, to cut or mutilate for the saw-mill or the turpentine-still any Pine-tree that has not attained a diameter of at least eighteen inches. If some such step is not taken, and taken speedily, the present generation will witness the virtual extinction of the most beneficent of all our noble forest-trees, the health-giving, balm-distilling, music-murmuring Pines.

Narcissi in Ireland and Elsewhere.

To the Editor of Garden and Forest:

Sir,—After reading, in the horticultural journals, the glowing accounts, by Mr. Burbridge, Mr. Hartland and others, of the luxuriance of the Narcissi in Ireland, it is comforting to read in the communication from John Quill (Garden and Forest, p. 322), of the same favored isle, that Daffodils should not grow too luxuriantly—but just luxuriantly enough. While his points seem to be commercial ones in trying to point out the superiority of Irish-grown bulbs, they are of interest to growers who have nothing except pleasure in view.

It is difficult to understand why, cultural skill being equal, Irish bulbs should be better than others, and no one doubts the skill of the Dutch in all that pertains to bulb-culture. If fat bulbs are unsatisfactory they would not long continue to grow them so. The early maturition of bulbs may be desirable for shipment, but is it of so much importance for other purposes? Take, as an extreme case, the Polyanthus section. These are, even now, scarcely showing signs of maturity, yet the Dutch send the bulbs here in immense quantities every year, firm, hard, bright-coated and sure to bloom. The early maturing of this section, at least, is apparently of not much consequence, for the Chinese bulbs sent here every fall show no signs of being ripened off; they are lifted with roots still alive, a coating of mud is daubed over these, and they are seemingly shipped as soon as this is dry. Surely no bulbs bloom more freely than these. On examination of a collection of Daffodils it will be found that they vary very widely in their time of dormancy and starting into growth. General rules will hardly apply here, but if early maturity is essential, it would appear that the Italian growers have by far the best of it, and they ought to lead the trade. Stock from Italy, however, is not so superior as to lead us to consider early ripening of first importance.

The buyer of new bulbs may well make the general rules to look over his new stock and carefully examine for maggots, and separate the soft ones for special care in the way of drier treatment than that needed by the main stock. Like the Dutch, not all of us "have the soil, you know," but we wish to know why Daffodils do uniformly well in one place and fail miserably in others. For an instance, *N. poeticus* grows finely in one place in my garden, blooming year after year; in all other places it grows and throws up flower-spikes which uniformly go blind. John Quill will have the thanks of many besides myself if he will tell us how to flower the Poet's Narcissus uniformly. Thanks to the commercial growers, we know pretty well the main points of the successful cultivation of the leading Narcissi, but, in my limited experience, I find that these points must be modified somewhat in practice. Ireland may be so fortunate as to possess large tracts happily adapted to the Daffodils, but there is no such uniformity, even in my small garden, every yard of which, I sometimes think, has different capacities. My little lot of Narcissi is not yet so happily planted as to show no failures, and I regret to say that I see no reason to think that I shall be successful with them by following any general rules, except keeping them vigorous and growing as long as possible. The time of blooming of Narcissi in the open with me seems to depend on the state of the season, not on the time of planting.

Elizabeth, N. J. *J. N. Gerard.*

A Weeping Apple-tree.

To the Editor of Garden and Forest:

Sir,—Some twenty years ago I planted an Apple-tree hedge, which it seemed best to remove after a few years. But one tree in the hedge had shown a marked tendency to droop its limbs, and was spared when the cutting took place. This tree now sweeps the ground over a space fifteen feet in diameter, and would spread farther if allowed. The habit is more marked than that of Weeping Linden, Cherry, Ash and other trees that I have planted. If the habit could be perpetuated by grafting, this variety would be an acquisition for those who have a fancy for such trees. I have no strong liking for them personally, and certainly they should always be used with caution.

Clinton, N. Y. *E. P. P.*

Recent Publications.

The Report of the Chief of the Division of Forestry deserves a more detailed notice than the mere mention it has received as a part of the Report of the Secretary of Agriculture. At the outset Mr. Fernow makes it clear how the work of the division has grown in the direction of giving information in answer to requests. To indicate the character of this part of the correspondence, a classified list of subjects is given, which covers a page. Under the heads of Technology, Forest-influences, Forest-planting, Forest-botany and Forest-management are embraced an immense range of topics, and the questions asked illustrate, in a striking way, the importance, variety and intimacy of the relations which forests bear to human society and life. Under the head of Statistics come inquiries as to the timber area of the United States, the present and future supply of various kinds of hardwood, and a hundred more, concerning which the information furnished must be very imperfect, because of a lack of means for acquiring it. We, therefore, agree with Mr. Fernow that it is a matter of regret that the opportunity afforded by the machinery of the eleventh census was not made use of to obtain some more definite data as to the present condition of our timber-resources. Since our forest-products amount in value, as raw materials, to not less than a quarter of the value of all the raw materials manufactured in the United States the subject is large enough to justify investigation. Mr. Fernow is certainly correct in saying that we ought to know, from decade to decade, what changes in our forest-area, and in their conditions, have taken place, just as we think it worth while to ascertain and compare the areas and crops of agricultural land, and such knowledge is needed more and more as the area of virgin timber-land shrinks and falls into the few hands which control the lumber-supply of the nation. When the division is asked to supply information as to where certain kinds of timber are found in abundance, or many other questions of this sort, only a very general and unsatisfactory reply can be made. In addition to the melancholy fact that the government does not know how much timber-land it possesses, nor what is the quality or the value of the timber on that land, we are reminded, too, that there is a total absence of forest-management on these timber-lands. Under such conditions the Division of Forestry is itself an incongruity. It seems absurd that there should exist a department whose function it is to give advice, which is never followed, about the management of a property which its owner, the government, does not pretend to manage, and about the extent and value of which the government has no definite knowledge, and makes no effort to obtain any such knowledge. All these discouraging conditions have been pointed out again and again by Secretaries of the Interior, as well as Chiefs of the Forestry Division, and yet our forest-resources are wasting away, and the protecting timber on our mountain slopes is disappearing, to the peril of the lives and property of those who live below, and nothing practical is done to quench incendiary fires or arrest the trespasser's axe.

Besides the information that has been imparted by letters in reply to specific inquiries, the Chief of the Division has addressed various associations, such as farmers' institutes and

forestry associations; circulars, too, have been issued, one, for example, giving directions for the growing of seedlings, and another for the treatment of young seedlings in the nursery. The important bulletin prepared by Mr. Tratman on the substitution of metal for wood in railway-ties, and issued during the year, has been previously noticed. The monographs on the life-histories of conifers are again promised. Many of them have been prepared for some time, and their publication should be no longer delayed. In connection with technological investigations, which are still in progress, this work is perhaps the most promising yet undertaken by the department.

One of the great difficulties in introducing good forest-management is the fact that no competent forest-managers can be found. Undoubtedly there will soon be a demand for men of training in this particular occupation, but it is difficult to see how forestry can be studied here to advantage so long as there is no practical illustration of good forestry, and, on the other hand, foresters imported from abroad will find it difficult to adjust their methods to the conditions existing here. Mr. Fernow, therefore, advises that young men with considerable preliminary preparation should go abroad and acquaint themselves, by study in the various academies and in practical work in the woods, with the theory and practice of forest-management. This might be accomplished in one or two years abroad by any one who is fitted with the necessary botanical and technical preparatory education. Persons who wish to prepare themselves for such a course may find very considerable facilities for this study in the libraries and museums of the department, and a list is also given to show what facilities are offered in the different states at the experiment stations and agricultural colleges on subjects which are necessary to a preliminary course in forestry.

Many other subjects are touched upon in this brief report which we have not space to notice in detail. Most interesting of these, perhaps, is the chapter on the wood-pulp industry, which has had a most rapid development in a few years. It certainly has not yet reached its full development, and perhaps Mr. Fernow is correct in saying that its expansion during the next few decades may bring revolutionary changes in our wood consumption, and modify to a considerable extent the practice of forest-management.

The report closes with the statement that increased appropriation will make it possible for the division to devote more time to missionary work, which is still sadly needed, before any intelligent forest-policy can be adopted in the United States.

Periodical Literature.

In the *Popular Science Monthly*, for July, Professor C. S. Ashley gives an account of "Our Agricultural Experiment Stations" which should interest those who see the reports from these stations constantly referred to in Garden and Forest. He traces their establishment to Samuel W. Johnson, now Professor of Agricultural Chemistry in the Sheffield Scientific School at New Haven, and Wilbur O. Atwater, now Director of the office of Experiment Stations in the National Department of Agriculture, who, having studied in the agricultural stations of Germany, made, in 1873, "the first direct effort to start an agricultural experiment station on this continent." This effort was made in Connecticut, and the first American station was there established, at Middletown, in the year 1875. In 1876 another was started in California, and in 1877 another in North Carolina, and in 1887, when the Hatch act passed Congress, there were eighteen stations spread through fourteen states. "This act made provision for an appropriation of $15,000 a year to each state or territory that would accept the trust, to establish a station in connection with its agricultural college, or to aid such stations already established. All of the states, except Montana, Washington and Idaho, have taken advantage of the act, as have also New Mexico, Arizona and Utah. Some have more than one, and some, who have only one regular experiment station, have organized one or more branch stations, located in different sections of the state. If these branch stations be excluded, there are now fifty-three experiment stations in the United States; while if these be counted, there are sixty-nine." Four hundred and twenty-three persons are now employed on the scientific staffs of these stations, including agriculturists, chemists, horticulturists, botanists, entomologists, veterinarians, meteorologists, biologists, microscopists, physicists, mycologists, viticulturalists and geologists. Each station is independent of the others, but a central bureau at Washington collects and publishes summaries of their work for the use of the public, special bulletins for the station-workers themselves, and reports and monographs of various kinds, and serves as a "medium of information and exchange." During the present year about $1,000,000 will be expended on these stations, and reports will be sent direct to nearly 400,000 farmers—and all this is a growth of the last fifteen years.

It seems odd to read that "the greatest obstacle which the stations have met has been a demand from the farmers for immediate results and a prejudice against the laboratory and its work"; but, we are told, "this gradually disappears as the farmer becomes more and more familiar with science." The way in which fraudulent fertilizers have been driven from the market by the action of the stations is named as one conspicuous instance of the practical good they have done, and others are the improvement in the methods of extracting sugar from cane in Louisiana and the introduction of the process of "Pasteurization" of wines in California, which does away with the use of antiseptics of any kind, while the new facts, theories and interests which the bulletins bring into the farmers' lives have, apart from their practical outcome, an educative and cheering influence which can hardly be overprized. Of course, at first it was difficult to get competent scientific workers for the various stations, but this hindrance is gradually disappearing.

In the same number of the *Popular Science Monthly* Mr. Joseph F. James writes of "Pollen and its Uses." We quote a single paragraph as a sample of the interest of all the others. "The immense number of pollen-grains," he says, "produced by a single flower apparently militates against the saying that Nature allows nothing to be formed but what is needful. It seems, indeed, a vast waste of material to have such a multitude of grains when so very few would answer the same purpose. In a single flower of the Peony there are about three and a half million grains; a flower of the Dandelion is estimated to produce nearly two hundred and fifty thousand; the number of ovules in a flower of the Chinese Wistaria has been counted and the number of pollen-grains estimated, and it is found that for each ovule there are seven thousand grains. While few fall below the thousands, many rise far above the Peony in point of numbers. These are the wind-fertilized flowers, and here Nature must provide for an immense loss of material. Darwin says that 'bucketfuls of pollen have been swept off the decks of vessels near the North American shore. . . . Kerner has seen a lake in the Tyrol so covered with pollen that the water no longer appeared blue. . . . Mr. Blackley found numerous pollen-grains, in one instance twelve hundred, adhering to the sticky slides, which were sent up to a height of from five hundred to a thousand feet by means of a kite, and then uncovered by means of a special mechanism.' The so-called showers of sulphur which have at times visited various cities, notably St. Louis, are nothing but clouds of yellow pollen blown from Pine or other forest-trees from some distant place. Perhaps, out of millions of grains thus scattered far and wide, only a single one may be of service. As if to compensate for this expenditure of pollen in some plants there are others in which the amount is very limited, and where nearly every grain is made to count. These are known as cleistogamous flowers, a term applied to those which always remain in the bud. These flowers are found in plants belonging to about sixty different genera of various orders, and generally in those species which at the same time produce the normal and conspicuous flowers. These large blossoms are often sterile, and the plant must depend upon the cleistogamous flowers for its seed. In the Wood-sorrel (*Oxalis acetosella*) these flowers have each about four hundred pollen-grains; the Touch-me-not (*Impatiens*) has only two hundred and fifty, and some Violets only one hundred. Even before leaving the anther-cells the grains in these cases have protruded their pollen-tubes; these seek the pistil and penetrate to the ovules. It might perhaps be supposed that, as the seed can be produced so easily, all plants would have cleistogamous flowers. But here comes into play the fact that that continual close fertilization is a great detriment, and not a benefit, and that it is better in the end that flowers produce an apparently wasteful amount of pollen and take the chances of a cross, than to be more economical and be perpetually self-fertilized."

As a companion to this article on pollen, the *Monthly* gives, from the *Cornhill Magazine*, one called "On the Wings of the Wind," which explains some of the methods used by plants in scattering their seeds. To hint at the variety of these methods we will merely quote the author's declaration that among the *Compositæ* alone "I can reckon up more than a hundred and fifty distinct variations of plan among the winged seeds known to me in various parts of Europe."

Notes.

A correspondent of the *Rochester Post Express* states that 80,000 plants of Roses, embracing 150 varieties, are growing in one block in the nurseries of Messrs. Ellwanger & Barry, while in another field near by there are 20,000 plants.

The growers of early fruit in California this year reaped a rich harvest. Early cherries, peaches, apricots and pears brought high prices in eastern markets, and some of the earliest peaches came from the northern part of the state.

Number one of *Meehan's Monthly* was issued on the first of July. It contains a colored plate of *Rhododendron maximum* and sixteen pages of reading-matter, and resembles very much, in typographical appearance, the *Gardeners' Monthly*, when under Mr. Meehan's direction.

Monsieur A. Lothelier, in a note recently laid before the French Academy of Sciences, declared his belief that in *Robinia Pseudacacia*, *Ulex Europæus*, *Berberis vulgaris* and other plants the formation of spines is dependent upon the action of light. If grown where the light is not strong, plants of this sort show few spines, while when the light is more powerful the spines are more numerous, better developed and more markedly differentiated.

Les Cypripedium et Genres Affinés is the title under which Angiolo Pucci publishes, in Florence, a volume of 218 pages, a history of Cypripedium, with a description of the species and the methods used for their successful cultivation. It is a French translation, or rather an adaptation, of Veitch's "Manual of Orchids," already noticed in these columns, and will be found interesting and valuable to the cultivators of these popular plants who are not acquainted with the English language.

The *Société Nationale d'Horticulture de France*, the chief horticultural association of that country, now includes nearly 2,500 members, of whom 914 reside in Paris, 379 in the Department of the Seine, and 982 in the remaining parts of France, while 175 are foreign associates, some of them living in lands as distant as China. The Society is divided into six committees: one each for fruit-culture, for the culture of ornamental trees, for horticulture proper, for vegetable culture, for artistic gardening, and for garden utensils.

The famous liqueur called "Chartreuse," from its makers, the monks of the Carthusian order, is composed of brandy, flavored by a mixture of herbs, the secret of which is carefully kept within the bosoms of the order. The Benedictine monks manufacture a similar beverage which, likewise, is called by their name; and now, we are told, the monks of Tre Fontane, near Rome, the place which has recently become famous for its vast plantations of Eucalyptus trees, are introducing a liqueur, the characteristics of which are explained by the name selected for it—"Eucalyptica."

The Proceedings of the American Forestry Association, at its late meetings in Quebec and Washington, have been published in a neat pamphlet of 112 pages. Summaries of several of the papers have already been given in this journal, but the matter is all well edited and of excellent quality. In a prefatory note it is stated that the association does not hold itself responsible for the views expressed at its meetings or published afterward in its reports. Its platform is offered, however, for the discussion of all important questions connected with forestry, and the encouragement of such discussion is most commendable. Indeed, this is the only way to promote the aims of the society, which are (1) Education, or leading the public mind to see the necessity of prompt and thorough reform in the treatment of American forests, and (2) Legislation for the enactment of proper laws under which to accomplish this reform. The association now has an earnest membership from thirty states and two provinces of Canada, and it is in every way worthy of public support. This report deserves a wide circulation, and persons who are not members of the association can secure copies of it for fifty cents by addressing Charles C. Binney, 218 South 4th Street, Philadelphia.

Writing from Chicago, with regard to the preparations for the World's Fair, a correspondent of the *American Architect and Building News* recently said that the work of dredging was being pushed with all speed, so that it was expected that the lagoon would be completed by the end of June, and also the grading which would make the sites ready for the foundations of all the buildings. "Over 900 men," he continued, "have been at work in this especial department, and three large steam-dredges have been constantly at work. Over 100,000 plants have been shipped to the place and are being cared for by a large force of gardeners. The proposed wooded island is already converted into a nursery, while on one part of the island it is proposed to lay out a primeval swamp, such as formerly occupied the site of Chicago, the plants for the purpose being already on the grounds. Three greenhouses have already been built and a stovehouse for Palms, and preparations are being made to receive wild herbaceous and aquatic plants from all parts of the country. Sixty thousand Willow cuttings are already in the ground, 10,000 of them being sent as a gift by the Park Commissioners of Buffalo, New York. Mr. Olmsted has presented the Exposition with Bamboos from Asheville, North Carolina, near to the park he is there laying out for one of the Vanderbilts."

The new body incorporated in Massachusetts by Chapter CCCLII. of the Acts of the last Legislature "for the purpose of acquiring and opening to the public, under suitable regulations, beautiful and historical places and tracts of land within this commonwealth," has organized by adopting a code of by-laws and electing as its first President the Honorable George F. Hoar, of Worcester. The Honorable William S. Shurtleff, of Springfield, is Vice-President, Mr. George Wigglesworth is Treasurer, and Mr. Charles Eliot is the Secretary. The direct management of the affairs of the corporation is vested in a Board of Control consisting of Mr. Philip A. Chase, of Lynn; Mr. Charles S. Sargent, of Brookline, and Dr. Henry P. Wolcott, of Cambridge, with whom are associated the Secretary and Treasurer. The corporation is empowered to acquire by gift, devise or purchase, beautiful and historical places in Massachusetts, and to hold the same free of taxes as long as the reservations are open to the public. Under the by-laws any person who subscribes $10 to the funds of the corporation becomes entitled to receive the annual report and an invitation to an annual conference with the Trustees. Clubs and societies may become entitled to send a delegate to the annual conference on the same terms, and it is expected that the Historical and Natural History Societies and the Village Improvement Societies of the state will in this way be able to assist a cause in which they are naturally interested. Any man or woman, whether a citizen of Massachusetts or not, who desires to take part in the work of this corporation may do so by communicating with the Treasurer, Mr. George Wigglesworth, 89 State Street, or with the Secretary, Mr. Charles Eliot, 50 State Street, Boston.

The last part of the *Contributions from the United States National Herbarium*, being Volume II., No. 1., to reach us contains the first installment of Professor Coulter's Manual of the Plants of western Texas, and embraces the *Polypetalæ*. The purpose of the manual, the author tells us, is to bring together and make easily accessible the scattered information which exists concerning the flora of western Texas, a region of great botanical interest as the meeting-place of the plants of the true North American flora with the peculiar forms of northern Mexico. The manual is intended to include all Texas plants found west of the ninety-seventh meridian. The introduction of useful analytical keys, local names, and the mention of the economic uses of the plants, greatly increases the value of the work which has been prepared, not only as a reference-book for botanists, but as a hand-book for Texas students, for which purpose it seems admirably adapted. It is to be regretted that Professor Coulter has not adopted some uniform system of nomenclature, and it is not easy to understand why, for example, if Marshall's name for the Fragrant Sumach, *Rhus Canadensis*, is to be taken up, his names for the Sweet Buckeye and for the Chicksaw Plum should be passed by in favor of much later ones. The supposition is that an attempt was made to follow the plan of nomenclature adopted in the last edition of "Gray's Manual," of which Professor Coulter was one of the editors, and in which appears a considerable number of plants under names sanctioned by long usage, although not the oldest, and, therefore, in danger of change at the hands of subsequent authors. But even the names of the "Manual" are not always adopted in this new work, for, in turning over the pages very hurriedly, the eye falls on *Cratægus arborescens*, Ell.—a plant which was correctly referred, by Watson and Coulter only last year, to the *Cratægus viridis* of Linnæus. Such details, of course, do not detract from the working value of a manual of this character, except in so far as they continue and extend the confusion of botanical nomenclature and complicate synonymy.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by . . . . . Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, JULY 22, 1891.

TABLE OF CONTENTS.

The Red Oak.

THE Red Oak is one of the largest and most beautiful of the deciduous trees of the American forest. It is the largest and the most widely distributed American representative of the so-called Black Oaks—that is, of the Oaks distinguished by the acute bristle-pointed lobes of their leaves, by the slow development of their fruit, which requires two seasons in which to reach maturity, and by their brittle and porous wood. There is no other American Oak of wide distribution which varies so little as the Red Oak in the form of its leaves and in the character of its fruit; and it is in western Texas only that it occasionally assumes an appearance which is puzzling to botanists, leading them to suppose that through this extreme form it may be possible to join it specifically with some of the other Black Oaks.

From Canada to Texas the Red Oak varies but little in what may be called essential characters; individuals are large when the soil is rich and moisture is abundant, and they are small and stunted in barren soil unrefreshed by copious rains. The leaves and the fruit are larger and better developed when conditions of growth are favorable, but in form they are very constant, and it is easy to distinguish the Red Oak, with a little practice, at all seasons of the year.

In habit of growth it varies considerably, but not more than other trees; for it must be remembered that the habit of a tree—that is, the form of growth a particular individual assumes—is dependent entirely on the local conditions and surroundings in which the individual is developed. It is exceptional when all the individuals of a tree-species assume the same habit of growth. Most trees form tall slender stems when other trees crowd them, as in the forest, and cause their lower branches to die from the insufficient supply of sunlight which reaches them. An individual of the same species standing by itself will send out long stout lateral branches which give to the tree an entirely different appearance. In the case of some trees the habit of individuals is influenced by the character of the soil in which they grow, and age, of course, brings many changes in form and general appearance to trees. It is for these reasons that the portrait of an individual gives only a partial and therefore an unsatisfactory idea of the general appearance or habit of the species, and why a hundred portraits would be necessary to give anything like a comprehensive idea of the appearance of a tree like the Red Oak, for example, as it appears in different parts of the country growing under the different conditions to which it is subjected.

The power to recognize trees at a glance without examining their leaves or flowers or fruit as they are seen, for example, from the car-window during a railroad journey, can only be acquired by studying them as they grow under all possible conditions over wide areas of territory. Such an attainment may not have much practical value, but once acquired it gives to the possessor a good deal of pleasure which is denied to less fortunate travelers.

The Red Oak (*Quercus rubra*) grows naturally in both rich land and in light porous gravel. Usually it selects a soil intermediate in character, between that preferred by the White Oak and the sterile soils occupied by the Black Oak. It is the only Oak which reaches as far north as the northern part of Nova Scotia, while westward it extends almost to the limits of the Atlantic forest region. It is one of the commonest trees in all this great territory, and grows from the immediate neighborhood of the coast to higher elevations on the Appalachian Mountains than any other Oak tree; it is as common west of the mountains as it is on the Atlantic sea-board, and it abounds in the south as well as in the north. The Red Oak cannot secure a foothold in undrained swamps or on the inundated banks of rivers, but in all other situations, from Cape Breton to the Rio Colorado, it can hold its own wherever trees grow. It is west of the Alleghany Mountains that the Red Oak, growing on rich intervale lands along the larger streams which flow into the great tributaries of the Mississippi, can be seen at its best as a timber tree. Here specimens can be found a hundred and fifty feet high, with stems as straight as arrows, free of branches for sixty or seventy feet from the ground, and five or six feet in diameter, above the great swollen buttresses which are characteristic of large individuals of this species. Such noble specimens occur, too, in the forests which clothe the slopes of the mountains of the south, but at the north, where the deciduous forests which Europeans found here when they discovered America have been replaced by a second growth, the Red Oak assumes, usually, a different habit. The trunk often separates, fifteen or twenty feet from the ground, into several stout branches which grow in an upright direction, and, gradually spreading outward, form a wide head in the shape of an inverted pyramid. Such a form indicates that the tree has grown in good soil and that it has succeeded in securing a fair amount of space in which to develop its head. In poor soil, and when crowded by other trees, the Red Oak makes a narrow head of small branches and does not grow to a large size. Sometimes it branches low, sending out at right angles with the trunk great wide-spreading limbs, like a pasture White Oak, making a round-headed top. Such specimens are not common, and perhaps represent the noblest type of individual beauty the species is capable of.

The bark of the Red Oak is dark brown and deeply furrowed on the trunks of old individuals; it is smooth and gray on young trunks and on the branches, unless they are very old and large. The bark of the branches is smoother and lighter-colored than that of the other Black Oaks which are usually associated with the Red Oak, and for this reason the tree can be easily recognized in winter by the color of the branches alone. The leaves are oblong in general outline, with five or six acuminate lobes on each side, separated by rounded shallow sinuses; they are rather thin, smooth, bright shining green on the upper

surface, and shining, although somewhat paler, on the lower surface. They are borne on long slender stalks which, like the upper side of the veins, are sometimes tinged with red; and in the autumn they turn first dull-red and then yellow before falling. The fruit is unlike that of our other Oaks. It is sessile or very short-stalked; the cup is flat or shaped like a shallow saucer, with a narrow raised border of small, close-fitting scales, and is often more than an inch across, enclosing the base only of the large oblong or ellipsoidal acorn, which is as long or longer than the cup is broad. The fruit is produced generally in great profusion, and in October often covers the ground beneath the trees.

The wood of the Red Oak, although strong and heavy, is coarse-grained and difficult to season; it is light reddish brown and contains the bands of large open ducts found in the wood of all the Black Oaks. Formerly it was little used, but of late years, since white oak has become scarce and expensive, it is employed in great quantities in cooperage, in the manufacture of cheap furniture, especially in some parts of the west, and for the interior finish of buildings, for which purpose, when "quarter-sawed," it is well suited and now highly esteemed.

The Red Oak grows rapidly. Very few of the American trees which produce hard wood increase in height and in girth of trunk as rapidly. Mr. Emerson, who devoted much attention to studying the rate of growth of different trees, found that the average increase of the Red Oak in Massachusetts during the first thirty-five years of its life was at the rate of about two inches in diameter every eleven years. In more favored parts of the country it would probably grow more rapidly. As a street or park tree the Red Oak is not surpassed in value by any of our trees, and it is surprising that it is not generally planted. There is, however, a popular belief that Oaks are hard to transplant and that they grow very slowly. White Oaks are certainly difficult to move, and must be set as seedlings if they are to grow into fine trees. But all Oaks grow rapidly when once established, and there is no tree easier to transplant than the Red Oak. Specimens ten or fifteen feet high can be moved with perfect safety from the woods, and if they are planted in good soil will make for many years an average annual upward growth of eighteen or twenty inches. If hardiness, good habit, adaptability to different soils, beauty of foliage, longevity and freedom from disease have any weight with planters of trees, the Red Oak should receive attention at their hands. It is valued in Europe, where, especially in Germany and in Belgium, it is more frequently seen, and in better condition, than any American Oak. But how many Americans plant Oak-trees or realize when they send to nurseries for foreign trees that their own town contains the best material for their ornamental plantations?

Some idea of the beauty of the stem of one form of the Red Oak can be gained from the illustration on page 341. It is made from one of Dr. Rollins' photographs of a tree growing in Dedham, Massachusetts, and one of the noblest specimens in New England.

Squandering a Nation's Patrimony.

At the recent celebration of the 4th of July at Woodstock, Connecticut, Mr. Murat Halstead delivered a striking address, to which he gave the title of the "Preservation of the People's Inheritance." It could be more accurately described as an account of the reckless way in which mankind in general, and Americans in particular, had squandered, and were continuing to squander, their inheritance. In speaking of the decline of certain nations, Mr. Halstead said:

The lands have been wasted, the forests are no more, the soil that once made fruitful hills and blooming valleys is at the bottom of the seas, and the streams that watered the peopled plains are lost in the sands that are the tombs of the profligates who have perished. The elements of possibility, the foundations of prosperity, are gone, never to be restored, and those cancers of the earth, the deserts, are eating away more and more that which should sustain the generations to come.

Coming down to our own country, the speaker referred to the exhausted fertility of tobacco-lands and wheat-fields; to the extermination of food fish and noble game and water-fowl; particularly to our vanishing forests.

The woods have been torn from the mountains, and brooks have departed because the springs have ceased to flow; and, when not dwindled almost to dust-beds, the ancient mill-streams are roaring floods, for the slopes of the ridges are bared and the rain-falls rush from them as over roofs of slate; the hill-sides are plowed up and down preparing gutters to feed the freshets with the soil that is far more precious, in the eyes of those who have been taught the art of seeing, than the precious metals. It is the passion and pride of the average American to smite the trees and shoot the birds and slaughter the last of our running game—and if there are laws for the protection of trees in parks, or game-laws to save the quail and squirrel, or to prevent scouring the rivers with seines out of season, and to provide fish-ladders and abolish fish-traps, they are regarded as tyrannical, a style of oppression identified only with effete monarchies and the tottering despotism of worn-out worlds. The buffalo have been exterminated—a noble race murdered, so that there are hardly enough to supply museums—and if there is a moose left in Maine he has been accidentally spared, and must be pursued by the hunter with remorseless fury to shed his blood to the final massacre. It is a crime to cut down the woods on a mountain, a crime to heedlessly kindle fires to burn forests, but our people have no realizing sense of the sort, and sneer at the Swiss and Germans who require three permits to fell one tree. In New York there is a struggle that seems hopeless to preserve the remnants of the once majestic and always romantic Adirondack wilderness. In our new states the statesmen dare not stand against the timber-thieves.

In some parts of the address Mr. Halstead's rhetoric was rather too intense for scientific accuracy, but, after all, the real sting of the indictment is in its truth. To the speaker's hopeful spirit the establishment of fish-hatcheries by the Government, the effort to protect the seals of Behring Sea, and the reservation of the Sequoia groves were acts which gave promise of a time coming when more serious thought would be given by our nation to the preservation of its heritage. He noted, too, as hopeful indications, that Arbor days were celebrated in many states; that tree-planting by children had become fashionable, and that the discussions over the Adirondack woods, although it might not save the wilderness, would ultimately, perhaps, save many other forests. We feel inclined to consider it another cheering sign that an orator of national repute has felt impelled, on that anniversary when Americans are in their most exultant mood, to raise his voice in earnest protest against the reckless destruction of our forests. No higher public service can be rendered by the country's leading men than the reiteration of warnings like this, until it comes to be universally understood what the ruin of our forests means.

How We Renewed an Old Place.

XIV.—THE ROSE-CHAFER.

There is no interim between our summer visitors. No sooner is the trunk of the last caterpillar packed than the rose-bug arrives, bag and baggage, to take his place. The half-eaten leaves that have been rescued from the jaws of the web-worm are in a few hours riddled with the bites of these winged pests, which are even harder to destroy than their predecessors, for they hunt in couples and fly, and cannot be stamped out of existence.

An imperturbable imp is the rose-chafer, descendant on one side from the scarabœus, and if his Egyptian ancestor was half as hard to kill as this other flying beetle, no wonder the ancients used him as an emblem of immortality.

This voracious summer boarder arrives with unpleasant punctuality upon the 10th of June—that is to say, the advance-guard of the great army shows itself in the shape of a scout or two, who merely precede the main swarm, which comes in a cloud, and settles everywhere, and stays nearly four weeks.

The opening Roses are their nominal prey, and are soon disfigured with their dingy yellow-brown carcasses; but that

is not the worst of them. Grape-blossoms are their dear delight, and nothing but the most unremitting attention will save the future bunches from their greedy depredations. There are at least two to every raceme of fragrant blossoms, and by the time one has disposed of that pair another is flying about all ready to take their places.

Arsenical poisons have no more effect upon them than a cold shoulder on an office-seeker. They may kill the plant, but never the rose-bug, which will crawl undismayed over its ruins, seeking new worlds to conquer. Having no delicate sensibilities, they are undeterred by whale-oil soap, which disheartens most things, and even a dusting with hellebore does not even make them sneeze. The great unterrified eat on in spite of all you can do to them, and no sooner is one set slain than you find another in its place. They remind one of the Jesuit monks in Bolivia, whom the inhabitants finally regarded as supernatural beings, because, no matter how often one cowled and sandalled form was laid low, another succeeded it, till the natives came to believe that the friar was an immortal, whom they vainly sought to destroy.

As to the rose-bug, hand-picking into a bowl of kerosene or hot water, begun at morn, continued till noon, and not intermitted till dewy eve, is the safest resource against the marauders, which devour not only Grape-blossoms and Roses, Spiræas and Syringas, Pæonies and Snowballs, but cover Birches, Oaks, Elms, and even Willows, with their ugly little forms, and leave behind them a lace-work of veins in place of leaves.

Nothing pleases them better than a Smoke-bush in blossom, the future fringe of which they will completely destroy in a few hours. We tried the experiment this year of tying ours up in mosquito-netting, but it seemed to accomplish nothing better than the excitement of the curiosity of passers-by, who could not make out whether it was a ghost on the lawn or a balloon waiting for a Fourth of July inflation. The indomitable chafers perched on the outside by the hundred and chewed at the blossoms through the meshes, so that, what with their attacks and the confinement, the smoke came to nothing after all, for when the cover was removed nothing was to be seen of the fringe but a few bare green stems.

Probably the rose-bugs do not publish a morning paper, or they would learn that the lawn at Overlea is an unhealthy situation for their race, and that their unprecedented mortality in that region ought to be a warning to them. Certainly in the height of the season the hecatomb of victims amounts to a thousand a day, but the cry is, still they come.

We hoped that the long, cold, easterly storm of June would prove a discouragement to them, but the minute it stopped raining they reappeared more numerous and hearty than ever, and made up nobly for lost time. They show a curious preference for old-fashioned Roses, and will devour them, leaving a bed of hybrids of modern varieties almost untouched, and they never are found here on the Tea Roses. They will eat the hardy Hydrangea voraciously, but do not affect the Weigelia. They spoil the Snowballs, but do not meddle with Lilacs. We have some young Canoe Birches that are struggling for existence, and I always imagine the departing caterpillar exchanging compliments with the arriving rose-bug and recommending them to his particular attention, after the fashion of guzzling Jack and gorging Jimmy:

> "Here's little Billee, he's young and tender,
> They're old and tough, so let's eat he."

Positively, if, during three or four weeks of their stay, those insects were not fought tooth and nail, there would not be one leaf left upon those unhappy little trees. As it is, when the brutes depart, the Birches look like a design in skeleton leaves.

This year our hopes were roused by a remedy called Sludgite, which was warranted to kill, not only the rose-bug, but the Colorado beetle and all other insects fatal to vegetation. Though scoffed at by incredulous friends we dared to send for a can of this evil-smelling mixture and applied it to the creature, with whom it undoubtedly disagrees. It is made of the residue of petroleum and soap, and smells to heaven, but, alas! the rose-bug has no nose—at least no nose that takes offense at bad odors. Sludgite is a thick, semi-solid substance that mingles readily with water, and is applied by a spraying-pump or a hand syringe, and kills by contact. The rose-bug and the Colorado beetle keel over with all their heels in the air as soon as the gummy fluid comes in contact with their wing coverings, but, curiously enough, it seems to have no power to destroy the larva of the potato-bug, and, not being a poison, it seems to have no deterring effect upon the little worm that eats the leaves of Rose-bushes, or even upon the Thrip, which whale-oil soap banishes for a long time. Therefore, I judge that the mixture clogs the wings and interferes with the breathing of beetles, or, possibly, whatever virtue it possesses lies in the volatile essence which escapes from it, for the fresh mixture is much more deadly than that which has stood for some time.

But the sad thing about its use is, that the rose-bug is a being that draws no moral from any tale, and he is totally devoid of sentiment. I cannot find that the corpses of his relations take away from his appetite in the least. Possibly the numerous attendants we see at the funeral come for a wake, and they are full as hungry and thirsty as Conn the Shaughraun's cousins on the same melancholy occasion.

Though I am disposed to think that the chafers may not be quite so ready to attack a bush or tree freshly anointed with the unsavory fluid, I am not sure but that the wish is father to the thought. In any case, it is not practicable to shower a bush every five minutes with anything, however deadly, so that it is almost as discouraging as hand-picking.

A distinguished horticultural authority, who takes very little stock in my new discoveries, declares that muscle is worth more than faith, and shows me perfect roses, as large as his fist, to prove it. This is all very well if you are lucky enough to have unlimited muscle at your command, as in an arboretum for instance, where every rose-bug has a man to catch him, but both hand-picking and insecticides are alike failures in a private family with one factotum. What the world demands is a warning of some kind that the chafer who runs may read, a something to convey to his insect-mind or nostrils the information that "no rose-bug need apply," and whoso can make this discovery palpable to the enemy will have his fortune in his red right hand.

The legends connected with the rose-bug are numerous. They tell us that he will not molest a Grape-vine or a Rose-bush close against a house, though he will devour the Virginia-creeper against the lattice of your veranda. He is supposed to object to the dust of the road and to a sprinkling of coal-ashes; but on our own windy hill neither of these deterrents can be made to stick.

Another legend belongs to the potato-beetle, which some of the farmers in this neighborhood vow will not trouble Potatoes planted in a hill with Beans; but this is merely a legend. We have tried it, and find the creatures as lively as ever.

To return to sludgite, I would say that its highest practical use is upon trees and shrubs without blossoms, for the sticky yellow fluid cannot be sprinkled upon roses without spoiling their fairness. So far it does not seem to damage foliage, but we cannot answer for the effect of such a viscid decoction if used many times a day. We have never tried it more than twice in twenty-four hours. It kills or drives away the insects that are there, but others return immediately, so that such insecticides are little better than substitutes for hand-picking.

Our struggles with the hated rose-bug, and the hopeless nature of any prolonged encounter with an inferior organism of overwhelming numbers, find such clear expression in the words of a correspondent that I subjoin an extract from a letter from a lady who has had similar sufferings with another insect:

"I am passing through the discouraging season of gardening, and am realizing more than ever the nature of Adam's curse. It sounds like a fine thing to be told we shall have dominion over the birds of the air and the beasts of the field, but what gain is there in that if we are to be beaten in the end by the angle-worm, the ant and the snail? To fight with a snail, and be beaten, isn't that humiliation? But I stand in the place of the vanquished, and it is the snail that has done it. I was born a sentimentalist, and had scruples about 'taking away the life thou canst not give,' that once hindered my career as a gardener. Now I grieve over the imperfect nature of the snail's nervous system that makes even death apparently painless.

"But he keeps up with the times, does the snail; he reads the seed catalogues, and he knows that Asters cost more than Marigolds; he has an eye for beauty, too; he knows a foliage plant very early in its career, and his taste is always for red rather than green.

"The snail is a much underrated power; his calmness, his persistence, his retiring nature, his thick-skinned endurance, make him a type that is bound to survive, and I predict for him a glorious future. If he can only find enough fools to cultivate gardens for his use he will enter in and possess the land, and develop into something quite grand." All of which quotation, with slight variation, will answer for our winged pest.

I was quite touched by the prediction of a member of the horticultural society of that state, that apparently the whole of

southern New Jersey will have to be abandoned to the rose-bug. This adds a new terror to the already complicated legislation of that unhappy region, for I am convinced, from my experience, that if the rose-bug wants anything he will get it, and no doubt we shall live to see him sitting in the gubernatorial chair.

Notes on North American Trees.—XXVI.

69. *Rhus cotinoides.*—The Tournefortian genus Cotinus, adopted by Linnæus in the early editions of the "Genera," and afterward united by him with Rhus, is re-established by Engler in his monograph of the *Anacardiaceæ*, published in the fourth volume of De Candolle's "Monographiæ Phanerogamarum." The genus, with its two species, one of the Old World and the other of the New, is well characterized by the numerous long accrescent plumose sterile pedicels, and by the unequal development of the fruit which brings its apex at maturity well down on to the side; and in "The Silva of North America" I shall follow Engler, and separate Cotinus from Rhus. There is not much doubt what the names of the two species should be. Linnæus first described the European plant in the first edition of the "Species Plantarum" as *Rhus Cotinus*. *Cotinus* is, therefore, the oldest specific name for the species which, if the genus Cotinus is maintained, must be called *Cotinus Cotinus*. Engler, unfortunately, passed over this Linnæan name, as Koch had done before him, and took up, as the specific name, *Coggygria* of Scopoli ("Fl. Carn.," i., 220) published in 1772, that is many years later than the date of the "Species Plantarum." There is even less room for a difference of opinion as to the correct specific name of the American species. Nuttall, who discovered it, called it as an herbarium name, without description, *Rhus cotinoides;* this name was first published in 1860 in Chapman's "Flora of the Southern United States." The plant was first described by Nuttall himself in the third volume of his "Sylva," which appeared some time between 1842 and 1850, under the name of *Cotinus Americanus*, and *Americanus* is, therefore, the oldest name, whether the plant is called Cotinus or Rhus.

72. *Rhus venenata.*—There is confusion of long standing in the case of the name of our Poison Sumach. It dates from the time of Linnæus, who believed that the Japanese Lacquer, or Varnish-tree, was the same plant as our North American Poison Sumach. He knew from the writing of Kæmpfer that the Japanese used the juices of their tree as a varnish, and so called his species *R. Vernix*. There is no question, however, that when he described *R. Vernix* he was describing the North American and not the Japanese plant. His descriptions in the "Species Plantarum" and the earlier one published in the *Hortus Cliffortianus* show this, as do his references to earlier descriptions and figures of the American plant. De Candolle, finding that the two plants were distinct, made new names for them both and discarded entirely the *R. Vernix* of Linnæus, calling the American plant *R. venenata* and the Japanese plant *R. vernicifera*. Instead of lessening the confusion, this only increased it, as it left a perfectly good Linnæan name without a plant to which to attach it. Professor Gray, as long ago as the publication of the first volume of the "Flora of North America," remarks in the supplement that "*R. Vernix*, L., was originally founded entirely on the North American species; hence the Linnæan name ought to have been continued for our plant." Unfortunately, however, he never corrected the mistake, and in all of his subsequent publications wrote *R. venenata*. I shall, nevertheless, restore the Linnæan name in "The Silva" in spite of the fact that the Candollean *venenata* has become firmly rooted in the literature of American botany. The most unfortunate part of the whole matter is, that our tree has a name which properly belongs to a Japanese tree, as the name *Vernix* was given to our plant on the supposition that the Japanese and American species were identical, and it was chosen, of course, on account of the properties of the juices of the Japanese, and not of the American species. *C. S. Sargent.*

New or Little-known Plants.

New Orchids.

Trichocentrum triquetrum, Rolfe, is a very distinct little species, introduced by Messrs. Charlesworth, Shuttleworth & Co., of Bradford, from Peru. It belongs to the section with equitant vertical leaves, like an Iris, and is allied to *T. iridifolia*, Lindl., though larger, and with very different petals and lip. It is about six inches high, the flowers straw-colored, with the lip variegated with dull orange. The spur is one and a quarter inches long, and the ovary strongly triquetrous, as in *Angræcum Leonis.*—*Gardeners' Chronicle*, June 6th, p. 701.

Oncidium urophyllum, Lindl., an interesting species, which has been lost sight of for many years, has now reappeared at Kew, having been received from the island of Antigua, in the West Indies. The habit is peculiar, as the leaves are sharply triquetrous, as in *O. triquetrum*, while the graceful panicle has numerous yellow flowers with some brown markings. Its whole history seems to be a mass of confusion, for the Brazilian habitat originally given appears to be erroneous, while in the "Flora of the British West Indies" Grisebach confuses both it and *O. Lemonianum* with the very distinct *O. tetrapetalum.*—*Gardeners' Chronicle*, June 6th, p. 701.

Rodriguezia anomala, Rolfe, is a remarkable little species, cultivated in south Brazil by Senor Azambuja, of Porto Alegre, but not yet introduced to Europe. In habit it resembles a Leptotes, under three inches high, but with very numerous racemes of highly fragrant white flowers, slightly tinged with rose and with a yellow crest. This floriferous little plant is very anomalous in structure, for, besides the terete leaves, the spur at the base of the lip is reduced to a sac of such minute dimensions as to be easily overlooked.—*Gardeners' Chronicle*, June 13th, pp. 728, 729, fig. 145.

Lælia-Cattleya × Arnoldiana is a very handsome hybrid, raised by Messrs. F. Sander & Co., of St. Albans, from *Lælia purpurata*, fertilized with the pollen of some variety of *Cattleya labiata*. The sepals and petals are pale purple, and the lip a brilliant dark shade of crimson. It was exhibited as *Lælia Arnoldiana* at a meeting of the Royal Horticultural Society, on June 9th last, and was awarded a silver-gilt flora medal and also a first-class certificate.—*Gardeners' Chronicle*, June 13th, pp. 741, 742.

Disa Veitchii is a handsome hybrid, raised by Messrs. James Veitch & Sons, of Chelsea, from *D. grandiflora*, crossed with the pollen of *D. racemosa*. Though fairly intermediate in character, the flowers most resemble the pollen parent, being of a bright rose-pink. It has flowered in the short period of one year and nine months from the time of sowing the seed. It was exhibited at a meeting of the Royal Horticultural Society, on June 9th last, and, like the preceding, was awarded a silver-gilt flora medal and also a first-class certificate.—*Gardeners' Chronicle*, June 13th, pp. 741, 742.

Sobralia macrantha, var. Kienastiana, is a dwarf and very handsome variety, with pure white flowers and some lemon-yellow on the disk. It was exhibited by Baron Schrœder at a meeting of the Royal Horticultural Society on June 9th last, and was awarded a first-class certificate.—*Gardeners' Chronicle*, June 13th, pp. 741, 742.

Kew. *R. A. Rolfe.*

Foreign Correspondence.

London Letter.

Iris Gatesii.—I noticed this new Iris about this time last year, when it flowered with Herr Max Leichtlin at Baden Baden. Blooms of it were exhibited a few days ago in London, and they fully bore out the high opinion formed of this species by Herr Leichtlin—namely, that its blooms are the largest and most beautiful of all Iris flowers. In habit the plant resembles *I. Susiana*, and it is very similar to that species in the size and form of its large flowers, so much so, indeed, that some authorities declare it to be only a color variety of *I. Susiana*. If anything, *I. Gatesii* is the larger of the two, and, instead of the dusky hue which characterizes *I. Susiana*, the color of the new plant is pale lavender, with a dull purple shade about the base of the falls. The two species ought to be grown together. They apparently thrive under the same treatment and bloom at the same time. *I. Susiana* has been very beautiful at Kew during the past fortnight, a bed of about

Fig. 58.—The Red Oak (*Quercus rubra*).—See page 337.

fifty strong plants having flowered well. The cultivation of this very old, rare and very handsome Iris is but little understood. It should here be planted in the open border, or in a bed of rich soil, in a sunny position, in November, and let alone until its leaves begin to turn yellow, say in July, when the plants should be lifted and dried exactly as though they were Tulips. This is the practice of the Dutch growers, who understand this Iris and all the species of its section better than we do. A well-known Dutch bulb-merchant recommended this treatment to be tried at Kew, and it has been followed with excellent results. *I. Gatesii* is at present somewhat expensive, but it will probably soon become as plentiful as *I. Susiana* is at present in Holland.

A TRIO OF GIANTS are now flowering at Kew for the first time in England; they are *Cereus giganteus*, the Mexican colossal Cactus which we know so well in pictures but have never seen alive until last year, when a specimen, fourteen feet high and weighing over half a ton, was obtained from Messrs. Blanc & Co. It is now in flower in the large Palm-house, where its tall columnar shape is an object of more than ordinary interest to visitors, some of whom have named it the Vegetable Cleopatra's Needle, from its resemblance to the column on the Thames embankment. The second of the trio is *Primula imperialis*, which is by far the largest of all Primulas. By the way, Sir Joseph Hooker has altered his opinion with regard to this plant and the Himalayan *P. prolifera*, which he once thought to be identical, but which, after seeing the two together in cultivation, he now admits to be both very well-marked species. I am certain that *P. imperialis* will fill a large place among popular cool-house, and possibly even hardy, plants before very long. *Iris Robinsoniana* is the third in the trio. Up to the present this plant at Kew has produced no less than 167 flowers since it first began to bloom on June 21st. I shall refer to it again next week; meanwhile I can say that it is the most interesting plant flowered at Kew since the time of the big Amorphophallus. It ought to become very popular in California, where, no doubt, it would be as happy as *Agave Americana*.

Weigelia hortensis, var. *nivea*, is a first-rate shrub with large pure white flowers, which are produced in clusters all along every branch. It was recently shown by Messrs. Veitch & Sons from their nurseries at Coombe Wood, where it forms handsome compact bushes, perfectly hardy, of course, and wreathed in flowers in June. *Indigofera Gerardiana*, var. *alba*, was also shown by Messrs. Veitch & Sons, and it is a good plant, too. The flowers are in erect axillary racemes, each about as large as the type, but pure white. Experience with it out-of-doors up to the present points to the necessity of some protection for it in winter, either by planting it against a wall or covering it during severe weather. Equally interesting with the above were two named varieties of *Azalea Indica* which Messrs. Veitch introduced a few years ago from Japan, and which have proved as hardy as the hardiest of Japanese shrubs. They differ in habit and foliage from the ordinary forms of the type, being dwarf and spreading, while the leaves are broader and thinner than in the greenhouse varieties of this species. In a few gardens near London *A. amœna*, which is also a small-leaved form of *A. Indica*, is grown in shrubberies and beds out-of-doors, and it thrives well without protection. But these new varieties, which are named Damio and The Mikado, respectively, have flowers as large as many of the greenhouse Azaleas, their color being rosy salmon. Both kinds had stood the past severe winter unprotected, and they were shown thickly laden with bloom.

DWARF CANNAS.—I believe these beautiful creations of the French nurserymen are the most talked-about greenhouse-plants in London at the present time. At the exhibitions and in public gardens they win universal admiration on account of their dwarfness, the elegance and sometimes purple hue of their foliage, but mostly because of the size, substance and beautiful colors of their flowers. Grown in a sunny greenhouse, and well fed at the roots, they form sturdy plants less than two feet in height, and each bearing several large spikes of handsome bloom. Everybody seems to be inquiring where these plants are to be obtained.

A HYBRID LILIUM.—Mr. C. G. Van Tabergen, of Haarlem, has succeeded in crossing *L. Martagon album* with *L. Hansoni*, and he has recently sent flowers of the hybrid to Mr. Baker, of Kew. He writes: "The cross was effected by me in 1886, and, singularly enough, all the seedlings have proved common red *L. Martagon*, except some five or six, in which the characters of both parents are clearly blended. The foliage is that of *L. Martagon*, but broader, and there are fewer leaves in a whorl." As a decorative plant this hybrid has little to recommend it, but it is most interesting, because of its being one of the very few known instances of Lilium hybridization. It is remarkable that, notwithstanding the efforts of many cultivators to obtain a good hybrid Lilium, not a single well-authenticated instance of success is known. Of course, we have several supposed hybrid Liliums, *i.e.*, *L. Parkmani*, of American origin, and said to be from *L. auratum* × *L. speciosum*, but now generally considered to be merely a variety of *L. auratum*. Mr. T. S. Ware, of Tottenham, also claims to have crossed *L. pardalinum* and *L. parvum*, but the result was a plant very like the first-named species. Good hybrid Liliums, such as, for instance, *L. auratum* with *L. longiflorum*, or *L. croceum* or *L. umbellatum* with *L. superbum*, ought to be possible, but apparently they are not. Can the physiologists tell us why?

Verbascum Olympicum is a giant Mullein which few people attempt to cultivate, possibly from a belief that it is not easily accommodated, or that it is rarely satisfactory in the garden. I believe it is a very good-natured plant if only its real needs are considered and supplied. Planted in well-drained, deep soil, and let alone, except in very dry weather, when it should be watered, it soon develops into a huge rosette of leaves, from which, in its second year, it pushes up a stout, tall, leafy scape, which branches freely, and finally develops hundreds of beautiful yellow flowers. Mr. Cannell showed three spikes of it last week which were fully eight feet high and simply sheaves of golden flowers. In a bed adjoining a greenhouse at Kew a fine example of it has been most attractive for weeks, and is still very handsome. So stately a plant deserves to be universally grown. I know one garden near Cambridge in which these giant Mulleins are a magnificent sight every summer.

Kew. *W. Watson.*

Cultural Department.

Stray Notes from the Arnold Arboretum.—V.

IT is not necessary to say that Lilacs are beautiful and valuable shrubs. Some of the species are as well known and as generally cultivated, in all temperate parts of the world, as any other shrub except the Rose, and it would be difficult to find a garden, here or in Europe, especially a garden of the old-fashioned sort, in which a Rose was growing, where there was not a clump also of the so-called common Lilac (*Syringa vulgaris*). This plant deserves its popularity; there is not a better garden-plant. Tough, reliable and long-lived, the Lilac goes on growing and spreading, year after year, and through generation after generation of human lives; every year it flowers, and every year the flowers are abundant, beautiful and fragrant. A Lilac-bush appeals to every one who sees it in flower, and the feeling for it grows continually stronger, as it does in the case of all plants with which we have been associated from childhood. There are certain plants which always appeal to the human heart and move its deepest sympathies—the Rose, the Violet, the Lily, the Lilac and a few others—different plants in different countries. Other plants produce more beautiful flowers, others are rarer and more wonderfully constructed, and a hundred times more expensive, perhaps, but none of these, not even the rarest and the most expensive Orchid, produces that peculiar sentiment which the true lover of nature feels for the humble Violet or the commonest Wild Rose.

The Lilac has been cultivated during so many years, and has been such a favorite, it is not strange that gardeners have paid much attention to producing improved varieties by selection, and, in some cases, by hybridization. There are now hundreds of these varieties in cultivation, and among those produced in comparatively recent years there are a few of extraordinary beauty and value. There is a collection of about a hundred of these varieties in the Arboretum, taken from the best French and German nurseries, and believed to contain all the best and most distinct forms. It is not my purpose to speak of the value of these varieties now, as they have not been sufficiently tested here yet to make it desirable to do so. It is proposed, next year, to gather them into one bed, three or four hundred feet long by twenty feet wide, at the foot of one of the road-slopes, where, once established, they should make a remarkable display, and, in time, show their individual peculiarities to the best advantage.

It may be mentioned that, among varieties that have been thoroughly tested here, none are better than Marie Lagrange, a variety with very large, pure white flowers in long clusters, the well-known Charles X. and Philamon. This last has dark red-purple flowers of immense size. The man who possesses well-established clumps of these three Lilacs in his garden

will have, when they are in bloom, three of about as handsome objects to look at as can well be found.

There is one serious drawback to all the varieties of the common Lilac. The leaves mildew badly during our summers, and the hotter the region is where they are grown the greater the disfigurement from this cause. In cold regions, as in some parts of Canada, the leaves are not disfigured from this cause, and retain their beauty until late in the autumn, although they never assume any brilliant autumnal coloring. There is a Chinese Lilac, however, which is not troubled by mildew. This is the plant found in gardens under the name of *S. oblata* (see GARDEN AND FOREST, vol. i., p. 221), although it resembles the common Lilac so closely that some botanists believe that it is only a form or variety of that species. As a garden-plant it has the merit of flowering ten or twelve days earlier than the common Lilac; the flowers are rosy purple and exceedingly fragrant, although the clusters are much smaller than those of any of the improved varieties of *S. vulgaris*. The leaves are large, broad, thick and leathery, and are never touched by mildew; in the autumn they turn deep vinous red, and at that season of the year are extraordinarily beautiful. Indeed, *S. oblata* is well worth a place in the garden for the beauty of its autumn leaves, quite apart from its value as an early spring-flowering shrub. It is a plant to which gardeners will do well to devote more attention than it has yet received, with the idea of producing improved seedling varieties. It may be expected, too, to aid, by hybridization, in the development of a new race of good Lilacs, with large and leathery foliage, able to resist mildew, and with the flowers of some of the best forms of the common Lilac. *S. oblata* has been an inhabitant of European and American gardens for many years, but, for some reason or other, its beauty and value have never been properly appreciated.

It is not necessary to speak here of the Chinese Lilac, *S. Chinensis*, so called, a variety, no doubt, of the common Lilac, a familiar inhabitant of the gardens of northern China, and now well known in those of America and of Europe, or of the Persian Lilac, with its narrow foliage and abundant flowers. These plants are both well known to every one who cultivates hardy shrubs. There are, however, five other Lilacs in the Arboretum which are still very slightly known to gardeners, although among them are some of the best garden-plants introduced in recent years. They can be most conveniently mentioned in the order of their flowering.

Next week I shall speak of some of the Lilacs which have been more recently brought into cultivation.

Arnold Arboretum. *P. C.*

[It is interesting to reproduce, in connection with our correspondent's remarks on Lilacs, the following extract from an article on the genus Syringa, from the pen of the distinguished botanist, Franchet, published in the 1st of July issue of the *Revue Horticole*. In speaking of the common Lilac, he tells us:

It was introduced into western Europe about the middle of the fifteenth century. Belon saw it about 1548 cultivated in the gardens of Constantinople. The first exact information, however, that exists about this plant dates only from 1565, when Mattiolus, in his "Commentaries of Dioscorides," gives in the edition of 1565, on page 1236, an excellent figure of the common Lilac under the name of "Lilac," adding that the figure was not made from the living plant, which he had not seen at that time, but from a painting brought back from Constantinople by Busbecq, Ambassador of the Emperor Ferdinand I. at the court of Soliman, who lived at Constantinople first in 1555 and again from 1556 to 1563. Busbecq is generally supposed to have introduced the Lilac into Europe, probably first into Italy, and then perhaps into Bohemia. In any case, Mattiolus, who says that he had not seen the living plant in 1565, relates in a later edition of his work that he had received before 1570 flowering and fruiting branches sent to him by Cortuso from the Botanic Garden at Padua. According to Cortuso, the plant was common in Africa in his day, and was known under the name of Syringa, a statement that needs confirmation.

In any case, the cultivation of the Lilac soon became popular in western and central Europe. Clusius, in his "Rariorum Plantarum Historia," published in 1601, says that at that time it was to be found in all the gardens of Belgium and Germany. It appears also under the name of Lilac, as cultivated in the neighborhood of Paris, in the catalogue of Robin, published at the same date; in the catalogue of R. Morin (1621) it is called *Siringa cærulea Lusitanica*. The history of the introduction of the Lilac is certainly well established, and it is surprising that A. P. de Candolle, usually so exact, should have affirmed in the "Prodromus" that the Lilac had been brought from Persia in the second half of the sixteenth century, although Boissier does not even mention the plant as usually cultivated in Persia.

The native country of the Lilac—that is to say, the region where the shrub grows spontaneously—is still undetermined. Most of the old authors, including Linnæus, ascribe it to Persia, which is certainly not correct. It was in 1828 that it was first stated that the Lilac belonged to the European flora, Heuffel and Rochel declaring at that time that it grew spontaneously in the Danubian provinces. Thirty years afterward, in 1858, Heuffel, in his "Enumeratio Plantarum Banatus Temesiensis," summed up in the following sentence everything he had said before on the subject: "Very common and truly indigenous in all the region of the Danube from its passage across the Banat to the Thermes of Hercules." Without absolutely denying that the Lilac is spontaneous on the banks of the Danube, it is well to remark, first, that the discovery of the shrub, so easily recognized from its abundance in situations where its presence would strike the eyes, did not occur until very late. Second, that it possesses in a remarkable degree the power of naturalizing itself and of spreading where it has once obtained a foothold. Third, that in the beginning of the sixteenth century it was, according to the testimony of Clusius, already widely distributed in Germany; while, on the other hand, the Emperor Ferdinand I., whose ambassador at Constantinople Busbecq was, was also King of Hungary. Fourth, that in the gardens of Pekin are two Lilacs so closely related to the common Lilac that it is not possible to distinguish them specifically, one of them being the so-called Chinese Lilac, or *Lilas Varin* of gardens. Fifth, that all the other species are incontestably Asiatic—that is to say, of Indian or Chinese origin. It must not be supposed that these doubts with regard to the spontaneousness of the Lilac in the Danubian regions are advanced in a spirit of scepticism; there is here an interesting question of botanical geography, and it is from this point of view only that these doubts have been raised.

To this Monsieur Edward André, who had just returned from a long journey in eastern Europe, adds the following editorial note:

We can add a few words to the facts which have aided our learned contributor in reaching these conclusions, having just seen the Lilac growing in abundance in a perfectly wild state on the mountains which separate Servia from Bulgaria. We found it most common on the precipices which rise from the narrow defile of the Nischava, near Nisch, where it was mingled with *Staphylea pinnata*, *Coronilla Emerus*, and other spring-blooming shrubs, and enlivened with the masses of the beautiful flowers of *Lunaria annua* and of *Adonis vernalis*. Any botanist who had passed in this picturesque region, remote from any habitation, would have believed as we did, that the Lilac was growing there spontaneously.

The issue of GARDEN AND FOREST (No. 165) containing Dr. Christ's letter with regard to the native country of *Syringa Josikæa* probably did not reach Monsieur Franchet until after he had written his communication. His argument, however, with regard to the naturalization of the common Lilac in Europe in recent years would apply with equal force to *S. Josikæa*, which is hardly to be distinguished specifically from the widely distributed and variable *S. villosa* of southern and eastern Asia. It is certainly remarkable that these two plants with showy flowers, and conspicuous throughout the year from the fact that they spread into large masses, should have escaped the attention of botanists and gardeners in the Danubian provinces until 1828 and 1830. Instances of plants, even trees and shrubs, establishing themselves in a comparatively short time in extra-tropical regions remote from their native countries are numerous. In this country a person unacquainted with the character or composition of our flora and its history would easily believe that the European Barberry and the Woadwax (*Genista tinctoria*) were natives of New England; and that the Cherokee Rose (a native of China), the Ailanthus and the *Melia Azedarach*, or Pride of China, were indigenous in many parts of the southern states. Not less remarkable is the spread and entire establishment in the southern Atlantic states of the Chickasa Plum, a native probably of the high plateau at the eastern base of the Rocky Mountains and brought east of

the Mississippi River, no doubt, by the Indians, through whose agency, also, the Catalpa has been made to appear indigenous in regions remote from its true home.—Ed.]

Hardy Flower Garden.

OWING to the genial growing weather and cool days, hardy plants of all kinds are rapidly occupying the space allotted to them. It is a good plan to make notes of any desired changes, and it is none too early to begin, for many of the earlier-flowering plants and bulbs have already died down, and, where this is so, the places must be carefully borne in mind or marked, so that when replanting is done in fall such plants may not be disturbed. Unless hardy plants are placed in position with the greatest care by one acquainted with the nature of each plant, it takes a season or two to get them so arranged that, by the contrast or the blending of colors, each one may produce the best effect, and none may thrive at the expense of its neighbors.

Polemonium pauciflorum is now in bloom with us, and, for a Polemonium, is very distinct, owing to its tubular yellow flowers, but as a garden-plant it will probably go the way of all the other species; there are none that are really worth caring for, now that we have so many better garden-plants.

Mr. Barker's note on *Heuchera sanguinea* fully corroborates my statement that there are inferior varieties in cultivation. He describes the flowers of his plants as "salmon-red," which is, no doubt, correct. Our plants have flowers of the most brilliant crimson, and this should be the proper color of the flowers as first described. An English writer describes this plant as the best hardy plant sent out for years; certain it is that seedlings vary a great deal in flower and leaf. Once in a while an extra large and bright flower is obtained, but much oftener the reverse. A remarkably good variety is said to have been produced in Ireland.

Aquilegia chrysantha alba seems, beyond question, to be the plant already known here as *A. cærulea alba*. It is identical with the blue Rocky Mountain Columbine in all but color, and it flowers at the same time. It is useless to depend upon seeds bought in Germany to produce a good-named collection of Columbines; the plants come fast enough, but it will save a lot of trouble and disappointment if they are left without labels. Columbines, of all other plants, need careful isolation to produce seeds that will come true.

We have six varieties of Lemoine's hybrid Montbretias, also *M. crocosmiæflora;* they were kept growing all winter in a cool house, and are now all flowering. The merits of the various kinds have been already commented on in Garden and Forest, and it is only necessary for me to add that all of the varieties we have are quite distinct, and some are much more showy than the parent plants. A large group of the Montbretias, Kniphofias and *Arundo donax versicolor* are planted together, and promise to make a fine display later on. The Kniphofias, or Torch Lilies, are already showing flower-spikes.

Young plants of *Phygelius Capensis*, raised from cuttings last winter, are flowering freely and make excellent border-plants, and, even should they not prove hardy, may easily be wintered in a cold frame. Of annuals, the Marguerite Carnation will be an indispensable plant for summer-flowering. Ours are just commencing to flower, and it would appear as if the strain has been improved upon since last season, as there is a much smaller percentage of single flowers, and all are flowering, while last year there were many plants which would not keep the promise to flower in a few weeks after sowing. When wintered over, however, they flowered this spring. We owe a great deal to the raiser of this pretty and precocious race of Carnations.

So. Lancaster, Mass. *O. O.*

A New Water-lily.

WITH the present extensive cultivation of Water-lilies and the widespread interest in them, it is to be expected that the present list of varieties will be continually extended by hybrids. We can hardly hope, however, for the frequent occurrence of one so beautiful as that which has appeared with H. F. Bahnsen, M.D., of Salem, North Carolina, an amateur cultivator of aquatics. The plant is apparently a cross between *Nymphæa odorata rosea* and *N. alba candidissima*. It is unnecessary, perhaps, to say that such a cross is likely to produce a valuable hybrid, the first-named parent having a beautiful flower, with all too short a season of bloom, while *N. alba candidissima* is a strong grower, always in flower. The new plant has strong rhizomes, resembling the latter variety, while the leaves (when well grown, about a foot in diameter) are intermediate between the two varieties, the Cape Cod Lily having cordate leaves, with a somewhat wide opening at the base, while in the other the opening is closed by the overlapping of the bases. The cleft in the leaves of the new hybrid is simply closed with a trifling lap. They have even stronger veinings than the parents, and in color resemble those of *N. odorata rosea*—green above and red beneath. But it is from the superb flowers that the variety is worthy of the name Superba. These are very fragrant, very freely produced, and in good specimens measure seven inches in diameter. The petals are somewhat narrow and very abundant, a flower now open being formed of forty-two petals, disposed in three rows.

The color is of the clearest rosy pink, which appears rather as a glow on the petals, the faintest tint at the points deepening into the heart of the flower. As one looks into the flower under the changing light the color seems to be a tint from the sun or clouds, rather than emanating from it; then, as the golden stamens are reflected, it takes on a most charming salmon tint, adding a final touch to its charms. Dr. Bahnsen needs no stimulus to his ardor in the cultivation of Nymphæas, but in this plant he is fortunate in adding a variety which must be considered among the very best of the race.

My studies of what we may call *N. odorata superba* have been made from flowers sent by Dr. Bahnsen, and a strong plant with which he also favored me. This latter, received in sphagnum, when first planted out in my tank, gave me an experience strongly confirming Mr. Meehan's theory as to the lack of coloring of flowers on plants not established (Garden and Forest, p. 333). The plant was well furnished with leaves and buds, one of the latter having apparently expanded once. This opened the next day, beautiful in color, like the previous samples sent me. The next day the color had entirely disappeared. The next bud also, which was in a forward state, also expanded, of full size and a noble flower, but with no trace of color. The reason must have been, of course, the lack of nutrition from the newly planted roots, which had no chance to become established. There is one point about colored Nymphæas on which interesting experiments might be made, namely, the influence of manures and soil on the coloring. It seems to me that, at least in the case of *N. odorata rosea*, the soil and the form of manure has an influence on the color. My flowers this year are not so dark on this variety as on the same roots the previous season, and they are growing in lighter soil and, perhaps, less manure, although otherwise under the same conditions. There are also other points to be determined, and the cultivator of aquatic plants has many interesting problems before him, as well as the beautiful picture of the water-garden.

Elizabeth, N. J. *J. N. Gerard.*

Basket-plants.

SOME well-grown basket-plants make a pleasing addition to a conservatory, and many beautiful species display their charms to better advantage under this method of culture than when grown in pots. Among this class specially adapted is *Torrenia Asiatica*, an old species, but a very pretty one, which has opposite, serrated leaves of bright green, the flowers being tubular and four-lobed, porcelain-blue in shade, and the tips of the lobes white. In habit it is much-branched and trailing, and the flowers are produced from the axils of the leaves in great profusion. *T. Asiatica* is propagated from seeds or by cuttings, the latter rooting very readily, and its cultivation is of the easiest.

Another showy basket-plant is *Begonia glaucophylla scandens*, a variety that does not seem very common, though it has been cultivated for many years. As indicated by its name, this plant is of scandent habit, which is somewhat unusual among the Begonias, and has dark green leaves of similar shape to those of *B. Saundersii*, but much larger; and the flowers, which are produced in short-stemmed clusters, are bright red, though becoming much lighter when fully open. This plant grows freely, and under favorable circumstances its shoots will hang two to three feet below the basket, and completely hide it from sight. *Cyrtodeira Chontalensis* (now reclassed under Episcia), to which reference has already been made in these columns, is another excellent warm house basket-plant, with ovate leaves, light green above and purplish beneath, and tubular flowers, lilac in color, with a yellow centre. This Cyrtodeira prefers some shade and a moist atmosphere, besides light rich soil and an abundance of water at the root. It is easily multiplied by means of cuttings, and fresh young stock should be selected each season.

Still another pretty plant for baskets is *Othonna crassifolia*, which has the additional advantage of being an excellent window-plant. It produces long trailing shoots that are thickly fur-

nished with short fleshy leaves of bright green color, and during the summer is profusely dotted over with star-like bright yellow flowers about half an inch in diameter. It is of the easiest culture, and enjoys full sunlight and plenty of water, and, when so encouraged, will soon entirely cover a basket with a mat of bright verdure.

The variegated form of the Ground Ivy, *Nepeta glechoma*, also makes a very pretty specimen when well grown in a basket, its kidney-shaped leaves being handsomely marked with white, and the long slender shoots are very graceful. Its flowers are not very showy, being quite small and blue in color. It roots very readily, and can be grown well in either a cool greenhouse or in a window, and it makes an admirable carpeting for a window-box.

Among summer-flowering plants that may be used in baskets with good effect the Achimenes are prominent. These plants comprise a very showy group of the *Gesneriaceæ*, and require a light open compost well enriched with old manure, as their growth is rapid under congenial conditions. By using large, deep baskets, shaped like an ox-muzzle, the Achimenes may be planted all around the sides as well as in the top of the basket, and, with the aid of a few stakes to keep the plants from falling about too much, the basket will be completely hidden by the mass of brilliant flowers and attractive foliage. The Achimenes are deciduous and must be watered occasionally during the season of rest, in order to keep the tubercles in good condition. At this period they may be stood under the bench in a warm house. The Achimenes now make a long list, and much variety in color is to be found among them, but the following are all good sorts: Ambroise Verschaffelt, pale lilac, with reddish spots in centre; Aurora, dark scarlet, yellow eye; Longiflora alba, white, with blue lines in centre; Major, large, bright blue.

Holmesburg, Pa. *W. H. Taplin.*

The Newer Varieties of Strawberries.

THE early part of the season just closed has been a very trying one for Strawberries, as we had but one inch of rain-fall from May 1st to June 15th, at which time the vines of many varieties had the appearance of being scorched by fire. On the 16th of June there was a rain-fall of nearly three inches, thoroughly saturating the ground, reviving a large number of varieties to such an astonishing degree that one of the best-paying crops ever grown in this section has just been harvested. Of the newer varieties tested for only one season, I should place first on the list of early ones Van Deman, a variety originated by J. C. Bauer, Judsonia, Arkansas, and not yet in market. This has proved the earliest variety from which a quart of fruit could be picked. The growth of plants is vigorous and stocky; foliage dark green; fruit-stems short, hiding the fruits, which are of a very glossy scarlet color, with yellow seed, firm, and of a brisk tart flavor. This berry, while not of mammoth size, will sell well both on account of its earliness and brilliant color. Michell's Early has failed to justify the claims made for it; it was neither extremely early nor very productive. The fruits are of but medium size, soft, and of a very poor color; too light for a market berry. The flavor, however, is very choice. I am of the opinion that if this variety could be grown on light sandy soil it might prove more productive, as it naturally would not exhaust itself in making the number of runners it does on well-enriched clay loam. Tippecanoe is an improvement on Sharpless, as fruited here this year, earlier and more productive. Phillips' Seedling and Greenville are of the same type, each as vigorous as Sharpless; fruits of same shape, but without the characteristic green tip of the latter, and larger fruits on individual plants. Improved Manchester, a cross of Manchester and Miner's Prolific, seems a promising sort, and quite productive; fruits similar in shape to Jersey Queen, of darker color, but with the distinct peculiar flavor of the latter.

Shuster's Gem has not done very well here. The growth of vines has been poor, and the yield moderate. California and No. 19, two varieties from Delaware, are of low stocky growth, but not productive, the former bearing long dark scarlet fruits of but medium quality; the latter with fruits a fac-simile, in every respect, of Jersey Queen. Oliver is an Illinois production of wonderful growth, each plant making a perfect ball of dark green leaves; fairly productive. Gipsey, from New Jersey, did not do as well as expected from reports. It is a very showy berry, firm enough to ship, and of excellent flavor. Mrs. Cleveland makes a very fine growth, and set a large quantity of fruits, but the fruits ripened imperfectly, having the end imperfect or hard. Edgar Queen gave promise of being a fine berry, but, with Cloud, suffered severely by reason of drought. Beeder Wood proved wonderfully productive. It is a stocky grower, but the fruit-stalks are weak, and, if grown in stool, plants would need to be mulched; fruit rather soft, but could be shipped to near-by markets. Its season is long, as we picked fruits of it for twenty-two days. Parker Earle has sustained the claims made for it, being in every respect, but firmness, perfect. One who has not seen a row of this variety when in full bearing, can have little conception of its appearance, with almost every berry of uniform size and shape. The brilliant scarlet color, the large yellow seeds and the immense clusters, combined with the final test of flavor, make it one of the most desirable of the newer varieties. Its season here has been about with Gandy, which, however, gave a good picking a few days after Parker Earle had finished fruiting. Eureka has proved itself to be a fine variety, the quality of the fruits superb, quite productive and firm. Stayman's No. 1, while above the average in productiveness, did not sustain its record of last year. It set a large crop of fruit, but was not able to withstand the drought.

The Jessie has given better satisfaction this year than in former seasons. The fruits have been of a uniform size, and, while not extra large, held good size through picking, and gave a very fair yield. The quality I have always considered fine, and where it can be grown under suitable conditions must take rank, in my opinion, with the best. Lady Rusk gave a larger yield than last year, but the fruits run small and ill-shaped. Bubach has never succeeded in bearing a good crop here, although highly spoken of in most localities. Haverland, a fine variety to look at when in full fruiting, is too soft for general use. Middlefield, while not up to its former record, is still, in my mind, one of the best new pistillate varieties, ripening its first fruits about midseason and continuing late in bearing. One variety, not as new as the above, should not be omitted in any collection, that is the Burt's Seedling, claimed to be the old Captain Jack revived. In general appearance and yield of fruit there is no difference between them. It proves a fine cropper in most localities. The fruits resemble those of Wilson, firm and subacid. Being a perfect flowering variety, is a first-class fertilizer for the early pistillates. During a recent visit to several of the Strawberry-plantations of Oswego County, I found Cloud, Eureka, Burt's Bubach and Warfield were the leading varieties grown. The soil being stony light loam, they had not suffered as much through the dry season as other sections of the state, and I was able to see the Cloud in what seemed its natural soil, and it was very fine. I was told that pickers were anxious to be assigned to that variety and Eureka, as the large yield and size made a difference of a number of quarts in a day's picking.

Agricultural Experiment Station, Geneva, N. Y. *C. E. Hunn.*

Correspondence.

The Northern Forest.

To the Editor of Garden and Forest:

Sir,—It is interesting to hear the surprised comments of friends from lower New England, and even from the Champlain valley, who walk with me through the woodlands of the Memphremagog region, or notice the transplanted trees upon my lawns. No Oaks, no Hickories, no Chestnuts, nor Black Walnuts, nor Horse Chestnuts,—no nut, in short, but beechnuts, hazelnuts and butternuts. Also no Locusts, no Lombardy Poplars, no Catalpas and no Wistarias; nor climbing roses, except at the cost of careful protection. Our hardy climbers are limited to the native and some foreign kinds of Clematis, Lonicera and Ampelopsis. But of hardy shrubs, native and foreign, there is a great variety, including many Viburnums, Lilacs, Barberries, Bush Honeysuckles, Elders, Alders, Shepherdias, Wicopy, Japanese Rose, Amelanchier, Philadelphus, Hamamelis, Eleaginus; to say nothing of Ribes and many other things of recent importation, along with the Russian fruits, though not yet much distributed.

But it is of the forest-trees particularly that I wish to take note. First among deciduous species stands the Sugar Maple, with its congeners. The Maples are among our largest as well as most numerous trees. They grow to a great size, and are never seriously winter-killed, yet one cannot examine them without being assured that they are nearing their northern limits on our mountains. Really sound specimens of large size are somewhat rare. Going north from our highlands (nearly all of north-eastern Vermont is from 1,000 to 3,000 feet above the sea-level), following the slope to the St. Lawrence River, Maples rather improve than otherwise—the lessening altitude more than compensating for change of

latitude. The White Maple is more tender than the Sugar Maple, outside the forest or as a lawn tree—the bark being frequently killed in exposed situations. Red Maples are more hardy, and the striped and mountain Maples seem quite iron-clad. Negundo has also been lately introduced with success.

The Beech thrives as well as the Maple, but is often unsound, and does not reach so large a size as it does farther south. It fruits freely, however, although all of the great county of Aroostook, in Maine, lies considerably to the north of Vermont, yet the effect of a lower altitude is shown in the greater perfection to which the Beech grows there, even up to the latitude of Quebec. The Yellow and Canoe Birches are our only species of this family, and they both thrive perfectly, being among our largest and tallest trees. The first is almost as abundant as the Maple in the untouched forests, but is removed preferably for fire-wood, and lately for lumber—the Sugar Maples being rarely taken for this purpose, except when too much scattered to be available for sugar.

Among other Maples is a tree, not uncommon on my farm, differing distinctly in some particulars from the other Maples, though I am not botanist enough to accurately describe the distinctions. But the most notable practical fact about the tree is the great amount of tannic or gallic acid in its sap. Sugar-makers avoid it on this account, for it strongly reacts upon the iron spouts, so as to give the sap an inky color and taste, ruinous to the sugar. Neither the White, Red nor Sugar Maple saps do this.

Among our evergreen forest-trees, now that the Pines have nearly disappeared, Spruces stand first in number and commercial value. The Black Spruce is everywhere abundant, but the Canada line seems almost the southern limit of the more beautiful White Spruce, the finest of our evergreens for ornamental planting. Both are perfectly hardy, and make fine lumber, though the larger trees are becoming scarce, except in inaccessible localities. The Hemlock Spruce, though it is abundant, and grows to a large size, I have found distinctly tender when planted in exposed situations, and it is perhaps due to this lack of absolute hardiness that the "shaky" character of a large proportion of our hemlock lumber is to be attributed. At neither of two large mills was I able, recently, to obtain hemlock planks sufficiently sound to make a watering-trough, though they had plenty of hemlock timber, such as it was.

It is often asked whether our forests are disappearing. In northern New England they certainly are not. The farmer has a constant struggle against the persistent spread of seedling trees over his cleared land; and if man should abandon this region I think in a hundred years it would hardly be possible for a visitor to realize that it had ever been inhabited by civilized man. It is this constant pressure of the forest upon intruding settlements that prevents the average farmer from taking an interest in forestry. He has to fight for his life against the forest, and the idea that the forests are likely to be extirpated seems to him quite absurd. One of the largest and finest sugar-orchards in this town was seventy years ago a wheat-field.

Newport, Vt. *T. H. Hoskins.*

[What our correspondent says of the pressure of the forest upon the cleared land in the eastern states is all true. It is also true that there are vast areas in the country which will never reforest themselves, when once stripped of timber, and that there are many places, even in the east, where the thin coating of earth left on the rocks after the forest-floor has been destroyed by fire, will not support a vigorous forest-growth. Of the deterioration of the quality of the forest, which is quite as important as loss in quantity, we have often had occasion to speak.—Ed.]

Recent Publications.

Landscape-gardening. By Samuel Parsons, Jr., Superintendent of Parks, New York City. Illustrated. G. P. Putnam's Sons, New York and London, 1891.

It is many years since Downing wrote of landscape-gardening for American readers, and, though helpful books by Scott and others have since been published, there was room for another. During the past thirty years the desire of American dwellers in cities to possess and beautify country homes has greatly developed, and such homes have been established along sea-coasts of very diverse character, as well as on mountain-sides and fertile valleys. The spread of wealth and culture through the western states and along the Pacific coast has likewise multiplied the problems with which the landscape-gardener has to deal in the disposition both of private grounds and of public parks; and the materials now offered for his use are infinitely richer and more varied than those of a generation ago. It would indeed be a complicated and difficult task to write a book on landscape-gardening which would cover the whole field to-day and be of use in all parts of our country. This task Mr. Parsons has not attempted. In his introduction he explains that his book is not a systematic treatise, but a series of "simple desultory talks," written with the desire to arouse increased enthusiasm for his art among men of moderate means.

Judging it from this point of view, it contains much that is of interest and value, and though it must be charged with some sins, these are chiefly sins of omission, partly chargeable to the fact that unless one writes very systematically on such a subject as this, points of vital importance are sure to be forgotten.

Unfortunately, the terminology of this art is not firmly fixed and generally understood. One who writes about landscape-gardening is compelled to begin by defining the terms he uses, and, with all possible care, he cannot always find terms of exact appropriateness. For example, Mr. William Robinson, writing recently in *The Garden*, used the word "garden" to indicate the grounds forming the immediate ornamental environment of the house, though this word is commonly employed to designate a place in which flowers are grown. He explained, however, that the lawn must be "the heart of an English garden." To indicate these same grounds Mr. Parsons uses the word "lawn," although the very first sentence of his first chapter explains that "to the minds of most readers the lawn suggests simply grass." He might better have employed the term "home grounds," a term that once was generally used, but now appears to have gone somewhat out of fashion. This term is never applied in a narrower sense than the one Mr. Robinson intends by "garden," and Mr. Parsons by "lawn," and a very brief and simple explanation would prevent its being taken in too wide a sense.

Mr. Parsons' first chapter is devoted to the proper way of laying out and making a lawn, in the narrower acceptation of the word, and is chiefly of practical value, although it contains some good suggestions of an artistic kind, notably one with regard to the placing of the house, so that the lawn shall come opposite the main living-rooms and not the entrance front. Then he treats, in an excellent way, of "Sloping Grounds," and of the effects which may be produced in the home grounds during the different seasons, giving lists of plants which are especially beautiful in spring, summer, autumn and winter. We are gratified to see the fact emphasized that all times of the year should be provided for in our home grounds, as it is common to find places at their best for a brief time only, or, if no season has been specially thought of, the effect is at no period of the year so beautiful as it ought to be. The possibility of creating a charming winter landscape is more commonly ignored than any other, and Mr. Parsons' words on this branch of the subject should be especially suggestive. Throughout these chapters much is properly said about the beauty and variety of the greens of foliage as well as about the colors supplied by the flowers amid the foliage. But in dwelling upon color in this unusually broad and artistic spirit, he has not given equal attention to the question of form. No matter how carefully trees and shrubs may be chosen with regard to their shades of color, no effect will be good unless the same thought has been given to their forms as they will appear when growing toward maturity, and to the final sky-line of the plantations. These facts Mr. Parsons clearly indicates in his introduction, but they might well have been enlarged upon in the subsequent portions of his book.

The texture of different kinds of foliage is another interesting matter, and one to which he barely refers. Trees of similar habit and a similar shade of green may vary much in aspect, according as their foliage is thick or thin, large or small-leaved, and endowed with more or less mobility when touched by the breeze; and the planter who does not recognize this fact loses many chances for increasing the beauty of his arrangements, although, of course, he does not run so great a risk of producing ugly effects as though he neglected to think of form or of color.

The lists of plants which Mr. Parsons gives as displaying their chief beauty during successive seasons of the year will probably be the most helpful, as they are the most complete, feature of his book. Of course, it is as difficult to draw up such lists to the satisfaction of every one as it is to make faultless collections of "favorite quotations" or of "beauties" from popular authors. A reader who is thoroughly familiar with garden-plants will probably miss some of his special pets from Mr. Parsons' pages, but one who is simply anxious to become familiar with them will certainly not complain that

too few are named. A tenth part of those which Mr. Parsons describes would amply fill home grounds of considerable size with all the variety that the most insatiate planter could desire. One omission seems worth remarking upon. More than once he mentions the Virgilia or White-wood (*Cladrastis lutea*), but he does not mention it when naming the trees which bear conspicuous blossoms in late June or early July, although, with its graceful light green foliage and its great pendent panicles of white blossoms, it is then the most beautiful of all the flowering trees which will flourish in the neighborhoods for which this book is specially helpful.

Mr. Parsons' selection of plants for popular use will meet with general approval. It would have been as well, however, to have omitted some trees and shrubs of abnormal habit and color, or else to include a comprehensive warning against their excessive use. Monotony in color should be avoided by the planter; but it should be avoided more by the employment of different shades of green than by the introduction of plants with purple or brown or yellow or variegated foliage. These may be beautiful and useful when intelligently used, but this means when used sparingly, as rare punctuation marks, in a scheme composed of greens. Every one who is familiar with Mr. Parsons' own practice knows that he realizes this fact. In Central Park, for instance, the eye is far less often offended by too brilliant a spot or mass of foliage than in any other park, American or foreign, which we remember. But the people for whom Mr. Parsons writes are certain to be less experienced and likely to be much less intelligent in these matters than himself, while the attraction of mere novelty will lead them to admire in excess many things which, to the horticulturist and landscape-gardener, are as commonplace as grass and Huckleberry-bushes. We should have been pleased, therefore, if the danger of using too many purple Beeches, golden Elders and spotted Negundos had been minimized by more stringent cautions than Mr. Parsons has given.

"It is," says Mr. Parsons, "the arrangement of foliage, of trees, and shrubs and grass that should compose and characterize the lawn," or, as we should prefer to say, the home grounds. "But," he continues, "I believe in making a distinct and comfortable abode for flowers—in a word, a flower-garden. . . . It should be one where everything conspires to favor the growth of flowers, so that one may gather them without stint. To look only at a tree or shrub satisfies the observer, but flowers, to be enjoyed to the full, must be plucked, their fragrance inhaled, and their beauty of detail admired at leisure." For this flower-garden Mr. Parsons very wisely recommends, above all others, "hardy herbaceous perennial plants," while acknowledging that "it is easy to name shrubs and bedding plants that bear plenty of flowers, and there is certainly no valid objection to planting them in the garden." This chapter on "Garden-flowers" and the following one called "Grandmother's Garden" are admirable, and the annexed plan of a small private place laid out by Messrs. Vaux & Company shows an excellent way to provide a large flower-garden without disturbing the repose and artistic unity of the grounds.

In the chapter on "Bedding Plants" Mr. Parsons sanctions the use of formal beds of brilliant hue because "the universal delight in rich color is satisfied by their employment." But confiding readers will be disappointed if they believe that "the expense of their employment is comparatively small." Of course it does not cost much to buy enough young plants to stock a bed or two in a door-yard. But carpet-bedding on a large scale demands a great preliminary outlay for this purpose every year, or the existence of greenhouses for wintering and starting the plants, and a corresponding force of gardeners to attend to their cultivation and transplantation. The sums annually expended to stock the beds in the Boston Public Garden, or in one of our large cemeteries, where the bedding-out system is extensively developed, are enormous. Again, while Mr. Parsons is undoubtedly right in saying that, were formal color-beds more harmoniously designed, persons of taste would less sternly condemn them, we should have been glad had he likewise accentuated the fact that they are good or bad according as they are properly or improperly placed. The most beautiful pattern-bed in the centre of a wide green lawn is an atrocity, while even a less artistically designed one close to the foundations of a house, or in some small enclosed spot, where a "natural" effect could not well be achieved by the planter, may have a very happy effect. Such beds, it cannot too often be said, are architectural in character, and belong amid formal, if not strictly architectural, surroundings. In the middle of Union Square, or at the entrance of Central Park at Fifth Avenue, nothing else would look so well as those which, year by year, Mr. Parsons tastefully arranges. But even the simple circles of Tulips, which were so beautiful in the latter spot last spring, would have grossly offended the eye if transported to the edge of one of the adjacent lawns, or if set, even in a more secluded locality, at the base of a rock draped with naturally growing creepers. These facts are again among those which Mr. Parsons mentions, and which he respects in his own practice, but he might have urged them more strongly upon his readers. We dissent, however, from his views when he says that the flower or foliage-bed is "apt to look stiff and inartistic" because its extreme edge or border is "usually too sharply cut in outline," and that "to overcome this stiffness of outline, single plants of the Coleus or Geranium size should be set out in the grass just beyond the actual border of the bed," and that lower plants, like Pyrethrums and Alternantheras, "should be brought forward close to the low border, and here and there several of them should be allowed to get over the border and establish themselves in the neighboring grass. This will create a properly related emphasis of outline, a pleasing variety, and irregularity enough to just escape formality. There must, necessarily, be a certain precision of lines, but the treatment should all the time bear a distinct and well-defined kinship to that employed by nature in our fields and pastures."

To our mind this is just the sort of kinship that the treatment of formal beds should not bear. One great reason why the art of gardening lags at the present time behind its sisters is, that gardeners are seldom clear in their minds with regard to the special kind of beauty they wish to attain, or are inconsistent in their efforts to attain it. Hence the confusion, the lack of coherence, and, therefore, of beauty, which mark most of our private grounds and many parts of our public parks. First of all, a natural or a formal scheme should be decided upon, or, if the place be large, a scheme in which natural and formal elements are properly contrasted and yet harmonized. And then the chosen idea should be definitely expressed and boldly carried out. So distinctly artificial a feature as a pattern bed should never be employed at all, except in places where there is no need to mitigate or half-deny its artificiality. If, when boldly formal, it looks too stiff, it had better be done away with entirely, for its stiffness, instead of being "inartistic," is its essential character, and, therefore, is artistic if the environment be such as to sanction its presence at all, and the outline of its border seems to us just the place where this character should be most clearly expressed. We follow Mr. Parsons gladly when he teaches that we often see too mechanical a regularity in the filling of formal beds, feeling that such beds are, in truth, of two kinds—those where delicate stiff patterns are wrought by the use of brilliant, low, close-clipped plants, and those where freer masses of taller plants are grouped in only a semi-formal way. But in both cases the ornamental bed should confessedly be a bed, with a distinctly marked form and outline. Some of the most beautiful beds we remember to have seen were in France, and were filled with white and pink flowered Geraniums, not set in a pattern but mingling naturally together. But the shape of these beds was marked, and their character expressed, by a low close-clipped border of some other sort of plant. In short, while a natural arrangement should be consistently natural, a formal arrangement should as consistently be formal. The only question is, whether the one or the other will look best in the given spot.

The charming chapter on the "Ornamentation of Ponds and Lakes" was noticed in these columns when it appeared, not long ago, in one of the magazines. The one on "City Parks" gives an interesting account of the formation of Central Park, but we should have liked to see the great skill of its designers more strongly emphasized as it is revealed in the arrangement of the roads and walks. In a small place planting is the landscape-gardener's chief task; but in a large place, and above all in a public park, where crowds of persons on foot and in carriages must be accommodated, and must have the various portions of the enclosure beautifully revealed to their passing eyes, his preliminary work in laying out the roads is almost more important and even more complicated and exacting. This work has been exceptionally well done in Central Park, while it was exceptionally hard to do it well, owing to the broken character of the ground.

"Landscape-gardening" is handsomely printed and bound, and profusely illustrated; but the larger illustrations, although often taken from very interesting objects or scenes, are not all of the first quality. On the whole, the volume is one for which we are grateful, and one which should do much to stimulate an interest in plants and planting and garden arrangement. There is still need, however, for a companion volume, in the shape of a systematic treatise on landscape-gardening considered primarily as an art of design.

Notes.

In November, we read in a recent book about Japan, "the coquette sends her lover a leaf or branch of Maple, to signify that, like it, her love has changed."

Mr. E. T. Ensign, Forest Commissioner of the State of Colorado, announces in a circular that the citizens of Colorado Springs have secured the reservation of extensive bodies of timber-land at the sources of the springs, in Pike's Peak region. It is to be inferred from the wording of the circular that these reservations are to be made by proclamation of the President.

The horticultural building for the World's Fair at Chicago, which has been designed by Mr. W. Jenney, of that city, will cost, it is said, about $600,000, and will stand on the edge of the lagoon. It will be 1,000 feet in length and 286 feet in breadth, and will consist of a central pavilion connected with two others by glazed galleries. This central space will be 187 feet square and 113 feet in height, and will be devoted to the display of tropical plants.

Some of the perennial Gypsophilas and Statices, especially *G. paniculata* and *S. latifolia*, are highly valued for their cut flowers, which are small and abundant and borne on slender stems, and, when mingled with other flowers, have the effect of a fine mist or halo. Another excellent plant for this purpose is *Asperula hexaphylla*. A specimen sent to this office from the Passaic Nurseries by H. Meyer, has minute flowers, pure white, and borne on a very loose panicle, and they have a fairy-like delicacy. A well-grown plant will make a mass three feet in diameter and nearly as high.

La Revue Horticole announces the death of Monsieur F. Hérincq, in his seventy-first year. Monsieur Hénricq was long connected with the Herbarium of the Museum d'Histoire Naturelle, in Paris, and was known to horticulturists as the editor of *L'Horticulteur Français*, a periodical which he founded, and which ceased to appear several years ago. He was intimately associated with the late Monsieur Lavallée in the study and arrangement of the plants in the Arboretum Segretzianum, and assisted in preparing the important work which Monsieur Lavallée, published under that name.

The *Planter*, of New Orleans, recently put forth a novel suggestion with regard to the employment of the low grades of molasses, which sugar manufacturers now do not know how to get rid of even at five, six or seven cents a gallon. So the *Planter* advocates the unfamiliar idea of using it as fuel in the place of coal in the sugar-houses. Combined with the dry stalks of the Sugar-cane, after the saccharine matter has been extracted from them, it would burn with a high heat, while it would cost from one-eleventh to one-fifth of a cent per pound as against the one-fifth of a cent now expended for coal; and even half the now available stock of molasses would, we are told, more than suffice for the manufacture of all the sugar of Louisiana.

A correspondent of the London *Standard* recently proved that the Edelweiss, that secluded inhabitant of high Alpine regions, may make itself thoroughly at home in a city, by telling about a small plant which a friend living near Belfast had raised from seed and sent him, with directions to leave it to itself in a corner of his garden. "Unhappily," he says, "London gardens are the hunting-grounds for innumerable cats, so I placed my treasure, for such I deemed it, on the sill of my drawing-room window, aspect south-east; and there, through the dismal sunless winter, now buried deep in snow, now frozen hard, the Alpine stranger remained, always reported dead by all who saw it; but toward the end of March life showed itself, and now it is a large healthy plant, with five lovely blooms, the admiration of all who see it."

We have recently received the prospectus of a new periodical, called *Zeitschrift für Pflanzenkrankheiten* (*Journal of Plant Diseases*), which is to be issued at Stuttgart, under the control of Dr. Paul Sorauer, who will have the assistance of the International Phytopathological Commission, which includes members residing in all the civilized parts of the world, the American members named in the prospectus being Professor Farlow, of Cambridge; Professor Galloway, of Washington, and Professor Humphrey, of Amherst. The journal will be published bi-monthly, with lithographed plates and wood-cuts in the text, and the annual subscription price has been fixed at fifteen marks. It will contain original articles of considerable length, shorter notes on subjects of current interest and full reviews of new books and treatises, and should be of great use to all who are concerned with the cultivation of plants.

In the preface to Mr. E. W. Hervey's interesting "Flora of New Bedford and the Shores of Buzzard's Bay," which we have already brought to the attention of our readers, he says that comparative reference to catalogues of various western localities shows that the blossoming season is earlier there than on the shores of the Atlantic. A catalogue of the plants found at Oquaka, Illinois, on the shores of the Mississippi, "discloses the interesting fact that the season there . . . is much earlier than that of New Bedford by the sea, though both places are practically in the same latitude, the spring plants of the former region blooming from ten to fifteen days earlier, and those of May, June and July from three to four weeks earlier," while an article by Mr. E. W. Hammond on "Winter Flowers in Oregon," published in Garden and Forest last January, seems to prove "that the season on the Pacific coast in latitude one degree further north is six weeks earlier than here."

Dr. Richard Schomburgk, for the last twenty-five years director of the Adelaide Botanic Garden, died there at the end of last March. He was a native of Freeburg, and was born in 1811. Political complications compelled him, with his brother Robert, to leave Germany. With the assistance of Humboldt he was able to reach Australia, where he has principally resided. In 1871 he published a catalogue of the plants cultivated in the Adelaide garden, and his elaborate annual reports testify to the energy and activity which he displayed in carrying on the establishment entrusted to his care. He published in 1876 his "Botanical Reminiscences of British Guiana," an interesting account of the Boundary Expedition of 1842, which was commanded by his brother, and to which he was attached as naturalist on behalf of the Prussian Government. His most important contribution to botany is, however, the synopsis of the flora of British Guiana, published in his "Reisen in Britisch Guiana" in 1848.

A recent number of the *American Architect and Building News* contains an interesting article on the great island of New Guinea, the least-known of any country on the globe. After speaking of the houses built on piles, the writer describes another type of house, which seems even more primitive, as it appears in an illustration reproduced from a photograph. The picture shows a sort of small clearing on a steep hill-side, and in the centre of it a tall, rather slender tree, apparently a Blue-gum, the head of which has been lopped off, so that nothing remains but a few short branches with scattered tufts of leaves springing from their extremities. About thirty feet above the ground, approached by a very frail-looking ladder and supported by the main branches, some distance above the place where they fork, stands the house which, oddly enough, always contains two stories, and has a platform on top whence the surrounding country may be scanned for signs of approaching danger. Resting thus on the lopped and naked tree, with the ragged thatch of its sides and roof hanging down in rough streamers, it looks not unlike a colossal nest—such a nest, on a larger scale, as the fish-hawk builds in blasted trees along our own Atlantic coast. Our "arboreal ancestors" seem closer to us as we think of human habitations in the tree-tops at the close of the nineteenth century.

The fact that the authorities of Kew Gardens have been endeavoring for a number of years to extend the scope and enlarge the usefulness of the various botanical establishments in the British West Indies has already been alluded to in these columns. To further this undertaking, which looks to the formation of a botanical federation for purely economic purposes, and which is likely to be beneficial to all English-speaking people in the Antilles, Mr. D. Morris, the Assistant Director of Kew, was sent last winter to make a tour of inspection through the West Indies. His report, containing much useful and interesting matter pertaining to the different islands, is now published in the May and June issues of the *Bulletin of Miscellaneous Information* from the Royal Gardens. The information it contains will be found useful not only to Englishmen, but to Americans who now visit the West Indies in larger numbers every year, both for business and pleasure. An appendix to the same useful publication contains a list of the new garden-plants described in botanical and horticultural publications, English and foreign, during the year 1890. It includes not only plants brought into cultivation in that year for the first time, but the most noteworthy of those which have been introduced after being long lost from gardens. In addition to these the list contains all hybrids, whether introduced or of garden origin, but described for the first time in 1890. The list will be found indispensable to all people who desire to keep informed of new plants available for garden decoration.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

Office: Tribune Building, New York.

Conducted by . . . . . Professor C. S. Sargent.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, JULY 29, 1891.

TABLE OF CONTENTS.

The Use of City Parks.

A FEW weeks ago the Park Board of this city granted permission to hold a public meeting in Battery Park. Whether or not the Board is clothed with any authority under the law to grant a privilege of this sort has been questioned, but it is not our present purpose to discuss this point. The meeting, however, deserves some mention; not because the park was in any way defaced or injured on that occasion, but because it was the first time, at least for many years, that any such a gathering has been held in any of the city parks proper. Manhattan Island is so densely inhabited, and its population multiplies so rapidly, that the pressure for more room is stronger here even than it is in most other cities. There is not a foot of open space which is not constantly coveted by some one for some purpose which seems a worthy one. But our parks have never been in any serious danger of invasion by public assemblies. Great efforts have been made to turn Central Park at times into a parade-ground for the display of our citizen soldiery, but we rarely hear of attempts to convert it into an arena for public argument and debate by civil or religious bodies.

In some sister cities labor organizations have endeavored to meet in pastoral parks to urge the enactment of an eight-hour law or agitate some other subjects of so-called reform. Religious organizations also have endeavored to secure the same privileges; and the arguments in favor of such assemblies are always the same. It is held, in the first place, that the parks belong to the people; next, that the people have the right to public assemblage, and that, therefore, they have the right to assemble on their own grounds. In most cases, too, it is urged that the matter to be discussed is of vital moment. Religious enthusiasts are convinced that in some way the salvation of men depends upon their efforts, and that their exclusion from the public parks means practically the ruin of human souls. In the same way agitators for some civil or political reform always feel and insist that the movement which they represent is one of paramount importance. The present case is remarkable in that the meeting in Battery Park was called for the express purpose of protecting it. The park is now contracted and disfigured by a railway which is constantly threatening more serious encroachment. This corporation needs room, and it could occupy to advantage the entire park area. Having obtained a foothold, each new aggression is more easy and natural, in spite of the fact that the border, which is now covered and blackened by the roads, makes a mute protest to every passer-by against the invasion. It is a fact, however, that the road is there only on sufferance; that the contract under which its owners have possession is a revocable one, and that it is in the power of the Park Commission to order the corporation to remove its structure. It was to advocate such a forcible removal of the railway that the meeting was called by some citizens, who felt that their rights had already been trampled on, and are in danger of further violation.

Here, then, was a singular case. If any one assemblage could ever be tolerated in a city park it would assuredly be a meeting of its defenders in the place they wished to save from ruin; and yet we cannot but feel that a precedent like the Battery Park meeting is a bad one to establish. It is true that every man in the city has a right in its parks, but he only has a right to them as parks, and no one has a right to them as anything else than a park. It will hardly be contended that there is only one justifiable reason for a public meeting in an urban pleasure-ground. If it is right to assemble to make a protest against invasion by a railroad, it is right to meet there for other purposes. Indeed, no sooner had this permit been granted than some of the people in the other end of the city declared that they would organize a meeting in Mount Morris Park for a directly opposite purpose—that is, the people at the northern part of Manhattan Island demand greater facilities for rapid transit, and inasmuch as it is their opinion that this can be more easily obtained by giving the Battery to the railroads, some of them are willing to make this concession; if it is proper for one side to make its argument before an assemblage in a park, it is equally proper for the other side to have the same privilege.

Of course, no city of any consequence should be without provision for public assemblies, such as the large open space in front of the main entrance to Prospect Park, in Brooklyn, and the area north of Union Square in this city, where preparation has been made for furnishing light and other conveniences needed at popular meetings. But, aside from the fact that such gatherings would be ruinous to the verdure of a pastoral park, nothing more discordant with the spirit of such a place can be conceived than an indignation meeting or a public demonstration in favor of some "cause" or "movement," for these would bring into the park the throng and stress and excitement and struggle which are the very things from which such quiet scenes are designed to offer relief. The only security which urban parks can have against destructive invasions of one kind or another is a universal public appreciation of the truth that their real purpose is the refreshment of mind and body which simple rural scenery alone furnishes. That this is not generally understood is proved every year by the efforts of many cultivated people to divert our parks to some other use, which seems to them a higher and a nobler one. But the truth is, that this distinctive function of city parks is by no means trivial or insignificant; indeed, it is quite as essential to the well-being of society, as it exists in modern cities, as are hospitals or schools or libraries or churches, and it is this serious estimate of their value which impels us so often to urge upon thoughtful and public-spirited men and women the duty of watching over them with jealous care, in order to prevent them from being perverted to any illegitimate use, and to protect them from every invasion which threatens to diminish, in the slightest measure, their beneficent influence.

Four Pictures of Gardens.

As the art of gardening has varied in different lands and successive ages, literature has recorded its work, usually painting with sympathetic touch the current fashions of the time, but in our day often going back with a sympathy as great to explain the charms of now neglected kinds of beauty. Some of the pictures thus built up in delightful phrases are famous and familiar, like Pliny's and Evelyn's and Bacon's. But others, though perhaps written by well-known authors, are less frequently quoted when the art of gardening is discussed; and four of these, sharply contrasting with each other, will perhaps make an interesting little gallery if hung here side by side. We have not been at pains to pick them out of the books where they first saw the light. With many others almost as detailed, and with a few that are much more elaborate, they may be found in Mr. Sieveking's delightful volume called "The Praise of Gardens."

The first is a portrait, painted by Sir William Temple, who lived between 1628 and 1700, of the garden at Moor Park, in Hertfordshire, which "was made by the Countess of Bedford, esteemed among the greatest Wits of her Time . . . and with very great Care, excellent Contrivance, and much Cost." "Because," explains further Sir William, "I take the Garden I have named to have been in all Kinds the most beautiful and perfect, at least in the Figure and Disposition, that I have ever seen, I will describe it for a model to those that meet with such a Situation and are not above the Regards of common Expence."

It lies on the Side of a Hill (upon which the House stands), but not very steep. The Length of the House, where the best Rooms and of most Use or Pleasure are, lies upon the Breadth of the Garden; the Great Parlour opens into the Middle of a Terras Gravel-Walk that lies even with it, and which may be, as I remember, about three hundred Paces long and broad in Proportion, the Border set with Standard Laurels, and at large Distances, which have the Beauty of Orange-Trees, out of Flower and Fruit; from this Walk are Three Descents by many Stone Steps, in the Middle and at each End, into a very large Parterre. This is divided into Quarters by Gravel-Walks, and adorned with Two Fountains and Eight Statues in the several Quarters; at the End of the Terras-Walk are Two Summer-Houses, and the Sides of the Parterre are ranged with two large Cloisters, open to the Garden upon Arches of Stone, and ending with two other Summer-Houses even with the Cloisters, which are paved with Stone and designed for Walks of Shade, there being none other in the whole Parterre. Over these two Cloisters are two Terasses covered with Lead and fenced with Balusters; and the Passage into these airy Walks is out of the two Summer-Houses, at the End of the first Terras-Walk. The Cloister facing the South is covered with Vines. . . . From the middle of this Parterre is a Descent by many Steps flying on each Side of a Grotto, that lies between them (covered with Lead and flat) into the lower Garden, which is all Fruit-Trees, ranged about the several Quarters of a Wilderness which is very Shady; the Walks here are all Green, the Grotto embellish'd with Figures of Shell-Rock-work, Fountains and Water-works. If the Hill had not ended with the lower Garden, and the Wall were not bounded by a common Way that goes through the Park, they might have added a Third Quarter of all Greens; but this want is supplied by a Garden on the other Side of the House, which is all of that Sort, very Wild, Shady, and adorned with rough Rock-work and Fountains.

Next to this portrait of one of these old English gardens which, alas, have almost wholly disappeared under the hand of iconoclastic fashion, may come a picture, drawn, in 1780, by William Beckford, the builder of Fonthill, and representing the celebrated Boboli garden at Florence, which still keeps much the same look it wore a hundred years ago.

This garden lies behind the Grand Duke's palace, stretched out on the side of a mountain. I ascended terrace after terrace, robed by a thick underwood of Bay and Myrtle, above which rise several nodding towers, and a long sweep of venerable wall, almost concealed by Ivy. You would have been enraptured with the broad masses of shade and dusky alleys that opened as I advanced, with white statues of fauns and nymphs and sylvans glimmering amongst them; some of which pour water into sarcophagi of the purest marble, covered with antique rilieves. The capitals of columns and ancient friezes are scattered about as seats. On these I reposed myself and looked up at the Cypress groves which spring above the thickets; then, plunging into their retirements, I followed a winding path which led me by a series of steep ascents to a green platform overlooking the whole extent of wood, with Florence deep beneath, and the tops of the hills which encircle it jagged with Pines; here and there a convent, or villa, whitening in the sun. This scene extends as far as the eye can reach.

Still ascending, I attained the brow of the eminence, and had nothing but the fortress of Belvedere and two or three open porticoes above me. On this elevated situation I found several walks of trellis-work, clothed with luxuriant vines. A colossal statue of Ceres, her hands extended in the act of scattering fertility over the country, crowns the summit. Descending alley after alley, and bank after bank, I came to the orangery in front of the palace, disposed in a grand amphitheatre, with marble niches relieved by dark foliage, out of which spring Cedars and tall aerial Cypresses. This spot brought the scenery of an antique Roman garden so vividly into my mind that . . . I expected every instant to be called to the table of Lucullus, hard by in one of the porticoes, and to stretch myself on his purple triclinias.

How different from this is the scene Miss Mitford paints in "Our Village," describing a typical English cottage-garden.

The pride of my heart and the delight of my eyes is my garden. Our house, which is in dimensions very much like a bird-cage, and might with almost equal convenience be laid on a shelf or hung up in a tree, would be utterly unbearable in hot weather were it not that we have a retreat out-of-doors —and a very pleasant retreat it is. To make my readers comprehend it I must describe our whole territories. Fancy a small plot of ground with a pretty, low, irregular cottage at one end; a large granary divided from the dwelling by a little court running along one side; and a long thatched shed, open towards the garden, and supported by wooden pillars, on the other. The bottom is bounded half by an old wall and half by an old paling, over which we see a pretty distance of woody hills. The house, granary-wall and paling are covered with vines, Cherry-trees, Roses, Honeysuckle and Jessamine, with great clusters of tall Hollyhocks running up between them; a large Elder overhanging a little gate, and a magnificent Bay-tree, such a tree as shall scarcely be matched in these parts, breaking with its beautiful conical form the horizontal lines of the buildings. This is my garden; and the long pillared shed, the sort of rustic arcade, which runs along one side, parted from the flower-beds by a row of rich Geraniums, is our out-of-door drawing-room. I know nothing so pleasant as to sit there on a summer afternoon, with the western sun flickering through the great Elder-tree and lighting up our gay parterres, where flowers and flowering shrubs are set as thick as grass in a field, a wilderness of blossoms, interwoven, intertwined, wreathy, garlandy, profuse beyond all profusion, where we may guess that there is such a thing as mould but never see it. . . . Nothing so pretty to look at as my garden! It is quite a picture, only unluckily it resembles a picture in more qualities than one—it is fit for nothing but to be looked at. One might as well think of walking in a bit of framed canvas. There are walks, to be sure—tiny paths of smooth gravel, by courtesy called such—but they are so overhung by Roses, and Lilies, and such gay encroachers—so overrun by Convolvulus and Heart's-ease and Mignonette, and other sweet stragglers, that, except to edge through them occasionally for the purpose of planting, or weeding, or watering, there might as well be no paths at all.

Very different again, in subject and treatment, is this picture of an Oriental garden, painted in "Eothen," by Alexander Kinglake:

Wild as the nighest woodland of a deserted home in England, but without its sweet sadness, is the sumptuous Garden of Damascus. Forest-trees, tall and stately enough, if you could see their lofty crests, yet lead a bustling life below, with their branches struggling against strong numbers of bushes and willful shrubs. The shade upon the earth is black as night. High, high above your head, and on every side all down to the ground, the thicket is hemmed in and choked by the interlacing boughs that droop with the weight of roses, and load the slow air with their damask breath. The Rose-trees which I saw were all of the kind we call damask; they grow to an immense height and size. There are no other flowers. Here

and there, there are patches of ground made clear from the cover, and these are either carelessly planted with some common and useful vegetable, or else are left free to the wayward ways of nature, and bear rank weeds, moist-looking and cool to the eyes, and freshening the sense with their earthy and bitter fragrance. There is a lane opened through the thicket, so broad in some places that you can pass along side by side; in some so narrow (the shrubs are forever encroaching) that you ought, if you can, to go on the first and hold back the bough of the Rose-tree. And through this wilderness there tumbles a loud, rushing stream, which is halted at last in the lowest corner of the garden, and then tossed up in the fountain by the side of the simple alcove. This is all. Never for an instant will the people of Damascus attempt to separate the idea of bliss from these wild gardens and rushing waters.

Notes from a Wild Garden.

MY wild garden is a narrow strip of land, less than an acre in extent, which I began to plant four years ago. Some twenty years before this it had been planted with Grape-vines, which were dug out so thoroughly that they have not since troubled me by sprouting. Already this little spot begins to assume quite a wild and woody look. A group of Sassafras trees is especially fine. Sweet Gum, Wild Cherry and Maples are also making a good growth. Conifers are doing well, none better than the Hemlocks. The finest one, planted four years ago this spring when less than three feet in height, now measures nine feet high, with a spread of branches eight feet in diameter. It is graceful and luxuriant, with nowhere a dead twig to be seen.

The frost of early May injured a good many trees and shrubs, among others the Hollies, Mulberries and English Walnut-trees; also the Japanese Akebia and Actinidia, but they are now growing rapidly, and are apparently making up for lost time.

Among the herbaceous plants is *Xerophyllum setifolium*, which is considered a most difficult plant to cultivate, but I have succeeded in establishing a number of fine plants. They were set four years ago, and this spring twenty-three bloomed, making a fine display. I was told by those who had tried to cultivate it that it would surely not live longer than the first summer. But I was undismayed, and had a strong man take up the plants with such great balls of earth that some of them could hardly be crowded into a bushel basket. I stood by during the removal, and rejected every one that could be suspected of mutilation. We had a great wagonful of them and other plants, and when we reached home the Xerophyllum was set in a trench somewhat lower than the surrounding ground, and well watered. This is all the care they have ever received, beyond an occasional watering the first summer, and every plant is flourishing.

Helonias bullata is also growing nicely. This charming plant blooms among our earliest flowers in April. Notwithstanding that its native home is only in dense Cedar swamps, where it is often entirely covered with water, it is not difficult to grow in common garden-soil. It is a rare local plant, belonging in the Lily-family, and in early spring sends up a naked flower stem, a foot or two high, surmounted by a dense raceme of showy purple flowers. The leaves are evergreen, and are handsome the entire year.

Under and among the trees and shrubs many creeping plants have become at home and are growing nicely. Trailing Arbutus blooms freely here, as does the Partridge-berry, while the aromatic Wintergreen is full of bloom now, with promise of pretty clusters of scarlet berries in late autumn and winter. The wild Yam is here too, climbing about in its graceful way. This vine is much handsomer and far more delicate than the Chinese Yam, which florists are sending out under the name of Cinnamon Vine. *Apios tuberosa* is clambering about here and there without care, having been brought in among clumps of plants from the damp Pines, where it is very abundant. But it is quite welcome here, with its dense clusters of fragrant dull purple flowers.

Wild Lilies and cone-flowers, Rudbeckias, and various Sunflowers, with one species of Golden Rod, *Solidago odora*, are now in bloom. Groups of Yucca, too, are scattered about with their wealth of flowers on the tall stems, which in the moonlight look like ghosts.

Among the shrubs, *Azalea viscosa* is still in bloom, and *Clethra alnifolia* is just beginning to open its flowers. This is one of our most desirable shrubs. Its dense raceme of white flowers is fragrant and handsome, and it remains in bloom a long time, commencing about the middle of July and continuing through August. The sweet-scented shrub Calycanthus is still in flower, and so are wild Roses from the Pines. But among the most attractive features of the wild garden are the Ferns, of which there are several species perfectly at home, growing luxuriantly in the shady places.

Vineland, N. J. *Mary Treat.*

Southern California Notes.

THE tall scarlet Larkspur (*Delphinium cardinale*) was introduced into cultivation, I believe, about the year 1858, from California. It has figured repeatedly in recent years as a novelty, although it may be found quoted constantly in many European catalogues.

I have lately seen this showy plant in great abundance on hill-sides east of San Diego, where the brush had been burned off the preceding fall. Attaining a height of five to ten feet, and covering densely almost the entire hill-side bordering the Potrero valley, the brilliant flaming flowers produced a striking resemblance to a hill-side on fire.

The large perennial roots, when in a dormant condition, may be sent with safety in a perfectly dry condition to any part of the world. The plants are also easily produced from seed, and will thrive luxuriantly in any rich soil. They are considered quite hardy. The sepals and two lower petals are scarlet; the two upper petals a delicate lemon-yellow tipped with scarlet and with a portion of the back also scarlet. The stigmas are tipped with scarlet. The sepals are tipped with a delicate pea-green, but scarlet is the predominating color, and unless closely examined no other color will be observed.

Dormant roots of *Dodecatheon Clevelandi*, sent to France in a dry state the past season, failed to grow in all but a few cases. No reports have yet been received from England or Holland, where roots were also sent, but as they are catalogued it may be presumed that they did well under proper treatment. This lovely plant has been denounced as one of the novelties lacking positive merit, but it is doubtless the handsomest of the genus. The centre of the flower is a rich prune-purple, bordered with bright lemon-yellow, the reflexed divisions of the corolla pure white, or tipped with lavender or phlox-purple. In individual plants the divisions are sometimes pure white throughout, or of a deep, brilliant purple, or of an intervening tint.

Papaver Californica is another plant of recent introduction. The flowers are about two inches in diameter, of a bright saturn-red to orange-chrome color, the centre of a delicate sulphur-yellow. Max Leichtlin writes that it has flowered with him the past season, but, while he considers it interesting botanically, he does not consider it worth cultivation. It has been curiously described in one catalogue as possessing flowers ten inches across, and of a different color from its own.

The effect of fire upon the vegetation of a country is an interesting subject for investigation. For the past twelve years I have been botanizing in southern and Lower California, and only in late years has *P. Californica* been seen either by myself or other botanists. John Spence was the first to find it on brush-lands in the Santa Ynez Mountains, but only found it where the land had been stripped by fire. In 1889, I believe, I first found it east of San Diego, near Campo, at a similar elevation, where the land had previously been burned over. Last year I found it sparingly in the same locality, and in great profusion in another locality near by that had been burned over the preceding fall. This year I could find no trace of the plant in either of these burnt areas. But between the two localities, where brush-fires raged last fall, I found it thriving.

Wherever fire has raged the previous year I have not failed to find this Poppy, but the second, or third year at most, it seems to again entirely disappear. As I have traveled over the same route yearly, its presence in previous years would have been detected long ago by myself and others as well.

In the mountain districts denuded by fire, the following spring is sure to reveal a wealth of unsuspected beauty. *Dicentra chrysantha*, in some localities, is sure to become surprisingly abundant. The scarlet Larkspur, as above noted, owes its luxuriance and abundance to the preparation of the soil by fire for its reception. *Calochortus Weedii* often appears by thousands in a burnt district where its presence previously was scarcely suspected. *Phacelia Orcuttiana*, as well as *Papaver Californica*, appears to be a "fire-plant." And the number of other plants which are found in their greatest profusion and at their best in a burnt area are legion. In a few years such plants retire again into comparative obscurity.

The Pride of California (*Lathyrus splendens*) is one of these plants which seem to be benefited by the ordeal of fire, which renders the vine more prolific and adds brilliancy to the blossoms.

Orcutt, Cal. *C. R. Orcutt.*

New or Little-known Plants.

Pinus cembroides.

THE Mexican Nut Pine (*Pinus cembroides*) is rather a recent addition to the silva of the United States, it having been detected only a few years ago for the first time within our territory, on the Santa Catalina Mountains of Arizona, by Mr. C. G. Pringle. Last year the same tree was found by Mr. Brandegee forming a forest on the flat top of the Sierra de Laguna, in Lower California, where it sometimes grows to the height of fifty feet, with a short stout trunk and a round top resembling in general appearance the better-known Nut Pine of Colorado and New Mexico, to which this species is very similar, except in foliage, which is much thinner than that of the other Nut Pines which form the small section to which Engelmann has given the name *Cembroides*. These trees are distinguished by their short subglobose cones with thick unarmed scales, large edible seeds with minute wings, and usually stout leaves varying from one to five in a sheath. *Pinus cembroides* is widely distributed through northern Mexico, where it often forms open scattered forests of considerable extent on the lower slopes of the mountain-ranges. The seeds, which are sold in the markets of all Mexican cities, form an important article of food, and are eaten roasted like peanuts or are ground into flour.

The illustration on page 353 is made from one of Mr. Brandegee's Lower California specimens. An earlier figure can be found in Forbes' "Pinetum Woburnense," an exceedingly rare work, of which only a hundred copies were printed, and in which our tree is called *Pinus Llavana*. This figure is reproduced in Antoine's "Conifers."

Iris Robinsoniana.

THIS is one of the most interesting of all cultivated Iridaceous plants. It was discovered in Lord Howe's Island by Mr. Charles Moore, Director of the Botanical Gardens at Sydney, who wrote of it, in 1869: "A large Iridaceous plant, termed the Wedding Flower, was found sparingly in two or three situations. Of this only seed-vessels were obtained, but the flowers are described as being very beautiful. The leaves were upward of six feet long, and from two to three inches wide. In appearance it resembles a large species of Moræa, but it will probably prove a new genus."

In 1872 Dr. G. Bennett communicated to the *Gardeners' Chronicle* an account of the plant as he had seen it growing in the Sydney Gardens under Mr. Moore's care. Bentham, in his *Flora Australiensis* (1873), describes the plant under Moræa, and states that it is the largest species of the genus, the habit of the plant being that of the nearly allied *Pardanthus Chinensis*, and the flowers nearly those of *Moræa iridioides*.

The introduction of this plant into English gardens, no doubt, took place soon after it was noticed in the *Gardeners' Chronicle*. There were large specimens of it in several gardens known to me twelve years ago, for the plant grew vigorously enough although it would not bloom. The example now flowering at Kew, and of which the accompanying figure (p. 355) is a photograph, is growing in the south end of the house devoted to large succulent plants. It is close to the doors, which are open all day during summer, and it is never shaded. Its habit and height are well shown in the photograph. The leaves are six feet or more long, by three inches in width, and the scape is six feet high to the first branch. The flowers are expanded in the morning and permanently close again before night. Each sheath will produce nine or more flowers, one after the other. The first flowers expanded on June 21st, since when up to to-day, July 3d, there have been 157 flowers. There is every promise that this number will be more than doubled. Eighteen flowers were the most we have had open together.

Each flower measures four inches across, the segments spreading almost flat, the three outer larger than the inner, all of them pure white, of about the same texture as the petals of *Phalænopsis grandiflora*. There is a crescent-shaped blotch of golden yellow at the base of each of the three outer segments.

The species is found wild only in Lord Howe's Island, and it is the only Iris or Moræa known in the whole of Australia. It is a noble plant, and worth cultivating for its foliage, as well as an exceedingly beautiful object when in flower. Unfortunately, only four flowers were expanded at the time when the photograph was taken.

Foreign Correspondence.

London Letter.

Conference on Hardy Herbaceous Plants.—The Royal Horticultural Society had arranged a two days' exhibition and conference to be held at Chiswick this week, the special object being the popularization of hardy herbaceous plants, which, in the opening remarks at the conference, was said to be, "as a rule, overlooked by gardeners." Mr. W. Robinson, of *The Garden*, contributed a paper on Wild Gardening, in which he advocated the planting among meadow-grass large quantities of such plants as Daffodils, Bluebells, Snowdrops, etc. It was asked what chance such plants would have in the struggle that would ensue between them and the grass, and particularly such enemies to bulbs as wire-worms, etc., and some one recommended feeding the worms with rapecake.

[The baiting of wire-worms has been found the most effective remedy for these pests in this country. The arsenites mixed with corn-meal dough or sprinkled on other baits are generally recommended.—Ed.]

The Rev. Mr. Ewbank, of the Isle of Wight, treated upon summer-gardening as practiced by himself. Mr. Ewbank is one of the few amateur horticulturists in England who delight in plants which other people find difficult to manage. His garden is, therefore, the home of the outcast and the unknown, and it is the scene of not a few very interesting experimental cultures and horticultural triumphs. The next paper was contributed by Miss Jekyll, who is known as a first authority upon æsthetic gardening. Names are of no account, labels are an abomination in this lady's garden, and no plant that is not decidedly beautiful to look at and easy to grow receives any attention from her. She and Mr. Ewbank practice the two extremes of hardy-plant culture. Of course, every one deprecated the total removal of labels. Who has not experienced the relief afforded by the label of a plant whose name is inquired after and which one feels he ought to know? If only a glimpse of the beginning or end of the name is caught it is recalled at once.

The second day's conference was devoted to strawberries chiefly; other fruits, such as gooseberries, raspberries and currants, also receiving attention, both from lecturers and exhibitors. The papers dealt chiefly with the cultural requirements and merits of the different fruits treated upon, and, while they contained much useful information, they revealed nothing new in the shape of novelty.

The exhibition of flowers was a pretty full one, and comprised all the popular summer-flowering herbaceous plants, as well as a few which are yet scarcely known. Unfortunately, the rain fell in torrents on both days, so that a most interesting exhibition and instructive conference were enjoyed by very few.

Lilium Lowii, Baker, new species.—This is a new Indian Lily which has just flowered in the nurseries of Messrs. Hugh Low & Co., at Clapton, and has been submitted to Mr. Baker for naming. It belongs to the Polyphyllum group, and is closely related to *L. Nepalense*, differing from this species chiefly in having smaller narrower leaves, flowers more distinctly funnel-shaped and colored white, with a few blotches of purple on the inside of the segments.

This is the third new addition to garden Lilies made by the Messrs. Low, the first being *L. Nepalense*, discovered by Wallich fifty years ago, but never introduced into England until two years ago, when the Clapton firm imported a quantity of it from the Central Himalayas. It is a most beautiful and stately Lily, a yard or more high, bearing a head of three or five flowers five inches long and nearly as broad, the segments recurved and colored lemon-yellow, the tube deep crimson inside, spots of the same color extending some dis-

tance up the segments. Here it requires the protection of a greenhouse.

About the same time the same firm introduced a grand variety of *L. Wallichianum*, which was named Superbum at Kew, and which is one of the most beautiful of all Lilies. Its flowers are as large as those of *L. Harrisi*, but wider and more campanulate, their color being creamy white, with a blotch of lemon-yellow in the throat. It also requires greenhouse treatment. Although a good garden Lily in appearance, yet the new *L. Lowii* is not equal in beauty to the other two.

ROSE REINE BLANCHE.—This is a new semi-double Rose which was submitted to the Committee of the Royal Horticultural Society at their last meeting by Mr. Ladham, of Shirley Nurseries, Southampton, and it received a certificate. Its beauty is in the dash of crimson on the margins of the otherwise pure white petals, and before the buds unfold this color has a very pretty effect. The open flowers are particularly charming, and they are as large as the flowers of *Anemone Japonica*. I am unable to state the origin of this Rose, but it is certainly a variety of the south European *R. Gallica*. It appears to be very free-flowering, and, altogether, I should say it is likely to prove a popular Rose wherever the single or loose-flowered Roses are in favor.

Cultural Department.

The Strawberry Season.

THE Strawberry crop of 1891 was a good one, much above the average. A favorable season, cool with sufficient moisture, contributed to a steady, healthy growth. The frosts of May, which excited so much alarm, did no injury in this vicinity, with a single exception, in which case the plants were almost entirely Sharpless and Great American. These varieties, besides being probably more tender than others, expose their flowers more. Within two or three mornings after the blossoms began to open I watched my plants closely, expecting much injury, but I found less than is frequently the case. This was, doubtless, due to the dryness of the air; with rain or heavy dews the damage would, no doubt, have been greater. This dryness of the air, together with the protection of the calyx, saved our peaches and cherries also, and rendered the published reports of great damage entirely premature.

Our Strawberry season opened May 25th, with a pint of Michel's Early, and closed, July 6th, with a quart of Stayman's No. 1 and Parker Earle. The birds anticipated us two or three days.

Michel's Early is a strong, vigorous grower, with tall, erect foliage, berries scarlet in color, of good size and quality, and from four to five days earlier than any others in my collection. It is moderately productive, and is desirable for family use on account of its earliness and quality; for these same reasons it may be desirable for near markets. Rusk, or Lady Rusk, was much more productive; it is dark crimson in color, average to large size, but it is in no way noteworthy. It is claimed that this berry dries up without rotting, but this claim did not prove valid. The Parker Earle has more of this quality than Lady Rusk. We shall hold this berry for another season's trial. Haverland is a handsome, perfect-shaped berry, long cone-formed, with a neck and reflexed calyx, of very good quality, and it is productive, all of which are prime requisites in a berry for popular favor. Stayman's No. 1 is a good grower, berry medium to large, scarlet, productive, but rather acid; it is better suited for market than for amateur purposes. Cloud's Seedling is very nearly a reproduction of Crescent, and is no better, if as good.

Warfield has been praised without stint, and declared to be the best of all. Grown in stools, thinly, it was of fair size, slightly necked, calyx reflexed, bright, glossy crimson color, attractive and handsome. But grown in matted rows, it was small, ranking with Cloud and Crescent under like conditions. I confess to disappointment as to size, and another season's trial is necessary to determine whether to keep it longer or not. Miami is a large dark crimson berry, more flattened than elongated, fairly productive and a vigorous grower, with no remarkable qualities so far as observed. Pine-apple is the most rank and vigorous grower of all. Its dark green foliage is pleasant to look at, but its few large, long, deformed, light dull scarlet berries are a poor substitute for good strawberries. It seems to be more fruitful in matted rows than in stools. Gandy is a light berry, and is large, handsome and good. The plants are strong and stocky, but do not promise to yield abundantly. Crawford is another large handsome berry of good quality. In stools the growth of plants was satisfactory, but the matted row resulting from plants set last spring, presented a sorry contrast to the fall-set plants, not fifty feet distant. Like the Gandy, it appears to lack the elements of productiveness, but both are deserving of further trial.

The above ten varieties comprise the bed of fall-set plants mentioned in Garden and Forest last autumn. They gave the best results I ever had from fall-set plants. The plants were taken from matted rows resulting from spring-set plants, thus giving two tests of each variety under the two systems, with results decidedly in favor of the stools from fall-set plants, with the single exception of the Pine-apple, and that is too poor to be taken into the account.

Shaw is a large berry of the Sharpless type, and the few plants I had in fruit promised as well as that variety ever did, with fewer deformed berries. A further trial is necessary to fix its value. Beederwood promised well; it is fairly productive, with large handsome berries. I shall give it another season's trial. Bubach 132 is a scarlet berry of good size and perfect shape, but seems to melt down if kept over-night, and is therefore not a good market berry.

Great Pacific is a fine, vigorous grower, but in size of fruit, quality and productiveness it proved a most dismal failure. I shall let a few of the plants set last fall remain over for another season. Gipsey proved little better than Wilson, and is disappointing on my soil.

Saunders, on fall-set plants, is large, handsome and good, and is very promising. This, with Gandy and Crawford, forms a trio of large berries that promise to supersede the Sharpless. Another season will fix their status in the long list of new ones, and the prospect is good for their standing near the head. The best and most remarkable of the new varieties is Parker Earle. The plant is stocky, vigorous and immensely productive. The berries are medium to large. They will not compare in size with Sharpless, Gandy, Saunders, Bubach, etc., but they are of good shape, handsome, and of good flavor, calyx reflexed, seeds prominent, after the type of Boyden's 30. It sets twice as much fruit as it should, for it is, I think, impossible for any plant to fully develop and mature so many blossoms. It appears to have good keeping qualities. At the first picking I gathered a quart without moving out of my tracks, a thing I never remember to have done before. Shuster's Gem and Lovett's Early were set later in the fall, and no fair estimate can be made; so far they show no remarkable features. Davis' Numbers Ten, Twenty and Twenty-five are vigorous growers, producing large handsome fruit, but the quality is inferior. Of nearly a dozen other new varieties not any, thus far, give promise of becoming standard sorts. Out of thirty new varieties fruiting this season, many of which cost one and two dollars a dozen, only about one-third seem to be worthy of further trial, and probably not more than half of that number will be regarded as standard sorts five years hence.

Among the older tested varieties the Pearl stands at the head with me. It is early, handsome, large, perfect in shape, has a reflexed calyx, is productive and very good in quality. It possesses more points of excellence than any other variety I know of. Next to Pearl is Bubach, altogether a different type of berry, much larger, very productive, but not as good in quality. Jessie is better in quality, but not as large as Bubach, and often ripens unevenly. It was better in this respect this season than ever before. Belmont nearly equals the Sharpless in size and is of better form, but does not produce as heavily. Jersey Queen has many friends; it is a late, large, handsome berry. With good care it will please those who like a rich acid berry. Jewell is a beautiful berry, but is too uncertain. It is very much given to blight here, from which all varieties have been exceptionally free this season.

Some large growers around Newark grow the Downing and Champion almost exclusively. About Irvington and Hilton the Great American takes the lead. Having found a berry which satisfies the requirements of their soils, the growers are content to let well enough alone; but should these varieties fail, as they may in time, they will be compelled, as I have been, to try other varieties, until they find suitable ones to take their places.

The best variety must be a matter for each grower to determine for himself, and when it is found it should be treated generously and grown as long as it continues to do well. The experiments here recorded are by no means conclusive, and allowance must be made for the soil, season, etc. The soil was a light clay loam, and the results would, no doubt, be different on a sandy loam or a heavy clay soil. Many of the varieties which are nearly worthless with me may prove of value under different conditions. Of course, it is unfair to condemn any variety for its behavior in one soil. Under different circumstances it may be good enough to fulfill the anticipations of its originator, although it must be confessed that these hopes are often more rosy than any experience will justify.

Montclair, N. J. *E. Williams.*

Stray Notes from the Arnold Arboretum.—VI.

Syringa pubescens (see Garden and Forest, vol. i., p. 415) flowers with the common Lilac. It is a slender upright-growing shrub with dark green ovate leaves, which are much smaller than those of the other cultivated Lilacs. The corolla of the flower consists of a narrow limb, with very short oblong lobes and a long slender tube; it is rose-colored at first, but turns pale or almost white before fading. The clusters of flowers, which are exceedingly fragrant, are small as compared with those of other Lilacs, but they are produced in the greatest profusion, and quite cover the branches of well-established plants. This species has never flowered as freely or produced such a charming effect as it did during the past spring; and there is now every reason to believe that it will prove a first-class plant, particularly useful for the decoration of small gardens, in which the other Lilacs might occupy too much space. The seeds from which the principal supply of the plants raised in the Arboretum were derived were sent here in 1882 by Dr. Bretschneider, at that time medical attaché to the Russian legation at St. Petersburg, to whom the Arboretum is indebted for the number of valuable and interesting plants. Living plants were received about the same time from the Arboretum Segretzianum, in France, and later it has been sent from other European gardens usually under the name of *S. villosa*, a very different plant, and a more valuable one, perhaps, from a decorative point of view, as it flowers several weeks after the common Lilac, or about the middle of June—that is, at the time when many shrubs have passed their flowering period.

S. villosa (see Garden and Forest, vol. i., p. 521) is also a native of northern China and is one of the plants sent by Dr. Bretschneider, and, like the last-described species, promises to be a real acquisition to American gardens. It comes from northern China and seems identical with the Syringa of the Himalayas, *S. Emodi*, and with *S. Josikæa*, of whose native country a good deal was said in a recent issue of Garden and Forest. This, however, is a question which need not be discussed in this connection, and it is sufficient to say that the plant grown here as *S. Emodi*, when it does flower, produces panicles which are smaller and much less beautiful than those of the north China plant; and that *S. Josikæa*, which flowers a week or perhaps ten days later, is in every respect less beautiful and desirable. The

seedlings of *S. villosa*, raised in the Arboretum, show a decided tendency to vary in the time of flowering, in the size and shape of the leaves, and in the size of the inflorescence—an indication, perhaps, that this species will respond readily to efforts made to improve it by selection. The best form here, and the last one to flower, has large, rather light green, ovate-lanceolate leaves, great broad terminal panicles which stand up on long stems above the plant and produce a remarkably attractive appearance. The flowers are individually large, with a rather short corolla-tube and short, ovate lobes; they are of a delicate flesh-color, shading into rose, and quite unlike, in color, those of any other Lilac. *S. villosa* is perfectly hardy and a vigorous grower, promising to attain, ultimately, a large size, the best plants here being now about eight feet high and eight or ten feet across the branches. It differs from the common Lilac in that the terminal bud develops, so that the inflorescence is terminal, three clusters of flowers being sometimes produced on the end of the branch instead of the two lateral ones of that species, which very rarely perfects its terminal buds. The flowers of the Chinese plant emit a strong and disagreeable Privet-like odor. In spite of this serious defect, however, many persons believe that this is the most valuable of the Lilacs recently brought into our gardens.

And this brings us to an entirely different section of the genus, the Ligustrinas, which botanists unite with Syringa, although they are distinct in habit and general appearance, and easily to be distinguished by their creamy white flowers, with a very short corolla-tube, barely exceeding the calyx in length. There are three of these plants now in cultivation. The best-known and the first to flower, the flowers appearing with those of *S. villosa*, is *S. Amurensis*, whose native country is explained in its specific name. It has been cultivated for a number of years, and is a bold, strong-growing shrub of irregular outline, with rather rigid branches and large, leathery, ovate-pointed leaves. The flowers are produced in short clusters

Fig. 60.—Iris Robinsoniana.—See page 352.

as broad as long, often inclined to be one-sided, and carried well above the plant on the ends of the principal stems. Here it is not a very free-blooming plant, but the clusters of flowers are large and make a great show in contrast with the dark green of the leaves below them. It is, however, less beautiful than its near relative, *S. Pekinensis* (see Garden and Forest, vol. iii., p. 165), which flowered here last year for the first time in cultivation from seeds sent to the Arboretum by Dr. Bretschneider. The flower-clusters produced last year were few in number and small in size, and gave little idea of the value of the species as a flowering plant. This year the plants flowered profusely about the middle of June, producing flower-clusters more than eighteen inches long, and were objects of unusual beauty and interest. The value of this plant, which seems destined to become a first-rate addition to the list of our hardy shrubs, is greatly increased by the graceful habit of its long, slender, arching stems, which now form masses some fifteen feet through and ten or twelve feet high. The foliage is peculiarly light and graceful, of a pleasing color and of late duration, although it does not assume a brilliant coloring before falling in the autumn. Altogether, *S. Pekinensis* is a more desirable plant than it was at one time supposed to be. It is well suited to stand by itself as an individual specimen on the lawn, where it can find plenty of room in which to develop its beauty of outline. It appears to require deep, rather moist, very rich soil, in which it grows rapidly; the plants do not flower until they are large and well established.

In 1878 the late W. S. Clarke, who organized the Massachusetts Agricultural College and then went to Japan, at the invitation of the Government of that country, to establish an agricultural college there on the American plan, sent a number of seeds, gathered in the neighborhood of Sapparo, in the northern island, to the Arboretum. Among them was a packet marked *Oleaceæ*. The seeds germinated, grew rapidly, and the plants proved, when they flowered, ten years later, to be the little-known *S. Japonica* (see Garden and Forest, vol. ii., pp. 293–295), which, like *S. Pekinensis*, the Arboretum first introduced into cultivation. So much has been said of this plant during the last two or three years that there is little left to say about it, except that it improves with age, producing, each year, larger and more abundant flower-clusters. It is absolutely hardy; it grows with great rapidity in good soil and is, in every way, an attractive and handsome plant of perfect habit; the foliage is ample and splendid; the inflorescence is not surpassed in conspicuousness by that of any other hardy tree. Rose-bugs take kindly to the flowers, but the leaves are as yet uninjured by any insect, and the only drawback to it is found in the fact that it loses its foliage early in the autumn, and that it falls without having first changed color. The fact that this plant flowers in July adds to its value as an ornament to the garden.

Arnold Arboretum. *P. C.*

Some Native Plants.

With the month of July many interesting species of the composite family commence to bloom. This number increases, until by the middle or last of August this natural order predominates among our wild flowers. It is a large and interesting family, represented in North America by 239 genera and upward of 2,000 species and varieties. The largest genus is the Aster, which contains 124 species. Many of these Asters are very handsome when in flower, and form a large share of the last wild flowers of the season. The next genus in size is the Solidago (Golden-rod), for which America is noted, and of which we have over a hundred species and varieties. Both genera are, for the most part, among the later-flowering plants, but the Golden-rods are the earlier of the two. Many of the Asters are quite late, some continuing to bloom until killed down by frost. As a rule, Golden-rods and Asters transplant well into any ordinary soil, and if they are cut back half or two-thirds their length, lifted with care, and not allowed to become dry before setting, there is no better time for this, all things considered, than when they are in flower. They need to be watered and cared for until established.

Lepachys pinnata, now in flower, is a showy composite, with flowers three or four inches wide, bright yellow, with a grayish centre. The rays are somewhat drooping, as in *Echinacea purpurea*. It is a slender plant, three or four feet high, each of the numerous branches terminating in a single flower. A dry sunny exposure seems to be its choice, and any ordinary garden-soil will suit it. The peculiar drooping habit of its petals, and the size of the flowers, which are on ample stems, suggest its value for cutting. Frequently blooming with it is *Heliopsis scabra* (the Ox-eye), a plant with darker golden, showy flowers not quite as large as those of *Lepachys pinnata*.

Another composite, conspicuous for its profusion of bloom at this season, is *Chrysopsis villosa*, the Golden Aster; it is a shorter plant and more spreading in habit, and is common on dry soil and along gravelly railroad banks. The golden-yellow flowers of this plant are an inch or more wide, and quite attractive. Still another striking species of this family, now beginning to flower, is *Vernonia Baldwinii*, the first of the Iron weeds to bloom. The large cymes of deep purple flowers are a pleasing change from the yellow of the three genera above mentioned, and which, as the season closes, is sometimes so universal as to become tiresome.

Scutellaria canescens, one of the Skullcaps, which blooms about the middle of July, is a hardy and interesting perennial three or four feet high, with leafy stalks, terminating in a good-sized racemed panicle of showy blue flowers. A sunny exposure and ordinary soil will suit it.

Verbena Aubletia, one of the Vervains, has been in flower for more than a month. It is a slender species, the spreading, almost procumbent, stems of which terminate in thickened spikes of showy reddish purple flowers. An inhabitant of open woods or prairies, it thrives in any common soil, in the sun or partial shade. Its near relative, *V. stricta*, the Hoary Vervain, is a taller plant, with clustered spikes of pretty purple flowers.

The genus Verbascum (Mullen) is a large one, embracing nearly a hundred species, which are natives of Europe, northern Africa and Asia. Most of these are biennials. We have four species in North America, all of which, I believe, have been introduced. *Verbascum nigrum*, the Dark Mullen, which is native to Britain, Europe and western Asia, is said to be a perennial. Its normal height is only three or four feet, but, under favorable circumstances, it attains a height of six feet and more. Its long spike, or spikes, of bright canary-yellow flowers are very handsome, and continue for a long season. It is a stately and striking plant, which seems to be quite hardy, and easily managed.

Botanical Garden, St. Louis, Mo. *F. H. H.*

Annuals New and Old.

Calendula suffruticosa is a neat growing plant, some eighteen inches high, and very free blooming. The flowers are single, about two inches in diameter, golden yellow, with narrow petals, Doronicum-like in form. This variety is useful for a quiet yellow effect in the garden. The flowers close in dull weather, and are probably not of much service for bouquets.

Centaurea Cyana nana compacta "Victoria" is a long name for a very small plant. This Cornflower forms rounded little plants only six inches high, covered with small blue flowers, resembling, in form and color, the ordinary Kaiserblumé. It does not seem to have a long season of bloom, and may be added to the long list of curiosities.

Zinnia Haageana pumila floro pleno is another accession to the list of dwarf plants to which florists will be sure to give attention. This little Zinnia forms a much-branched bush, about a foot high; it blooms profusely with semi-double flowers about one and a half inches in diameter, of a rather dull orange shade. If some good bright Zinnia colors could be infused into this strain it would be very useful in many places where the larger variety would occupy too much space. There is no sentiment about the Zinnias, but they have wonderfully bright clear colors, are very lasting, and there are, perhaps, no plants which give a more dazzling effect for so little expense and labor.

The double *Chrysanthemum coronarium imbricatum* strikes me as a curious example of the vagaries of the seed trade. *C. coronarium* is one of the commonest of annuals, with rather soft foliage, but with good double yellow or yellow and white flowers. It seems to have occurred to the florists a few years ago that it was a very good thing, and now small plants are largely sold in the spring sales, and the seedsmen have exercised their ingenuity in getting out slight variations. This year's offering differs from the type only in that the petals, instead of being flat, are vaulted. The general effect of the flowers is the same, but the price, it is perhaps needless to say, has quintupled.

Carnation Margaret, half dwarf, is a selection from the quick-growing Carnations introduced last year by Dammann & Co., who also offer these in separate colors and a dwarf kind. Like the variety of last season, they are rapid growers, coming into bloom in five or six months under ordinary culture. The

flowers are of rather thin texture, but are fragrant, mostly double, and very satisfactory out-of-doors. The colors are white, red and yellow, and are selfs. Unlike most Carnations in a young state, they do not seem to be at all hardy. This strain is very slightly more dwarf than the first offering.

Torenia Fournieri is not a new annual, but it is worth noting as having proved very satisfactory out-of-doors, where it does not seem to be much used. It forms neat, sturdy little bushes, with somewhat ruddy stems. Its elegant violet and royal purple flowers always attract attention, and, as it blooms freely, it is useful as a front-row plant, where the color is desirable.

Gaillardia amblyodon is another annual too seldom seen. It has very attractive single flowers, about two inches in diameter, of a rich mahogany-red. It is one of the most distinct of annuals, the coloring being very rich and peculiar. The plants are about eighteen inches high, and should be grown in clumps.

Elizabeth, N. J. *J. N. Gerard.*

Iris Susiana.—Plants that are fickle in their behavior or that stubbornly refuse to comply with the wishes of growers have a peculiar fascination for determined gardeners, and among such are *Iris Susiana* and *I. Robinsoniana*. The latter plant has been grown in this country a number of years, but, so far as I know, it has not yet been flowered. At the Harvard Botanic Garden it has been tried out-of-doors and under glass, in rich soils and poor, in moist, dry and medium situations, in pots and borders, in shade and sunshine, and still no blossom, nor even a sign of one appears. It grows freely enough, forming vigorous and handsome specimens, but never a bloom.

Although rather eccentric, *I. Susiana* is much more tractable. It is a Levantine species, originally found in Persia, and has been cultivated in western Europe since 1573. It was cultivated in England in the time of Gerard, for in his "Herbal," under the name of *I. Chalcedonica*, it is spoken of as "a rare and beautiful flower to behold." Parkinson, also, in his "Paradisus Terrestris," speaks of it as "The Great Turkey Flower-de-Luce." The specific name it now bears refers to an ancient city of Persia, and it was the French, I believe, who first gave it the common, and not inappropriate, name of "Mourning Iris." The plant attains a height of from one to two feet, the light green, ensiform leaves being a trifle shorter than the stem, at the top of which appears a single flower, magnificent in size and of weird aspect. Ordinary flowers measure six inches across by eight inches from base to apex, and I have often seen them larger. The ground color is a grayish lilac, indescribably lined, spotted and shaded with rich purple. I have had no experience with the plant in this country, but I know that precautions similar to those described by Mr. Gerard (page 273) are necessary to its successful management in British gardens. As Mr. Orpet recommends pot cultivation in a frame for these plants, I was prepared to consider them not hardy in Massachusetts until my neighbor, Mr. Thomas N. Cook, who manages a small villa garden with consummate skill, invited me to see one of these Irises in bloom on the 11th of June. Last October Mr. Cook secured a few roots of the plant, and, not having the protection of a cold frame or greenhouse, he set the roots ten inches deep in a mixture of sand and well-decomposed cow-manure. They occupied an exposed position ten yards away from the house and were slightly mulched with dry litter. The situation was neither particularly wet nor dry. The late winter was not unusually mild here, and people in eastern Massachusetts may therefore have a reasonable hope for success with this beautiful species, if Mr. Cook's method is adopted.

Cypripedium Lawrenceanum.—This species has bloomed here for more than two months, and is, beyond question, the most decorative Cypripedium in cultivation. The oblong leaves are from six to twelve inches in length, and beautifully tessellated with greenish white and dark green, the colors being irregularly distributed in about equal quantity. The foliage excels that of all other Cypripediums in beauty, and the genus is one in which attractive leaves are not rare. The distinctness of the variegation would in itself be sufficient to commend the plant to the notice of growers. The flowers, measuring five inches from tip to tip of the petals, and four and a half inches from the base of the lip to the tip of the dorsal sepal, are borne singly, seldom in pairs, on a scape from twelve to eighteen inches long, erect, hirsute, and of a purplish color. The lower sepal is small, ovate-oblong, greenish, with dark lines, the upper one large, between two and three inches across, almost circular, white, with purple and bright rosy purple lines; petals ligulate, pale green, tipped green, with little black excrescences of roundish outline and numerous hairs along the margin; lip large, dull purple in front, and pale green behind. Sometimes the flowers retain their full form and color considerably over a month, and they have been kept two weeks in water. The plant succeeds best in a stove temperature.

There are now many excellent varieties recognized by the trade. Among the best of these are Atro-purpureum, Coloratum, Elegantissimum, Expansum, Hyeanum, Majus, Marmoratum and Superbum.

Botanical Gardens, Cambridge, Mass. *M. Barker.*

The Forest.

Its Significance as a National Resource.

UNDER the title of "What is Forestry?" the United States Department of Agriculture has published a bulletin prepared by Mr. B. E. Fernow, Chief of the Division of Forestry. Most of the subject-matter, it is stated in the letter of transmittal, has already been presented by Mr. Fernow in the form of public addresses before different bodies like State Boards of Agriculture and the Chamber of Commerce in Rochester, New York, and the interest shown in it suggested the desirability of publishing it to a larger audience. The subjects of forest-management, that is, forestry in a wooded country, and forest-planting, or forestry for the treeless plains, are both considered in this bulletin. In treating of the first of these general subjects much practical information is given on reproduction, on thinning, on undergrowth, on the influence of light, and other matters of detail in the actual practice of the art of forestry, and, besides this, there is a discussion on the profitableness of forest-management, together with some notes on European government forestry and on working plans for large forest-areas and the needs of a well-organized administration. All that is set forth on this part of the subject has been derived from experience, and it is a valuable résumé of the most important points in recognized forest-practice. Of course, it is not assumed that what is proper management in one country is proper in all others, and Mr. Fernow lays down the qualifying proposition, which should be borne in mind by every one who takes an interest in the forests of the country, as follows: "Before we may apply the finer methods of forest-management as practiced abroad, it will be well to begin with common-sense management, which consists in avoiding unnecessary waste, in protecting against fire, in keeping out cattle where young growth is to be fostered, and in not preventing by malpractice natural reforestation."

Under the head of forest-planting, Mr. Fernow speaks of the necessity of co-operation. He gives a list of such trees as are more liable to succeed, together with some directions how to mix them, and adds some notes on the proper methods of planting. This subject of tree-culture on the western plains is also illustrated by two letters from correspondents, who give their experience in tree-planting on the prairies of Dakota, and this record of personal effort is an instructive commentary upon the suggestions of the bulletin. The whole makes a pamphlet of rather more than fifty pages. We quote a portion of the introductory paragraphs, which are found under the title of "The Forest and Its Significance":

The forest primeval is our most valuable inheritance. It is the ready cash of nature's bountiful provision for our future. Of all the natural resources reserved for our use it is the most directly useful, for in the forest we find ready to hand, without further exertion than the mere harvesting, the greatest variety of material applicable to the needs of man, the means to satisfy every direct want of life. The accumulations of centuries are stored in the tree-growth of the virgin forest and in the forest-floor of decayed foliage. Nature has taken no account of time or space, both of which were lavishly at her command; nor did she care whether the forest was composed of the timbers most useful to man; tree-growth, whatever the kind, satisfied her laws of development.

But when man begins to occupy the ground, when a growing nation has need of the soil for agricultural use and for timber, when the forest gives way to the field and meadow, it becomes necessary in time to introduce economy into the use

of our inheritance, to relegate the forest to the non-agricultural soils, and to make the soil do full duty in producing only that which is useful to man.

Then a new conception of the forest arises. The "forest primeval," together with the young natural growth of the better class, becomes "woodlands"; the brush-lands, which result from the careless treatment of the original growth, become "waste lands," and the name of "forest" is reserved to those woodlands, which have become objects of human care, producing to the fullest capacity of the soil the most useful material. No more convincing argument for the importance of this resource in a nation's economy can be offered than to state the value of the forest-product in the United States.

The total annual product of wood-material of all sorts consumed in the United States may be valued in round numbers at $1,000,000,000, representing, roughly speaking, 25,000,000,000 cubic feet of wood, or the annual increase of the wood-growth of 500,000,000 acres of forest in fair condition. This value exceeds ten times the value of our gold and silver output, and three times the annual product of all our mineral and coal mines put together. It is three times the value of our wheat crop; and, with all the toil and risk which our agricultural crops involve, they can barely quadruple the value of this product yielded by nature for the mere harvesting. If to the value of our total mining product be added the value of stone quarries and petroleum, and this sum be increased by the estimated value of all the steamboats, sailing vessels, canal-boats, flatboats and barges plying in American waters and belonging to citizens of the United States, it will still be less than the value of the forest-product by a sum sufficient to purchase, at cost of construction, all the canals, buy up at par all the stock of the telegraph companies, pay their bonded debts, and construct and equip all the telephone lines. The value of the annual forest-product exceeds the gross income of all the railroad and transportation companies. It would suffice to pay the indebtedness of all the states, if we leave out New York and Pennsylvania, including that of all counties, townships, school districts, and cities within those states (in 1880); and it would more than wipe out the remaining public debt of the United States. In fact, ranking manufactures of all kinds and agriculture as respectively first and second in importance, as far as production of values goes, the forest-product occupies the third place. This was the case according to the census of 1880. It is claimed that since then the lumber industry has enlarged to such an extent as to make its product second, if not first in value.

Not only does the forest furnish the material for the construction of dwellings and other structures, our railroad consumption of 500,000,000 cubic feet of timber included, but it yields to two-thirds of our population the fuel to warm their houses and to prepare their food; it gave us the first means of using our mineral resources, and even now 600,000 tons of our iron product depend upon charcoal. Not only does the wood in its natural form serve our needs, but our ingenuity has invented methods by which we can transform it into cellulose, paper, and even silk, while lately it has become possible to prepare from the brushwood a feed for cattle more nutritious than straw and equal to hay. By distillation of the wood numerous new products are derived from it, like alcohol, acetic acid, gas, vanillin, etc.; the bark yields indispensable tanning material. Resin and tar to pitch our vessels, and turpentine, sassafras oil, and quinine to cure our ills, rubber and cork for a great variety of uses, maple sugar and cinnamon to flavor our food, all are derived from the forest; an enumeration of the use of forest-products would be almost endless.

While this direct usefulness of the forest is patent to every one, there are to be noted some more hidden indirect phases of utililty as important as those which are presented by its material. The forest, with its decaying vegetation, has furnished the fertility of our fields and waters, for the mineral soil without the humus or vegetable-mold would never have produced food enough for mankind.

Another incalculable benefit of the forest-cover is the part which it plays in the great economy of nature, the recognition of which led Humboldt to exclaim: "How foolish do men appear, destroying the forest-cover without regard to consequences, for thereby they rob themselves of wood and water."

It is only within a century or so that the value of a forest-cover as a protection against destructive natural forces and as a regulator of favorable cultural conditions, by its influence upon climatic conditions and upon the flow of water, has been recognized and proved. Whatever may in general remain unexplained in regard to these influences of the forest, it is well established by observation, experience and experiment that, under certain conditions of soil, topography and climate, these influences not only exist, but are of considerable importance in preventing the washing and shifting of the soil, regulating the surface and subterranean drainage of waters, breaking the force of and tempering hot and cold winds, and thus acting as a regulator of cultural conditions.

The significance, then, of the forest is twofold. For the private interest it is, in the first place, only a source of profitable products; for the interest of the community, the state, or nation it forms an indispensable basis of material prosperity, directly and indirectly. Forest-management, therefore, including a proper maintenance of forest-cover where desirable, supplies not only profitable employment for private enterprise, but is also an important factor of public economy, and the application of proper forestry-principles is hence a matter of the highest public interest.

Correspondence.

Our Neglected Native Flowers.

To the Editor of Garden and Forest:

Sir,—It is a fact to be regretted that the value of plants is so commonly rated by the remoteness of the country from which they have been brought. The cold inhospitable regions of Siberia and Kamtchatka, the torrid jungles of Africa, the wilds of Australia, the distant Indias, the treeless Brazilian Pampas, and the forests of the Amazon are eagerly searched for floral treasures, while our native plants, such as Laurels, Magnolias, Andromedas, Rhododendrons, Lilies, Irises, Cypripediums, Cacti, Phloxes, Passion Flower, Verbenas, Calycanthus, Trailing Arbutus, Calamus and Pond-lilies are comparatively neglected.

A few persons are beginning to appreciate this class of plants, but our people generally are willfully blind to their beauty. In my own little backwoods corner of the south-west we have *Clematis coccinea*, *Ipomea pandurata*, *Bignonia radicans* and Virginia Creeper among vines, Cornels, Red-bud, Hydrangea and Viburnums among shrubs, Phloxes, Lobelias, Penstemons, Verbenas, Ageratums, Aquilegias and other herbaceous plants, all growing wild. One of my neighbors once lamented the poverty that had kept her yard bare of flowers for fifteen years. When I suggested that her boys could get her a great many flowers in the woods a quarter of a mile away, she drew herself up with sudden dignity and freezingly remarked, "that she supposed she could if she wanted *wild* flowers, but she didn't." The sarcastic emphasis on that word "wild" showed that she considered the suggestion a positive insult. Again, while traveling in Arkansas, we passed a grove of beautiful trees, which were then unknown to us. Meeting a family group a little later, we asked the name of "those grand trees, remarkably handsome," we told them, "tall and straight, with corky bark and curious five-pointed leaves, shining as though varnished." But the more we explained, the more puzzled the party became. At last an old lady recognized the description, and burst out with, "La sakes! stranger, them aint nuthin' but Sweet Gums! The men thought yer meant sumthin' fine." "Sumthin' fine" meant something they could not see every day, and it seems to mean this with most people.

Nor is the contempt of wild things confined to the uneducated classes. A certain academy town, whose citizens pride themselves on their culture, has several amateurs ambitious of being considered connoisseurs of choice and rare flowers. Twenty years ago, within a radius of two miles of this village, one could find *Lilium Canadense*, *Cypripedium spectabile* and *C. pubescens*, Gaultheria, *Sarracenia purpurea* and *Trillium grandiflorum*. A choicer or more distinctive half-dozen plants could hardly be named. To-day not one of these plants can be found in that neighborhood, and it is but a question of time when the Cardinal-flowers and Lobelias, the Phloxes and the Hepaticas will also be extinct there. In this same town a lady once received a gift of a rare hybrid Azalea. The premises included a river-bank, and here the precious treasure was planted, and watched until it was a thrifty, good-sized specimen that each year gave large clusters of rich scarlet blossoms. In time a new owner changed the boundary-fences, and this bank was thrown outside of the enclosure. The river-side soon became the promenade-ground of the town, and though the beautiful Azalea was quite conspicuous, it was supposed to be indigenous, and so was unprotected and uncared for. Lovers sat beside it and picked its leaves and blossoms to pieces as they talked; stray cattle ate it down, until but dwarfed shoots remained; baby-buggies were trundled over it, and people stepped on it in their haste to witness a boat-race or a baptizing. A few years after, one who knew of this rare shrub

came from a distant state after it, and found it gone, root and branch, not even a stump remaining to show where it had once stood. How the amateurs of that town would have rivaled each other in their eagerness to secure a root or sprout of it had any one told them what a rare exotic it was. But, with all its exquisite beauty, it perished because people thought it a native plant, and would not take the trouble to transplant it where it could have liberty to grow unmolested.

The study of botany in our common schools and the organizing of wild-flower clubs would tend to popularize our home-plants and to demonstrate that there is as much genuine beauty in the daintily-poised Blue-bell of the meadow as in the more pretentious cultivated flower, and that a fine flower is beautiful wherever found, be it in greenhouse, door-yard or woodland. It would be easy to interest our children in collecting native plants and in having them care for them in the home grounds, and there is as much pleasure and recreation in a day of plant-gathering as in hunting or fishing.

I have noticed that a few persons lead the floral taste of each town, and that every successful flower-garden has many imitators, and if persons who appreciate wild flowers would give them a place in the garden for their own pleasure, they would soon find the little floral world around them growing the same kind of plants. If, in the neighborhood summer-outings plant-collecting trips were included, beds of native flowers would soon be as much a feature of the garden as the ribbon, foliage or sub-tropical beds now are.

Among the encouraging signs to be noted is the prominent position which Garden and Forest and other good journals give to articles on native plants and flowers, and the increasing number of advertisements, which show that the propagation and sale of native plants is receiving more attention.

Pineville, Mo. *Lora S. La Mance.*

A Redeemed Swamp.

To the Editor of Garden and Forest:

Sir,—In an editorial article in Garden and Forest, for July 8th, on the Value of Rural Beauty, the encouraging fact was noted that there is an increasing tendency to purchase so-called waste places and to hold them for the enjoyment of the people. This is, without doubt, true, and few of us whose travels are confined to main thoroughfares realize how much is being done in this direction. The workers are immersed in their creditable work and seek no notoriety, and their efforts seldom find a recorder. A very interesting public improvement, carried on by private enterprise, I found a few days since in the near-by town of Clifton, New Jersey. Along the Dundee Drive, at the foot of Dundee Lake, a reservoir on the Passaic River, there was a swamp stretching for a thousand feet along the road. The swamp occupied a depression between the drive on one side and a sloping hill on the other, and like the usual waste place of this character, was an eyesore, filled with weeds, wild grasses and decaying vegetation, and covered in summer with a pall of dust. Mr. S. C. Nash, who occupies a residence opposite, acquired the property, and with energy inspired by a love of nature in general and aquatics in particular, has widened the swamp into a small lake, waged war on the unsightly vegetation, started a garden of native plants on the border, established the hardy Water Lilies, and has already effected a transformation which promises the town a never-failing attraction.

Mr. Nash has not redeemed this place without a constant struggle with uncompromising and sleepless enemies, and he reads Mrs. Robbins' account of renewing an old place with a sympathy which comes from similar trials and experiences.

The Nymphæas, Pontederias, Irises, Wild Rice, Sagittarias, and the like, have already taken hold with vigor, but to one only accustomed to growing aquatics in an artificial pond it was interesting to note the numerous indigenous wildings exactly adapted to their environments, which grew apparently for the delight of rebellion against constant efforts to exterminate them. But Mr. Nash will learn, as many of the rest of us have already learned, that these trials are the true sources of delight in the garden.

Elizabeth, N. J. *G.*

Are Fungicides Abused?

To the Editor of Garden and Forest:

Sir,—Under the head of "The Abuse of Insecticides," Dr. Hoskins, on page 247, protests against using mineral poisons as fungicides, and declares that he cannot consent to the use of arsenical sprays in his orchard either as an insecticide or fungicide. While not wishing to discuss the question of the danger of arsenical compounds, it seems only just to state that the accepted formulæ for fungicides do not call for any compound of arsenic. This does not mean that fungicides are harmless to man if taken into his system in considerable quantities. Many substances are used to prevent the growth of mildews, molds and blights, but usually they contain some compound of copper as the effective ingredient, which is not wholesome, although lacking much of the poisonous nature of the arsenical insecticides. That these copper compounds can be used as a spray in such large quantities as to do injury to the person afterward using the treated fruit or vegetable for food is possible, but the experience of many, extending over several years, indicates that the chances of harm are too few to be worth considering. In other words, the standard fungicides, when properly applied, are practically harmless. Their effectiveness is now generally admitted. Thousands of Grape-growers, for example, now spray their vines with as much faith in the process as they have in the value of manures for crops. Again, it has been shown that the copper mixture will save the foliage of Pear-trees from the leaf-blight, and bring a prize crop of fruit when only leafless and fruitless branches would remain if the fungicide was withheld. Practice has demonstrated that fungicides pay. It would be unfortunate if fruit-growers or gardeners should be deterred from using them by an imaginary danger.

Exhibitions.

The free Saturday exhibitions of the Massachusetts Horticultural Society can generally be depended upon to bring together some interesting plants and flowers, and are often more instructive than the more elaborate exhibitions given by this society at stated periods during the year. That which was held on the 19th of July may be called a Hollyhock exhibition, as the principal prizes awarded were given to this popular flower. Mr. Joseph S. Fay, of Woods Holl, who in the last year or two has come into the very front rank of exhibitors before the Massachusetts Society, easily took the first prize, both for cut flowers and for a collection of spikes, which were nearly six feet high, and proportionately strong and vigorous. Flowers almost as fine were exhibited by Mr. Nathaniel P. Kidder, of Milton, who took the second prize. Very interesting and beautiful was a remarkable collection of Sweet Peas sent by the Reverend W. T. Hutchins, of Ellington, Connecticut, comprising forty-four varieties, in many colors, some exceptionally dark. It contained many of Mr. Hutchins' own seedlings, and, altogether, was one of the most attractive exhibits which has been seen in Boston for a long time. A collection of the Shirley Poppies, from F. S. Davis, attracted considerable attention. These are charming flowers of the most delicate and delightful shades of color, but it cannot be denied that they possess the disagreeable odor of their race, and that, like all Poppies, they last a very short time. Mr. Benjamin B. Smith, of Cambridge, showed a basket of the large fruit of a dwarf Shad-bush (*Amelanchier Canadensis*, var. *oblongifolia*), to the cultivation of which he has for several years devoted careful attention. This, on the whole, is the most promising of all our wild fruits, with the exception, of course, of that of some species of Vaccinium and Gaylussacia, and only requires time to develop it into a first-class table berry, although it must not be called a berry, being really a little apple, or something very much like it. Very fine Versailles Currants were shown by William Doran & Sons and by B. G. Smith. The first prize for White Currants was awarded for White Grace, and the second for Dana's Transparent. An unusual and most remarkable collection of peas appeared on the table devoted to vegetables, the first prize being awarded for Stratagem, the second for Telephone, and the third for the Duke of Albany. This last, a new variety, was sent from the gardens of Mr. D. B. Fearing, of Newport. The dish of Stratagem, in size and in perfection of pod and seeds, eclipsed anything which has been seen in Boston for a long time.

Notes.

In Mrs. Scidmore's recently published "Jinrikisha Days in Japan" she hints at the fact that landscape-gardening is practiced by amateurs and even by ladies, saying that the Countess Okuma designed the "paradise of a garden" which surrounded her husband's town residence, now the home of the French legation.

Paris is probably the only northern city where brides may obtain Orange-blossoms at all seasons of the year. When they

are in bloom in the south they are, of course, imported, but at other times the greenhouses of the city and its vicinity furnish an uninterrupted supply; and it is said that the forced flowers are superior to those brought from the south, as the latter soon turn gray and dingy when exposed to the air.

It has been claimed by many growers of Roses that the temperature of the water applied to them is a matter of no consequence, but in the last number of the *American Florist* Mr. John N. May considers it an important point that the water should be tepid. Hydrant water in winter he thinks much too cold to be applied to the plants. In the summer, water which is supplied to towns, however, is not often much below sixty degrees, and therefore will do no injury.

One of the oldest wooden stairways that exist is the flight which leads up to the gallery of the Sainte Chapelle, in Paris, on the north side of the shrine, its companion on the southern side being a restoration. It was built during the first half of the thirteenth century, when Saint Louis erected the chapel to contain the Crown of Thorns, now preserved at Notre Dame. It is very delicately carved, and is regarded as a masterpiece of the finest period of Gothic art. The stairs wind about a central newel and are supported on the outer side by uprights, which form an open-work cage.

The following advertisement is one of a large class which appeal, we fear with some success, to a puerile craze for novelty on the part of persons who think that they "love plants"; but it is the first we remember to have seen where an appeal is likewise made to a pseudo-religious sentimentality. Singularly enough, it was allowed to appear in an English journal called *The Christian*, for it runs: "Wonderful Symbolical Plant—Calvary Clover, leaves three in one, with blood-like spot, seed-vessels surrounded with mimic crown of thorns. Grows freely in pot or open ground. Healthy plants, two for one shilling."

Every one knows that "elbow grease" is the best polish for mahogany, and it is interesting to learn how it is applied in Japan to produce the beautifully polished floors of cheaper wood, upon which one is not allowed to tread with shoes. "They are not varnished, nor oiled, nor waxed," says a recent traveler, "but every morning rubbed with a cloth wrung out of hot bath-water, which contains oily matter enough to give, in time, this peculiar lustre. Three years of daily rubbing with a hot cloth are required to give a satisfactory result, and every subsequent year adds to the richness of tone and polish, until old tea-houses and temples disclose floors of common pine looking like rose-wood or six-century-old oak."

A correspondent sends us some spikes of bright pink flowers, and inquires what they are and why they are not often cultivated. They prove to be flowers of the Hardhack (*Spiræa tomentosa*), which ought to be familiar to all persons who have passed much time in the country at this season. This is among the latest of the Spiræas to bloom, and it is really one of those handsome plants which would be often found in private grounds but for the fact that it is native and common. It is usually found in low grounds, but not always, and it will thrive in any ordinary position. When planted in rich soil, and occasionally cut back, it makes a dense shrub, and the beauty of its flowers, as well as the season of its bloom, make it a very desirable plant.

At the last session of the Ontario Legislature an Act of Parliament was passed for protecting the plant Ginseng (*Aralia quinquefolia*), and the Honorable John Brydon, Minister of Agriculture, has thought it advisable to publish a bulletin, so that the people of Ontario may be better acquainted with a plant of so much economic value. The bulletin contains a figure of the plant, with both popular and botanical descriptions and notes on its distribution, which show that it is comparatively common throughout the province. Of course, it is used for export to China. Twenty thousand dollars' worth was shipped over the Kingston and Pembroke Railroad last year, and the price of dry roots ranged from $3 to $3.50 a pound. Whether it would pay to cultivate the plant is a question now considered. The law referred to forbids any one from rooting up, gathering or destroying Ginseng wherever it may be found in a wild or uncultivated state, except for the purpose of clearing land and bringing it under cultivation, between the first day of January and the first day of September in any year.

There may be some reality in the danger explained by a writer in the *New York Tribune* who recently described the butler in a large country house arranging the flowers with which the rooms were filled, renewing those in each receptacle with the greatest skill, but merely adding a little fresh water to that already polluted by the blossoms of the day before. "I knew by experience," says the commentator, "how fetid and offensive water becomes from decaying stems of plants, and I spoke to my friend on the subject, believing, as I did, that the standing water in so many open receptacles was positively unhealthy. 'How often do you clean the vases completely, James?' she inquired. 'We wash everything once a week, ma'am,' he answered respectfully; 'the rest of the time I only take out the flowers that are faded and replace them with fresh ones.' 'Just take out those," she directed, pointing to a big yellow bowl filled with purple Irises. As he lifted the wet mass from the dish the odor was so sickening that it filled the whole room. Now here, I thought, is surely a question for a physician, and yet I have never heard it mentioned. Wherever houses are profusely decorated with flowers, this stagnant water is presumably standing constantly in living-rooms, and people are continually breathing what, even out-of-doors, under the fresh winds of heaven, is generally accounted unhealthy."

In speaking of the planting of home grounds, Mr. Parsons, in his recently published *Landscape Gardening*, well says: "The tendency of those who think of trees in mass, and in their mass relations, is to crowd them too much with their companions, to fail to comprehend their appearance at maturity, and thus to develop their proper effect imperfectly. Such a tendency is apt to 'crib and confine' the trees and to undertake to make them do duty after a fashion that is not altogether adapted to their nature. . . . On the other hand, a person who dwells specially on the development of the individual character of a plant is liable to err in another way, and to sacrifice the broad effects and harmoniously combined relations of trees to the exhibition of characteristic and highly perfected individual excellences. . . . A middle way of arrangement may be pursued, with reasonable satisfaction, which will secure good mass effects and a fair consideration for the character of individual specimens. . . . Outlying specimens of choice trees and shrubs will vary the outline of the masses here and there, and, perhaps, stand alone at a few points without shrubs. . . . A simple negative rule for the arrangement of trees, shrubs and herbaceous plants is never to plant them in a continuous straight line, but in groups with curving boundaries, and placed on the specially prepared crests of swelling spots or portions of the lawn."

A recent writer in the *Cornhill Magazine*, speaking of "elastic fruits" which explode when their seeds are ready to be scattered, says that the examples of these elastic capsules produced in the tropics, where plants have to fight against a greater multitude of powerful enemies than in temperate regions, "are by no means mere toys to be lightly played with by babes and sucklings. The Sand-box tree of the West Indies has large, round fruits, containing seeds about as big as an English horse-bean, and the capsule explodes, when ripe, with a detonation like a pistol, scattering its contents with as much violence as a shot from an air-gun. It is dangerous to go too near these natural batteries during the shooting season. A blow in the eye from one would blind a man instantly. I well remember the very first night I spent in my own house in Jamaica, where I went to live shortly after the repression of 'Governor Eyre's rebellion,' as everybody calls it locally. All night long I heard somebody, as I thought, practicing with a revolver in my own back garden—a sound which somewhat alarmed me under those very unstable social conditions. An earthquake about midnight, it is true, diverted my attention temporarily from the recurring shots, but didn't produce the slightest effect upon the supposed rebel's devotion to the improvement of his marksmanship. When morning dawned, however, I found it was only a Sand-box tree, and that the shots were nothing more than the explosions of the capsules."

Catalogues Received.

A. Blanc, 314 N. 11th St., Philadelphia, Pa.; New Floral Electrotypes.—William Bull, 536 King's Road, Chelsea, London, S. W., England; New and Rare Plants and Orchids.—Ellwanger & Barry, Mount Hope Nurseries, Rochester, N. Y.; Pot-grown and Layer Strawberries, Bulbous Flower Roots for Fall Planting.—W. B. Hartland, Cork, Ireland; Carefully drawn Illustrations of nearly fifty varieties of Daffodils.—J. L. Normand, Marksville, La.; Rare Oriental Plum Buds.—J. J. van Loghern, Haarlem, Holland, Otto Schmitz, Fuller Building, Jersey City, N.J., Ag't; Wholesale Price List of Dutch Bulbs.—Van Velsen Bros., Haarlem, Holland; Flower Bulbs.—James Veitch & Sons, 544 King's Road, Chelsea, England; Catalogue of Plants, including Novelties for 1891.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

Office: Tribune Building, New York.

Conducted by . . . . . Professor C. S. Sargent.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, AUGUST 5, 1891.

TABLE OF CONTENTS.

An Object-lesson in Road-building.

THE trustees of Cornell University at their recent meeting took action which promises to give important assistance to the movement for reform in the construction and care of country roads. Whenever a community is urged to mend its highways, the usual response is the inquiry, What kind of roads shall we build? This is a simple and pertinent question, but in most cases it is a difficult one to answer. The subject of road-construction is not so thoroughly and generally understood that it is an easy matter for the intelligent people of any community to say what form of road-bed would best suit the conditions of the country and the capabilities of the tax-payers. There are whole counties in the rural districts which do not contain a single engineer who is competent to give professional advice on a matter of this sort, and there are hundreds of square miles which do not contain a single rod of roadway which can be used as an example of good and economical construction. It is, therefore, a matter of prime importance to multiply examples of good roads, so that their advantages can be appreciated and their construction understood.

Now, the action of the trustees of Cornell University is particularly encouraging, in that it does propose to furnish the necessary object-lessons for studying the practical benefits of the best available roads, and to offer accurate explanations of the methods used. It was on motion of President Andrew D. White that a resolution was adopted directing the Professor of Civil Engineering, the Professor of Agriculture, and the Professor of Horticulture in the university to prepare a plan for putting the roads in the university property into the best possible condition. These officers are instructed to use the material which shall be most suitable and economical, preferably such as can be obtained in the neighborhood of the university, and that the project shall be carried out with a view to secure thoroughness and permanence, and, at the same time, with the strictest regard to economic construction. The committee is to prepare estimates of the cost of various methods of road-building and improvement, and they are advised that it is the opinion of the board that the different roads should not be all constructed on one plan, but upon the different systems, which experience elsewhere has proved to be worthy of a trial. It is, of course, understood that a careful account shall be kept, not only of the cost of constructing these various roads, but of maintaining them. It is further ordered that, when any road shall have been completed, an inscription shall be set up near it, at some point within public view, giving in detail, for the information of the public the cost of a mile of such a road. At a later period a statement shall be added as to the average cost of its maintenance by the mile every year.

In more than one of our agricultural colleges courses of lectures are already given on road-construction, and it is certainly important that these institutions, which are founded by the bounty of the Government for the promotion of agriculture and the mechanic arts, should give instruction on a subject which is so vital to these interests. But this is one step in advance, and will offer opportunities for investigation to every one who wishes to estimate the advantages of good roads over bad ones, and to compare intelligently the merits of one good road with another. The influence of these model roads will extend beyond the immediate range of the community whose members ride over them daily, for the university attracts many visitors as a growing centre of interest to all interested in rural affairs in one way or another, and besides this, its professors, who publish bulletins of progress and who attend farmers' institutes in various parts of the state, will not fail to sound the praises and illustrate the value of these model highways.

It is altogether proper that the Professors of Agriculture and Horticulture should unite with the Professor of Civil Engineering in this matter. One of the most important matters in road-construction is proper drainage, and those who deal with soils should be competent advisers in the disposition of surplus water. Besides this, a road means something more than a mere wheelway. It should not only be a smooth surface to ride over, but it should be a pleasure to the eye. Even in its grading and alignment the appearance of the country should not be neglected, and on its borders the question of what to plant and how to plant, what vegetation to encourage and what to destroy, are matters in which the counsel of a professor of horticulture and landscape art ought to command respect.

New Hampshire Scenery.

THROUGHOUT the entire broad belt of parallel mountain-ranges included in the Appalachian system and extending from Quebec to Alabama, there is hardly a square mile in which the scenery is altogether tame or uninteresting. Persons who have been born and reared among these foot-hills or in these mountain valleys are almost invariably depressed when they find themselves in a land which is flat and comparatively featureless, because the variety of prospect which arises from a diversified surface has come to be a part of their mental conception of a country which is home-like and hospitable. From every elevated point in all this region one can enjoy a picture which has a character of its own, and yet shows a kinship to all the rest. The constitution of the forest may vary, the sky-line of the distant mountains may have a different sweep, the flowers by way-side or by brook-side may be unfamiliar, but, after all, a subtle relationship can be traced between them all, so that one who has passed his life among the luxuriant forests and towering heights of western North Carolina will find enough that is distinct in the scenery of New Hampshire to invest it with the charm of novelty and yet enough that is familiar in its character to remind him pleasantly of home.

As the Appalachian system is narrowed in and lifted to greater elevations in New Hampshire, its mountain scenery is, of course, bolder than that of Pennsylvania, for example, but a picture of one of its quieter landscapes, like that in the foreground of the illustration on page 366, might have been taken in any one of half a dozen states. The dim outlines of the distant mountains, however, have a nobility which belongs peculiarly to the White Hills—a certain massiveness and grandeur which is only seen at points where the Appalachian ridges attain their greatest altitude. Aside from the distant mountain view, the sparkling water and graceful masses of foliage which make up this picture can be found in an hour's walk from almost any part of the hill country of which we speak. This particular picture seems so beautiful because the artist who caught it has the rare instinct to select the proper point of view to make a perfect composition. There are a hundred brooks which hurry down the slopes and loiter in these valleys which are as beautiful as the one in the picture. They may be overhung, as this one is, by Elms and Alders, or by Birches and Willows, or by Hornbeams and Black Ashes, but they always foam and tumble in the same happy way down mountain-slopes among rocks covered with ferns and mosses and then spread out in shallows, as this one does, to mirror the light of the sky and give life and sparkle to the landscape. A country where the air is filled with the murmur of brooks is always a beautiful country. Running water is itself beautiful, and it means a rolling and broken surface with hills and mountains down which it flows with abundant moisture to ensure a mantle of verdure for every scene.

A "Massachusetts Forest."

IT is remarkable how little the populations of our great cities often know of prominent and important features of the landscape close at hand. A notable instance of this is to be found in the beautiful range of the Blue Hills, near Boston. These hills are the highest elevations in eastern Massachusetts, and are the only eminences of a distinctively mountainous character near the Atlantic coast-line of the United States south of Mount Agamenticus, near Kittery, in Maine. The highest summit is known as the "Big Blue," and is the westernmost of the range, where stands the stone tower of the Rotch Meteorological Observatory, a privately endowed institution, which is performing a valuable scientific service. This summit is 635 feet above the sea-level, but being so near the ocean that altitude shows for its full value, giving an appearance of height greater than that often possessed by inland elevations very much superior.

The Blue Hills are the most prominent landscape feature of the coast of Massachusetts Bay and of the "Boston Basin," as it is called, of which they form the southern wall. Their noble undulating lines, presenting a succession of gracefully sweeping curves, like inverted crescents, form charming backgrounds of the views to the southward from Franklin Park and the Arnold Arboretum. From the former, the range, lifting itself without foreshortening on the thither side of the Neponset Valley, and thereby gaining in dignity and apparent elevation, appears to be included in the park which, in the noble vista from the southern end of the Playstead Overlook down the great central meadow of the Country Park, seems to stretch away to the very base of the hills. This lovely pastoral landscape has a beautiful complement near by. From the outlook point of the recently completed Loop road of the Wilderness in the park, the Blue Hills form the background of a perfect sylvan picture, making the focal element of the composition, as it may well be called, of one of Mr. Olmsted's most exquisite creations. Whoever has seen this enchanting view—standing at the edge of a parapet at the head of a rocky ravine in the steep hill-side, with a glimpse of the main drive of the park smoothly gleaming as it curves and loses itself in the trees just below with a sort of river-like effect (very much, it may be presumed, like those simulations of water made with surfaces of sand in the gardens of the Japanese), and overlooking an unbroken billowy expanse of woodland, varied with the shadings and forms of commingling deciduous and coniferous trees, the stately hills closing in the vista—whoever has seen this will not be likely to forget it. It is one of those rare landscape passages which, like that sight of the Wartburg framed in the foliage of the Thuringian forest from a hill-side near Eisenach, is treasured most preciously in the memory, and is destined to become equally famous.

The Blue Hills are thus familiar to thousands at a distance, and very many who have thus gazed in delighted admiration have been filled with the curious longing, that generally arises at such times, to know them close at hand and gaze from their summits over the widespreading landscape that must thence be disclosed. But of those thousands very few have ever visited the spot, although the hills are, indeed, a favorite excursion-ground for many nature-lovers—like the members of the Appalachian Club, for instance. It would be thought, however, that a range of hills like this, close to a great city, would long since have become popular and celebrated as a pleasure-resort, as they certainly would in the neighborhood of a European metropolis.

The views from those summits are remarkably far-reaching and varied. They embrace a great extent of coast and inland scenery: the blue sea indenting the shores, meandering rivers, wide meadows and plains, clustering towns, forest-expanses, hilly undulations, and the lofty peaks of far-away mountains—Monadnock and Wachusett, with other ranges more distant. To the northward lies the great city, spreading until its mass of buildings is lost beyond the hills which they cover. Its noise is hushed, its bustle not apparent save in the smoky streamers that float like dusky pennants in the air. One feels no sense of the swarming multitudes with their manifold occupations, burdens and cares, concentrated in that space which, though so limited in comparison with the vast encircling horizon, holds a third of the population of the next to the most densely populated state in the Union. To the southward, however, the contrast to the city is impressive. Save for a peeping spire, or a distant town that seems but a wee cluster of houses, seen at intervals, the earth's surface appears as a vast wilderness, almost as unbroken as it must have looked when the eye of a white man first gazed from these hill-tops. Close at hand, on the southerly side, just at the foot of the Big Blue, nestles the beautiful placid sheet called Ponkapog Pond. Near by Mr. T. B. Aldrich, the poet, has his summer-home amid surroundings where it seems hardly possible that it could be only twelve miles removed from the turmoil of a great city.

In all this varied landscape human occupancy seems but a passing incident, much as it has done to change the face of nature. The abiding impression is that of Nature herself, and humanity appears to be but one of her forces, temporarily modifying the earth's surface, like the beavers, the ants or the earth-worms. And how the trees serve to veil the structures of man! I have been struck by this even on the verge of London, where trees seemed the main feature, with brick walls and roofs but peering between them. After all it would take but a few years of absence on the part of man for all this expanse to relapse into utter wildness, wiping out all signs of our handiwork just as the sponge effaces the chalk-marks from a blackboard.

The air on these hill-tops is like that of the mountains, pure and bracing, for the winds sweep freely from all sides. Here would be an ideal place for a great sanitarium, for close-at-hand people of limited means, who cannot afford long journeys, would find all the attractions of air and scenery for which many are accustomed to travel hundreds of miles.

The most convenient way to reach the Blue Hills is to take the cars of either the Providence division of the Old

Colony, or the New York & New England, to Readville Station, in the town of Hyde Park. The two stations are within a few hundred feet of each other. From here it is an easy walk of something over two miles to the place where the Canton turnpike crosses the westerly shoulder of the Big Blue. There are also carriages always to be had at the railway-stations at reasonable rates. The way to the hills is over pleasant roads. It is only a short distance to the Neponset River, which is crossed by a picturesque stone-arched bridge. Passing the river we come into the town of Milton, one of the wealthiest and most beautiful in the neighborhood of Boston. It is filled with fine country-seats. The land is mostly in large holdings, the cutting up into small lots and the encouragement of a numerous population having been discouraged by the residents. The consequent effect is to give the town a peculiarly English, park-like character.

The Blue Hill range is chiefly in Milton, though a large portion lies in Canton, the next town to the southward, and in the city of Quincy, to the eastward. It is not generally known that it is to these hills that the commonwealth of Massachusetts owes its name. The country about the bay was called by the Indians living hereabout "Massachusetts," a word which in the Algonquin tongue literally means "the Great Hills Place." Thus it was that Massachusetts Bay received its name; thence the colony and the province of Massachusetts Bay, and finally the commonwealth of Massachusetts. It seems appropriate that the last remnant of the Indians hereabout, the Ponkapog tribe, lived on the southerly verge of these hills at the place that still bears their name, and where possibly some of their descendants may yet be found absorbed in the rural population of the neighborhood.

Even merely for the sake of commemorating the origin of the name of the great state from which has arisen the glorious fabric of our mighty republic, with its free institutions—aside from the remarkable beauty and picturesque character of the region—it would seem to be extremely desirable that this noble range, which thus gave Massachusetts its name, should in some way be forever dedicated to public uses. The best way to accomplish this end would seem to be for the state to take the entire region occupied by the hills, which is still for the greater part in a wild, woodland state, and make a permanent forest-reservation of it. "The Massachusetts Forest" would be an exceedingly appropriate name for the place.

It would require a special legislative act for the purpose. Action under the Public Forest Law—under which, by the way, nothing has ever yet been done—would be hardly practicable, as it would be difficult to get the three communities in which the range lies to unite to this end. If the matter were properly brought before the legislature the patriotic purpose underlying the proposition, which should appeal to every true son of Massachusetts, ought to be sufficient to secure favorable action, to say nothing of the great benefit which would be conferred upon the entire state by the creation of so beautiful and valuable a public domain. Within sight of these hill-tops there lies more than half the population and more than half of the property value of this thickly peopled and rich commonwealth. The establishment of such a public forest would greatly advance the happiness and health of this population, and would thereby, in increasing the attractiveness of the region, correspondingly enhance its prosperity.

A special act, taking this region for the purpose, and providing the means for its administration and improvement, would, therefore, be necessary. It would probably be a good idea to place the domain in charge of the newly created society called "The Trustees for the Preservation of Beautiful and Historic Places." The task could be entrusted to no more willing and capable hands.

The cost would not be great. The land is rough and of comparatively little value. Much of it would probably be given by the owners for such a purpose, as was the case with the Great Woods of Lynn. The rest could be obtained at low figures, either by ordinary purchase or under the right of eminent domain.

The improvement of a tract of such a nature would be comparatively inexpensive also. The most that would be needed would be to protect it from fires and other devastations, and to secure a forest-growth where desirable. Then a system of good roads, winding along the slopes, with vistas opening out through the trees here and there, and with branches to the summits, should be created. This system, connecting with the nearest railway points, would render the range easily accessible to the great population of the city and of the entire surrounding region. It would form one of the most beautiful drives, and a service of popular conveyances could be arranged for at cheap rates that would take passengers from one end of the range to the other, going by one railway route and returning by another. A round-trip ticket, covering the entire excursion, would bring it within the means of the multitude.

Favorable sites for hotels, sanitariums, restaurants, etc., could be leased to the right parties, under proper conditions, and, possibly, these might be approached by lines of electric railway connecting with the suburban services of the steam lines. With such conveniences these institutions could not fail to be liberally patronized, with a long season, lasting from spring-time well into the autumn.

By all means, then, let us have our "Massachusetts Forest." To that end I would suggest that persons naturally interested in bringing it about—such as the members of the Trustees for the Preservation of Beautiful and Historic Places, or of the Appalachian Club—take the matter definitely in hand, inform themselves as thoroughly as possible on the subject, including the character and conditions of the region, and unite in bringing it to the attention of the next General Court of Massachusetts.

Boston. *Sylvester Baxter.*

How We Renewed an Old Place.

XV.—SUFFERINGS FROM DROUGHT.

On the south shore of Massachusetts Bay almost every summer sees a long period of rainless weather. The thunderstorms that gather portentously after hot days are apt to drift away to the north, with only the tiniest sprinkling of our dusty roads and parched fields, to pour their wealth upon the crags of Swampscot and Lynn, Beverly and Marblehead. With jealous eyes we watch the rain descending upon our opposite neighbors of the north shore, while we continue to dry up for want of it.

This period of dry weather usually begins about the last of June and continues well into August, which is ordinarily wet and muggy, but the spring and summer of 1891 seem disposed to defy precedent. April, which from time immemorial has been depended on for showers, this year completely spoiled its record, and only gave us an inch and a fraction of rain. This was followed by a dry, cold May, and then came the first half of June without a drop, culminating in two days the like of which we seldom see, the mercury touching ninety-seven degrees in the shade. Then, at last, down came the floods with a rush, and refreshed the parched and thirsty earth for days, the first continued rain-storm for three months, sorely needed by the suffering hay-crop and the dwindling trees.

During a rain in this locality, where the soil is light and sandy, the care of lawns and gardens has to be incessant. Fortunately our old town has a fine supply of aqueduct water brought from a nearly inexhaustible pond within its limits, and the hose can be brought to bear with effect upon the worst places; but this, like other restoratives, must be used with moderation. Too much water cakes the soil and draws the roots to the surface, so that, once begun, it must be continued or the plants die. It is better, we find, to water heavily two or three times a week than to keep up a continued sprinkling. If the water plays upon trees and shrubs during hot sunshine, the leaves are apt to scorch and shrivel, and the same is true of vegetables, which are well known to resent being watered on a hot day.

At Overlea the garden, which lies low along the edges of the meadow, can get along very fairly without watering. Even this year the strawberry crop, which is very sensitive to a lack of moisture, did not suffer from the dry weather, possibly owing to heavy mulching with straw while the ground was

moist from showers. The worst of droughts in June is never so bad as the same dryness in July, for plants, which are then in fullest vigor, can better bear the strain upon their constitutions at that time; it gives them a set-back, however, which prevents a vigorous growth. Grass is the greatest sufferer, and the first hay-crop is often ruined by lack of rain, as was the case this year in our neighborhood.

Upon the sandy knoll where our house is situated, and especially along the street, in places only accessible to a very long hose, the trees and turf suffered greatly, and the sudden drop of fifty degrees of temperature at the end of the period of drought, had a most disastrous effect upon the leaves, which shriveled and curled and turned red, and dropped off in many instances. A vigorous young Catalpa on our lawn, which, after the cautious manner of its kind, only ventured to put on its spring gown after the first of June, and then undertook to blossom freely, was so distressed by the changes of the weather that, after the storm, we found at least two bushels of leaves strewing the ground beneath it, and many others in such a condition that the lightest touch would detach them. Enough remained, however, to protect the blossoms, which are wonderful productions for a tree to bear. If each one grew in a garden on a single slender stem one would value it for its exquisite painted beauty, and delicate perfume; and to find a great spike of them decorating a burly tree is a constant source of astonishment at the prodigality of Nature. It is like the appearance of a fine gentleman of the last century in a ruffled shirt and diamond shoe-buckles, among the more plainly coated *fin de siècle* beaux of our own day.

I have a great admiration for a Catalpa; its huge vivid green leaves give it a semi-tropical air, and its sensitiveness to cold and storm shows that it comes naturally from a warmer clime than ours. I try to console it for its exile by lending it in summer-time our Amazon parrot for a companion, and there is no prettier sight than the vision of this lovely green bird, of exactly the shades of the sunlight and shadow on the Catalpa-leaves, pluming himself untethered upon the inner branches, only caged by the dome of the great boughs with their verdant canopy. When the leaves are in their prime he is perfectly concealed from view by his color, even when he takes a fancy to perch upon an outer bough; and there he mocks and jeers at the passers-by with songs and laughter and merry cries, till you would think a whole primary school was let loose upon the lawn and all the pupils calling each other by name, or else that this was a lunatic asylum.

To return to the line of trees that border the street. We find that it is not safe to leave them without a heavy top-dressing to act as mulch, and this application having been delayed this year by press of business, we found one good-sized Elm, that we imagined to be settled for life, dropping its leaves and turning brown in a most unbecoming manner, while the smaller and more recently planted trees were also showing signs of distress. A good dousing and dressing brought them all to, however, and when the mowing of the swale after the rain allowed us to make the rounds of the plantation, we discovered that the only serious sufferers were our newly set Pines, which are bringing the hill into disrepute by their brown and sear condition. This eminence naturally suffers severely from drought and hot weather; the little Oaks and Chestnuts burn up, and the Pines wilt distressingly, but they are so numerous that there is nothing to be done for them but to await the survival of the fittest. An Oak once rooted is rooted forever, but it is a question of time as to when it can maintain its top, and ours have burned off year after year, until now they seem to have gained vigor enough to hang on in spite of fate.

Among the searching questions that are put to the members of the Society of Friends, in their meetings for the investigation of personal character, one of the queries is, "Has any Friend entered into business beyond his ability to manage?"

This question we are obliged to answer in the affirmative when we take time to ask it of ourselves, for, having outlined work enough for a dozen men, it becomes a puzzle how to carry it on with only the aid of one factotum; extra hands being very hard to obtain in this village during the summer months. Much that we do is accordingly a makeshift. I am sadly obliged to confess to the existence of weeds where no weeds should be, of neglected spaces, of trees on the hill smothered by grass, of rose-bugs unslain, and caterpillars left at large; of a struggle for general effect, rather than a realization of neatness in detail, all of which is most reprehensible and melancholy. We look at our neighbors' neat gardens with remorse and envy, and can only console ourselves by reflecting that when they are gone the weeds will have their way, but that in our struggle with nature in the end the trees will win and trample the weeds under their mighty feet, and rear their stately heads proudly, while the Beets and Carrots of a future generation are still struggling with their yearly foes.

In a recent visit to the shores of the Merrimac, I have seen hills carpeted with the fallen leaves of haughty Pines that have numbered some centuries of growth, and I can smile at the flaunting Daisies of the hill, which overtop our baby Evergreens, and threaten to exterminate them. Your days are numbered, O weeds! Wave now and dance in the sunshine while you may, for the first nails are being driven in your coffins. Little you reck that the small brown spines that disappear at your roots are the first drops of a rising tide that is to bury your bright blossoms, and strangle your weedy growth. For a few years to come you may preen yourselves upon the hill-side, but the tiny seedlings below are rising higher and higher, wider spread their green arms, thicker falls the brown shower, which at first nourishes your gaudy uselessness, but at last shall arise and overwhelm it forever. The gay and trivial have their little day of sunshine and triumph, but the strong roots of serious vigor endure when the sunlight fails and the winter winds blow. Everything in the lower is typical of the higher life, and the Ephemeral for a time seems brighter and stronger than the Eternal; but not forever. Though speed may tell in a short race, it is bottom that wins the long ones, and it is the patient who inherit the earth.

This is the great lesson of the forest, the philosophy it plants in him who nourishes it and awaits its growth. In the faint rustle of the tiny leaflets I hear the murmur, "Wait!" and as I wander under the shade of trees a hundred years old, I hear the echo far above me of that tender cry, in a solemn whisper: "Wait! They, too, shall be as we are, giants in their day. What matters it that thy little life will be long over? for thee the weeds and battle, for others the shade and rest. Plant thou! that is thy mission, and the joy of him who reaps the fruit of thy labors shall be no greater than thine. Knowest thou not, O thou of little faith! that to look forward is the best of joys? Thy reward is renewed to thee daily in thy hope. Learn patience, and content thy soul."

And so the young trees and the old alike give counsel to him who can understand their language, whether he bends to listen to the soft voice at his feet, or lifts his head to catch the diapason of the overarching forest; encouraged by the lesson, we take up our burden anew, in our case the burden of a watering-pot, and do battle with the drought with a braver heart and sturdier resolution.

Hingham, Mass. *M. C. Robbins.*

Changes Which Trees Create.

APART from the influence of trees upon the general climate of a country, which has over and over again been proved to be very great, trees play a very important part in ameliorating the extremes of temperature in a local sense. Many of what are now our most enjoyable country-seats but for the presence of trees would be little better than bleak and comfortless downs. In situations where hills and valleys alternate, much may be done by a judicious selection of the spot where the dwelling is to be placed; but even then, without the presence of trees, the site is never complete. The charm of what are now some of the most lovely spots in these islands would at once vanish if they were deprived of their trees, and not only their charm in a picturesque sense, but in that of bodily comfort. To one who has dwelt upon a more or less bare and wind-swept upland, the sense of comfort in the removal to a spot sheltered by clustering woods will be very grateful, and more eloquent than the most fluent description.

In considering the best use which can be made of trees for shelter, the conditions existing must, of course, be taken into account, namely, whether the house is already in existence, and the trees have to be arranged to produce the greatest amount of shelter in harmony with the necessities of the landscape, or whether the trees and woods are already growing, and the position of the house has to be determined upon from these. In the former case, for climatic reasons, the situation and alignment must be determined on to give the greatest resistance to the prevailing winds. In some cases other circumstances may interfere with this, but it is not often, with proper arrangement, such difficulties cannot be overcome. Other pens have condemned the practice of dotting trees about instead of throwing them into suitable masses, as an offense to the eye, and if it is desired to defeat the end of obtaining shelter from trees, this objectionable system will be the sure means of doing it, as trees so planted can be of no appreciable use for the purpose.

As in the landscape, so for equalizing heat and cold, trees and woods are required, and must be grown in masses. In

some parts of this country, although not the coldest, the winds, which are generally most unpleasant on account of their strength and prevalence, are the west and south-westerly ones. From these some shelter is most desirable, but as, on the other hand, the afternoon sun shines from this direction, some discrimination is necessary that in cutting off the effects of the wind the sun is not excluded as well. There is no reason, however, why the advantage of both should not be gained, as by the suitable arrangement and selection of subjects there need be no great difficulty in the matter.—*The Garden* (London).

New or Little-known Plants.

New Orchids.

Odontoglossum × excellens, Rchb. f.—It is interesting to observe that the parentage of this handsome natural hybrid has now been proved. Mr. Seden, the well-known hybridist of the firm of Messrs. James Veitch & Sons, of Chelsea, has obtained it by crossing *O. Pescatorei* with the pollen of *O. triumphans*, the plant having flowered for the first time during May of the present year.—*Gardeners' Chronicle*, June 20th, p. 754.

Zygopetalum guttatum, Rchb. f.—This long-lost species has apparently reappeared, a specimen having been sent to Kew for identification by Mr. J. O'Brien, of Harrow-on-the-Hill, which, although not quite identical with the original form, still appears to belong to the same species. It belongs to the section *Promenæa*, and bears much resemblance to the elegant little *Z. xanthinum*, with which it grows, as both appeared out of the same clump of plants. The flowers are light yellow, the sepals and petals with numerous light brown spots, the base of the column dark purple, and the basal half of the lip marked with the same color.—*Gardeners' Chronicle*, June 27th, p. 784.

Odontoglossum × Leroyanum, Castle.—This interesting hybrid, in reality a variety of *O.* × *Wilckeanum*, and proves the parentage so long suspected, was raised by Monsieur Leroy in the collection of Baron Edward de Rothschild, of Armainvilliers, near Paris, by crossing *O. crispum* with the pollen of *O. luteopurpureum*. There is an excellent colored plate in the April number of *L'Orchidophile*, p. 112.

Aeranthus brachycentron, Regel.—A species said to have been imported by Messrs. F. Sander & Co., of St. Albans, probably from the Comoro Islands, and received at the St. Petersburg Botanic Garden as *A. Grandidierianus*, Rchb. f., which, however, is quite different. I do not see any character by which the supposed novelty can be distinguished from *Aëranthes* (not *Aeranthus*) *grandiflorus*, Lindl., with which I believe it to be synonymous.—*Gartenflora*, xl., pp. 323, 324, fig. 68.

Kew. *R. A. Rolfe.*

Plant Notes.

Some Recent Portraits.

The July issue of the *Botanical Magazine* will not, from the nature of the plants figured, be found as interesting, perhaps, as usual to horticulturists. It contains portraits of *Musa Basjoo* (t. 7182), a species which has the habit and general characters of the common *M. sapientum*, although differing from all other cultivated Plantains and Bananas in structural details. This plant, which was introduced into England from Japan by the Messrs. Veitch, in whose nursery at Coombe Wood it stood in the open ground for a number of years, is supposed to be a native of the Liu-kiu Archipelago, a group of islands which stretches from Japan nearly to Formosa, and to be the plant cultivated in southern Japan for the fibre yielded by its leaves; *Hibiscus venustus* (t. 7183) is described as a magnificent species whose native country is doubtful, it having first been made known from a plant cultivated in Java. The portrait is from a specimen grown in England, and supposed to have been procured from the island of Tahiti. *H. venustus* is a large shrub clothed with short, close pubescence, stout branches, large, nearly orbicular, deeply lobed leaves, and pale yellow inclined flowers three inches in diameter; *Synadenium arborescens* (t. 7184), a Euphorbiaceous shrub of Natal, rather curious than beautiful; *Masdevallia platyglossa* (t. 7185), a small and very inconspicuously flowered species of no more garden value than many others of this now popular genus. The leaves are three or four inches long, oblong or elliptical-lanceolate, acute and coriaceous. The flower-stems are as long or longer than the leaves, and are pendulous, as thick as crow-quills, sheathed with pale greenish yellow sheaths and bear pale yellow flowers streaked bright red on the ovary; *Stenoglottis longifolia* (t. 7186), a terrestrial Orchid from Natal, with lilac-purple flowers. The genus to which it belongs has hitherto been represented by a single species, the *S. fimbriata* of Lindley, also a native of Natal, and distinguished from the present plant by its shorter oblong leaves, narrowed at the base and blotched with black, a slender scape, and fewer and smaller flowers.

A beautiful colored plate of *Nepeta Mussini* is published in the 1st of July number of the *Revue Horticole*, accompanied by a note from the pen of Monsieur André, who recommends this small Caucasian Labiate as an admirable subject to grow in the rock garden in sunny and exposed situations. Like the other species of the genus, the whole plant possesses a strong and aromatic odor. The flowers, which are light blue and contrast pleasantly with the pale puberulous foliage, appear from May to July in the neighborhood of Paris. If the flower-stalks are removed, the plants will produce another crop of flowers toward autumn.

The *Gardeners' Chronicle* of July 4th contains two figures of *Acer Vloxemi*, a fine Maple discovered by Mr. Jean Van Vloxem in the Caucasus, and heretofore generally believed to be merely a form of *A. Pseudo-Platanus*, although Dr. Masters, in whose garden it has been growing for a number of years, has always considered it distinct from that species. His idea is now confirmed by the character of the inflorescence, which has been produced in Mr. Van Vloxem's garden, and which, instead of being racemose and pendulous, is erect and corymbose, with glabrous filaments. Whether this handsome tree, which is remarkable for its robust and rapid growth and for the silvery whiteness of the under surface of the leaves, is distinct from *A. insigne* of Boissier, is a question which Dr. Masters promises to discuss in connection with the figure of this last species, which is to appear, he tells us, in an early issue of the *Gardeners' Chronicle*. Whether *A. Vloxemi* is a distinct species or not, it is certainly a beautiful and distinct plant from the horticultural point of view, and well worth growing wherever the climate suits it.

Cultural Department.

Stray Notes from the Arnold Arboretum.—VII.

We are accustomed to think of the fruits of ornamental trees and shrubs as if they belonged to the autumn or to the winter, and do not always remember that some of the most beautiful of them ripen in summer, and so do not always sufficiently consider shrubs from this point of view in studying the composition of our shrubberies. Many shrubs, however, are better worth cultivating for the display of fruit they can make than for the flowers which cover their branches earlier in the year.

The earliest hardy shrub which makes any great show of fruit in this climate is the Mezereum (*Daphne Mezereum*). This is a small plant which belongs to the colder parts of Europe and Asia, and is so hardy that it is able to grow on the borders of the Arctic region itself. The flowers are pink or sometimes white, and they appear (by the middle of April in this climate) in little clusters, which cover the stems formed during the previous summer. One of these plants in flower is a bright and beautiful object, and it is all the more beautiful because the flowers open very early in the season, sometimes before the snow has disappeared and when flowers are scarce, and therefore more valuable than they are a week or two later. But this plant is more beautiful two months later, when the large bright red, lustrous fruit ripens. This quite covers the branches, and makes a fine contrast to the dark green leaves. It is a hardy and beautiful little plant, which has been cultivated in European gardens for three centuries at least, and yet we rarely find it in those of this country. There is no better plant for a small garden, especially for the garden of the man who, like many Americans, is away from home during the summer months and wants his garden attractive before the hot weather drives him to the sea-shore or to the mountains. Now, a plant like *D. Mezereum*, which does its work for the year between the first of April and the first of July, showing all its beauty during these few weeks, is the plant of all others for the spring garden. It is hardy; it flowers every year; it is not very particular about soil or exposure, and it only grows two feet high. These would seem to be qualities which would make a plant popular; and it is remarkable that florists and small nurserymen, who make a business of supplying plants for the door-yards and small gardens of our cities and their suburbs, have not yet got hold of the Mezereum. Perhaps it is because it takes some time to make a plant large enough to sell, as the Mezereum cannot be struck from soft-wood cuttings like Hydrangeas, Spiræas, and other coarse-

Fig. 61.—A New Hampshire Brook-side.—See page 361.

growing shrubs. Bigness and cheapness are still, unfortunately, the chief factors which influence the choice of the great proportion of American plant-buyers. The popular plant is pretty sure to be the one which will grow quickest to the largest size, and is therefore the most profitable plant to sell.

The florist and the nurseryman set the fashion in planting for nine-tenths of us Americans, and until we instruct ourselves about plants and learn their good and bad points so as to have opinions of our own, we must be satisfied with second-hand knowledge, and go on planting what we are told are the finest novelties which have appeared for years. We can get some idea of a plant by reading about it, or by seeing a picture of it; if it is not one of those pictures used to decorate that branch of the literature of horticulture from which most people draw their inspiration; but the real way to know a plant is to see it growing, and to watch it from month to month and from year to year. This is why arboreta and botanic gardens can be made of popular interest and value, if they are managed with the view of affording information with regard to plants in their horticultural aspects, and why each centre of population in the country should be supplied with a well-equipped establishment of this class. In these establishments people can see plants of all sorts growing, and can learn which ones are best suited to their particular needs.

A summer-fruiting shrub which is beautiful in July is the Japanese *Elæagnus longipes*, of which a figure was published in the first volume of Garden and Forest (499, f. 78). It has now become well known, and a few nurserymen are raising it in considerable quantities. Their confidence seems to be justified, for this is a plant which improves with age, and has not developed yet any disease, want of vigor or special attractions to devouring insects. It bears great crops of fruit which ripens about the middle of July and hangs for some time on the branches. The fruit is brilliant, although, as it is suspended on long stalks under the leaves, it does not make much show from a distance, and the branches have to be turned up with the hand in order to bring it into full view. It is edible, and some people find the sub-acid flavor delicious. Certainly it is as good as a currant, and better than a gooseberry, and with good cultivation and careful selection might develop into something for the table really worth talking about. The leaves, too, are beautiful—very dark above, and silvery white on the lower surface. The flowers, like those of most of the genus, are small, yellow, and not conspicuous. *E. longipes* appears to be entirely worthy of confidence, so far as can be determined by the results of the experiments which have been made with it in the Arboretum, in which it has now been growing and fruiting for a number of years.

The great summer-fruiting shrubs, however, are the so-called Bush Honeysuckles. The most commonly cultivated and best-known of them is the Tartarian Honeysuckle, a very hardy and reliable plant which gardeners in some northern countries, especially in Russia, have worked over for many years, producing many varieties with flowers of various colors, ranging from pure white to dark rosy red. The Tartarian Honeysuckle is one of the best all-round shrubs known in gardens; it is hardy and easily propagated; it grows rapidly, and forms a great bush a dozen feet high sometimes, and as deep through the branches. The flowers are abundant and beautiful, and the fruit, which ripens in July, is brilliant, bright cherry-red on some plants, orange on others, and dark red on others; it is lustrous and almost translucent, and it looks as if it would be delicious to eat. Really it has about as nasty a taste as any fruit can have; but this serves to protect it from the birds, and so it loads the branches for weeks, and makes a brave show. But, fine as it is, there are finer Bush Honeysuckles at this season of the year. One of these is *Lonicera Ruprechtiana*, a very large shrub, or a small tree sometimes, it is said, in its native country, which is the region of the Amour River. The fruit is a third larger at least than that of the Tartarian Honeysuckle, and even more brilliant in color, so that a large plant of this species covered with fruit, and it is always covered at this season of the year, for it is a regular and profuse bloomer, is a remarkable object. Not less beautiful is the Japanese species, *L. Morrowi*, which is as hardy and as desirable in every way. The fruit is as large and as brilliant, but the flowers are rather less showy, although attractive and abundant.

There is a race of Bush Honeysuckles in the Arboretum which came here from a German nurseryman, under the name of *L. bella*. They appear to be hybrids between the Tartarian Honeysuckle and one of the two species just mentioned, although little is known about them. They are handsome plants, but not better or more beautiful than *L. Ruprechtiana*, as regards their flowers or their fruit, and, except as curiosities, are probably hardly worth growing for general decorative purposes.

The Bush Honeysuckles, or some of them (many of the species produce inconspicuous flowers and fruit and come from countries of less severe cold than those which have been mentioned), flourish, as Professor Budd has told the readers of Garden and Forest, in the cold dry climate of the western plains; they are hardy where no other shrub with such beautiful flowers and fruit can grow, and they succeed as well in the mild climate of New England and the middle states as they do in Canada or Nebraska. They are valuable plants for the gardens of the northern parts of this country and of British America, and it is to be regretted that the fine Russian varieties, raised by the gardeners of St. Petersburg, are not within reach of our people.

The Bush Honeysuckles grow so well, and endure so much neglect and bad treatment, that they are admirable plants for public parks, city squares and the grounds of railway stations, and all such places where it is impossible to give to plants the care they receive in good private gardens. Their fruit adds greatly to their value for such purposes, for they serve to bridge over the period of the year when shrubberies are apt to be less attractive than at any other—after the flowers have gone, and before the fruits of autumn ripen and the leaves take on their autumn colors. A plant of one of these Honeysuckles, loaded with its ripe fruit, which enlivens a whole shrubbery for weeks, is always a pleasure and a delight.

Arnold Arboretum. *P. C.*

The Persian Ranunculus.

DO you delight in variety of color? I say advisedly I do not know any class of flowers where the range is so great—from black, at least as black as we get in any flower, to pure white, through every shade of red and yellow, olive-green with yellow ground, edged with darkest markings like a variety of Picotee; some striped like a Carnation, others spotted, veined; in fact, there is hardly a tint of color which exists in flowers that may not be found in a good bed of Ranunculus. Do you admire symmetry of form? What can be more exquisite than the beautifully molded petals of this flower? Some may term it formal, and all double flowers as compared with single ones are liable to this charge; but there is an exquisite finish in the form of these flowers that wins admiration, perhaps even from the rigid botanist who declaims against all these things as monstrosities and violations of the laws of Nature.

One objection to growing the Ranunculus has been their supposed difficulty of cultivation. I used to imagine that the depth at which they were to be planted was to be so exactly gauged (an inch and a quarter) that I had my beds boarded round, and then a board cut to the required depth was forced into the beds, making a drill of that depth, at the bottom of which the tubers were placed, and then covered over; but I have found that this exactness is altogether unnecessary. I endeavor to plant them about this depth, and am convinced that shallow planting is required, but I do it in the ordinary way—draw a drill with a small hoe and then plant.

The plan which I adopt with my beds, which are about thirty-five feet long and four wide, is to prepare them in the autumn. The soil is ordinary light garden soil, and in the month of October, if it is in a fit condition, I dig in a good supply of old hotbed refuse, between three and four barrowfuls to each bed. This is left through the winter, and, if there is frost, it is turned up roughly, so that it may get the full benefit of it, leveling the soil, and, perhaps, destroying grubs, etc. I say perhaps because I am somewhat doubtful as to the effects of frost. About the 12th of February I prepare for planting, but I am not particular as to date. If the weather is favorable before that I do not hesitate to plant, and if it is unfavorable at that time, to defer it for a little longer. [In this country the planting in the latitude of New York could rarely be done before the middle of March.—Ed.] It is essential that the soil should be in good condition at planting time. The bed is then raked down and leveled, the rows are drawn about four inches apart, and, as I have said, from one and a half to two inches in depth. I have previously gone through my boxes, for I do not keep to names, but grow in mixture, and pick out for the principal bed the largest tubers. Allowing for three rows to a foot, and twelve in each row, the bed will take about 1,250. Of course, smaller beds can be made. As the Ranunculus, like most of its family, is fond of water, a dry spring is against them, and in such a case they may be watered thoroughly, once or oftener, if needed. I used to take a good deal of trouble to place an awning on the beds; for some years I have discontinued it, and am quite satisfied to do so for the

future. The flowering season may be a little shortened, but a good deal of trouble is saved, and the beds look better.

The harvesting of the roots is a matter of supreme importance. They must not be taken up before they are ripe, or they will shrink very much, and be feeble next year; nor must they be left too long, which is even more fatal to them, as they then begin to start, and when this is the case the tubers are good for nothing next year; so that should showery weather occur, as it very often does in the early part of July, a good deal of watchfulness is needed to catch the right time for lifting them. They should be placed, after the foliage has been cut off, in a cool, shady place, where they can get all the influence of the air without being exposed to direct sunlight. A cool, open shed is a capital place. They can be laid out thinly, and when they have been thoroughly cleared of all dirt they may be placed in boxes and brought into the house and placed anywhere free from frost.

Some years ago I obtained from Messrs. Ant. Roozen & Son, of Overveen, Holland, a few hundreds of Persian and Scotch (so-called) varieties. They were all named, and have, with some remains of Lightbody's collection, formed the foundation of my present one. I put them into mixture, knowing that I should probably have to weed out a good many, and so the event proved. Neither in these nor in Tulips are growers particular as to correctness of form, and admit among their Ranunculuses many that are not sufficiently double, and which show the black centre much too soon. These I have gradually weeded out, and I can now look on my beds with much satisfaction.

Of late years there has been a race introduced which is called the Giant French Ranunculus. The flowers are much larger than the ordinary Persian varieties, but they are not so double, and have the great defect of showing the eye very soon. They are brilliant in color, but not so varied. They make a good show in the garden, but will not please the critical taste of a connoisseur.—Correspondent of *Journal of Horticulture*, London.

Notes from the Harvard Botanic Garden.

Alströmeria aurantiaca.—Several of the Alströmerias are highly decorative border-plants, and were at one time very popular in gardens, but they have been much neglected of late years. *A. aurantiaca* is one of the best. It is a hardy herbaceous, tuberous-rooted perennial, introduced from Chili in 1831. The erect stems, from three to four feet high, are well clothed with linear-lanceolate, glaucous-green leaves from three to four inches long, and curiously twisted at the base, reversing the normal position of the upper and lower surfaces. This peculiar twisting of the leaves is, however, a feature of all the Alströmerias, and also of the closely allied genus Bomaria. The flowers of *A. aurantiaca*—the two upper divisions of which are deep yellow, with numerous longitudinal lines of dark red, the others of a bright orange color—are about two inches across, and as many as twenty of them appear in the form of a terminal umbel. They last a long time when cut, and the long, straight stems upon which the heads of bloom are borne, render them doubly useful for that purpose. If we except the Lilies, it would be hard to find a plant whose flowers produce a more pleasing effect. But while less striking than many members of this royal race, its floral charms are longer continued, lasting throughout June, July and August, three very severe months on most flowers. The plant likes an open, sunny position and rich sandy soil. Excessive moisture about the roots in winter is dangerous, and therefore it should be planted from six to nine inches deep, but at a considerable elevation above the general level. Mulching with dry litter also tends to ward off superfluous water. Abundant moisture, however, is indispensable during the drought of an American summer, and in dry weather a thorough watering is a daily necessity. It is propagated by dividing the crowns late in autumn, or by sowing the seeds under cover when perfectly ripe. The latter method is much the safest, old established roots being rather uncertain in their behavior after they are transplanted.

Anemone Robinsoniana.—This is perhaps the prettiest of the several varieties of *A. nemorosa*, the Wood Anemone. It was brought prominently before the gardening public some years ago by Mr. William Robinson, editor of *The Garden*, and named in compliment to him. It is a rare plant, growing wild in various parts of England. The blue form of *A. nemorosa*, sometimes found in American woods, resembles it very closely, but the English variety, under the same treatment, bears larger flowers of a deeper color. *A. Robinsoniana* is about six inches in height, the deep sky-blue flowers, an inch and a half in diameter, cresting the compact mass of elegant pale green foliage. The blooms do not last a great length of time when cut, but the plant is very desirable on account of its early and free-flowering qualities. The flowering season proper extends from the latter end of March until the middle of May, and in cold, late seasons the charming blossoms may be seen as late as June and July. There are no difficulties attending the cultivation of this plant provided it is given a dry position, well shaded by trees, and soil in which leaf-mold predominates. These conditions are found on the margins of natural woods composed in greatest part of deciduous trees, and the cultivator of the Wood Anemone, or any of its varieties, who can reproduce these conditions most perfectly will obtain the greatest amount of satisfaction from his plants.

Epilobium angustifolium.—This is a common plant in many parts of the world, including the United States, but is not unworthy of a place in gardens. It has many common names, among them Great Willow Herb, French Willow, Rose Bay and Fire Weed. It occurs most plentifully in newly settled districts, and soon forms a conspicuous feature of the landscape of those woody regions that have been swept by fire; hence the name Fire Weed. The plant attains a height of five feet and spreads rapidly under cultivation, bearing large racemes of bright purple flowers in June and July. These are followed by numerous long seed-pods, containing, with the seeds, a large quantity of fine white silky down, which, when the pods burst in July and August, is scattered about all over the plant, giving it a fluffy appearance. A variety, *E. angustifolium album*, has pure white flowers. Both are eminently floriferous and useful for cutting. They thrive well in any ordinary soil, but should be given abundance of space, as, otherwise, they are liable to smother plants of a less aggressive character. The seeds are easy to raise, and those who have attempted to remove the roots of *E. angustifolium* do not need to be told of their vitality, as every piece an inch in length is almost certain to grow and form a plant.

Lythrum Salicaria.—Few of the European plants which have become naturalized in this country are more desirable than the Purple or Spiked Loosestrife now common in wet meadows, from Nova Scotia to Delaware. In Europe it is usually found on the banks of rivers and ponds, and it is useful for the adornment of artificial pieces of water. It is also a desirable border-plant, thriving luxuriantly in a deep, moist loam. The plant is from three to four feet high, the stems and numerous branches four-sided, well clothed with dark green, oblong leaves, and each terminating with a long spike of dark purple flowers. The flowering season extends throughout June, July and August, and the tall inflorescences have a charming effect when loosely arranged in suitable vases. There are two well-known varieties of this plant; one known as Roseum, with paler flowers than the species, and the other Superbum, in which the flowers are larger. Either one of the varieties is preferable to the type, inasmuch as they flower more freely. All are readily increased by cuttings and by division. *L. Salicaria* has an interest from the fact that Darwin used it, with many other plants, for illustrating the theory of evolution.

Cambridge, Mass. *M. Barker.*

How to have Clean Flower Pots.

HAVING been very much annoyed by the rapid growth of Algæ (Protococcus) on pots in greenhouses, a trouble which necessitates the frequent shifting of plants from foul pots to clean ones, besides attendant scrubbing with soap and sand, I have been lead to try a large number of preparations for the prevention of this fungal growth which, at the same time, would not injure the health of plants. After many experiments I have found that new pots, soaked in ammoniacal solution (United States Department formula), become impregnated with the copper salts, rendering it impossible for the germs of this fungus to obtain a foothold. Experiments with this solution, extending back to February, prove its value, as pots soaked then have resisted the attacks of this fungus and are as clean as when first used, while new pots, used at the same time, without being soaked, are completely covered, and in every case the same results have been obtained, both in the greenhouse at this station and in the houses of one of the leading nurserymen of this place. I am of the opinion that it will be necessary to soak the pots at intervals of at least once a year, which will not be a very serious matter, considering the large saving, both in time and money, which is accomplished by this method.

Almost all nurserymen and florists find that there is a considerable expense connected with the washing of pots, even

when done by boys, but as this solution is quite inexpensive, and pots can be soaked so readily, this cost can be reduced to a trifle. It seems probable that, after this bath has been thoroughly tested and in general use, the manufacturers of pots and other earthenware will offer on the market goods soaked in copper solutions, as they can accomplish the same end cheaper than individuals, thus lessening the expense to the florist or private gardener who takes pride in having his pots clean at all times.

These soaked pots have been used for several classes of plants, Roses, Gloxinias, Primulas and others, and at this writing I can perceive no indications of injury to any of them; in fact, I think the ammonia in the solution is, to a limited extent, a benefit. The formula for this solution is as follows: five ounces of copper carbonate dissolved in three pints of ammonia, twenty-six degrees strength, diluted with fifty gallons of water.

Experiment Station, Geneva, N. Y. *C. E. Hunn.*

Cypripedium Curtisii.

THIS remarkable plant is now tolerably well known to all growers of Orchids both in England and on the Continent, and, no doubt, also in America. It is well worthy of a place in every collection, as it is easily grown, and repays the attention given to it by its large flowers and handsome foliage. Like many other Orchids, it improves under cultivation, both leaves and flowers becoming larger, more substantial, and better colored year after year. In a fine specimen which I recently saw, the broadly cordate upper sepal was large, and had a conspicuous white border surrounding a deep green area, the surface of which is longitudinally striped alternately with dull purple and dark green, and is also decorated near the base with a transverse zone of dull purple. The lower sepal is much smaller, whitish, with pale green stripes. The ligulate petals are slightly bent down, and are more or less recurved or twisted at the pointed apex. Three colors are chiefly noticeable on the surface, namely, dark olive-green at the base, which passes into white or whitish green in the centre, and bright rose beyond this to the apex. The whole is covered densely with blackish purple blotches, which stand out prominently on the middle and apical portion, owing to the delicacy of the ground color. The first thing that strikes one in beholding the flowers of *C. Curtisii* is the enormous size of the lip, that is, in comparison with the other parts of the flower. In front it is of a dull purple-red, with deeper colored veins, becoming pale green behind, while the inflexed lobes of the base are of a soft pinky rose, studded with purple warts, the tips of which sparkle like diamonds in the sunlight. The upper sepal, especially on the back, and the petals on the margins are all very hairy, the large lip even having short stubby hairs arranged round the edge of the orifice as well as on the surface. The leaves are elliptic-oblong, light green, with oblong patches of dark green, presenting a handsome chequered appearance. As a rule, the flowers appear singly on the tops of the dark purple pubescent scapes, but instances have been noticed where two flowers have been produced on one scape. Where there are several plants, flowers may be expected to appear between January and July—some plants flowering earlier than others.

The native country of *C. Curtisii* is Sumatra, where it was discovered on the mountain-ranges, at an elevation of from 3,000 to 4,000 feet, in 1882, by Curtis, one of the collectors of the Messrs. Veitch & Sons, whose name it bears. Plants will thrive if grown in a rough compost of peat and loam, either in well-drained pots or planted out. The winter temperature should not be allowed to fall lower than sixty degrees Fahrenheit, and attention to watering must always be given at this season. In the summer months the atmosphere should be well charged with moisture, which may be accomplished in the usual way of damping the floors and the houses and sides of stages at frequent intervals during the day. Air may also be given liberally during hot weather, when, owing to evaporation, greater quantities of water will naturally be required by the plants.

Isleworth. *J. Weathers.*

Lettuce for Summer and Autumn Use.

DURING the hotter summer and early autumn months, when a fresh, crisp salad is one of the most relishable additions to the breakfast-table we rarely find, either in the private garden or the market, a supply of good lettuce. Yet, wherever the appreciation or demand warrants it, a little extra effort will secure lettuce which is fully equal, and generally superior to that obtainable earlier. The method which we have found successful is the following: Prepare a bed or field of friable well-tilled soil, making it very rich, especially in nitrogenous manures, using very liberal quantities of well-rotted manure and of nitrate of soda. Wet the bed thoroughly and wait until it has dried out, just sufficiently not to pack under pressure, or, in the case of field culture, wait long enough after a rain to secure the same condition, and then sow the seed in drills, two feet apart, running north and south, covering the seed lightly and pressing the soil well over it. Now set along the row, eight feet apart, stakes four to six inches wide, one inch or more thick, and fifteen to eighteen inches long, so that they will project four to six inches above the surface, and on these lay common six-inch fencing boards, tacking them to the stakes with a single wire nail. These will generally shade the rows during the heat of the day sufficiently to secure a stand and a rapid growth. The rows can at least be watered with far less danger of injury than if they were unshaded. When the young plants are two or three inches high, remove the boards, thin out so that there will be from three to ten plants to the yard, according to the age and size when the lettuce is to be used, raise the stakes until they are from eight to ten inches above the surface and replace the boards.

As to the best kinds for summer planting, the European sort, Marvel or Red Besson, and its American representatives, Long Standing Bronze, Shotwell, Brown Head, etc., make a compact plant, deep red in color, with a solid head of thick, rich-flavored, crumpled, yellow leaves of the finest quality, and is one of the best sorts to resist the hot sun.

Deacon, Defiance Summer, New White Russian Summer, if not identical, are very similar, and form solid heads of very thick, rich-flavored leaves—the outer ones a rich green, the inner white, or yellowish white. These are good varieties, especially for those who use oil or butter with lettuce.

Hanson, Henderson's New York, Marblehead, Mammoth Cabbage are all larger and coarser-growing than the others, and the heads are looser, and made of much coarser but exceedingly crisp and tender white leaves, which might be preferred by those who eat lettuce with vinegar and sugar.

Any of the above varieties can be grown so as to be in perfection at any time from July 1st till October 15th, and we think cannot be grown so as to be at their best until about the earlier date; while Tennis Ball, Black Seeded Simpson and some other sorts must be grown so as to mature not later than July 1st, in order to be at their best.

Detroit, Mich. *Will W. Tracy.*

A hardy Indian Azalea.—Some ten or twelve years ago Mr. George C. Woolson imported from Japan some plants which he ordered as *Azalea amœna*, but which proved to be another variety which blossoms very much later, sometimes holding flowers until the middle of July, although its season usually begins soon after the middle of June. It seems in this latitude to be rather less able to withstand the winter than *Azalea amœna*, but this year it has flowered very abundantly. It is a dwarf plant, ranging from twelve to fifteen inches high here, and the flowers are a bright scarlet and as large as those of the typical Indian Azalea. The plant is identified as *Rhododendron Indicum*, var. *obtusum*. It will be a valuable shrub in this latitude and farther south.

Morristown, N. J. *S.*

Hollyhocks.—These favorite old-fashioned flowers have for some time past been at their best, and they are very attractive at the back of a wide border. The Hollyhock disease has done much to discourage growers in this region, where it has prevailed, and therefore success is the more pleasant. We used to have much satisfaction from the named collection of some two dozen varieties, which were mostly Charter's kinds. Some of these Charter Hollyhocks still live, and are well worth growing when they can be obtained. As Hollyhocks come true from seeds, in some sections there would be no difficulty in keeping the varieties year after year. Situated as we are, it is best to obtain fresh seed each year, and start a new lot to secure a good display of stems six to eight feet in height. As perennial plants they are very uncertain in our colder states, and only a part of the crop will survive even the first winter. There are three periods at which seed may be sown with about equal success, the difference being principally in the amount of trouble and space involved. Seed may be sown early in January, and if the plants are grown on without a check they will flower the same year, but the trouble is that a warm greenhouse is indispensable, and so also is plenty of space at a season when space is scarce. Seed may also be sown in March, and the seedlings planted in the open ground in May; they will make strong plants and flower the following year. Plants grown from seed sown in July, or very early in August,

should, when they are large enough, be set out in a bed of rich soil. When cold weather comes the plants should be covered with a few dry leaves and protected by a frame of rough boards. In early spring they may be uncovered and planted in the places where they are to flower. From this method we have had the best results with the least trouble. Hollyhocks like rich soil, and should be watered well in dry weather; strong stakes are necessary to protect them in rough winds. I am not aware that any remedy has been found for the disease, but if there has been, many lovers of these flowers would be glad to know of it.

Correspondence.

A Forest Under the Equator.

To the Editor of Garden and Forest:

Sir,—The port of entry to the Amazon Valley is the city of Pará, which stands on the southern bank of the great river, and fears no rival city on the northern bank because that shore is too unhealthy and too difficult of access ever to become inhabited. With never a blighting frost, and with plenty of moisture, for a daily shower is expected to fall throughout the year, it is not strange that every inch of fertile soil under a vertical sun teems with vegetation, so that this little-known city of the south is embowered in a luxuriant forest that sweeps away in every direction as far as the eye can reach, draping the whole land with fadeless green and veiling the face of the continent for 2,000 miles westward to the foot of the Andes.

During the two years in which I lived in Pará many longings for my New England home were alleviated by walks in the narrow forest-paths that terminate the city streets. The landscape is nearly the same at all seasons. Very few of the trees shed all their foliage before the new buds expand, and one leaf at a time falls silently, while others as silently unfold. Few flowers are found blooming freely in the shady recesses of this woodland. Occasionally by the path a solitary scarlet Passion-flower flames like a beacon from the green drapery to which it clings. In partially cleared spaces, or upon the outskirts of the wood, I often saw white Convolvuli, occasionally the purple and white Passion-flower, and also a plant which resembled the scarlet-flowered Canna; the blossom was quite small—perhaps because of the deep shade in which it unfurled its wide green leaves. Many of the trees have small or inconspicuous flowers, but some of the tallest ones open showy clusters of purple or of yellow flowers.

The farther we advance into the forest the less dense becomes the undergrowth, so that one catches more extended glimpses of the vast wilderness that sweeps away on either hand. But it is far from easy to make one's way from one path to another as the tree-trunks are everywhere linked and bound together by gigantic vines or sipos, and you begin to understand what is meant by climbing trees. Their flexible stems twine and creep in every direction or fall in loops strong enough to make a swing for two or three adults. Their leaves are mostly borne when the leaning stems have at last wound their way up to the sunlight that sifts into this dense canopy of foliage which is supported by the columnar trunks of the trees. Underneath this high green firmament the bare, brown, vine-like stems and dark tree-trunks are here and there interspersed with long brown threads that dangle over the pathway and sway with the passing breeze. These woody lianas, suspended from the branches above, are not the ends of vines that have lost hold upon their supports, but they are the air-roots of epiphytal plants that are growing on the interlocking boughs. Some hang like scattered threads of fringe, other strands are clustered, but all are stretching and reaching toward the bosom of the earth, and when they touch the ground they quickly strike their rootlets into the moist soil, no doubt giving new lease of life to the plants lodged on the tree above.

The green leaves of the enormous air-plants or parasites give tone to the grays and browns of the bare trunks, and to the vine-stalks that appear almost sombre in the semi-twilight of the woods. It is a marvelous sight to see wide, flag-like leaves growing luxuriantly in massive clusters at a dizzy height, upon the side of a gigantic tree-trunk. In some strange way many of them have been supplied with a big lump of black soil. One might imagine some grotesque gardener had uptorn the huge root from the ground, and, in some magic way, flung it, with the soil adhering to it, "right side up with care," against its perpendicular perch. Too rank a growth, or some mischievous flying missile may dislodge one, but many are left to cling among Orchids or Ferns, whose home is high on the bark of the tree.

Except in the most moist and densely shaded parts of the forest, the ground is thickly covered with Lycopodiums. They grow a foot or more in height and then bend over, to take root again at their tips, like Walking Ferns. This foot-deep, dark green, mossy cushion is, in itself, worth all the trouble it takes to visit it. In the swampy localities we find Caladiums that are especially graceful in style of growth, and have very brilliant markings. Another plant, whose thick, fleshy and heart-shaped leaves resemble the foliage of the Caladium is the Pothos. These climbing shrubs twine their cord-like stems around the trunks of the trees, here and there emitting false roots, by means of which they attach themselves to the bark of their appropriated support, and clamber on toward the light that filters through interlacing boughs overhead.

An exceedingly interesting study is found in the almost endless variety in the foliage. There is every conceivable form between the fine pinnate leaves of the many Mimosas and the sword-shaped leaves of *Urania Amazonica*, wild Banana, which measure eight feet in length by one in breadth, and stand upright from the top of a five or six foot stem. No words are adequate to express one's admiration for a single one of these stately, colossal trees, and a chill of awe comes with the effort to estimate the number of these giants in the vast forest whose majestic and imposing beauty is the slow and steady growth of unrecorded ages.

Lordsburg, Cal. *Mrs. W. F. Wheeler.*

Community Gardens.

To the Editor of Garden and Forest:

Sir,—The pleasure of gardening would be increased if we were not confined by fashion and custom to a limited number of plants, so that gardens are repeated over and over again. And to make the repetition more marked, not only are the same plants used, but many of them are trimmed and pruned to the same artificial forms. The Rose is indispensable, but its season of bloom is short, and the half-dozen larger Pinks in general cultivation are fine and pleasing. These, with perhaps a dozen other plants, form the staple garden material over considerable sections of the country.

If instead of confining ourselves to a few stock plants, beautiful as they are, there were added to these some of the really attractive flowers which can readily be bought, but which are seldom seen, the garden would have a continuation of bloom and verdure throughout the entire season. There is unlimited variety in the graceful natural effect of shrubs and trees, but the Maple, the Willow and the Poplar are not allowed to assume their natural grace, but are often pollarded or pruned into formality and stiffness, while evergreens are fashioned into even more grotesque forms.

In order to prevent this endless repetition of gardens, each fashioned after the same model, I have a suggestion to offer which may be too fanciful for practical use, but which may perhaps widen the scope of some one's thought or encourage some one to larger enterprise in gardening. What an endless variety of things, little and big, might be grown if a community would organize to grow them. My neighbor A could purchase, plant and enjoy a hundred Sedums, more or less; B could fill his garden with Cactuses; and the Misses C. could cover their two or three hundred feet of rock-margined border with such pretty low plants as the mountain, alpine and spiny Alyssums, the Egyptian and golden Yarrows, the three or four Æthionemas, as many Androsaces, Arabises and Aubrietias, the silvery prostrate and dense Antennarias, *A. dioica* and *A. tomentosa*, the gray-foliaged and white-flowered Cerastiums, the creeping and tufted Astragaluses, the rosy and white-headed Armerias, and even such mild, free and lightly spreading little specimens as our own native *Hosackia Purshiana*, whose claims to garden space I am, I imagine, the first to advocate.

Behind all the above edging species, our friends, the Misses C., could set the more brilliant Figworts, the taller and shorter Mimuluses, Pentstemons, Alonsoas, Antirrhinums, Calceolarias, Nemesias, Linarias, Lophospermums, Digitalises, etc. One entire garden could be filled with the twenty or thirty species of cultivated Oxalis, the advertised twenty or thirty species and varieties of Lobelia and Veronica, with Gypsophilas, Galiums and Statices added to mystify and unite the whole.

The Crucifers, the Pinks, the Pea tribe, the Composites, the succulent Mesembryanthemums, the Night-shades, the bulbous plants would each supply a garden-enclosure with candidates sufficient to fill it.

This plan would afford great variety, with harmony in each individual garden, together with endless diversity, as I have indicated above, in each group of gardens included within the bounds of a civil parish, township or county. Thus arranged, each house-lot, as will be seen, would hold out a continuous invitation to the holders of a thousand other house-lots to come in, examine and admire. Each citizen, with kindest intent, would have large interest in the enclosures of all his neighbors, far and near; consequently, calls and inspections would ever be in order and never completed, as it would take more than one season—more than two, perhaps—to exhaust the green treasures of a single village only.

A township-wide garden, of which each lot-holder would be the owner of a fragment, I offer as a new departure for American gardening.

Santa Clara. *L.*

Recent Publications.

Last year Professor Roberts, of Cornell University, published a bulletin to show how much loss of fertilizing matter occurred when manure was permitted to lie exposed to the weather for considerable periods of time. The trials which were then made have been repeated, with some variations, and on a larger scale, and Bulletin 17, from the Cornell Experiment Station, is devoted to the same subject. In the trial recorded a pile of two tons of horse-manure and cut straw was accumulated in the latter part of April, and analysis was then made of the mass. This remained exposed until the middle of September, when it was carefully scraped up, weighed and analyzed by samples. The season was a wet one, and a great deal of loss occurred. The 4,000 pounds of original gross weight had shrunk to 1,730 pounds, and, although there was an increase in the percentage of phosphoric acid, and but a slight diminution in the percentage of nitrogen, the total loss, owing to the general shrinkage, was very great; that is, of the nitrogen there was a loss of sixty per cent., of phosphoric acid a loss of forty-seven per cent., and of potash a loss of seventy-six per cent. Estimating the value of the fertilizing ingredients at current prices, a ton of the original compost was worth $2.80, while the value of what that ton had dwindled to at the close of the experiment was only $1.06, or a loss of 62 per cent. in the fertilizing power of the manure. The loss in this case was more serious than it was last year, owing to the fact, perhaps, that the heap was larger, and, as it contained some straw, there was a greater degree of heating, or what is known to farmers as firefanging.

A similar experiment was made on a pile of cow-manure, amounting to five tons. The total shrinkage in gross weight was, in this case, about one-half. The loss of nitrogen was forty-one per cent., of phosphoric acid nineteen per cent., and of potash eight per cent., and the value of the manure was depreciated to the amount of about one-third. From this it appears that the waste was only one-half as much as in the case of the horse-manure. One reason for this is, that the fermentation in this case was not sufficiently rapid to cause firefanging.

From these tests Professor Roberts reaches the following conclusion: "It seems safe to say that under the ordinary conditions of piling and exposure the loss of fertilizing material during the course of the summer is not likely to be much below fifty per cent. of the value of the manure." Of course the moral of this is to use great care in preserving such fertilizing material for farm or garden. It is too often the case that farm-yard manures are piled under the eaves of outbuildings or upon a steep hill-side by the borders of a running brook, and this fact is made graphically clear in the bulletin by some pictures from actual photographs of country farm-yards. Professor Roberts recommends cheap buildings or covered yards which will protect the manure from leaching.

Increased interest would have been given to this bulletin if Professor Roberts had explained where the lost fertilizing material had gone. The potash cannot evaporate, so that the potash and phosphoric acid must have been carried away in the drainage. It would seem, therefore, that the best way to save these elements would be to spread the manure at once on the surface of the ground where it was needed, so that the soluble salts might be washed into the soil and held there. The most expensive ingredient, however, is the nitrogen, and in the course of fermentation this can pass into the air as ammonia or as a free gas. It would be interesting to know how much of it escaped in the drainage and how much was dissipated in the air. Fermentation to some extent would go on in the manure even under cover, and in some cases this fermentation adds value to the manure. If Professor Roberts continues his experiments he could give cultivators some useful information by ascertaining for them how much in actual weight a ton of manure would lose if kept under cover or in a pit, and what portion of the waste is material which is valuable plant-food. The proper care and the most effective application of manures may be considered the basis of all good agricultural practice, and our experiment stations can do no better work than by making careful researches in this direction.

Periodical Literature.

In the August number of *The Forum* Ex-Governor Sheldon writes on the Profits of Fruit-culture in California, naming as the fruits which are successfully grown in that state the apple, the apricot, the peach, the pear, the plum, the prune, the nectarine, the cherry, the fig, the olive, the guava, the loquat, the orange, the lemon, the lime, grapes for the table, for raisins and for wines, the English walnut and the almond. The richness of some of the valleys, where the fertility has been washed down from the mountains for ages, is so great, and the consequent production of all kinds of crops is so abundant, that many Californians have been led to believe that this fertility cannot be exhausted. This belief has led to imperfect cultivation and the continuation of successive crops in some places until production has been materially reduced. Vineyards have borne fruit for a hundred years in some cases without any fertilization. The orchards of deciduous fruit are rarely enriched, and Orange-groves have not been fertilized until within ten or fifteen years. Of course, in order to secure future crops, some return must be made to the soil, and cultivators are now beginning to study methods of cultivation and to make use of both home-made and commercial fertilizers with excellent results.

Perhaps the most instructive part of the article is not the general statement of the large production, but the specific examples cited of the crops which have been produced in different parts of the state. For example, 250 acres of wine Grape-vines in Los Angeles County have for several years netted their owner $100 an acre. Raisins yield a profit in four counties of from $150 to $400 an acre when the vines are in full bearing. Walnut-orchards yield from $200 to $400 per acre when the trees are twenty years old. Seventy-two Fig-trees, planted at the rate of 108 to the acre, have netted the grower $600 a year for four years past, and the same grower has received $150 for the lemons grown on one-third of an acre, although they were not cured, but sold to local dealers. The fruit from thirty-eight acres of Peaches, Apricots and Prunes in Pasadena was sold for $9,294, and the cost of production was $1,000, and in the same place the peaches from one and a half acres sold for $500 on the trees. In San Diego County the prunes from five and a half acres brought $2,600, and the cost of production and preparation for market was $300. From sixteen acres of Apricots a grower in Azusa received $7,300 net. One acre of Orange-trees in South Pasadena produced in the fourth year after bearing $350, with a cost of production of $36. Last year a grower in Alhambra raised on eight acres 7,000 boxes of oranges, which were sold at $1.35 a box, while trees planted at the rate of 120 to the acre yield at the rate of $4 a tree. In Riverside, the most celebrated place for orange production in the state, the receipts have been as high as $1,200 to the acre, and $400 and upward are not uncommon returns.

These cases exaggerate general results when the production of all the orchards and vineyards of the state are taken into account, for this includes those which have suffered from neglect and unintelligent management. If these figures are reduced one-half they will still be above the general average production, and then it will be seen that the profits from fruit-culture in California exceed anything that has been achieved elsewhere in the country in horticultural or agricultural production.

The great increase of fruit-production within the last few years has raised the question whether there is not danger of over-production in the early future to such an extent that reduced prices will leave no profits. In proportion to the value of the land and expense of production these profits have been enormous, and prices might be largely reduced before the fruit-industry would cease to be remunerative. But production is still far below the demand. Peaches, for example, are popular all over the country, while the areas where they have been successfully grown are not increasing in the east. Prunes are raised in several parts of California, and yet the state itself imports them largely. Apricots, figs, raisins, walnuts and olives are only grown in a few places except in the southern half of California, and the wine-grape is cultivated in but a few and restricted districts outside of the state. The orange crop

of Florida is practically out of the way before the California fruit is ready for market, and the orange season in California will probably be prolonged in future, since the growers are planting Valencia Oranges, which do not ripen until July. The Lemon is more sensitive to frost than the Orange, therefore it can be grown with less difficulty in California than in Florida.

Beyond question the production of fruit in California will increase out of proportion to the increase of population, but, meantime, fruit is becoming more and more a general necessity, and abundance stimulates efforts to find new markets and extend trade. Millions of people in the United States only occasionally see oranges, and many others do not use fruit as a regular article of food, and since Americans are the greatest consumers in the world, producers, dealers and transporters will exert themselves to place fruits within the reach of all. Probably prices will be reduced in future, but orchards and vineyards will then have reached full-bearing condition, and their yield will be much greater, without corresponding increase in cost of production, and transportation can be materially reduced as tonnage increases. On the whole, Governor Sheldon thinks that, although Californians have large ideas on the subject of profits, and what, in other countries, would be esteemed as princely they are likely to look upon as moderate, and, perhaps, unsatisfactory, nevertheless their ideas can be considerably modified, and prices can be materially reduced and still leave a satisfactory margin of profit. When fruit-culture does become unremunerative it will be time to discourage it, but it is not probable that this period will arrive within the lifetime of the present generation.

Notes.

Elæagnus longipes is proving itself one of the shrubs which thrive well near the sea.

At the imperial Chrysanthemum festivals in Japan one may see single plants bearing from 200 to 400 blossoms each, which are placed in isolated positions of honor and protected by silken tents.

Dr. Dieck recently announced the blooming in his arboretum at Zoeschen, in Germany, of *Robinia Neo-Mexicana* with red flowers. It withstands a cold of twenty-four degrees Reaumur, and "otherwise resembles the blue-green small-leaved form of Robinia Pseudacacia."

A correspondent of the *New York Tribune*, writing recently from Paris, says that it is estimated that the sale of Lilies of the Valley in that city annually amounts to $160,000, vast quantities of the flowers being forced for the winter season as well as brought in from the country in spring.

A writer in the New Bedford *Standard* recently suggested that the Massachusetts Society for the Preservation of Natural Scenery might well acquire that extremity of the Island of Martha's Vineyard which is known as Gay Head, from the brilliant colors of the stratified clay of which this promontory is composed, and which is now threatened with destruction by those who are carrying away its clays and who propose to work its lignite beds.

A favorite sweet in Japan is *midzu ame*, or Millet-honey, made from rice or millet which has been soaked, steamed, mixed with warm water and barley-malt, and left to stand a few hours, when a clear yellow liquid is drawn off which can be boiled down to a thick syrup or paste. This paste street-venders blow into odd forms with a pipe for the delectation of children, and it is also made into fanciful flower-shapes, which are used to decorate the dinner-table, even in the emperor's palace.

Last year we noted the fact that a species of Begonia with tuberous roots, known as *B. Baumanni*, had been collected in South America, with flowers which were agreeably fragrant, and it was suggested that this might enable hybridizers to produce a cross which would have perfume and thus give the final charm to these beautiful flowers. We are not aware that any success in this direction has as yet been achieved, but Mr. Thomas Griffin, who has some 20,000 seedlings of tuberous Begonias growing near Westbury, Long Island, claims that one of his plants bears distinctly fragrant flowers.

The Humboldt *Times* having stated that California Redwood "comes nearer being fire-proof than almost any other material of which buildings are constructed," the *Commercial News*, of San Francisco, replies: "The kindling wood sold by the retail coal and wood dealers of this city is redwood; it is hard to get anything else from them. This ought to prove that the wood is inflammable. That redwood absorbs water like a sponge and that it is free from the resinous quality common to other soft woods enables it to resist fire better than pitch-pine, and once ablaze the flames are more easily extinguished, from the fact that water soaks into the wood. These qualities make redwood valuable as a building material, but it is absurd to speak of the wood as fire-proof."

The Star, of Wilmington, North Carolina, cites the example of Mr. W. H. Dunn, of Newbern, as one who believes in an intensive system of agriculture. He bought sixty acres of land in 1881, paying for it $50 an acre. He values it now at $1,000 an acre, and it has netted, this year, more than twenty per cent. on this valuation. His profits, above all expenses, have been $11,500. He raises everything for which there is a demand in southern markets, but relies mainly on the Irish Potato, with which he finds no danger of overstocking the market. He insists that that man who understands trucking, and knows what to raise, cannot fail to prosper.

Probably the earliest reference to the cultivation of plants under glass occurs in the writings of Columella. He tells us that the Emperor Tiberius, being in ill health, was ordered to eat cucumbers every day. The Roman gardeners, therefore, cultivated them in frames filled with fermenting manure, exposed to the sun at the foot of a wall, mounted on wheels, so that they could be moved about at will, and covered with pieces of talc to protect the vegetables agaist frost and cold. "Thanks to this invention," says Columella, "Tiberius was supplied with cucumbers at nearly every season of the year." Seneca, however, distinctly tells us that Roman hot-houses were heated by artificial means. "Do not those," he protests, "live contrary to nature who require Roses in winter, and who, by the use of hot water and the application of heat, compel the Lily to blossom in winter instead of in the spring?"

The New York *Journal of Commerce* relates this incident to prove that good roads may be a profitable investment: A wealthy prospector, who was looking for a rural home in which to give a safe and pleasant summer outing to a large family of children, returned from a tour of inspection and handed the maps back to the agent who had instigated the quest. When asked about the prospect of a sale he shook his head with a very decided negative. The agent was confounded; would none of the places suit? There was no malaria; there had never been a case of typhus; mosquitoes were unknown; the springs of water were abundant and delicious; the woods waved their leafy boughs in every landscape; the air in each quarter bore on its wings the fragrance of a thousand flowers; what could be the objection? The answer was short and sharp: "There are no drives; I do not own a carriage that would endure for one season on those terrific roads." An unkept highway is worse than the plague to deter investors in rural homes.

A comprehensive study of the influence of forests on the daily variation of air-temperature has been recently made by Professor Müttrich (*Nature*, May 21st), the data being from stations in Germany and Austria. Inter alia, this influence is greater in May to September or October than in the other months. In Pine and Fir woods it rises gradually from January to a maximum in August or September, then falls more quickly to a minimum in December; but in Beech-woods a minimum occurs in April, then there is a quick rise, till the maximum is reached in July. The daily variation itself is greatest in May or June, both in forest and open country. The influence of the forest is to lower the maxima and raise the minima, and the former influence is in most months greater than the latter; in December and January, and occasionally in neighboring months, it is less. The influence on the maxima in summer is greatest in Beech-woods, less in Pine, and least in Fir. The absolute value of the influence in woods of a given kind of tree is affected by the degree of density of the wood, being higher the denser the wood. The character of the climate (oceanic or continental) also affects the results. From daily observations in forest and open country, every two hours in the second half of June, it appears that, soon after five A. M. and eight P. M., the air-temperature in the wood was equal to that in the open; that the maximum was about 0.9° lower in the wood, and the minimum 0.6° higher; that in May to September the difference sometimes reached 2.7°; that the maximum in the wood occurred about half an hour later, and the minimum a quarter of an hour earlier, than in the open; and that the daily mean air-temperature was about one-third of a degree less in the wood.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, AUGUST 12, 1891.

TABLE OF CONTENTS.

The Summer Vacation.

THE summer vacation has come to be an important feature of American life. In a striking article in *The Century* for August Mr. Edward Hungerford shows how it affects the intellectual and material product of the country; how it scatters hoarded money and influences the rate of wages; how it directly improves agriculture and increases the value of land; how it encourages new industries and domestic handicrafts. It may help to solve the problem of abandoned farms, and, on the contrary, it may help to destroy the simplicity which gives to rural life its greatest value and highest charm. This is not the place to discuss social problems of such weight, but it may be said that the country will receive but little moral benefit if it is to be filled with idlers from the town all summer long. Extravagance and love of display is contagious, and they may engender discontent and thriftlessness among those who are brought into daily contact with an army of restless pleasure-seekers. But, after all, the majority of those who seek a change of scene are not of the class who drive four-in-hand. To these people all the year is a vacation from any remunerative work, but the men and women who really need the change from active daily occupation usually bring with them to the fresh country air a wholesome moral atmosphere, and the places they visit profit in every way by their presence. The real trouble is not that they harm others, but that they fail to secure for themselves the highest advantage which their opportunities offer.

For overworked bodies and minds absolute rest may be desirable, but, in spite of all that has been written about the universal nervous exhaustion of our people, the majority of them enter upon their vacation days with minds reasonably alert, and with muscles which long for exercise. To many of them woods and mountains offer few attractions in themselves, and the sea-shore is only inviting when it has drawn together a multitude. It is the crowd and the excitement, and not the ocean's majesty nor the thunder of its surf, which is expected to restore wasted energy. The recuperating force of personal contact with nature is not thought of, and yet, to minds prepared for such communion, its influence is distinctly sanative, and it ministers directly to mental and spiritual health. We may not be able to give the reason for this, but it is a truth as well substantiated as any other in human experience. Great poets and others who give expression to the elemental emotions of the human soul unite in bearing witness to it. In the language of profound thinkers, Nature "soothes and sympathizes," brings "refreshment to the spirits of man," and "pours wine and oil on the smarts of the mind."

It is evident that many of us fail to reap in full measure the advantages of this remedial agency. Indeed, it is often said that only in exceptional instances are Americans sensible of this influence—that is, this inflowing of the spirit of abounding life and multiform beauty of nature with all its transforming and vitalizing energy. Nevertheless, this susceptibility to the charm of natural beauty and grandeur seems to be one of the primary instincts of the race. It may lose its power by lack of exercise, or by indulgence in grosser pleasures; it may be dwarfed by faulty systems of education, or by devotion to what is insincere and artificial in social life, but the faculty is original, and asserts itself wherever men lead natural and wholesome lives. Taking this view of the case, the man who neglects or impairs this power loses more than the mere capacity for one form of pleasurable emotion. He wastes what may be a genuine recuperative energy and inspiration. This is not fancy, but fundamental truth, and these vacation days can hardly be put to better use than to the exercise and development of a faculty which may be so potent to lift us out of the prosaic weariness of work-day life.

Now, this contemplation of Nature on what may be called its imaginative or poetic side differs widely from the mere study of natural science, but it implies some knowledge, and a growing knowledge, of Nature, and science is only knowledge systematized. It is therefore directly in the line of the suggestions already offered to commend to those who have never made the trial the advantages of studious attention to some of the natural objects with which they are brought into daily contact. The essential point is to examine the objects themselves, and not to read about them in books. It will not rob the woodlands of their charm to be able to identify the various species of trees of which they are composed. Indeed, it would seem hardly possible to enjoy them thoroughly without this elementary knowledge, and yet a majority of the men and women we meet can hardly name a dozen of the more common native trees in the forest or the fields, or a dozen of the so-called ornamental trees in parks and gardens. Fewer still can identify the bushes on the road-borders, in the forest-undergrowth or in planted shrubberies. Every one who has directed the attention of a bright boy or girl to efforts in this direction must have observed the eager interest with which each new discovery is made. Trees and shrubs which were formerly passed by unnoted become attractive, every leaf has a new meaning, and even the bark on every tree-trunk becomes a study and a delight. The study, beginning in this small way, may broaden out into fields that are limitless, and may provide wholesome recreation for a life-time. The simple delight in the acquisition of such knowledge is its own reward, but, besides this, it may furnish the mind with an unfailing safeguard in the future against the tedium of many a long journey and lonely hour.

The material for this vacation improvement is always at hand in infinite variety. Any one can begin it with trees or flowers or grass, with birds and their music, or even with the insects or stones, and no one who enters upon such a course of education will fail to find in it so sure

tonic for his mental and moral nature that it is hardly profane to characterize it as a means of grace. It has been objected that a devotion to the study of natural things is liable to become such an absorbing passion as to leave the mind unbalanced, but, in reality, the attitude toward Nature here suggested is the normal and wholesome one; it is the opposite mood, the indifference to Nature and the insensibility to her kindly influences, which is morbid.

New England Parks.

MORTON PARK, PLYMOUTH, MASSACHUSETTS.

THE wish to preserve pleasure-grounds, not only in the neighborhood of the larger cities, but also in the smaller and less-rapidly growing towns, is one of the interesting signs of the times in New England, and it is a taste that may well be cultivated. The Lynn Woods, bordering upon a chain of ponds, and the beautiful Forest Park in Springfield, are charming instances of what Massachusetts is doing outside of her chief city, while the neigborhood of Boston rejoices in many resorts where the toil-worn citizen may find rest and comfort in the shade and refreshment of the woods.

It is appropriate that in Plymouth, which saw the first dawn of New England civilization, such an enterprise should have been undertaken by the citizens and carried to a successful conclusion, so far as organizing upon a substantial and permanent basis goes, while it is still a rural town, scarcely in need of a breathing-space other than is afforded by its own spacious garden-spots and the broad harbor it overlooks, though in securing such a resort it has added another attraction to its already charming quaintness.

The houses of the old town lie huddled together around the Rock, after the fashion of English villages, being planted directly on the street, and climbing the hill, which rises steeply from the bay. The top of the hill is crowned by a most sociable burying ground, which seems to serve as a thoroughfare from one part of Plymouth to another. This sleeping-place of its departed inhabitants is neither mournful nor deserted. Along its convenient walks the pedestrian hurries to his home, carrying bundles under his arm; children play beneath the shadow of the Lindens that overhang the graves of the Pilgrim Fathers, and one may watch a troup of merry girls wandering about the grounds, examining the epitaphs upon the venerable tomb-stones as he sits upon the benches and looks out upon the smiling bay. No dweller in Plymouth ever calls this cemetery anything but "The Hill," which robs it still more of all funereal terror, and to a stranger it is a cheerful spot, from which he may view the sea and look down upon the roofs and towers of the town at his feet.

Descending the hill, old-fashioned gardens full of flowers are to be seen behind the houses, and at its base you come to that time-honored institution, the town brook, which, in some wide reaches, certainly deserves to be dignified by a more imposing title.

Up this historic brook the Pilgrims sailed, to deposit their belongings at a more convenient landing-place than the Rock on which they first set foot, and the traveler of to-day, following its course for a mile or so toward its source, finds himself upon the shores of a lake, apparently so wide and long that the first discoverer deemed it an arm of the bay, and, with a certain grim humor at his expense, the forefathers called it Billington Sea, which name it bears to this day. Lying for a mile along this pond of over three hundred acres in extent, and completely encircling a smaller sheet of water called Little Pond (our ancestors certainly were matter-of-fact in their names), there lies a tract of woodland which is now the Park.

For many years the late Dr. Le Baron Russell had kept about fifty acres of this land open for the use of the public, but some six years ago the only access to the water was by grassy cart-paths through the Oaks and Pines, which brushed the passer-by with their low-sweeping limbs; that approach is now rendered easy and agreeable by well-graded winding roads that lead in all directions through the forest and along the lovely lakes, with openings cut at intervals that give pleasing views of the sparkling water and its farther shores.

This improvement is due largely to the personal exertions of one man who, to a strong affection for the woods, added a fine public spirit for the town, of which his Pilgrim ancestor, whose name he bears, Nathaniel Morton, was a founder.

Encountering obstacles at first, as he who seeks to benefit a community invariably does, Mr. Morton finally succeeded in persuading other citizens of Plymouth to unite with him in inducing the town to acquire, partly by purchase and partly by the acceptance of gifts of land, the property of 150 acres, which, in consideration of his efforts, the townspeople have decided to call Morton Park.

This park still keeps its wild woodland aspect, and it has been the aim of the commissioners to preserve its forest character by making the driveways narrow and permiting the natural shrubs to grow closely along their edges, and to clamber at will through the openings made by the removal of dead or unnecessary timber.

There are few very ancient trees in these woods, most of the Oaks and Maples being coppice-growth from the roots of trees felled some seventy years ago. Such growth, in sandy soil, is not likely to assume large proportions, but it forms the best of shelters for seedlings, which are everywhere springing up among the close-set stems of the parent forest. Where Beeches appear they are encouraged to grow broad and stalwart by making openings for them, gradually removing such trees as interrupt their spread, and letting in air and light by clearing away around them.

In a part of the wood there is a swamp, where are numbers of stately old Red Cedars, and through the wild tangle of shrubs and trees that are engendered by the moist peaty soil a corduroy road is in process of construction, so that one can now walk on planks into the very heart of the forest.

Along the border of the smaller pond are groves of tall Pitch Pines, and between their columnar trunks the water gleams in the distance. White Pines also are found in various places, but the Oak seems to predominate, though there is a good sprinkling of Maple and some planted Canoe Birches and other trees.

On one side of Little Pond rises a hill, wooded to the summit, and playfully called The Mountain, which serves to diversify the generally level character of the grounds, to which, however, the varied views of the two lakes afford endless opportunities for charming effect when the hand of man shall have modified the wild into the picturesque.

The advantage of such a resort is fully appreciated by the townspeople, who frequent the park in great numbers, bringing their boats with them on wheels, or anchoring the smaller ones along the shores of the ponds. Very few restrictions are imposed; the visitor is allowed to gather at will great bunches of the fragrant wild Azalea, which grows here in profusion, or to fill his carriage with the blossoms of the flowering shrubs that load the air with perfume; but the small wild animals and birds are carefully protected in these their native haunts, and no one is permitted to molest or destroy them, so that the wood is full of the sound of their happy voices.

There is a delight in knowing that the enjoyment of this woodland seclusion has become a permanent possession for the dwellers in Plymouth. This provision for the future is a sign of maturity in a nation. In youth, a country, like an individual, is careless and prodigal, apt to waste substance rather than to acquire it; but as advancing years add wisdom and forethought to municipalities as well as man, there comes the wish to secure for the coming generation some of the fast-vanishing youthful pleasures that they remember. The woods in which a man has played when a child he rejoices to retain for the enjoyment of his grandchildren, and to this worthy sentiment we owe the preservation, from the demands of pure utilitarianism, of much that will make the life of future generations rich and beautiful. Could the Pilgrims in their century but have foreseen the joy with which their descendants of to-day would have beheld some surviving monarch of the forests they so ruthlessly destroyed, they might have treasured and protected a few old trees which would now be the glory of the Plymouth Park; but when every trunk might form a shelter for an Indian enemy, small wonder that our anxious sires made haste to clear the region round about them, and left to their descendants the task of raising up again that which it cost them so much labor to destroy.

That the old town of Plymouth should manifest this enthusiasm in so good a cause is a sign that it is still in the van of civilization. Morton Park, with its area of 500 acres of land and water, is an honor to any community, and will yearly become a more valuable possession. Delightful as its wildness and freedom are at present, perfectly as it retains the forest-charm, the growth of new trees, the training of old ones, the gradual opening of other outlooks upon the water, in short, the touch of the intelligent hand will but add to its beauty, and endear it the more to the people.

Hingham, Mass. *M. C. Robbins.*

Tropical Nymphæas in the Open Air at Berlin.

THE tropical Nymphæas, and especially the African species (*N. Lotus*, *N. Zanzibarensis*, etc.), far excel most of the species of cooler climes in the dimensions of their leaves and in the size and colors of their flowers—so much so, that in our colder latitudes lovers of these flowers will sometimes incur considerable expense in supplying them artificially with the conditions of growth which will enable the cultivator to enjoy the full development of their beauty. In some botanic gardens and in the gardens of some rich amateurs we meet with glass houses in which spacious tanks of water are kept constantly warm by means of a powerful heating apparatus, and the interior of these covered aquariums often presents a heightened and more pleasing effect when contrasted with the winter's snow or the summer's drought which may prevail at the time out-of-doors. In somewhat warmer latitudes such an expensive mode of culture is not necessary, and then tanks in the open air, of dimensions proportioned to the size of the plants, and deepest at the centre, take the place of tanks under glass. A few coils of hot-water pipe sunk into the water raise its temperature to the proper degree during the early period of the growth of the plants, while all through the summer the sun's rays, acting on the comparatively small volume of water in the tank, heat it sufficiently to induce and maintain an abundant and continuous bloom on the plants. It is in this way that Mr. E. D. Sturtevant, in the vicinity of New York (that is, in the same latitude as Madrid), successfully grows the fine *Nymphæa Lotus*, *N. scutifolia*, *N. Zanzibarensis*, etc., and the numerous forms of hybrids of the first-named species. Cultivated here under less artificial conditions, these plants seem to harmonize more with the surrounding vegetation, which is quite of a southern type.

But what will your readers say to the astonishing spectacle of tropical Nymphæas growing and flowering in the open air, in pieces of water of some considerable area, and that, too, in the latitude of Berlin? This is a sight which may be seen in the garden of Herr Borsig during many of the summer months. The solution of the riddle (which for a long time has been no secret to many of your readers) is, that an application has been made of the warm water formed by the condensed steam which issues from the machinery workshops of Herr Borsig, which stand close to the garden. The idea of utilizing this condensed steam in raising the temperature of pieces of water first occurred to the grandfather of the present proprietor, who, being a well-informed lover of gardening, made his park, and even his dwelling-house, a centre and museum of the most interesting horticultural collections. A description of all these would occupy too much space here. I shall confine myself to the pieces of water in the park which are filled with Nymphæas. The grounds are about five acres in extent, and are pretty thickly wooded. Through them flows a canal, raised four or five feet above the level of the river Spree, which runs close by. This canal is divided into two or three basins, averaging ninety-seven feet in length and thirty-two feet in width. On the banks handsome trees temper the sunshine, especially about the upper basin, into which the warm water flows, under gentle pressure, through a pipe about as thick as one's wrist, and a few yards in length. Its temperature, on issuing from the pipe, is about seventy-six degrees Fahrenheit, and in the basins from sixty-one to sixty-nine degrees Fahrenheit.

The varieties of Nymphæa grown here are pretty numerous, and have more or less intercrossed with one another. The principal one, both in numbers and effectiveness, is a variety of *N. rubra*, seven or eight strong specimens of which grow in the upper basin. This variety has peltate leaves, brown underneath, and at least sixteen inches across, floating on the surface of the water, and half raised at the centre of the cluster of foliage. The flowers, which stand from six inches to one foot above the water, are of a fine rose color, and more than eight inches in diameter, with very numerous, thin, narrow, limp petals. The characteristics of the plant very much resemble those of another hybrid, which was formerly named *N. Ortgiesiano-rubra*, but are on a much larger scale. *N. rubra*, considered as the type of this species, if it is one, is not so largely developed as the handsome plant of which I have just spoken.

Among the blue-flowered kinds, *N. Zanzibarensis* appears to yield the best results. Its clusters of foliage, which are not so broad as those of *N. rubra*, are more compact, and the leaves are greener in hue. Its handsome flowers remain open only for a few hours every day.

A hybrid between the last-mentioned species and *N. rubra* was pointed out to me. This was still a young plant, but was commencing to flower. Its flowers are of a violet-rose color. *N. scutifolia* does not flower so well as *N. Zanzibarensis*. A variety named *N. cærulea odorata* has quite a pleasing fragrance; it is of vigorous growth and carries its flowers fully sixteen inches above the water. *N. Lotus* has not as yet flowered here, although it produces an abundance of its dentate leaves, which are green underneath.

These Nymphæas remain in the open air for about six months. Toward the month of October the water in the basins is let off into the river Spree, and the rhizomes of the plants are taken up, washed, drained dry and wrapped up in dry moss, after which they are stored under the shelves in a temperate house, where they remain dormant and in good condition during the winter. In the following March a little water is given to them, and they are removed to a house which is slightly heated, where they soon put forth new leaves and later on fresh roots. About the end of April or early in May they are replanted in the basins, each rhizome having a quantity of rich soil or compost placed around it. The warm water is then let into the basins, and these very soon afterward resume the imposing aspect of a river in the tropics.—*Maurice L. de Vilmorin, in Revue Horticole, translated in The Garden.*

The Weeds of California—III.

OF the great Leguminous family only four members can be said to be generally obnoxious to farmers—namely, the Bur Clover (*Medicago denticulata*), the Sweet Clover (*Melilotus Indica*), the Sand Lupin (*L. formosus*, Greene) and the native Licorice (*Glycirrhiza lepidota*). It is true that some of the many native Clovers (Trifolium), though mostly annual, do persist for a while among the grain; but they soon disappear from cultivated fields, and only remain in pasture-grounds, where they are all welcome.

But the Bur Clover, apparently one of the earliest European importations, is of a very different temper. Although an annual, its long, wiry, deep-going roots enable it to survive repeated croppings even unto another season. Under the influence of somewhat generous spring rains, its usually decumbent stems will become assurgent and clothed with luxuriant foliage, forming on the ground a heavy, dense mat, six to ten inches thick, and apparently a most inviting pasture. But its inherent bitter taste prevents any serious damage being done to it by pasturing cattle, which pick the early grasses by preference. Thus the Bur Clover is allowed to mature its coiled pods, armed with hooked bristles, and borne in such abundance that they often form a layer over an inch thick, where the plant, after the cessation of rains, has disappeared before the summer "northers," only a few wiry stems remaining. These burs form a highly important ingredient of the "dry pasture" in the Coast ranges, where cattle get fat on ground that looks to the new-comer as barren as a burnt prairie on the plains. Sheep, of course, also thrive on the pods, but the damage done to the value of their fleece by the inextricable burs is so great that Bur Clover pastures are sedulously avoided by the sheep men.

But during the summer drought this plant changes its nature to suit the altered conditions, and where the ground is cultivated the seed of the same season soon germinates, and a second crop comes up to worry the cultivator. It does not take the insidious little plant long to develop into wheel-shaped mats of all sizes, lying flat on the ground, with minute leaves only, and soon covering themselves with closely packed burs in great profusion. At this time the stems are wiry and tough, and only a very sharp hoe will cut either root or stem. But the seeds acquire germinating power so early that, unless eternal vigilance is exercised, a close mat of young plants will be found in spring where an apparently wretchedly depauperated specimen seemed hardly to maintain life the previous summer. It appears as though the Bur Clover had found in California conditions more favorable to it than anywhere else in the world.

The yellow Melilot also appears to find a most congenial home in all the richer soils where moisture is not too deficient. Thus it grows not only on the banks of brooks and ditches in the Coast ranges as well as in the great valley, but is also found on roadsides and in the cereal fields, completing its growth and fruiting, like the latter, in spring or early summer. Hence, when the cereals are cut for hay the Melilot goes in as a flavoring ingredient to an extent which renders the hay distasteful to horses at least. Worse than this, it is harvested with Wheat, and if left even in the sheaf for any length of time so flavors the grain that the flour made therefrom has a distinct "gingerbread" flavor that is strenuously objected to by millers

both here and in England, and has caused serious discounts upon many a cargo of wheat. Where this plant is mixed with the grain it is very important that the reaping, threshing and winnowing operations should follow each other as quickly as possible; as in practice is done by the "combined harvester and thresher." Even then, if any considerable amount of the seed is left with the grain, the "gingerbread" flavor will gradually communicate itself to the wheat grain and through it to the flour.

The Sand Lupin is naturally at home on deep sandy soils, both in the Coast ranges and in the great valley of California. In these it extends its long, tough root-stocks in all directions, and sometimes forms a mat-work of roots that renders it difficult to keep the plow in the ground. As even short pieces of these root-stocks will sprout, this Lupin—one of the handsomest of its tribe—is a very unwelcome denizen and difficult to extirpate. Its decumbent, assurgent stems form large, low bushes, brilliant with purple flowers, which will shade out every seedling within their reach. In heavier soils it is much more easily dealt with.

The native Licorice shares with the Lupin, as with its Asiatic relative, the possession of long subterranean stems, of which even short pieces will sprout into independent plants. It is especially troublesome in the lighter alluvial soils, in which it finds sufficient moisture throughout the season, and which are its natural habitat. But it gathers fresh strength under cultivation, and if not summarily dealt with when the land is first broken, will be much more difficult to eradicate after the fragments of its root-stocks have been farther disseminated by the plow. Fortunately, it is not as common in California as it is in some parts of Oregon and Washington, where it is known as "Buffalo Brush," and covers large areas almost exclusively.

University of California. *E. W. Hilgard.*

New or Little-known Plants.

The Japanese Photinia.

A FIGURE of one form of this variable plant, cultivated in the Arnold Arboretum, was published in an early issue of Garden and Forest (i., 67, f. 12); the illustration on page 377 represents another inhabitant of the Arboretum which, although very distinct in several minor characters, is believed by those botanists who have had the best opportunities to study the flora of eastern Asia to be only a form of the same plant, *Photinia villosa*, a species in which they include a number of plants very dissimilar in the shape of their leaves, in the character and amount of the pubescence which clothes them, and in the size of their flowers; and which thus considered is widely distributed through Japan and China.

The plant figured in this issue appears identical with one collected by Maximowicz, near Yokohama, during his second journey in Japan, his "forma minor et parviflora" of *Photinia villosa* (see "Mél. Biol.," ix., 176), the *Cratægus lævis* of Thunberg ("Fl. Jap.," 204).

This smooth form of this Photinia was sent to the Arboretum in 1878 by the late Monsieur Lavallé from his Arboretum at Segrez, under the name of *Pourthiæa arguta*, a very different plant, and a native of the warmer parts of the Himalaya. It forms a shrub here six or eight feet high, with slender graceful branches, covered with smooth pale gray bark. The leaves are ovate, usually contracted at the apex into long slender points, finely and sharply serrate, slightly hairy, especially along the midribs on the lower surface and on the short petioles, or often at maturity quite glabrous; they are thin and membranaceous, two and a half to three inches long, an inch and a half broad, and turn bright red in the autumn some time before falling. The white Hawthorn-like flowers are produced in few-flowered, long-stalked, slightly pubescent corymbs, the peduncles and pedicels being covered with lenticels, which are conspicuous on the inflorescence of all the forms of this plant. The flowers appear here about the 1st of June, and are followed late in the autumn by brilliant bright red oblong fruit half an inch, or rather more, in length. This is produced in considerable profusion, four or five fruits sometimes ripening from a single corymb of flowers.

As a garden-shrub the smooth Photinia is, perhaps, less desirable than the stouter pubescent plant, which was figured in the first volume of Garden and Forest. It appears to be of more southern origin, and the ends of the branches are sometimes killed back here in severe winters. The habit is less compact and handsome, and the foliage and flowers are smaller. It is more fruitful, however, and the fruit is more brilliant in color, as is the autumn foliage. Both plants are well worth cultivating, and should be much better known and more often seen in gardens than they are at present. *C. S. S.*

Foreign Correspondence.

London Letter.

Allamanda Williamsii.—Messrs. B. S. Williams & Son, of Holloway, exhibited a plant in flower under this name, at the last meeting of the Horticultural Society, where it received a first-class certificate. In its shrubby habit it is not unlike *A. neriifolia;* indeed, it is said to be a hybrid of this species and *A. Chelsoni*, though this appears to be merely a surmise. *A. cathartica*, as known to botanists, is a very available species, and it includes all those Allamandas known in gardens as *A. Chelsoni*, *A. Hendersoni*, *A. magnifica*, etc. It varies in habit as well as in the size of its flowers, and I think it probable that *A. Williamsii* is merely a form of that species. Compared, however, with garden Allamandas, it is a distinct gain. The stem and leaves are slightly tomentose, and the flowers, which are as large as those of *A. cathartica*, are slightly fragrant. The three well-known types of Allamanda in cultivation are *A. grandiflora*, a really beautiful stove-flowering plant, smaller in leaf and less rambling in habit than the second, namely, *A. cathartica* and its forms. The third is *A. neriifolia*, which is a compact shrub, about two feet high, with flowers two inches across. To these we may now add the purple-flowered *A. violacea*, reintroduced through Kew two years ago, and the new plant now under notice.

Delphinium Zalil.—Flowering examples of this interesting species were exhibited this week by Messrs. Kelway & Son. Owing to what must have been an oversight, the committee of the Royal Horticultural Society awarded it only a botanical certificate, whereas, in its exceptional color, yellow, and in its good garden qualities generally, it fully merited a floral award. We are indebted to Dr. Aitchison, of the Afghan Delimitation Commission, for the discovery and introduction of this plant. It flowered at Kew for the first time in 1889, and was figured in the *Botanical Magazine*, where it was described as forming a great portion of the rolling downs of Badghis, where, when in blossom, it gave a wondrous golden hue to the pastures. Its flowers are borne in erect spikes ten inches long, and they are bright yellow. In the Kew Bulletin for May, 1889, an account of the economic properties of the "Persian Zalil" was published, from which it appears that the flowers are collected largely for exportation for dyeing silk and as a medicine.

Portlandia grandiflora.—This is one of some eight species of Portlandia, all natives of the West Indies or Mexico, and all large-flowered shrubs or trees. The genus is related to the North American *Pinckneya pubens*, which, by the way, is growing nicely in a greenhouse at Kew, as well as in several other English gardens. The Portlandia under notice is now in flower at Kew. It is an erect shrub, one and a half feet high, branched near the top with lanceolate Laurel-like leaves and large, tubular, pure white flowers. In form and size the flowers are very similar to those of *Lilium longiflorum*. Although scarcely known in Europe yet, this Portlandia was introduced into cultivation here more than a century ago. It appears to be a favorite garden-shrub in some of the West Indian Islands. It is easily raised from seeds, and flowers when about five years old.

Lilium Grayi.—This pretty species is now nicely in flower for the first time at Kew. It is growing in a bed

of peat-soil, with *Azalea amœna* for its companion. We attribute the exceptional success with Liliums generally at Kew to this plan of planting them among low-growing shrubs, such as Rhododendrons, Kalmias, Andromedas, etc. *L. Grayi* has stems about eighteen inches high, whorled lanceolate leaves, and solitary nodding flowers, which are small for a Lily, being barely two inches long and almost campanulate. But what they lack in size is more than compensated for in color, the outside of the segments being crimson, while inside they are rich orange-red, thickly blotched and spotted with maroon. A figure of the plant has been prepared for the *Botanical Maga-*

Fig. 62.—Photinia villosa (smooth form).—See page 376.

zine. [It was figured in Garden and Forest, vol. i., p. 19. —Ed.]

Primula Poissoni.—I have already noticed the flowering of this new Chinese Primrose at Kew, and only mention it again for the purpose of drawing attention to its exceptional floriferousness. Unlike its ally, *P. Japonica*, the new one does not flower with a rush, but continues to push up spikes from lateral growths after the first central spike has passed. Thus at Kew plants of *P. Poissoni* have been in flower over two months, and are still gay with bloom. If this species only proves hardy it will be a most valuable plant for the rock-garden, and, even if unable to withstand our winters, it is, nevertheless, a first-rate plant for the conservatory. *P. imperialis* has the same flowering habit as *P. Japonica.*

Spiræa Bumalda, Knap Hill Variety.—This was exhibited recently by Mr. A. Waterer, the Woking nurseryman, and was awarded a first-class certificate by the Royal Horticultural Society. It differs from the type in having flowers of a pleasing shade of pink. Mr. Waterer says it is a most profuse flowering shrub, being covered with bloom just now in his nursery. The shrubby Spiræas do not receive the attention they deserve in England. It would be easy to name a dozen species which for habit and beauty of flowers would compare favorably with the very best of summer-flowering shrubs. Even in the poor sandy soil at Kew the Spiræas are beautiful shrubs, and in rich soils they are much finer still. No plants are more easily accommodated in the garden.

New Peas.—The annual trials of new vegetables and flowers conducted at Chiswick under the superintendence of Mr. F. Barron are of value as affording some indication of the merits of the new things in the market. The Peas selected this year as being of first-rate quality are: Duke of Albany, Telephone, Chelsonian, Tall Green Marrows (Veitch); Extra Dwarf (Carter & Co.); Critic, Essential, Epicure, The Echo (Eckford); Alderman, The Marquis (Laxton); Early Green Marrow, Empress of India (Sutton & Sons); Ameer (Harrison & Sons).

London. *W. Watson.*

Cultural Department.

Stray Notes from the Arnold Arboretum.—VII.

Shrubs which bear handsome and showy fruit in midsummer were briefly discussed in the last issue of these rambling notes. The subject is an interesting one to gardeners, and one full of promise to the student of the beautiful in plants. The list of shrubs which are noticeable at this time on this account is really a surprisingly long one, and every week new beauties are discovered in the shrub-garden, in which handsome fruit is to be seen from now until the first of next April. The most showy plant here now, so far as the fruit is concerned, is the Wayfaring-tree.

Why Wayfaring—

> What ancient claim
> Hast thou to that bright pleasant name?

William Howitt asked long ago in the Book of the Seasons, and no one appears to have found a satisfactory answer. But never mind the English name; the plant is a Viburnum (not a difficult name, certainly, to remember), and its second name, from its old anti-Linnæan appellation, is Lantana. It is a common road-side and wood-side shrub, or small tree, in Europe and western Asia, and has been an inhabitant of gardens as long as any shrub has been cultivated in modern Europe. It has rigid upright-growing branches, which form a mass of rather stiff outline. The flowers are small, creamy white, in dense cymes two or three inches across, and open here very early in the season before those of any other of the Viburnums, with the exception of our native Moose-wood (see Garden and Forest, vol. ii., p. 535). The flowers are not beautiful, although they make an interesting contrast with the developing leaves, which are covered, as are the shoots at that time of the year, with thick, white, mealy down, and which, late in the season, are large, sharply toothed, heart-shaped at the base, pale gray-green, and soft and downy. The fruit, which is dark blue-black when it ripens, passes, like that of a good many of the species of Viburnum, through a red stage, and just now is the very brightest shade of coral-red imaginable, one side of each fruit being often pale and orange-colored. A compact cluster of this brilliantly colored fruit several inches across terminates every branch of a well-grown shrub, for the Wayfaring-tree is exceedingly free with its flowers; and the fruit-clusters contrast well with the dark foliage and produce a beautiful and striking effect not surpassed in showiness by many shrubs when in flower. A good effect can be produced by placing this Viburnum near a *Cornus circinata*, a plant which has already been alluded to in these notes. The fruit of the Cornus, which at maturity is of a dull white color, ripens just at the time when that of the Wayfaring-tree is most brilliant, and if the two plants are side by side, the fruit of the one sets off that of the other; and the beauty of the light green foliage of Cornus appears all the more beautiful as it comes in contrast with the dull dark shades of the large leaves of the Viburnum. This is mentioned merely as an illustration of the fact that plants to be grouped, in a way to bring out all the beauty they are capable of giving us, must be known thoroughly, and that the planter or landscape-gardener, to deserve the name of artist, must study his plants in all their aspects—that is, from one year's end to another, and year after year, until he knows just what each is capable of in a given position and in what manner each must be placed to produce certain effects at certain seasons of the year. But such thoughts as these must not make us forget our Viburnum, which reminds us that another species, the Cranberry Bush, *Viburnum Opulus*, is very beautiful in midsummer, too. Late in the autumn the fruit of this plant, which it produces in abundance, is scarlet, remaining bright and comparatively fresh on the branches until early spring. Now it is a deep orange color, with one red cheek, and beautiful against the rich green foliage. Something of this plant was said in the first number of these notes, but its claims cannot, perhaps, be set forth too often, and it is well to call attention to its midsummer aspect. It is a great plant, but how rarely one sees it in gardens, and yet how few shrubs there are which can boast of beautiful flowers, fruit which is handsome during nine months of every year, vigor and good habit, and a constitution upon which cold, at least the cold of inhabitable regions, makes no impression.

Very handsome just now with its fruit-laden branches is a shrub of which we know very little in this country. This is the *Cotoneaster vulgaris* of Europe, a member of a large genus which has no representative in the flora of this country. It is an irregular-growing, rather sprawling, plant with rigid branches covered with dark reddish bark, small ovate leaves, rarely more than an inch long, coated on the under side, as are the young shoots, with dense white cottony down. The flowers are small, greenish white, and have no ornamental value or significance whatever. But they are followed by bright red apple-like fruit, which, individually, is not large, rarely more than a quarter of an inch across, but which is clustered along the whole length of the branches, which it covers from end to end, almost hiding the leaves, and making a great show. *C. vulgaris* is a very hardy and easily grown plant, but for some reason or other it appears to have escaped attention in this country; in its native land, which is all the colder parts of eastern, central and southern Europe, and central and Russian Asia, it usually, but not always, selects limestone soils; and it is so hardy and vigorous that it grows to the borders of the Arctic Circle and on mountain-sides to the very edge of glaciers.

The Cherry Plum, or Myrobalan, is a handsome object now. This is a small Plum-tree much cultivated in some European countries, with erect rigid branches, and conspicuous in spring from the fact that the flowers do not open until the leaves are about half-grown, an unusual thing among Plum-trees, and one which greatly increases the beauty of the Myrobalan at that season of the year. Indeed, it is one of the most charming of all fruit-trees in the spring, and it is the handsomest, too, of the Plum-trees in fruit, which ripens here earlier than that of the other species. The fruit is globular, or nearly so, and hangs on long slender stems; it is orange on some trees, bright yellow, with a red cheek on others, and as the branches grow upright it hangs down in such a manner that it is not hidden under the leaves, and so makes a conspicuous show in contrast with the foliage, which is dark and rich in color. The well-known purple-leaved Plum (*Prunus Pissardi*) is a variety of this tree, and is beautiful, too, at the flowering time from the contrast of the pure white flowers with the bright red color of the unfolding leaves. The fruit, however, although individually very handsome, is identical in color with the leaves, and therefore is not distinguished except on close examination. The curculio does not appear to

attack the fruit of the Myrobalan here, and the trees are very productive. In Europe the fruit is much esteemed, especially in cooking and for compôts and preserves.

There are other plants in the collection which are handsome this week from their showy fruit, and some which are interesting from their flowers, but the columns of GARDEN AND FOREST are not elastic, as the editor feels obliged to remind me once a week, and the time to bring these notes to a close has already elapsed.

Arnold Arboretum. *P. C.*

High Culture and Tenderness.

A WRITER in the *Weekly Tribune* says: "Mr. H. M. Greeley remarked of Osage-orange, 'Hardy under neglect; tender under high culture. This is true alike of all the fruit-trees and vines we cultivate.'" He then quotes the veteran pomologist, J. J. Thomas, as advising only a moderate growth—say, for an Apple, Pear or Cherry, not less than eight to twelve inches of new terminal growth, and not much more. Excess either way is a sign of impending decay.

All my early instructions in fruit-growing, received in Maine and Massachusetts, agreed with this formula; and when later, in Kentucky, I undertook to surround my garden-farm with an Osage-orange hedge I received the same caution. Later still, in northern Vermont, trying to establish an orchard where all the old settlers insisted that no tree-fruits other than the Siberian Crabs and the native red Plums would survive the hard winters, I tried, but in vain, by following this tradition, to succeed with the hardiest known varieties.

But when, after much discouraging failure, I got hold of the Russian Apples, behold a joyful change! Vermont's winters (with forty degrees below zero no unfrequent experience on Lake Memphremagog) had no power to harm them. In the beginning my land was not very rich; but as I kept on improving it our young orchards of Russian varieties persisted in far outgrowing these standard rules, and I feared the consequences threatened under them. For a while I cut back, though with a new growth yearly of three or four feet I hardly had the courage to retrench it to the extent of the rule. I tried summer pinching; but this resulted in a brushy growth of small branches, which would not do at all.

Seeing no evil resulting where the luxuriant new wood was suffered to remain, I abandoned the practice of cutting back, and limited my pruning to the removal of ill-placed shoots. I have continued this practice now for twenty years; and as I received from year to year various new Russian varieties I have followed it without variation, not only with Apples, but with the Plums, Cherries and Pears of the Budd-Gibb importations, and in every case where the variety has proved a true iron-clad, with unvarying success.

Frequently of late I have been honored by visits from eminent fruit-growers from different sections of the continent; but I need here perhaps only refer to the remarks upon the thrift of my orchards appearing in the notes of Mr. Van Deman in the last report of the Secretary of Agriculture. Some of these visitors have shaken their heads warningly at the free growth allowed, especially with the Russian Pears, one variety of which, Bessemianka, has never made less than three feet growth of its leading shoots, yet not one has suffered the loss of a bud from successive winters exceeding in severity any previous ones in my experience here.

Some of my expert visitors have assured me that I would never get any fruit on these Pear-trees unless I root-pruned them, or otherwise arrested their strong growth. But I had not found such a resort to be necessary with the Russian Apples, nearly all of which, nevertheless, proved early bearers. After six years of such vigorous existence, with a present height of twenty feet, several of my Bessemianka-trees (after blooming fruitlessly the two preceding years) are now carrying quite a respectable crop; and though the curculios, in this plumless year, have defaced the young fruit, I am in good hope that I shall eat my first Russian pear before winter.

Now, what is the lesson to be learned? I think it is that the dictum of moderate growth holds good mainly where the trees in question are not quite hardy. Where the growth of the shoots, however free, becomes early determinate by the maturity of all their buds, their luxuriance does not indicate a likelihood of "impending decay" in the orchard or in the forest. Take the Osage-orange, which in Texas is a large tree, as an illustration. In the Ohio Valley it is far from "iron-clad"—being often badly killed back in winter where its growth is vigorous. About Louisville I have never seen it become a tree of much size, even when grown singly. It is there much the same as with the slightly tender fruit-trees in our northern orchards. In the light of my experience I would never cut back, or restrain by economy of manure, the growth of any fruit or forest-tree that, so treated, survives the hardest winters entirely uninjured. And I am inclined to add, that I would never, or hardly ever, plant any other sorts—certainly not in the "cold north."

Newport, Vt. *T. H. Hoskins.*

Crowded Shrubberies.

CROWDED plantations and shrubberies are far too common, where private grounds are laid out and planted, either by landscape-gardeners or by nurserymen, or by both. What they have to study is, how best to create an immediate effect, at the same time arranging the trees and shrubs, deciduous and evergreen, so that the best of everything should ultimately be left in sole possession. The latter being distributed with due regard to their habit of growth, all intervening spaces are filled in with what may be termed supernumeraries as distinguished from those permanently planted. In many cases, or where carte blanche is given to the planters, comparatively thick planting is practiced, the shrubberies having a well-filled appearance at the outset, and the ground being trenched and otherwise well prepared, the growth of the majority of trees and shrubs is rapid. Before, however, the commoner and more vigorous occupants of these newly formed shrubberies overrun, impoverish, and literally spoil the choicer and more delicate subjects, the thinning out ought to commence, leaving only those originally intended to be permanent. In how many instances is this judicious thinning carried out? Chaos is the word that really describes the state of these neglected plantations. The more robust subjects do certainly manage to hold their own, but even these would have been far more handsome and valuable had they not been obliged to struggle for the supremacy.

There are two ways of getting over this difficulty of thinning out plantations and shrubberies: one, wholesale transplantation, entailing a considerable amount of labor, and often shirked accordingly; and the other the destruction of, in the shape of cutting down or rooting out, much that might well have been saved. If the thinning out was taken in hand before the trees and shrubs had overrun each other, those not required for their present position could be safely transplanted elsewhere, much other effective planting up being done largely with the aid of these thinnings. Forest-trees should be confined to the park or anywhere else well away from shrubbery, flower-garden and kitchen-garden.

Nor would I tolerate the presence of the heavy Scotch Firs and several others of the more dense Pines anywhere near dwelling-houses and shrubberies, where they soon overshadow everything else. Either isolate them or else cut them out. This rule may not be so strictly enforced in the case of various other conifers, but the majority of these even are out of place in mixed shrubberies, being far more effective well clear of everything else in a pinetum or on the turf. Whether only common Firs or choicer species of conifer are used, and whether planted in groups or in long belts, at the outskirts of parks, the same rule holds good as to the necessity for timely thinning out, all the trees being kept well clear of each other, and thus allowed to develop in a natural manner.

Forest-trees and conifers are not the only subjects requiring thinning out. Other strong-growing deciduous trees and shrubs should be restrained, for if allowed to extend as much as they will, the coarse, hungry-rooted kinds completely overrun the borders and monopolize more than their share of head-room. Many of them ought either to be transplanted elsewhere or rooted out, and the least that can be done is to cut them well back, so as to give more valuable shrubs all the room and daylight they require.

If fewer shrubs were planted in the first instance, far more pleasure would, in many instances, be derived from the shrubberies. In this case it would be possible and commendable to intersperse Hollyhocks, Foxgloves, Delphiniums, Sunflowers, masses of Sweet Peas, Lilies, perennial Asters, and many other flowering bulbous-rooted plants, perennials and annuals, among the shrubs, and there would then be something in the flowering line to admire, and, it may be, to cut from, all the year round.—*The Field* (London).

Raspberries in 1891.

THE first red Raspberry to ripen is Thompson's Early. It is a fairly good berry, but I get nothing of marked value from it. In size it about equals good wild berries or Marlboro when not grown in hills. Close after comes one of my own seedlings, a cross of Philadelphia and Cuthbert, a large dark red berry, growing like Philadelphia but much larger. It not

only bears early, but holds on late. The berry carries well, and promises to be valuable. Then comes Marlboro, a good berry if grown in hills or very thin rows and cultivated, but it easily runs wild. With Marlboro comes a second seedling, with stout canes, growing late; it has a large, round, bright scarlet berry. Like the first, this is from a batch of seedlings of Philadelphia and Cuthbert parentage. This berry carries finely, and is handsome. Turner and Philadelphia come quickly after these, and Turner is grand if grown very thin and highly cultivated. The chief trouble is it runs thick and wild and fruitless if it has a chance.

Hansell and Crimson Cluster are worthless with me. They bear a little in the fall, but it is not a crop to desire. They are practically weeds. Lost Rubies lingers about my vineyard, but is not a berry of value. Its real name is in doubt.

Franconia, among yellows, ripens with Turner, but is very soft, and decays quickly. Golden Queen is a fine berry, ripening immediately after Marlboro and before Cuthbert—that is, Golden Queen averages a few days ahead of its brother or its parent. I do not believe it is a sport of Cuthbert, but a seedling of it, such a chance as appears in our fields occasionally. It is a grand berry when there is a market for yellow sorts. But this must be borne in mind, that it neither carries as well as Cuthbert nor is it as good a keeper. I always pick mine at night for next morning's delivery, or, if possible, on the morning of delivery. Cuthbert is the standard for general market purposes, and a really ideal fruit. It will do well on the same ground for ten years or more. It is important that the old canes should be cut close when cut out in October; but it does not injure the Cuthbert to stand close in rows. Mine have for eight years grown in rows only four feet apart.

I prefer taller plants than those usually grown—that is, six feet in preference to four. To be sure, the main crop is high, but the advantages are that the ground is shaded, and in dry weather is kept moist. There is also much advantage to pickers, as a grown person can stand erect most of the time, and be fairly well shaded at that. I have experimented with still higher clipping, but have decided that six feet is about right. The canes are all tied to a wire running from post to post about four feet from the ground. The posts need not be closer than twenty-five feet. Tie four or five canes together below or above the wire—not to or around the wire. I cut out old canes, and tie new ones in October. The old canes may lie for mulch through winter. In the spring they are raked up and burned, and the rows are cultivated and hoed twice. After which plants are left until the crop is gathered.

Schaffer's Colossal is a marvelous fruit, with only one fault, that of color. If scarlet it would hardly be open to any criticism, but it is a purple. The canes always die back somewhat in winter, but the crop comes on most abundant and without fail. This variety yields five baskets to three of Cuthbert and two of Philadelphia. The Rochelle is also purple, and a fine cropper, but not large, and has rusted with me. This year it is excellent.

Of black Raspberries I place Palmer and Souhegan ahead on the hardy list, but Gregg would stand foremost if hardy. I have at least a dozen seedlings that are equals to the choice sorts, and I am in hopes to secure from them a hardy Gregg. Wherever a black Raspberry comes up it is allowed to grow until it shows its quality. Birds sow them very freely. Black Caps cannot be grown for profit unless in connection with an apparatus for drying.

Fig. 63.—Abies lasiocarpa and Tsuga Pattoniana on Mount Ranier, Washington.—See page 382.

The Water Garden.

Sagittaria Montevidensis.—The flowers of this variety are usually described as having a red blotch at the base of the petals, and probably this is the habitual coloring. It seems, however, that the flowers are variable, one of my seedlings producing flowers with no trace of red, but with a lemon-yellow shading at the base of the petals. This Arrowhead is the tallest member of the family, and is very useful where a tropical effect is desired in the water garden. The leaves are scarcely larger than those of a well-grown specimen of our native variety, but they are borne on tapering stalks some four or five feet high and some three inches in diameter at the base. The flowering scapes are also massive, and even longer than the leaf-stalks. The flowers, which are freely produced, are two

inches in diameter, pure white, blotched at the base, and quite fugacious. The female flowers are borne on the lower part of the scape and are larger than the male ones, which occupy the upper portion. *S. Montevidensis* was the first of the family to flower, possibly, however, because, being a tender species, it had been kept in warmth and had some start of the other varieties, whose tubers, though probably hardy, were wintered in a cool cellar. Plants of this variety are readily grown from seed, and they will flower the first season if sown early. It is necessary for their germination that the seed-pans be kept in strong heat, and soil slightly covered with water. Arrowheads usually make numerous tubers and increase rapidly.

Myriophyllum heterophyllum (Water Milfoil) is a plant usually grown in aquariums, but it proves very satisfactory and free-growing in the water garden. The leaves are very small, finely cut, and arranged in whorls on long creeping stalks. A mass of this plant is very attractive and distinct. It proves hardy in this locality.

Aponogeton distachyon.—The fragrant peculiar bracts of this plant have a certain attraction, and the plant is a good grower, but the brown tips of the anthers are unpleasantly suggestive of aphides, and aphides are one of the minor afflictions of water plants. Amateurs are not inclined to dwell much on the subject of drawbacks to the culture of favorite plants, but a full discussion of all such points is sometimes of more importance to a beginner than glowing accounts of perfect culture with drawbacks unnoticed. The aphides which affect aquatic plants are as black as the flies so well known to the Chrysanthemum grower. During the present abnormally dry season they have been unusually abundant. Fortunately, if looked to in time, they do very little injury. Various concoctions are recommended for their suppression, but the most simple and usually effective plan to get rid of them is to wash them into the water by spray from a hose or syringe, when the fish and frogs soon dispose of them. Fish and frogs are, of course, a necessity to the garden. Gold-fish may be classed among "reliably hardy" subjects; my stock was frozen solidly in the ice last winter and thawed out as lively as ever. Even in my small tank these fish multiply, and the small fry just now are very numerous.

Elizabeth, N. J. *J. N. Gerard.*

Orchid Notes.

Anguloa Ruckeri.—This South American species was introduced about 1845, and it is one of the best in the genus. The smooth, dark green pseudo-bulbs are oblong-ovate, from four to six inches high, bearing at the apex three or four plaited, pale green leaves of light texture, eighteen to twenty-four inches long by five or six inches broad at their widest part. The stout scapes, more than half the length of the leaves, proceed from the base of the previous year's pseudo-bulbs, and are well furnished with conspicuous green sheaths. Each scape carries a single flower, which bears some resemblance to a slightly compressed tulip, the longest diameter measuring two inches, the shortest half an inch less. The parts are all of thick, fleshy substance; sepals and petals oval, dull orange-yellow, with a profusion of crimson spots on the inner surface; lip trilobed, deep-crimson; column white, with occasional streaks of yellow and numerous rose-colored spots. The plant has a bold, striking aspect, and blooms regularly and freely in June and July, the flowers lasting several weeks. It thrives best at the cool end of an intermediate house, in a well-drained pot containing coarse peat-fibre which is covered with sphagnum. Repot early in spring, keeping the pseudo-bulbs an inch or two above the rim of the pot. This plant should never be allowed to become quite dry at the roots, and it requires a free supply of water during the season of growth.

Brassia verrucosa.—It has been said that the Brassias are not worth growing. This may be true of some of the species, but it is certainly too sweeping with *B. verrucosa* and its fine variety, *B. verrucosa grandiflora*, in view. The species is an elegant plant, introduced from Mexico in 1838. The compressed, ovate, channeled pseudo-bulbs are from two to three inches high, bearing two dark green, strap-shaped leaves, from nine to eighteen inches long, at the top, and two shorter ones at the base. The raceme, springing from the base, attains a length of two feet, and bears ten to twenty flowers, distichously arranged on the upper two-thirds of its length. Sepals about three inches long, tapering to a point, greenish white, with purplish spots; petals half the length of sepals, and of similar form and color; lip shorter than petals, spreading into a cordate tip, white, with numerous warty excrescences of greenish color. The plant is of free growth, flowering profusely in June and July. It should be grown in pots or pans in an intermediate temperature, using ample drainage with fibrous peat and sphagnum. It should be potted immediately after the flowering season, and watered copiously during growth, with a slightly restricted supply afterward. The variety resembles the species, but, as its name implies, has larger flowers, and is of a more vigorous character generally. Both plants will be found useful where it is difficult to command a high range of temperature, and, for Orchids, they require but a small amount of attention when once established.

Saccolabium curvifolium.—This is a charming little East Indian species, seldom exceeding nine inches in height. The pale green, two-ranked, linear leaves are about six inches long and beautifully arched. The flowers are borne in neatly arranged erect racemes, which equal the leaves in length; they are of a showy reddish color, with reddish purple column and short yellow spur. It usually blooms early in June, and the flowers are freely produced and retain their vivid hue for quite a long time. Altogether it is a fascinating little plant, and one which well deserves a place in every garden. It requires a high stove temperature and abundant moisture when in active growth, but a lower degree of heat and less water when at rest. A well-drained basket and a little peat, the whole covered with clean sphagnum, are the best materials for the roots. There is a variety of this plant, *S. curvifolium luteum*, which occasionally finds its way to those gardens in which Orchids are the most conspicuous feature. It is rarely offered for sale, however, and differs from the species in the attractive yellow color of the flowers.

Botanical Gardens, Cambridge, Mass. *M. Barker.*

Lindera sericea.—Many plants of the Laurel family are known for the strong odors which are intensified in their essential oils, and *Lindera sericea*, which is a member of this family, has this characteristic. The plant has long been known to the Japanese for its aromatic properties. The wood has been largely used for tooth-picks, which are known to preserve their odor for a long time. The plant is a deciduous shrub, chiefly found among the mountains south-east of Tokio, in the provinces of Idzu and Sagami. The bark, which is brownish black when old, is the most odorous part of the wood. The cheerful tender green of its leaves makes it worthy of cultivation in any garden, although the panicle of flowers, which is produced in early summer, is quite insignificant. When the plant is pruned the fragrance emitted can be observed at a considerable distance. Three kinds of essence have been prepared from this plant by a friend of mine, Mr. Takatori; they range in color from light orange to pale green, a diversity due to the varying purity of the oil. It has a spicy and burning taste, and an aromatic odor which, to me, resembles the oil of turpentine and cinnamon. No doubt, this oil would have a high commercial value for use in perfumery and in soap. It is already so used to some extent in Japan.

College of Agriculture, Komaba, Tokio, Japan. *H. Yoshida.*

[The letter from Professor Yoshida contained some leaves of the Lindera and a small fragment of Japanese paper which had been moistened with the oil. Notwithstanding its long journey, the odor from the paper was still pungent, and suggested the peculiar fragrance of our native Spice-bush, *Lindera Benzoin.*—Ed.]

The Forest.

Some Points in Practical Forestry.

In an interesting review, by Dr. Brandis, of Dr. Schlich's "Manual of Forestry," published in a recent number of *Nature*, attention is called to the fact that this book was prepared by the author primarily for the use of the students at the Cooper's Hill Forest School in England. That school was established seven years ago, in connection with the Royal Indian Engineering College, in order to give the needed professional training to young Englishmen who desired to enter the Indian Forest Department. When the first volume of this handbook appeared some persons, who took a deep interest in the progress of forestry in the British Indian Empire, were surprised that it did not deal with Indian trees, but that its teachings were illustrated by the Oak, the Beech, the Scotch Pine and other trees of Europe,

and the book was, therefore, pronounced by them a failure. But the principles of silviculture are the same everywhere, and the application of these principles to the treatment of different woods in different parts of the globe will lead to the adoption of similar methods; and, therefore, according to Dr. Brandis, the author of the manual was right in selecting the timber trees of Europe to illustrate these principles and the practice based upon them, because these trees are at hand for example, and because the systematic treatment of European forests is of long standing, and has endured the test of experience, while the methodical care of Indian forests is not more than thirty-five years old. As an interesting example of the way in which similar practices have developed in the rearing and tending of woods in Europe and in India we quote the following parallel from Dr. Brandis' review:

In a loop of the Main River, in Lower Franconia, east of Aschaffenburg, rises an extensive mountainous country, clothed with almost unbroken forest of singular beauty and of enormous value. It is the Spessart, in old times known as the home and haunt of great highway robbers, but also known from time immemorial as the home of the best Oak timber in Germany. The red sandstone of the Trias, which everywhere is the underlying rock in this extensive forest-country, makes a light sandy loam, which, where deep, is capable of producing tall, cylindrical, well-shaped stems. Having grown up, while young, in a densely crowded wood, the Oak here has cleared itself of side branches at an early age. Hence these clean straight stems which, in the case of Spruce, Silver Fir and other forest-trees, may justly be said to be the rule, but which the Oak does not produce, save under these and similarly favorable circumstances. The species here is *Quercus sessiliflora;* this species does not form pure forests, but is always found mixed with other trees, the Hornbeam, the Beech, and on the lower slopes of the western Schwarzwald, the Silver Fir. In the Spessart, the Beech is associated with the Oak in the same manner as the Bamboo is the chief associate of the Teak-tree in Burma.

The principles which guide the forester in the proper treatment of his woods are the same in India as in Europe. In the Teak-forests of Burma the Bamboo has a position similar to that of the Beech in the Oak-forests of the Spessart. Oak and Teak are both trees with comparatively light foliage. Pure woods of these species, while young, are sufficiently dense to shade the ground, whereas at an advanced age the wood gets thin, the canopy light, and the result is that grass and weeds appear, and that by the action of sun and wind the soil hardens and is less fertile than the loose porous soil, which is shaded by dense masses of foliage. Hence the advantage of associates, which, like the Beech in Europe and the Bamboo in Burma, shade the ground with their dense foliage, and enrich it by the abundant fall of their leaves. But it is not only the condition of the ground which is improved by these useful associates. Teak and Oak have this specialty also in common, that, when growing up alone, their stems, instead of running up into clean cylindrical boles, are apt to throw out side branches, which greatly impair the market value of the log. But when growing up in dense masses with their natural associates, these latter, crowding in as they do on all sides around the Oak in the Spessart and the Teak in Burma, prevent the development of side branches, and thus produce clean and regularly shaped stems.

In these and many other ways are the associates of the Teak and of the Oak useful friends, so to speak. Under certain circumstances, however, and at certain periods of their life, they are dangerous enemies to their more valuable companions. On the sandstone of the Spessart, and elsewhere, the Beech, as a rule, has a more vigorous growth than the Oak; it gets the upper hand, and, unless it is cut back or thinned out in time, the Oak, if both are growing up in an even mixture, has no chance. The Bamboo is even more formidable as an enemy of the young Teak-tree. Though the Teak may have had a long start, if a crop of Bamboos—either the shoots of old rhizomes, or, perhaps, the result of general seeding of the old Bamboo-forest, cleared away to make room for the Teak—springs up among it, the Teak is doomed. As soon as the rhizomes of the Bamboo have acquired sufficient strength they produce, within a few weeks, during the rains, such a profusion of full-sized shoots, say twenty to thirty feet high, that the young Teak-trees among them are throttled and extinguished.

The similarity in the relations of Teak and Bamboo in Burma, and of Oak and Beech in the Spessart, has led foresters in both countries to devise similar arrangements for the regeneration of these forests. In the Spessart, when the old timber in a compartment of the forest is cut, the best places for the growth of the Oak are selected, and the Oak, which here sells at the rate of from two shillings to three shillings a cubic foot for sound and well-shaped pieces, is sown on soil most suitable for its development; while the Beech, the timber of which only fetches about one-fifth of that amount, is allowed to reproduce naturally from self-sown seedlings over the rest of the area. Among the Oak also a certain but small proportion of Beech springs up, and even where pure Oak woods may be the result of these proceedings, it will not be difficult, when they are sufficiently advanced, to introduce such a proportion of Beech as will secure their satisfactory development. In the same way in Burma, selected areas are cleared for the growth of Teak in the original forest, the clearance being effected, and the Teak planted, with the aid of that rude mode of shifting cultivation, known as the Toungya system.

Correspondence.

Conifers on Mount Ranier.

To the Editor of Garden and Forest:

Sir,—I send you a view of a group of trees on the south side of Mount Ranier (see page 380). The tallest is a fine specimen of the Mountain Hemlock, *Tsuga Pattoniana*, and the trees which surround it are *Abies lasiocarpa* (*subalpina*). A few notes on this last, as it appears on Mount Ranier, may be interesting.

Abies lasiocarpa occurs on Mount Ranier at altitudes varying from 5,000 up to nearly 8,000 feet. At 5,000 feet it parts company with its two near relatives, *Abies nobilis* and *Abies amabilis;* and from this elevation up it is invariably accompanied by the Mountain Hemlock, and less frequently by the Nootka Cypress, *Chamæcyparis Nutkaensis*. At 6,000 feet *Abies lasiocarpa* is in all its glory; at 7,000 feet and over it spreads on the ground in great mats still accompanied by *Tsuga Pattoniana*, and occasionally by *Pinus albicaulis*. Only one conifer, the little alpine Juniper, grows at higher elevations than *A. lasiocarpa* on Mount Ranier.

The illustration represents a small grove at 6,000 feet altitude. These groves occupy only the drier ridges, and frequently are very symmetrical in outline. Nothing in the forests of Washington can equal them in beauty, and one never tires of admiring the vivid light green color of *Abies lasiocarpa*, which is made still more beautiful by contrast with the sombre hues of the Mountain Hemlock. The interior branches of these groves are literally festooned with lichens, and this, together with their pitchiness, renders these trees exceedingly inflammable.

Several Pine-groves on Mount Ranier have been destroyed by fire, and, to any lover of trees, their tall dead trunks make a mute, although forcible, appeal for greater care.

Seattle, Washington. *Charles V. Piper.*

[Our correspondent's discovery of *Abies nobilis* on Mount Ranier extends the northern range of this species, not known before north of the Columbia River, very considerably; and his observations show that on this mountain as large a number of coniferous trees of the north-west are aggregated as in any other one locality. Very possibly there is no other mountain on which the four north-western Firs—*A. amabilis*, *A. nobilis*, *A. lasiocarpa* and *A. grandis*—are growing.—Ed.]

The Destruction of California Wild Flowers.

To the Editor of Garden and Forest:

Sir,—The extensive floral decorations which are a general feature of private and public entertainments in San Francisco were formerly committed to florists. More recently professional decorators are employed, who draw as much as possible on the wild plants of the California forests and cañons, instead of buying garden-grown blossoms. Many of the great cañons and mountain-slopes, wooded with Oaks, Madrones, Pines and a great variety of smaller growth, are within a few hours' journey from San Francisco. The professional decorator can easily hire men for two dollars a day and car fare, who will bring back immense loads of Ferns, wild Violets, Rhododendron-branches, and whatever has happened to strike the fancy of the hour. Properly worked up, with perhaps a small ex-

penditure for cultivated flowers, this wealth of greenery and woodland bloom in the the hands of skillful decorators is very charming.

On the Oakland ferry-boat, a few days ago, I first noticed one of the sad results of the fashion for decorating with wild flowers. There were large baskets full of False Solomon's Seal (*Smilacina amplexicaulis*) that gives so much beauty to many a ravine of the Coast range. The plants had been uprooted in every instance. I began to investigate, and soon discovered that few, except coarse and common plants, are left in the cañons near the bay, and the Ferns have disappeared from places within three or four hours' travel. In many counties public sentiment is becoming ready for a law that shall adequately protect certain wild plants of California.

In the case of *Smilacina amplexicaulis* all that is needed to preserve it is reasonable care in cutting. Like the allied species, *S. sessifolia*, it grows from a hardy and stout root-stock. If this is undisturbed and a few leaves left, the plant will thrive for years and furnish large quantities of its graceful foliage. Among the Ferns that are disappearing from our cañons are *Adiantum emarginatum* and *A. pedatum*, *Pellæa andromedæfolia* and *P. Ornithopus*, and *Gymnogramme triangularis*. Even the Woodwardia (*W. radicans*), which was once so abundant, is in danger of extinction in many districts of the state. The coarse bracken Fern, *Pteris aquilina*, forms dense thickets acres in extent in the northern counties of Humboldt, Klamath and Siskiyou, and is a troublesome weed in garden and field. But no other Fern appears safe, and such delicate species as *Cheilanthes Californica*, the Aspleniums, and others that have always been rare, are threatened with extermination.

The careless ravages of picnic parties and tourists have disturbed thoughtful people, but it is only the showy annuals and such things as readily recover which are gathered by this class. Eschscholtzias and Larkspurs are nearly as numerous in the Marin County pastures this summer as they were twenty years ago. Berkeley cañons are still brilliant with flowers, and there are miles of rose-hued wild Currants along Strawberry Creek. But the Trilliums, that used to grow by thousands in shady places under the Oaks, are becoming scarce. All the finer bulbous-rooted plants are fast disappearing, not so much because a few careless young people wander into the woods, but because of the ravages of the hired men of the professional decorator.

Private ownership of land has not prevented the gathering of wild plants, because California is full of large ranches, and many of its wilder cañons—the sheltered haunts that the shy wild plants love best—are so unfit for cultivation that they remain unfenced and unprotected. Thousands of pounds of "green stuff," as the vandals call their spoils, may be gathered and carried off without hindrance. I know of perhaps half a dozen small cañons that are fenced and well guarded during the season, and in one or two cases there is even some replanting and wild-gardening done. For the most part the land-owners have not awakened to the situation. When they do, the native plants will receive, at least, as much care and protection as do the quail and other game. Signs like these will then perhaps be seen scattered along our ravines: "Use scissors on Ferns and other small plants"; "Do not break or trample"; "Leave some flowers of annuals for seed."

A story was recently told to me by a lady who had just returned from camping in the Yosemite Valley. A friendly guide, when asked about the Ferns of the region, answered that he would have to know her a long time before he would be willing to tell her about the kinds in the valley, and continued: "I know you don't mean any harm, but there was a young woman here from the Bay—a great botanist—and I told her of a Fern that only grew in two places, so far as I knew, in the whole region. Then she was wild to see it. I told her she might have some leaves to press in her brown-paper books, but warned her not to pull up any. 'Don't you s'pose I know better than to spoil your Fern-garden?' replied the college girl. So I showed her where the stuff grew—one place, where the most of it was, under some dry brush I had put there—and I made her promise again not to tell any one, and not to pull it up. I said to her, 'I guess there ain't but two clumps of it in the Yosemite, and my idea is it ought to stay here. It would be a kind of murder to drive it out.' Then she looked real pretty, and said she entirely agreed with me. It might be a new species, she remarked, and it might be named after me if I would let it be taken away, but then I was exactly right, and it belonged right here.

"Two or three weeks after that her camp broke up, and she went up the valley and dug up every root of the Fern that she could find. Fact. I saw her doing it. When I went down to camp to tell them good-by, that cussed little hypocrite sidled up and begged me to take good care of the Ferns—specially of that new kind! No, mum, I'll show you everything in the line of plants, from the Merced River to the top of El Capitan, except one little bunch of Fern—all that was left by that young woman from the Bay."

Niles, Cal. *Charles Howard Shinn.*

Recent Publications.

The Cauliflower. By A. A. Crozier. The Register Publishing Co., Ann Arbor, Michigan.

In most gardens of the United States the Cauliflower is considered an uncertain vegetable. This is due to the fact that American gardeners are not well acquainted with the methods of cultivation suited to our climate and with the best modern varieties of the plant; and yet such varieties can, as a rule, be grown with success wherever the soil and climate is particularly suited to the Cabbage. The fall crop is to be relied upon mainly here, for it will be waste of effort to grow Cauliflowers when they head in the heat of our summers, and, although the time may come when we can have Cauliflower and Broccoli here as they do in England the year round, as yet it is only under the most favorable circumstances that it pays to do much even with a spring crop of these plants.

Mr. Crozier has prepared a manual which he has endeavored to adapt to the different conditions found within the limits of the United States. He has laid down rules for cultivation, but he has explained how they must be adjusted to suit the different localities. The directions are minute, but, at the same time, the grower is cautioned against following them implicitly, and he is advised to make personal experiments after he has gained some general information, so that he can determine for himself the details of the cultural methods required by his soil and exposure. The book opens with a brief chapter on the Origin and History of the Cauliflower, and this is followed by a sketch of the Cauliflower industry both in Europe and the United States. Under the head of the "Management of the Crop" will be found the most important information for cultivators relating to soil, fertilizers, transplanting, cultivating, harvesting and marketing, and the chapter entitled "Cauliflower Regions" gives the records of experience from growers on the upper Atlantic coast, the lake region, the prairie region, the south, and on the Pacific coast, all of which will be found of special interest for each locality. The chapter on Varieties is very complete, and the sections devoted to the insect and fungal enemies of the plant contains the most recent information as to approved methods of fighting all these pests.

Altogether, Mr. Crozier has furnished an excellent handbook on the subject, and one which will prove of great help to any one who is beginning to cultivate the Cauliflower for market purposes, and Professor Goff, of the Wisconsin Experiment Station, is quoted as saying, "I incline to think that there is a fortune in store for the energetic young man who finds a favorable locality for growing this vegetable near any one of our large cities, and who will make a specialty of the work." It may be well to add a recapitulation of the points which are important in Cauliflower culture, according to Mr. Crozier: (1) The best localities for Cauliflower are those where the climate is cool and moist, as, for example, near some large body of water. (2) The Cauliflower will endure nearly as much dry weather as ordinary crops while growing, provided it has a cool, moist time in which to head. (3) The best soil is a sandy loam, though any cool, moist, fertile soil will answer. (4) While a moist soil is desirable, thorough drainage is essential. (5) An abundance of manure is necessary, as the Cauliflower is a gross feeder. (6) Frequent tillage is needed, that there may be no check in the growth of the plants until they are ready to head. (7) The leaves should be tied over the heads, as soon as they appear, to keep them blanched and protected from frost. (8) If any plants have failed to head on the approach of winter they should be removed to a shed or cellar and they will head there.

Notes.

According to the New York *Sun*, "Sod No. 14, in the Central Park grass-garden, has made the best growth of any of the sixteen varieties set out last spring. It is a close and fine variety of Rhode Island Bent-grass. A bit five inches square has developed into something like a square yard of thick velvety turf."

As is well known, the chief source of the vanilla of commerce is an orchidaceous plant, *Vanilla aromatica*. But a

substance identical in its qualities has been procured from other sources also, as from Beet-sugar, Asparagus, Asafœtida and the ashes of Olive-wood; and it is now stated in the *Illustrirte Gartenzeitung*, of Vienna, that the seeds of *Rosa canina* contain it in such large quantities that they will soon "rival the Vanilla-bean in the trade."

In the last number of *The American Florist* Mr. Edwin Lonsdale comments on the fact that there are so few clear yellow flowers among the new sorts of dwarf French Cannas, and so many which are spotted and freckled. Mr. Lonsdale truly remarks that the public taste favors self-colors, and he wisely counsels the raisers of new Cannas to turn their attention to the production of such varieties.

We have received from the American Economic Association Part Three of the sixth volume of their publications. This contains the papers by Mr. Gifford Pinchot, Mr. Edward A. Bowers, and Mr. B. E. Fernow, which were read last winter before the American Forestry Association. All three of these essays will be found to have great interest and value to every one who is giving any thought to the subject of Forestry in America.

We have observed that the hybrid Clematises are blooming with remarkable freedom in many places this year, and a photograph of a specimen of *Clematis Jackmanni*, on the grounds of Mr. Charles Mead, of Goshen, New York, has been sent to this office, which shows a remarkable plant. It spreads over a trellis more than twenty feet high and almost as wide, and seems literally covered with large and perfectly formed flowers.

To show the abundance of oranges in Paraguay, Mr. Theodore Childs, writing recently in *Harper's Magazine*, cites the case of a plantation owned by an Englishman where there are 20,000 Orange-trees, but for want of means of transportation the fruit has no market value. "Under the trees the oranges lie on the ground a foot deep, and the cattle eat them and fatten well." As the people have oranges in this abundance and a plenty of mandioca, too, "they need not work, and they will not work."

The published programme of the meeting of the Society of American Florists, to be held in Toronto next week, shows that the subjects to be discussed are of the highest practical interest. The different members of the Committee on Nomenclature, each of whom is giving attention to a particular flower, have been actively at work, and there is promise that much good will be done in the way of bringing about something like uniformity of names in the catalogues of garden-plants in commerce.

In an article on "American Roses," published in the *Illustrirte Gartenzeitung* for July, it is stated that "the possibility of growing Roses so that cut flowers may be had from them at all seasons of the year is the result of American methods of culture"; and that "thus far the Americans have, in all, produced thirty new Roses." These are then named and described at considerable length. The article concludes by saying that "as Waban is the last in our list of American Roses, so it will probably prove, with The Bride, to be the best of them all."

As to the connection between the density of timber and the rapidity of growth, Dr. Schlich, in his manual, states that in the case of broad-leaved species, which have the pores in the spring-portion of the wood, a large annual growth, indicated by wide rings, shows high quality; and narrow rings show low quality. It is probable that the same rule holds good for species which have the pores distributed uniformly over the ring. In conifers, however, the reverse is the case, broad rings representing inferior quality and narrow rings the opposite.

The *Gardeners' Chronicle* recently announced that a Rose with variegated leaves has been obtained from a branch of the Charles Lefebvre Rose, the foliage of which was richly marked with golden spots, and, when young, was of bronze color with a carmine tinge. In commenting upon this novelty a German journal says that it will "meet a deeply felt need"; but all true lovers of Roses and all those who have a keen sense of what constitutes beauty and harmony in a plant will continue, we think, to prefer Rose-trees with old-fashioned foliage of simple green.

A few shrubs which flower abundantly early in the season have the merit of producing blooms occasionally all summer long. There is hardly a day from early June until frost comes, for example, when a well-grown specimen of *Rhodotypus kerrioides* will not give a few sprays with a single flower at their extremities. The pure white blossom among the light green leaves is very attractive, and a half-dozen of these sprays will help to add lightness and grace to a vase of the highly colored flowers which usually prevail at this season. It is also a point in favor of *Rosa rugosa* that, even in this hot August weather, it is rarely altogether without bloom.

The twenty-third biennial session of the American Pomological Society will begin at the hall of the National Museum, in the city of Washington, on the 22d of September, at 10 A.M., and will continue for three days. The preliminary programme shows that more than the usual attention will be given to scientific pomology, while the commercial aspects of fruit-growing will by no means be neglected. Judging from the titles of the essays and the standing of the men who are to prepare them, it may be safely predicted that the meeting will be one of more than ordinary interest. The society offers no premiums, but there will be an exhibition, as usual, and the Wilder medals will be awarded to fruits of special merit.

It has been for many years a current newspaper item that one of our well-known weeds, the Mullein, is a common garden ornament in Europe, where it is called the American Velvet Plant. The same statement has been recently made in an article in one of our leading magazines; but the fact is, that our way-side Mullein grows as commonly by European way-sides as by our own, and any traveler can see it from the windows of his railway carriage without searching for it in gardens. Further than this, it is not an American plant at all, but one of those exotics which followed the white man across the sea, and has now become firmly established here. A reference to Gray's Manual will show that, although it is now a common weed, it is said to be naturalized from Europe.

An interesting feature of the methods by which Paris is so profusely supplied with flowers at all seasons of the year is the localization of their culture. Almost all the Azaleas come from Versailles; Neuilly is devoted to Lilies-of-the-Valley, Fontenay to Roses, and Fontenay-sous-bois to Parma Violets (which are also grown at Clamart and Verrières in large quantities) and to Cinerarias and Chinese Primroses. From Vitry-sur-Seine come chiefly Lilacs, and Roses from Jory, Bourg-la-Reine and Brie Comte Robert, while Montreuil, famous for its peaches, also produces Camellias, Gardenias, Narcissuses, Hyacinths, Hydrangeas and Cyclamens. Between 400 and 500 gardeners give themselves up to supplying the Paris trade, and at Vitry, in addition to twenty gardeners who cultivate Lilacs, there are ten who make a specialty of Orchids, fifteen who grow Ferns, and one who grows Orange-flowers only.

A report on the cultivation of Sisal Hemp in the United States, made by Mr. Charles Richard Dodge as special agent, has just been published under the authority of the Secretary of Agriculture. It has been proved beyond question that the Sisal Hemp-plant will grow in this country, for it was introduced into Florida more than fifty years ago, and it is now growing wild in many portions of that state. Much is to be learned, however, concerning the growth of the plant and the best means of extracting the fibre, and this report, which embodies a very thorough investigation regarding the industry in general, seems to be a timely one. More than 60,000 tons of this hemp, amounting in value to some $10,000,000, have been imported into this country during the last two years, and this does not include the imported articles manufactured from the hemp, which are considerable. The hemp is used in America largely for the manufacture of rope, binding-twine and similar cordage, and is regarded as one of the most valuable of the commercial fibres.

Mr. J. J. Thomas, in the *Country Gentleman*, remarks that the Baldwin, which once stood far above all other winter apples for marketing, has lately failed in western New York. It is not improbable that the trees of this variety may again bear abundantly, and yet, although successful apple-growers must depend in the main on a few varieties, every grower should have a knowledge of a more extended list. It is a good plan, therefore, to select a dozen or twenty kinds for a trial orchard, which in a few years will give its owner the information he wants. Mr. Thomas gives the following list of Apples which are easily procured of reliable nurserymen, and with which he thinks every one who grows apples should be acquainted: Baker, Belmont, Buckingham, Canada Reinette, Chenango Strawberry, Cogswell, Cole's Quince, Danver's Sweet, Dyer, Evening Party, Fanny, Grimes' Golden, Lawyer, McIntosh Red, Mother, Richard's Graft, Smokehouse, Shiawasse, Shockley, Sutton, Wealthy, and such common varieties as Peck's Pleasant, Jonathan, Lowell, Hubbardston and many others.

TABLE OF CONTENTS.

Architectural Fitness.

AMERICANS are gradually learning that fitness, appropriateness, is the foundation of all artistic excellence, and, though the lesson is not yet fully acquired, we are making visible progress toward the realization of this quality in our various classes of buildings. The improvement is perhaps most manifest in our country houses, which we design with a more intelligent regard for the requirements of site and environment than we did even ten years ago, and a truer sense of the fact that in such houses simplicity is a cardinal virtue. There has been a reaction against conventionality on the one hand, and against ostentation on the other, and it has been inspired by a new-born feeling for architectural fitness.

But in a reaction men are almost certain to go too far, and so it is not surprising to find that in trying for simplicity we sometimes fall into rudeness. This shows, of course, that we have not fully understood the meaning of fitness as an architectural term; we have remembered that a structure should harmonize with its surroundings, but have forgotten that it should also harmonize with the ideas of cultivated men and women who are the heirs of all the ages, living in a state of superior enlightenment, and inheriting the practical processes as well as the tastes of countless generations of skillful builders. Moreover, in thus trying to express part of the significance of the word fitness, we may miss true simplicity; for civilized, intelligent men can produce rude-looking structures only by an effort so deliberate and self-conscious that it lays them open to the charge of affectation.

We cannot object to an Adirondack camp or a fishing-lodge or a hill-side studio, be it ever so rough and rude. It is designed as a shelter in a semi-savage sort of existence, and may be as appropriate to the temporary needs and pursuits of its inhabitants as to the wild scenes amid which it stands. But when costly buildings in civilized neighborhoods are built for permanent use in imitation of the materials and methods naturally adopted for temporary homes in the wilderness, it may be questioned whether the interests of true simplicity, or of true appropriateness, are subserved.

The tendency to which we have referred finds many illustrations in the use of boulders, or roughly cut stones, in constructions which should wear a refined and dignified aspect, as well as a simple one. Undoubtedly, this practice has been largely inspired by the example of Richardson. An architect so original, strong and skillful as he could not fail to influence profoundly the general course of his art; and, as with every great master, this influence has been partly for good, partly for evil. Few other buildings in this country, and certainly no other small building, have excited so much attention, been so often described, pictured and discussed as the gardener's lodge which he built, of huge rough boulders, in the village of North Easton, near Boston. It is, indeed, a picturesque and interesting piece of work, but it has certainly been imitated in ways which Richardson never anticipated, and he would have been distressed by a sight of some of the progeny it has engendered.

In certain places and for certain purposes the use of boulders, whether large or small, is not only allowable, but praiseworthy. It is both sensible and appropriate to use them, for example, in the foundations or the basement of a country house on land where they abound and can be had at little cost and trouble. But even in such spots as this it is seldom desirable that whole houses should be built of them, for we do not want an American country home to wear the aspect at once rude, unrefined and ponderous, which their sole employment gives.

In other parts of New England one may wisely use, instead of boulders and for a similar purpose, stones roughly split from neighboring granite-ledges; but, again, and for the same reasons, it is seldom wise thus to construct a whole house. We want simplicity and we want solidity, but we do not want coarseness or the affectation of simplicity. A house with an interior such as every American demands, made comfortable by a hundred ingenious devices and beautiful by the skilled work of a score of different artisans, should have an exterior of consonant expression; and rough-hewn stones or roughly cemented boulders cannot give this expression.

But it is not only in private country homes that our methods of using stone are frequently erroneous. Country churches and public buildings, and even the most ambitious city structures, are often open to criticism in this respect. Even in urban parks the effort to adapt the architectural work to rural surroundings may be a departure from genuine simplicity. A park is one of the most complicated and refined of the artistic creations of mankind; and its beauty and unity may be impaired if any feature of man's creating does not show the same kind and degree of skill and refinement as the others that surround it. A park must depend for the most part upon nature for its charm, but it must also conspicuously depend upon art; and it is trite to say that when art is set to work its activity should be frankly and clearly confessed. No matter how rural in character a park may be, or how pure and undisturbed the sylvan charm of some of its remoter parts, there is no place where the work of man ought to be done with greater skill, more perfect finish, or (using the term in its best sense) a franker artificiality. Almost all such work is done in this manner in all our parks. Their driveways are not constructed like country roads of even the better sort; their lawns are not left like fields to a growth of untended grass; nor are their shrubberies allowed to grow in the wild luxuriance so beautiful beside a rural highway. When the engineer and the horticulturist are thus showing the highest level to which modern science and art have attained, the architect should work in a spirit similar to theirs. Structures which look rough, casual, almost barbaric and affectedly simple are not appropriate in a carefully tended pleasure-ground,

planted with exotic trees and flowers and bisected by scientifically built and neatly curbed roads, even though we may know that as much thought and as much pains, of a certain kind, have been expended on their construction as though the outcome were more clearly artistic and refined.

The Central Park was laid out before the modern taste for boulders and rough-hewn stones had developed, and in it one may well study the method of treating architectural features in such a place. Here and there, in quiet corners and shady nooks, we find rough little flights of steps and rustic summer-houses of unhewn wood; but in all conspicuous places, and for all important constructions, work of a more polished and elegant sort is employed. But in the new Franklin Park at Boston, for example, there are structures in the most conspicuous situations which would seem more appropriate in a woody glen a hundred miles from any town. A drinking-fountain, carefully built of jagged stones so that it looks as if carelessly thrown together for a temporary purpose, may have a beauty of its own, but whether it is fitly placed beside the principal building, and near the principal driveway of an urban park, is open to question. Steps of rude slabs, scarcely revealing the use of the chisel, hardly seem appropriate in contact with the accurately shaped and smoothed curbing of this drive. In building the gateways at the principal entrance to this beautiful pleasure-ground it seems to have been the artist's purpose to make them inconspicuous, and thus disturb as little as possible the rural effect of the outlook over the distant country. But the existence of gateways, and their eminently artificial character, cannot really be disguised; and to build them wholly of small boulders sacrifices beauty and appropriateness to an unattainable end. A comparison of these gateways with those recently erected at one of the southern entrances to Prospect Park, in Brooklyn, would prove, we think, that the more confessedly artistic a work of art is made the better is its effect in such a situation. And at Prospect Park the low marble seats, small classic-looking shelters and graceful piers, interfere no more with the prospect than the rugged-looking seats and shelters at Franklin Park.

Of still more doubtful propriety is the use of unhewn stones in the construction of bridges. It seems contrary to the primary canons of art that an arch should have voussoirs of irregular shape and different lengths, so that, instead of seeming strong and homogeneous, they appear to be sliding past one another. Yet many rustic bridges have been erected in this fashion. How Richardson thought a bridge in a park ought to be built is shown by the one over which Boylston Street crosses the Fens in Boston. It is entirely devoid of ornament, perfectly simple; but with its wide, graceful, yet vigorous sweep, its beautifully modeled buttresses and coping, and the carefully finished surface of its stones, it is as true and refined and as noteworthy a work of art as any of the more elaborate things he ever built. Not far away now stands another bridge of three arches, built in the prevalent "natural" manner. In general design it is very good, and were its fabric as architectural and its finish as perfect as those of Richardson's bridge, the two would form a most happy contrast. But it looks weak despite its actual solidity, and careless despite the careful study unquestionably bestowed upon it, while its curtain of vines is not, we think, a fortunate substitute for an architectural balustrade in a work of art designed for a place which will soon be in the heart of a great city. In structures such as these we seem to be trying to go back to the infancy of art, but such efforts can hardly result in true simplicity or true appropriateness to modern tastes, conditions and abilities.

We invite attention to a letter from Mr. Charles Eliot in another column of this paper. Referring to Mr. Baxter's project for a Massachusetts forest, Mr. Eliot suggests the creation of a general Board of Commissioners who can act for all the cities and towns which are comprised in Greater Boston. It is generally admitted that, as this large and populous district becomes still more densely inhabited, there will be need for many more open spaces for recreation-grounds and breathing-places. As the case now stands, each of the municipalities can select grounds within its own limits, but where this is done the action must necessarily be controlled by purely local considerations. In many cases the most favorable grounds to be selected would extend across one or more of these town or city boundaries, and unless something like united action can be secured on a plan which embraces within its scope the entire area in question, there is little hope that a sufficient number of plots will be reserved, or that these plots will be the best ones for the purpose they are intended to fulfill.

It is very plain that co-operation is an absolute necessity in a case like this. This principle is one with which our people should become familiarized, for it is capable of a much wider application. Wherever forests need to be reserved at the sources of rivers the importance of co-operation by different states is apparent. Such rivers as the Connecticut, the Merrimac and the Ohio, whose head-waters are in the highlands of different states, can never be adequately protected unless all these states unite upon some general plan of forest-preservation. The board suggested by Mr. Eliot might therefore prove of value not only immediately to the eastern part of Massachusetts, but it might set an example which could be followed to advantage on a much more comprehensive scale throughout the country.

The Seeding of the Bamboo.

The hardier species of Bamboo are becoming deservedly more popular year by year for the adornment of English pleasure-grounds. One thing, however, seems not unlikely to be lost sight of, namely, the fact that the culms of the Bamboo flower but once, the plant perishing immediately after the ripening of the seed. After flowering and seeding, when the plants have reached the climax of their grace and beauty, no art of the gardener can stay their death. It would be, I imagine, almost impossible to determine the age at which these hardy Bamboos will produce flowers when grown in this country; most probably the term of years will differ with the various species.

With regard to the great Bamboo of tropical India, *Bambusa arundinacea*, it is a well-ascertained fact, that the coming to maturity of this gigantic Grass only occurs after a growth of some fifty years' duration; and the phenomenon of its flowering, seeding and subsequent death in India and other climes—where it covers with its huge and picturesque clumps many square miles of country—is an extraordinary spectacle which can have been seen but by few Englishmen of the present generation.

It is unnecessary to give any lengthy description of the plant; suffice it to say, that in the locality in India where I had the rare fortune of witnessing the flowering and seeding of this gigantic Grass on a large scale, the culms frequently attain a height of from sixty to seventy feet, and a diameter at their thickest part of from eight to ten inches. These culms are furnished with lateral branches, throughout their whole length adorned with a profusion of light green leaves. The plant is deciduous, shedding its leaves in India during the dry season, and renewing them on the approach of the spring showers. The clumps present the apppearance of colossal plumes of feathers, and when seen in full leaf are beautiful beyond description.

The soil of the tract of country the Bamboo affects in south India is mostly shallow, with a gritty, ferruginous subsoil, and it is not found where the rainfall is excessive. When the clumps are in full vigor, the culms are produced of the above dimensions with amazing rapidity.

It was during the years 1863–1864, while engaged in Coffee-planting in the district of Wynaad, in the province of Malabar, that I witnessed the phenomenon of the seeding of *Bambusa arundinacea*. The plantation I had charge of at the time was situated in the midst of an extensive Bamboo jungle within but a short distance of the frontier of Mysore, and on the main road from the Malabar coast to Seringapatam and Bangalore. At the time of my arrival in the district, the magnificent Bam-

boo-forest, interspersed with such deciduous hard-wooded trees as Teak, Kino, Rose and Sandal-woods, and others of an equally valuable description, was, although unknown to me at the time, upon the eve of a sudden and wonderful transformation. Hundreds of square miles thickly covered with the exquisitely graceful clumps of the Bamboo, giving to the landscape as far as the eye could reach a beauty difficult to describe, were to be changed by fire in the brief period of a little over a year into a charred and blackened wilderness. The myriads of nodding plumes that for half a century had graced the woodlands were, at the call of Nature, to blossom, yield their seed, and disappear from the face of the earth as by the breath of a destroying angel.

The south-west monsoon rains of 1863 had ceased about the middle of September, and left the jungle tracts of Malabar in the very heyday of their glorious greenery. The Bamboo-plumes waved to and fro by the gentle breezes which still prevailed from the westward and glistened in the light of a tropical sun, as yet showing no trace of the change they were so soon to undergo. As the season advanced, hot parching winds from the east began to take the place of the more kindly breezes from the west, and by Christmas the leaves of the Bamboo thickly covered the ground. Simultaneously with the disappearance of the leaves from the laterals, the inflorescence began to appear, and the aspect of the country in every direction changed as if by magic. No one was prepared for such an eventuality, and the English planters in the district were struck with something akin to alarm when the fact dawned upon them that, in the course of a very brief period, not a living Bamboo would be left in the forest. A few there were who refused to believe that the culms would perish after ripening their seeds, and were only persuaded by the actual realization of the fact. As nearly as I can remember, the seed was matured by the middle of May, the panicles of grain weighing down the culms to a third of their length, and giving them withal a graceful as well as fruitful appearace. When the seed, which was about the size and had much the appearance of small oats, had fully matured, it fell to the ground in showers by every passing breeze, and then came a happy season for both man and bird. Sea-fowl, spur-fowl, partridge, jungle-fowl and quail, with which the jungles abounded, reveled in and fattened upon the plentiful supply of good food so suddenly bestowed upon them by the hand of Nature, and man himself was not slow to take advantage of the offering. The coolies from Mysore employed on the Coffee-plantations could with difficulty be induced to remain steadily at work during this Bamboo harvest, and the jungle tribes could not be persuaded to work at all, but subsisted solely on the fallen grain of the Bamboo so long as any could be gathered from the ground. This seed they appeared to highly value, and it seemed to be very nutritious. The grain was ground into meal by the aid of small hand-mills, and baked in the form of cakes, or boiled into a thick porridge. I myself ate the cakes on several occasions, and found them fairly palatable. These jungle tribes, although perfectly aware of the value of the vast granary thus laid at their feet, were, notwithstanding, improvident to a degree. They ate abundantly of the fruit while it lay on the ground, but made no provision against the approaching destruction of the whole by jungle-fires. So, after these had licked the ground, they had, perforce, to return to work on the Coffee-plantations. At the height of the dry season, and when the earth was thickly covered with a coating of Bamboo-leaves and seed, these fires began to do their work, and apparently so completely, that it was hard to believe that a single Bamboo-seed could have escaped destruction, and that in the course of a decade or so, another such magnificent Bamboo-forest could be produced. But Nature in some mysterious way was equal to the occasion, and before I left India, in 1877, the Bamboo zone of Malabar and Mysore was clothed with another jungle, consisting of clumps approaching in size and grandeur those that perished in 1863.

From the date of the seeding of the Bamboo the clumps stood throughout the following monsoon leafless and dead, but intact; it was not till nearly a year after that their complete destruction by fire began. When the dead and sapless clumps caught light the whole country was filled with flame and smoke for weeks together; loud reports were heard night and day without intermission, resulting from the pent-up gases within the hollow culms, and the whole Bamboo zone, so picturesque and beautiful but a twelvemonth before, was quickly reduced to a scene of desolation. The total destruction of the clumps, however, was not accomplished in one season, many escaping the fires till the second, and some till the third.

The young seedlings soon began to appear, but made slow progress for several years. As time went on the annual growth of culms waxed stouter and stouter, till at last a thick undergrowth of low Bamboo tufts covered the ground, which, in the fullness of time, began to send up gigantic canes, till the forest was restored to its former strength and beauty.

With reference to the period of time required for the maturation of *Bambusa arundinacea*, I was at some little trouble, while in India, to ascertain from the native tribes inhabiting the jungles of the district the approximate duration of its existence, and was told by several men, apparently about sixty years of age, living widely apart, that they remembered a similar phenomenon of the seeding of the whole of the Bamboos of the district when they were boys. From this I concluded that about fifty years was the limit to the life of this giant species of Bambusa.

About three months before the flowering of the Bamboo I had occasion to clear some thirty or forty acres of land for the purpose of Coffee-planting, the culms of the Bamboo being cut close to the ground. I waited patiently, curious to know the result of such an operation. When the monsoon rains began the huge stools left in the ground began at once to send up numerous small culms of from eight to ten feet in height, and furnished with laterals. On the cessation of the rains these immediately flowered and seeded, after which the old stools perished absolutely, so that the act of cutting down the original culms had only the effect of delaying, not frustrating, Nature in her efforts at reproduction.—*J. Lowrie, in the Gardeners' Chronicle.*

How We Renewed an Old Place.

XVI.—THE BLESSING OF THE RAIN.

A KINDLY critic has remonstrated with me for setting flowering plants around the trees, as contrary to good rules. I freely admit the fact, but in extenuation of the fault would urge that for the first year or two the bare polls of the trees, cut in till they were not much better than scrubbing-brushes, were so ugly that I wanted to distract people's attention from them. Moreover, the Geraniums and Heliotropes and Nasturtiums were handy for watering and plucking, facts worthy of consideration in a region of dry, hot summers, so that I was tempted, like my mother Eve before me, into willful sin.

Unlike the fault of our first parents, however, my fall from grace is not permanent. The trees have taken it upon themselves to correct the error in taste by taking all the nutriment away from the flowers and by spreading out their branches until the beds are too shaded to furnish blossoms. This summer the cold June has added to their other discomforts, and the day of flower-beds in the neighborhood of the trees is ended. Should these last do their duty this year as they promise, they will be far enough along for us to permit the grass to grow close up to their trunks, which will greatly improve the beauty of the lawn, and the natural look of the trees themselves, which began to make their best growth about the first of July, after they had reaped the full benefit of the heavy rains of later June and were rid of the rose-bugs.

Refreshing, indeed, was the long storm that succeeded the burning days, and it was a joy to see the thirsty grass and plants drinking in life with every drop. I am convinced that the true way to render yourself indifferent to inclement weather in the country is to plant trees. No rain can ever hurt them, and, when they are freshly set out, each shower is a satisfaction to their owner, for it seems as if they could be seen to grow under its kindly influence, and thus a day or week of hard rain, instead of a weariness, becomes a positive delight. I am not sure that this would bring compensation to the young for having to forego their active pleasures, but the more I become interested in gardening the more I am convinced that it is the appropriate pleasure for middle life and old age.

Youth hates to wait for anything, and wishes to realize its dreams so soon as they are conceived; but as we advance in years we take a sober satisfaction in waiting a little for our pleasures, and also we like something that can recur, and that is interminable. Most other delights once experienced are exhausted, but gardening grows by what it feeds on. It is the same, and yet never the same; it can be forever renewed; it can be indefinitely extended; it is within the reach of all dwellers in the country, where home amusements are most needed. It can be compassed by the slenderest purse, and it will give a man a chance to spend a fortune if he so desire. It has its agreeable economies, and its fascinating extravagances. It can be made to satisfy the most orderly dispositions, and also return beauty and grace from careless and wild

arrangements. It can be utilitarian and lucrative, it can be merely æsthetic and ornamental, or all four, just as the fancy takes you. In fact, it may be briefly characterized as Happiness for the million with no patent on it.

Added to all these charms is its wholesomeness, its absorbing character, and, best of all, a certain humanness about the occupation that brings one into pleasant relations with all sorts of people, and affords one a topic of conversation and a meeting-ground, even where he is limited to the most unpromising companions. The village crone forgets her gossip when you talk to her about her Rose-bushes or her last new Geranium slip; the rustic waxes eloquent over the merits of a new potato or a way of protecting melons, and you find yourself always interested and instructed, instead of bored, since almost any one you meet in the country can tell you something you are glad to know, or else he is eager to learn what you are doing yourself, which is a sure way to afford you entertainment, since every man is happy when allowed to ride his own hobby. All of which has a connection with rain, however little obvious it may be, since the moral of my discourse is, that when one becomes, not only resigned to rain but glad of it, he has taken a step toward true philosophy.

A garden after a shower has always an especial charm; everything is sweeter and fresher, even in its often bedraggled condition. I have a passion for dabbling in water-coloring of this description, and cannot keep my hands from the weeds and flowers when I venture forth to see how my favorites have borne the storm. It is a delight to put one's arms about a bouncing pæony, with its red cheeks all cold and dripping, and tie a string around it to keep its bright faces clean. The forward flowers kiss you as you struggle to encircle them; the wet leaves box your ears as if you were taking a liberty. It is some time before you can accomplish your purpose, and you arise from the encounter quite breathless and dripping, with the pink and white faces, huddled up together, all laughing at your condition.

It is June, and the last of the Fleur-de-lis are quite broken down, their pearly petals draggled in mud and defaced by water. This delicate French beauty will put up with no plebeian contact, but withers and dies if brought in contact with the earth. The Roses stand up, after their bath, quite fresh and shining, but the buds, which are so blighted by a heavy rain that they do not open afterward, remind me of the Austrian violinist who greatly admired an English beauty, but confided to a friend his reason for not offering to marry her:

"She vould *vash* me, and I should die."

Many things are broken down and require tying up. If the rain has continued for several days the chickweeds are rampant and overrun everything. New plants that have been on the anxious seat during the dry weather have decided to stay, and are putting forth satisfactory leaves.

The joyful Pear-trees shake their drops down upon you, the cat-bird sits on the grape trellis and inquires what you are doing there. It is a way he has. He lives in the box arbor and thinks he owns the earth, and that our strawberries are his. He scolds the cat and defies the robin, and has such a trig, gentlemanly air about him, with his well-brushed dark coat, that one might christen him Sir Charles Grandison. He makes me a bow and says civil things (or uncivil) in his own tougue, which, unfortunately, I do not understand.

"I thought you told me this parrot could talk?"

"So he can—ze parrot lankwich—you don't expect all ze lankwiches for ten tollar, do you?"

Thus our cat-bird, which costs us nothing but strawberries, discourses in a jargon which we would fain comprehend, so as to answer him according to his deserts; and sometimes of a Sunday morning he sings us a glorious tune.

When the rain comes, Apollo, the parrot, climbs to the top of the tree in which he is perched and spreads all his bright feathers to catch the shower. Elongating his wings, he makes them meet over his brow in the very altitude of the cherubim, and there, turning a somersault, he hangs head downward, that the water may thoroughly drench his plumage. With all his gold and red and green glittering with rain-drops, he resembles some superb blossom quivering on a stem, and makes a beautiful spectacle of himself. When his bath is done he chatters and laughs with glee, and sings his merriest song, with some disregard of rhythm and tune, but none of harmony, till all the smaller birds begin to pipe in company.

The dusty foliage emerges brilliantly shining and fresh. Every shower seems to bring a new spring, and the world never fails to be surprised at the renovation which succeeds the rain. There seem, indeed, to be new heavens and a new earth. The drooping evergreens lift up their tasseled heads and take courage; to them it means life and new hope. The vines throw out their tendrils, and the Honeysuckle emits a keener perfume. The white Lilies that come to rejoice us just as the Roses are going, gleam in the twilight, tall and fair. Who is it that says that it is a figure of the poets to mingle Roses and Lilies, since they do not blossom at the same time? With us the Irises and the white Flower de Luce linger till after the Roses are in bloom, and then, before the Queen is wholly out of sight, come these stately princesses, her followers, like train-bearers of high degree, all clad in white and gold, nearest the throne, if not rivals for the highest place of all. Is it the thorns that make the Rose the royal flower by rendering her difficult of access and surrounding her with a body-guard of lances? Who shall say? There are moods in which her sumptuous beauty and heavy fragrance seem less regal than the haughty, willowy grace of her rival flower, and we hesitate to choose.

And not the flowers alone rejoice in the life-giving drops, but the "sweet smale grass," refreshed and strengthened, lifts its green blades like the spear-heads of a rising army. The dusty mantle that has veiled its gentle beauty falls from it, and the wonderful variation of its tints again delights the eye. Those artists who set our teeth on edge with verdigris and arsenic floods, to represent this dearest and homeliest garment of our mother earth, seem to me never to have entered into and possessed its secret, the secret of myriad shadows, of myriad lights, each catching a reflection from its neighbor blade, the brown earth below, the azure sky above. No greenest green of foliage or meadow ever shocks the most sensitive vision, for Nature, truest of painters, never fails to break her colors with such subtle mixtures that only the utmost training of eye and hand enables the artist to hint her secret upon canvas; and he who, with a palette of crude pigments of raw primary colors, seeks to render the shifting emerald of spring, the topaz of the new-mown field, or the golden harvest, is as one who would catch the flash of the diamond or the burning heart of the ruby on the brush's point and think to imprison it forever.

There are some lines of Matthew Arnold that a wet garden always brings to mind, in which the poet has truly caught the spirit of the fragrant scene. None but a frequenter and true lover of gardens could in a few words have thus pictured the mingled dismay and hope with which one views his garden-plot after a rain has both distressed and refreshed it:

So, some tempestuous morn in early June,
When the year's primal burst of bloom is o'er,
Before the roses and the longest day—
When garden-walks, and all the grassy floor
With blossoms, red and white, of fallen May,
And Chestnut-flowers are strewn—
So have I heard the cuckoo's parting cry,
From the wet field through the vext garden trees
Come, with the volleying rain and tossing breeze;
The bloom is gone, and with the bloom go I!

Too quick despairer, wherefore wilt thou go?
Soon will the high Midsummer pomps come on,
Soon will the musk carnations break and swell,
Soon shall we have gold-dusted snapdragon,
Sweet-william with his homely cottage smell,
And stocks in fragrant blow;
Roses that down the alleys shine afar,
And open, jasmine-muffled lattices,
And groups under the dreaming garden trees,
And the full moon, and the white evening star.

Hingham, Mass. *M. C. Robbins.*

New or Little-known Plants.

New Orchids.

Ada Lehmanni, Rolfe.—A new species of Ada, originally introduced from New Granada by Mr. F. C. Lehmann, German Consul to the Republic of Columbia, after whom it is named. It has been in cultivation for some time. It is readily distinguishable from the well-known *A. aurantiaca* by its more rigid habit, shorter, broader and darker green leaves, which are mottled with gray, and by its white lip. It usually flowers during the summer, while the old species is well known as a winter-flowering plant.—*Gardeners' Chronicle*, July 11th, p. 34.

Catasetum atratum, Lindl., ♂ and ♀.—The female only of this species can claim to be a new garden Orchid, as the male has been known for many years. A very interesting case of the production of flowers of both sexes on the same raceme has occurred in the nursery of Mr. W. Brooks, of Weston-super-Mare. The two sexes are less dissimilar than usual, except in the column and ovary, which present the usual dif-

ferences. The sepals and petals are light green, with numerous blackish spots. Although borne on the same raceme, the females expanded several days in advance of the males, thus pointing to earlier development in this sex.—*Gardeners' Chronicle*, July 11th, p. 36.

Cirrhopetalum Thonarsii, Lindl.—Although described nearly seventy years ago, and the original species of the genus, this rare Mauritian plant has only recently appeared in cultivation, for it is now evident that the Philippine plant which Lindley thought identical, and which has borne the name in gardens for so many years, is a different species. Plants were sent to Kew by C. W. Bewsher, Esq., of the Oriental Bank, Mauritius, together with other native Orchids. One plant which has now bloomed has light yellow flowers, without any spots. A second plant, believed to be spotted with red, has not yet flowered.—*Gardeners' Chronicle*, July 18th, p. 69.

Cycnoches chlorochilon, Klotzsch, ♂ and ♀.—As in a previous case, it is the female flower which is new to gardens, the other sex having long been known. A female flower has appeared in the collection of Monsieur Houzeau de Lehaie, member of the Chamber of Representatives, of Hyon, near Mons, Belgium. It is larger and more fleshy than the male, with broader sepals and petals, and the crest of the lip much more obtuse. The ovary is also more than twice as thick and more strongly grooved, and the column scarcely half as long, at least four times as thick, without pollinia, but with a pair of large fleshy wings on either side of the well-developed stigma. The color is identical in the two sexes, which are thus far less dissimilar than in most other species of this singular genus.—*Gardeners' Chronicle*, July 18th, p. 69.

Odontoglossum Bergmani, L. Lind.—A handsome Odontoglossum in the way of *O. luteopurpureum*, but with chocolate spots on a white ground. It was awarded a first-class certificate of merit at a meeting of the Orchidéene, of Brussels, on April 12th last, when it was exhibited by Monsieur Bergman. It is suggested that it may be a variety of *O. luteopurpureum*, but I consider it a natural hybrid with *O. crispum*.—*Lindenia*, t. 286.

Kew. *R. A. Rolfe.*

Plant Notes.

Phalænopsis Schilleriana.

The numerous species of Phalænopsis that have been introduced within the past thirty years are far from being as satisfactory as this fine old favorite, and, indeed, those that were known previously lack some of its best points. The utility of the plant is found in the profusion and lasting quality of its attractive flowers, and in the handsome character of its variegated foliage. Some descriptive and cultural particulars have already appeared in this volume of Garden and Forest, on page 117.

P. Schilleriana was introduced from Manilla in 1858 by Mr. Consul Schiller, a gentleman who had a famous collection of Orchids in Hamburg at that time, and in compliment to whom this species was named by Professor Reichenbach. This importation consisted of some thirty plants, only one of which, however, survived, and flowered at Hamburg two years later. In 1862 it flowered for the first time in England, at Broomfield, the place of the Mr. Robert Warner famous in Orchid history. Mr. Warner's plant seems to have been collected privately, and its native locality was not disclosed at the time. An idea of the progress which has been made in the search after new Orchids—of the devastation wrought by collectors, some will have it—may be obtained from the statement that only five kinds of Phalænopsis were known in England when *P. Schilleriana* had been introduced; between thirty and forty are now being cultivated in that country.

Many fine specimens of *P. Schilleriana* have been grown in England, and in late years a few have been produced in this country and Canada. A plant sent from London by Mr. Warner to the Russian International Exhibition, held at St. Petersburg in May, 1869, bore 120 fully developed flowers at one time. Two excellent plants, grown in the collections of Frederick Scholes, Esq., of Brooklyn, New York, were figured in the *Gardeners' Chronicle* of April 28th, 1888, and noted in the first volume of Garden and Forest. Mr. Scholes attributed his success with this plant to a liberal use of cow-manure.

The specimen, from a photograph of which the accompanying illustration was prepared (p. 390), flowered at the gardens of John Hoskins, Esq., Toronto, Canada, in 1890. It carried about seventy flowers. The same plant had 129 flowers this season, all fully in bloom at the same time. It is grown in a well-lighted stove in which the atmosphere is kept constantly moist by means of a hot-water tank in the centre. In other particulars the treatment does not differ from that observed in other establishments. An engraving of a plant at Melchet Court, England, the most extraordinary Phalænopsis of which we have any record, was given in the *Gardeners' Chronicle*, August 7th, 1875. This plant measured seven feet in height and five feet through, bearing flowers to the number of 378. When sold at auction a few months later it realized a sum exceeding $150.

Cambridge, Mass. *M. Barker.*

Some Recent Portraits.

The August issue of the *Botanical Magazine* contains figures of *Faradaya splendida* (t. 7187), a handsome tropical climbing plant, a native of Queensland, and dedicated to the physicist Michael Faraday. The plant is described as conspicuous by its handsome bright green foliage and copious panicles of very fragrant snowy white flowers which appeared at Kew for the first time in September of last year. An allied species, *F. Papuana*, of New Guinea, is also in cultivation at Kew, but has not yet flowered; *Cypripedium Californicum* (t. 7188), the handsome California Lady's-slipper which was figured in the first volume of Garden and Forest (page 281); *Pleurothallis immersa* (t. 7189), a New Granada Orchid, with small dirty brown flowers borne in elongated racemes rising above the leaves. It is a plant of considerable botanical interest, although gardeners generally will be inclined to pass it by. *Synantherias sylvatica* (t. 7190), a small East Indian aroid, is another plant which is curious rather than beautiful from the horticultural point of view; *Rehmannia rupestris* (t. 7191), the representative of a genus of *Scrophulariaceæ*, now known to consist of six or seven species, all natives of China, Formosa and Japan. It was discovered by Mr. A. Henry, in the province of Hupeh, growing only in almost inaccessible places on the faces of mountain-cliffs. It is a semi-prostrate plant, densely coated with whitish wool and having solitary axillary flowers, with long yellow tubes marked with purple on the inner surface of the limb. Of its horticultural value very little can be said, as the specimen which flowered at Kew, and which had been raised from seed taken from one of Dr. Henry's herbarium specimens, died as soon as it had flowered.

Cultural Department.

Russian and Polish Pears.

I began to try these Pears with many misgivings, but I think better of them every year. The hardiest of our old kinds I have been obliged to give up, after long and repeated trials; even our mildest winters blackened their new wood. Rather colder winters killed back nearly all the new growth, while one of our "rippers" killed every tree to the snow-line. There is rarely an interval between these extreme seasons long enough to enable us to see any fruit; and after twenty years of such experiments I gave it up beaten, having gathered just one ripe pear—from Jackson, a New Hampshire variety. When a fruit named for Old Hickory had to succumb, I felt justified in abandoning the field.

But before this end of the struggle I had received from my kind friends, Professor Budd, of Iowa, and the lamented Charles Gibb, of Quebec, a lot of cions from their then recent importations. From these, worked close to the ground on Vermont-grown stocks, I grew quite a lot of trees of many varieties. Professor Budd also sent me a few young trees from his earliest home propagations, so that I started almost even with them in my testings of their hardiness, and I have now a fine collection of these trees from six to twenty feet high, not one of which has lost a bud. Even Sapieganka, decidedly the

Fig. 64.—Phalænopsis Schilleriana.—See page 389

tenderest among them (and said to be the best in quality), is only a little discolored in its new wood by our worst winters. I should call it as hardy as the Fameuse Apple. Lutovka, a Polish Pear, said to closely resemble Flemish Beauty, is of about the same hardiness.

Bessemianka takes the lead of the whole list as a hardy and vigorous tree. My oldest specimen, from Professor Budd, is now over twenty feet high, and with three others, which he sent me the next year, is bearing some fruit, having bloomed for two seasons before. Merely as an ornamental tree the Bessemianka is well worth planting. Its remarkably rapid upright growth, its large, thick, glossy leaves, apparently impregnable both to insects and fungi, seem to indicate close relationship to the Chinese Pears; but Mr. Gibb thought the fruit to be of the Bergamot type. We shall learn more on those points hereafter. As this Pear (as its name, both in Russian and also in German, Samenlose, or Kernlose, indicates) has rarely any perfect seeds, I have feared in regard to its setting any fruit until other varieties bloom near it, though the flowers seem perfect. We shall know more about this hereafter. Certainly it can set some fruit unaided. Its season is from September to October.

Lutovka is a Pear whose fruiting I await with much interest. Though said to be like Flemish Beauty in fruit, it does not resemble it in growth. It makes but few branches, and hardly needs any pruning, but still it makes a good annual increase of woods.

Sapienganka is a straggling, strong-growing tree, quite noticeable for the bright red petioles of its leaves, which are so distinct as to impart a character to the tree. It is probably the tenderest of the Budd-Gibb importation, and is condemned for the north-west as lacking hardiness, but I think it will do for northern New England. It is said to be a native of Lithuania, and to be generally planted there and in Poland. When well started it grows nearly as fast as Bessemianka, but much more slowly and unshapely in the nursery. It is said to be very productive—the fruit in form like a Bergamot (that is, roundish ovate), and might be mistaken for the Summer Bergamot. The flesh is described as yellowish white, juicy, and finely flavored, and it is said to be a good market pear. Season in Poland, August and September.

Tonkovietka.—This seems to be a very slow-growing variety in the nursery and when at first transplanted, but after getting under way it makes a good growth; yet at eight years old it is not half as high as Bessemianka. It is hard to get a straight shoot from it when young. Mr. Gibbs speaks of it (Eighth Report Montreal Horticultural Society, p. 53) as "the hardiest Pear I know which bears an edible fruit—hardier even than Bessemianka." The name means "slender stalk." A fairly good eating pear, but not equal to Bessemianka.

Gakovskaya is a strong-growing, very hardy Pear, reported by Professor Budd to be somewhat like our old Pound Pear, and suited only for cooking. Season, October.

Besides these, there are several Russian Bergamot Pears, varying in season, that are hardy here, and grow well.

Newport, Vt. *T. H. Hoskins.*

Mistakes in Growing Strawberries.

For a number of years my beds averaged over 200 bushels of berries per acre. Many acres within the last ten years have yielded not less than 10,000 boxes per acre. This year the average yield has been about 6,000 boxes or quarts per acre. An account of my mistakes may be worth more than one of my success.

In the spring of 1890 we set our plants for this season's crop. After they had been set, early Peas, Beans, Onions, etc., were planted between the rows. In this way a crop can be obtained from the land the first season, and be out of the way by the time the runners need it. Our plants between the rows yielded well. The vines and refuse were taken off and added to the compost-heap. But the weeds—how they did grow! We were driven with work until we hardly knew what to do first. It seemed very difficult to get help, and I kept thinking that by "to-morrow" we would be able to finish cleaning out the Strawberry-beds, and so matters went on until something like half an acre was overgrown with weeds. Finally, it actually cost me more to clear away the weeds when at last I did it, than it would, had I done it before they had caused any damage. I cannot tell just what that neglect has cost me; but Nature charged it up against me, and has taken full pay out of the crop. It was certainly more than $100, and, I believe, it was nearer $150.

One more mistake: We are passing through the driest season I have known for thirty years. The Strawberry crop about here was almost an entire failure, except where it was carried through by artificial watering, and we are almost the only growers in the county who have facilities for so doing. The drought commenced early in the spring, and I noticed that my Strawberry-plants scarcely started even after the growing weather had come. I knew that they were in need of water, but kept thinking that rain would surely come within a day or two, and then they would soon catch up. Rain did not come, and after waiting too long I started the water-pipes upon them. They were kept well watered from this time to the close of the season, but they had been damaged in a way I had not anticipated. They came out with as great an amount of bloom as I had ever seen; but the foliage to carry such a crop was not there. The result was that the berries were not of their usual size, neither did the late sets fill out as they should have done.—*J. M. Smith, in Rural New-Yorker.*

Rose Notes.

The large-flowered Roses, now so popular, are highly ornamental, yet some of the smaller-flowered varieties are equally useful in their way, and, for certain purposes, are most appropriate. Among these Bon Silene continues to hold high rank, and is still the most satisfactory small pink Rose for in-door use, while Douglas, an old Rose of the Bengal class, producing crimson buds of about the same size, is its worthy companion. Both of these are among the sturdiest of growers, and will give a succession of bloom through the whole season, the flowers being much improved in substance when grown cool. Duchesse de Brabant is also a good pink, though, when growing strongly, the flowers are often produced in clusters. These three Roses may be grown for several years without replanting if they are placed in a solid bed, the Bon Silene, particularly, giving better flowers the second season than the first. It is also benefited by moderately hard pruning.

Young Roses of recent planting should now be growing away freely in order to be in good condition for the winter, and some care in watering is quite necessary during the muggy days that often prevail in August, for the roots will not have spread very far, as yet, in the new soil, and they are easily discouraged by too much moisture at their new roots. Thorough ventilation is essential, not only in the day, but also at night, for long, sappy growth is generally undesirable.

If space can be spared for such purpose, a strong plant of Marechal Niel, trained on wires attached to the roof of the greenhouse, may be made to produce large crops of flowers, if its roots are under control so that the plant can be given a season of rest. It seems almost a pity that this Rose is a cropper in blooming, though its immense golden flowers are of such beauty as to be well worth waiting for, even though they have the disadvantage of having very weak stems.

Another old Rose that is seldom seen of late years is Caroline, a Tea Rose of very good form and fair size. It is light pink in color, the buds being long and pointed, while in habit it resembles Niphetos, and, like the latter, will give the best satisfaction when grafted on Lamarque.

Among the Hybrid Perpetuals for early spring-flowering in pots, Eugenie Verdier should not be overlooked, its silvery pink flowers being peculiarly attractive; in fact, it is one of the best of the Verdier type.

Some discussion has been carried on among Rose-growers as to the necessity or advisability of packing the soil tightly in the benches in which Roses are planted, and the correct method seems to depend upon the character of the soil. In some localities the soil is more liable to become too hard than too loose, and consequently it does not need very much pressure in planting, while in other instances it may be an improvement to compact the soil by pressure with a brick or block of wood after planting.

The application of fertilizers to young Roses should be made with caution, for if overdone the soil may become soured, to the serious injury of the crop, but, as much depends on the character of the soil used, the question of manuring must be decided by the circumstances of the individual grower.

Among the newer Roses we find still another Duchess that is very highly recommended, namely, Duchess of Leeds, a Hybrid Perpetual, described as "a highly colored La France," but said to be quite distinct from Duchess of Albany. It is claimed for this Rose, too, that it lasts well when cut; but as this new-comer has not yet been tested to any extent in this country it is too soon to pass upon its merits.

A new Tea, Mrs. James Wilson, is also well spoken of in England. Its color is pale lemon-yellow, with rosy margins,

and in shape, size and growth it is said greatly to resemble Catherine Mermet.

Ernest Metz apparently did not strike the popular fancy to any great extent as a dark pink Tea, and has not proved able to compete with others of purer color, and consequently but little is heard of it now.

The future of Waban seems assured from the favorable reports received from all sides upon this fine sport from Mermet, and it has been planted in large quantities by the leading cut-flower growers to supply the market for the coming winter. There is apparently but little change among the Hybrid Perpetuals planted for winter use, except the improvement made in quality of flowers produced, and the favorites of former years, such as Mrs. John Laing, Madame Gabriel Luizet, Heinrich Schultheis, Ulrich Brunner and Anna de Diesbach, will doubtless continue among the most popular.

Hardy Plant Notes.

THE successful cultivation of *Iris Susiana* out-of-doors (see Garden and Forest, vol. iv., p. 357) is rather unusual, but I think it can be explained. The cultivation of this Iris in Holland has apparently been better understood of late years, and, as I have before stated, seven out of twelve rhizomes, purchased last fall, flowered this spring. This success is also unusual, but is owing, perhaps, to the very fine roots the Dutch growers sent us last fall. The principal reason for advocating pot-culture is, that all of the Oncocyclus group of Iris enjoy a thorough baking in the sun after the flowering season is past and the leaves have died off. Our plants are now undergoing this treatment in a cold frame, and after this thorough ripening will start to grow vigorously next fall. I have never heard of any one who has successfully grown this Iris in the open air any length of time. Our experience has been similar to that of Mr. Barker's in the Harvard Botanic Garden, and a good round number of roots have been used to experiment with.

We hear much of the new *Iris Gatesii*. It belongs to the same group as *I. Susiana*, and is, we are told by Herr Max Leichtlin, the largest-flowered Iris known, and exceeds the Mourning Iris in beauty; let us hope that the plant may soon be common. *I. Iberica* is, to me, quite as beautiful as *I. Susiana*, and I think the markings are much more delicate and refined. The plant itself, when in flower, does not exceed six inches in height. With me it flowers perfectly well in the open ground, but we do not often see it in bulb lists. I quite agree with Mr. Gerard (vol. iv., p. 334) that it is "difficult to understand why, cultural skill being equal, Irish bulbs should be better than others," but certain it is that in Ireland the Narcissus has found a most congenial soil and climate, for any one who has seen them there will find it hard, as I did, to believe they are not indigenous. But the fact is, that many of the commonest weeds here in New England are not native, and yet they grow with more vigor than in their original homes.

Mr. Orcutt's notes on the new Californian Poppy suggest the query why the lovely *Romneya Coulteri* is scarcely to be had here in the east. I have repeatedly purchased seeds and sown them with all care, but have failed to raise anything besides weeds. I sent to California for plants last fall and received nothing but excuses in return. A leading eastern firm to whom I applied "did not have it," although it was advertised in their lists. It is common in England, and I suppose the only way to get it is to send there, for American plants are appreciated there as they deserve to be; even the common *Rudbeckia hirta* is there thought worthy of two synonyms, and the number of these may sometimes be taken as a fair index of the popularity of a plant.

So. Lancaster, Mass. *E. O. Orpet.*

Some New Tufted Pansies.

THE cultivation of the so-called tufted Pansies is increasing in this country, and is likely to become still more general, and we therefore reproduce from *The Garden* some notes by Mr. W. E. Gumbleton on the merits of a few of the newer varieties sent out by Messrs. Dobbie & Co., Rothsay:

Wonder.—This is an extremely pretty variety of most compact and tufted habit of growth in the way of Ardwell Gem, but a decided improvement on that good old variety. It is a profuse and continuous bloomer, and has flowers of a good size, of a clear, pale canary-yellow, with a deeper centre clearly penciled with a few distinctly marked black lines. This is quite an acquisition.

Cottage Maid.—This is in the way of Countess of Kintore but an improvement on that pretty old variety, with most distinct, deep plum-colored centres and almost pure white upper petals. It is also of good and compact habit of growth.

Vernon Lee.—This closely resembles the excellent and effective older variety Jackanapes, with flowers of the same combination of golden lower petals and rich brown upper part of flower, the only difference being that in the newer variety the flowers are of more perfect form and better substance, and the outer half of most of the upper petals is distinctly laced with gold, which is never seen in Jackanapes. The habit is also compact and good.

Queen of Scots.—This is much in the way of Cottage Maid save that the flowers are rather larger, the upper petals of a purer white and the centres purple instead of plum color. The habit of growth, however, is not quite so satisfactory.

Mrs. Grant.—This is a rather pretty and extremely free-blooming sort, of compact habit of growth, and may be briefly described as a paler own sister to Cottage Maid, with more clearly colored upper petals.

Bronze Medal.—This variety has nothing to recommend it save its compact habit of growth. Its flowers are small and poor and of a pale washy shade of brown, quite inferior to many older and better-known varieties.

York and Lancaster.—A most striking variety mottled somewhat like the old Rose of that name, but with purple instead of rose color.

Blue Cloud.—A most lovely variety, which may be briefly described as a white Duchess of Fife with a distinct bordering of pale blue round all the petals. This should prove a great acquisition.

Dawn of Day.—This is also a most distinct and showy variety with large white flowers distinctly and most effectively penciled with blue. Quite an acquisition.

Bullion.—A fine, deep, bright golden yellow, rather a small flower, but a very telling shade of color.

Max Kolb.—This is one of the older sorts, but not so well known as it deserves to be. It is quite the best and most continuous blooming blue Pansy known to me. The flowers are of large size, borne on stout erect foot-stalks well raised above the foliage, and of a fine intense shade of blue, not quite so deep as those of A. Grant, but of rather larger size than those of that fine variety. The centres of the flowers are black, with a small yellow eye. Altogether a most excellent variety.

Orchid Notes.

Cypripedium barbatum, var. superbum.—The numerous varieties of *C. barbatum* are all more or less useful—as, indeed, is the species itself—and they find favor with many growers in preference to the more expensive species and hybrids. The flowers of this variety are much larger than those of the type, and their coloring is more distinct and beautiful. The purple of the lip is deeper in shade; there is more of the purer white in the dorsal sepal, less green, and the purple lines are broader and brighter, approaching reddish purple. It is even more floriferous than the free-flowering species, and the length of the erect scapes, often exceeding fifteen inches in strong plants, with the superior lasting quality of the flowers when cut, admirably adapts them for decorative work. The variegation of the foliage, too, is more distinct and handsome. Had I to choose one Cypripedium, conspicuous above all others for beauty combined with utility and ease of management, from the already long list of species, hybrids and varieties now in cultivation, I should select this variety. It will give satisfaction as to growth, and bloom in an atmosphere of intermediate warmth, but plants grown in the higher temperature of a stove have the flowers and leaves of a somewhat better color.

Phalænopsis Luddemanniana.—Many of the Phalænopsis are more showy than this one, but it is a pretty free-flowering species, well worthy of a place in any general collection of stove-plants. It was introduced to English gardens from the Philippine Islands in 1865, but appears to have flowered earlier with Monsieur Luddemann, of Paris, in compliment to whom it was named by Professor Reichenbach. This Monsieur Luddemann was one of the great Orchid kings of his time, and the now historical collection of Monsieur Pescatore had been under his management. *P. Luddemanniana* is small of growth compared with most other species, the succulent, oblong, acute, light green leaves being little more than six inches in length at their best. The flower-stems are usually longer than the leaves, and appear at various seasons of the year, bearing from four to six blooms two and a half inches across. Petals a trifle smaller than sepals, both oblong, acute, white, with numerous trans-

verse bars of purple; lip trilobed, the central lobe rich violet, the lateral ones white or pale purple. The flowers hold their color from six to eight weeks, but they retain their rigidity and perfection of form in a blanched state much longer. The stems should not be removed when the flowers have fallen, if it is desirable to increase the stock, as afterward they almost invariably bear plantlets. There are several varieties of this species, differing chiefly in the color of the flowers. Some of these varieties are rather scarce, and they all thrive under the ordinary treatment of Phalænopsis.

Cambridge, Mass. *M. Barker.*

Correspondence.

Dr. Schlich's Handbook of Forestry.

To the Editor of Garden and Forest:

Sir,—The publication of the second volume of Dr. Schlich's treatise on forestry, which has been reviewed in your paper, is an event of much importance in the development of an English forestry literature. This volume, which deals with the "Formation and Tending of Woods, or Practical Sylviculture," is the most thorough work upon the application of scientific principles of forestry that we have in our language. Dr. Schlich has arranged and condensed his material with care and skill, and has packed a vast amount of information into the first two hundred and thirty pages. The latter part of the volume consists of "Sylvicultural Notes on British Forest-trees."

While Dr. Schlich's work must always be of value to foresters in any part of the world, a perusal of it suggests that the conditions under which the principles of forestry must be applied in this country are so different from those prevailing in European countries that no book of this kind not written with special reference to the United States can be entirely satisfactory to the American forester. Dr. Schlich seems to contemplate only cases in which forest is to be established upon areas practically treeless. Of the treatment of vast areas of forest suffering from neglect, or from our brutal methods of lumbering, he says little or nothing. Yet in this country such areas, too extensive for the comparatively elaborate systems of culture that he describes, must first receive the forester's attention. Our task is not so much to establish new forests as to treat those that we have in such a way as to obtain the greatest possible amount of forest-products without destroying the forests. The problems peculiar to this country must be worked out here. Probably, even the experience of Dr. Schlich and Dr. Brandes with the old forests of British India would be of comparatively little value in solving these problems. It is at least safe to say that in some of the small details of practical forestry, the irrepressible Yankee will apply his own ideas. Thus, he would devise his tools without reference to the traditions of the Old World. Dr. Schlich gives a number of cuts of tools, of which some are probably excellent, but some seem to the American eye to be too awkward for the use of man. That this is the case is not surprising in the light of the European creed as to hand-tools, thus set forth on page 58 of the volume:

"Many and various are the forms of the several tools which have from time to time been recommended for use in the preparation of the soil. Of these, a considerable number are of doubtful utility. As a general rule, the ordinary laborer gets through more and better work by using the tools with which he is acquainted than by substituting even an improved form of tool, the use of which he has first to learn."

If this comfortable and conservative doctrine had prevailed in this country, how far should we have advanced toward that mechanical superiority that we boast of? The Yankee who learns from a countryman returned from studying forestry in Europe that French and German foresters fear to use their axes in frosty weather lest these tools should be broken, will not believe very readily that we cannot devise our own forestry tools. At least, in the article of axes we may claim some superiority. With what Homeric laughter would the hardy forest-destroyers of Maine and Michigan shake their snow-laden Pines if some trained woodsman from the Black Forest should expound to them in friendly warning his theory of axes and frost!

A perusal of Dr. Schlich's list of twenty British forest-trees, not all natives of the British Isles, and not all trees that we should think of including among timber-trees, brings to mind the wonderful variety of forest-wealth of our Appalachian region, not to say of our whole country.

But with these empty gratulations our self-satisfaction must cease. Our chief instrument of forest-destruction is better than the European's; and nature has bestowed upon us a wonderful variety of valuable trees against which we may turn this instrument. It is idle to deny that in all essential points of scientific forestry we must look to the Old World for instruction. Dr. Schlich's book is so clear and interesting in its presentation of the subject that all in this country who have any interest in the subject should read it with care. Such a book as this should do much to temper and direct the often-distorted enthusiasm of our forest-lovers.

New York. *James W. Pryor.*

Experiments and Expedients.

To the Editor of Garden and Forest:

Sir,—For thirty years it has been difficult to raise a good Quince-crop in this section, but the fruit can be had with proper precaution. The trees are more tender when young, and I then take special care to secure well-ripened wood, and in October tie it about with straw. As the trees get older they become hardier, but the fruit is likely to be scarce, on account of the weakening of the terminal wood; I therefore tie the limbs together with hop-twine, a coarse, soft, but strong twine, and after that tie about the bunched limbs straw or hay. This precaution, with hedges of Arbor-vitæ to the west and north, leaves the trees vigorous enough to produce full crops. Quince-trees are worth growing for their beauty in the blooming season, and an Orange-grove is hardly more beautiful than a Quince-orchard in full-bearing.

It has been difficult, too, for the last half century to grow Peaches in this region. Fifty years ago I saw my father pick Sweetwater grapes, peaches and wagon-loads of quinces from his gardens. But the borers came, and then followed greater inequality of temperature. I have for twenty years persisted in growing Peach-trees, both seedlings and grafts. Unprotected, we secure a crop just about once in ten years. This year I have fifty-five trees loaded. My experiments have included: (1) Winding the bearing limbs in straw, which is rarely of much avail; (2) bending down limbs and covering with sod or soil, which leads to rot of buds and sometimes branches; (3) bending down the trees and holding them with spikes, which is efficient in a limited degree; (4) building a rude house over a tree or close row of trees, which is less trouble than it appears in the telling, and when the trees are so covered, and fine hay stuffed in over the tops before nailing on a roof, this affords sufficient protection for our hardiest sorts. But (5) my best experiment has been the planting of a large, cheap, roofless house with six trees. Over the top I nail narrow slats, and allow my hens to run in it for the summer; during winter I spread over corn-stalks, and hold them in place with poles. Of course, the roof must be firmly supported. Here my trees are full of fruit. Another (6) plan has been to grow a few trees in boxes and set them in the cellar for the winter. These do well with little care. In a Peach section such precautions would be laughable; but here peaches are peaches, and it pays to take much care and try many experiments.

Clinton, N. Y. *E. P. Powell.*

A Good Example.

To the Editor of Garden and Forest:

Sir,—In the passage leading to the town library at Tunbridge Wells, an exhibit is made, and constantly renewed, of the local flora and common plants. The specimens are placed in separate glass vessels and in front of each is a label bearing the common and botanical names. Such a means of popular instruction and interest might be well adopted at some of our American summer resorts, and at very small outlay.

Tunbridge Wells. *Francis Skinner.*

Recent Publications.

Jinrikisha Days in Japan. By Elizabeth Ruhamah Scidmore. Illustrated. New York: Harper & Brothers. 1891.

Many books have been written about Japan, and most of them contain descriptions of its forests and gardens, its flowers and flower-festivals. But the subject seems inexhaustible, for each gives us new details and general pictures. Mrs. Scidmore's little book is not written from the scientific or from the artistic point of view. It is for popular reading, and professes merely to sketch "something of the Japan of to-day as it appeared to a tourist, who was a foreign resident as well," being "the outcome of two visits, covering nearly three years' stay in the Island Empire." But its author has a keen eye and a knowledge of the value of definite information, as well as a

feeling for the beautiful and the picturesque, and a very graceful pen. So her book is interesting from end to end, and when we lay it down we feel that, despite all we may have read upon the subject before, she has taught us something fresh and given us another and very charming general impression of the delightful land she describes.

The first thing she speaks of, after landing at Yokohama, is the colony of florists at the west end of the town, where one finds "toy gardens filled with vegetable miracles; burlesques and fantasies of horticulture; dwarf trees, a hundred years old, that could be put in the pocket; huge single flowers and marvelous masses of smaller blossoms; Cherry-trees that bear no cherries; Plum-trees that bloom in midwinter, but have neither leaves nor fruit; and Roses—that favorite flower which the foreigner brought with him—flowering in Californian profusion." And from here on we read so continually of the skill of the horticulturist and the passionate love of the people for flowers that once more we feel, as other writers had already made us feel, that if Japan is the land of art it is still more distinctively the land of flowers. At Yokohama "a large business is done in the exportation of Japanese plants and bulbs encased in a thick coating of mud, which makes an air-tight case to protect them during the sea-voyage. Ingenious Fern-pieces are protected in the same way. These grotesque things are produced by wrapping in moist earth the long woody roots of a fine-leaved variety of Fern. They are made to imitate dragons, junks, temples, boats, lanterns, pagodas, bells, balls, circles and every familiar object. When bought they look dead. If hung for a few days in the warm sun and occasionally dipped in water, they change into feathery green objects that grow more and more beautiful, and are far more artistic than our own conventional hanging basket."

Mrs. Scidmore makes a novel suggestion when, after recognizing the fact that the Japanese are the foremost landscape-gardeners in the world, giving their genius "equal play in an area of a yard or a thousand feet," she says that "a Japanese gardener will, doubtless, come to be considered as necessary a part of a great American establishment as a French maid or an English coachman. From generations of nature-loving and flower-worshiping ancestors these gentle followers of Adam's profession have inherited an intimacy with growing things, and a power over them, that we cannot even understand. Their very farming is artistic gardening, and their gardening half necromancy."

Near Yokohama is the little village of Kawana, whose headman has a famous collection of Chrysanthemums, the goal of many autumnal pilgrimages. His great thatched house, in a courtyard, is faced in front by rows of mat-sheds, "covering the precious flowers that stand in files as evenly as soldiers, the tops soft masses of great frowsy, curly-petaled, wide-spreading blooms, shading to every tint of lilac, pink, rose, russet, brown, gold, orange, pale yellow and snow-white. It was there that we ate a salad made of yellow Chrysanthemum petals, most æsthetic of dishes. The trays of golden leaves in the kitchen of the house indicated that the master enjoyed this ambrosial feast habitually, and, perhaps, dropped the yellow shreds in his *saké* cup, to prolong his life and avert calamities, as they are warranted to do." Not far away is Sugita, where the Plum-trees bud in January and blossom gradually, so that "the last week of February finds the dead-looking branches clothed with clouds of starry white flowers." Around the thatched roof of an old temple stand Plum-trees covered with blossoms of various colors, white, pale pink, yellow, rose or deep carnation-red, and "just outside the temple door is a Plum-tree whose age is lost in legend. Its bent and crooked limbs and propped-up branches sustain a thick-massed pyramid of pale rose-pink. The outer boughs droop like a Weeping Willow, and their flowers seem to be slipping down them like rosy rain-drops. Poets and peers, dreamers and plodders, coolies, fishermen and the unspiritual foreigner, all admire this lovely tree, and its wide arms flutter with poems in its praise"; for, as Mrs. Scidmore remarks, "spring poetry" is not a drug in Japan, and the trees themselves gladly accept the shower of manuscripts annually produced in their honor. We cannot follow all her descriptions of the flower festivals of a Japanese spring, when, as our readers have often been told, the whole population turns into the suburbs for merry-making, philosophers and statesmen leave their labors to journey to some famous garden, perhaps a three days' trip away, and the newspapers print daily bulletins to tell how the blossoms are progressing. But, she says, fair as the spring days are, the autumn, when an Indian summer lasts sometimes four months in unbroken loveliness, is equally attractive. When the Maple-leaves begin to turn, "autumnal Japan is the typical earthly Paradise."

Near the Ikegami temples the priests display with pride a Moutan, or Tree Peony, "now three hundred years old, whose solid trunks and wrinkled bark uphold a multitude of stately blossoms." And when these bloom, and Azaleas of varied colors crowd every garden and line the river-banks, then, too, the *Fuji*, or Wistaria, is in blossom, "and at the Kameido temple makes an eighth wonder of the world. Every householder has his Wistaria-trellis, generally reaching out as a canopy over some inlet, or, as at Kameido, forming the roofs of the open-air tea-houses edging the lake. . . . Blossoms two, and even three, feet long are common, and only a great swaying tassel, four feet in length, draws a 'Naruhodo!' (wonderful!) from the connoisseurs." The great objects of wicker-work, clothed completely with Chrysanthemum-blossoms which amaze every traveler, are described at length by Mrs. Scidmore, who says that, in addition to single forms of men and beasts, one sees "whole mountain-sides of flowers, with water-falls of white blossoms spreading into floral streams, and Chrysanthemum women leading Chrysanthemum horses ridden by Chrysanthemum men across Chrysanthemum bridges. Gigantic flowers, microscopic flowers, plants of a single blossom, single plants of two hundred blossoms, have Bamboo tents to themselves" at the shows where these figures are exhibited; and their special attractions are as loudly proclaimed as the charms of fat women and skeleton men in the side-shows of American fairs.

A little description of the "Maple-leaf Club-house," near the Shiba temples, well shows the feeling of the Japanese for artistic decoration. Here there was a "long low room, usually divided into three by screens of dull gold paper. One whole side of this beautiful apartment was open to the garden beyond a railed balcony of polished cedar, and the view across the Maple-trees and dense groves of Shiba to the waters of the bay was enchanting. The decorations of the club-house repeat the Maples that fill the grounds. The wall-screens are painted with delicate branches, the panels above the screens are carved with them, and in the outer wall and balcony-rail are leaf-shaped openings. The dresses of the pretty *nesans*, the crape cushions on the floor, the porcelain and lacquer dishes, the *saké* bottles and their carved stands, the fans and bonbons, all display the Maple-leaf." On another page we read that even the charcoal under the tea-kettle is an artistic object, being twigs of Azalea charred and coated with lime without injury to their delicate forms.

In the chapter devoted to the theatre we find flowers again playing a prominent part. The actors enter the stage by two long raised walks through the auditorium, broad enough to accommodate horses and *jinrikishas;* these walks are called *hana michi*, or flower-walks, "and as a popular actor advances his way is strewn with flowers." Garden, forest and landscape effects are made on the stage "by using potted trees and shrubs uprooted for transplanting. The ever-ready Bamboo is at hand, and the tall Dragon-grass and the scene-painters produce extraordinary illusions in the backgrounds and wings." But we should never end if we tried to extract all the suggestive passages by means of which Mrs. Scidmore paints the love of the Japanese for flowers. We can only recommend her book to our readers as containing not only many more such passages, but delightful descriptions of scenery and sympathetic accounts of the people who live among these marvels of beauty, and have themselves produced so many of them.

Bulletin No. 93 of the Agricultural Experiment Station connected with the University of California is devoted to the investigation of different varieties of Oranges and Lemons grown in that state. The purpose of the investigation has been to show in a comprehensive way the composition of the leading varieties of these fruits, as they are grown in the different Citrus regions, and this is of great value to cultivators inasmuch as it shows the influence of various conditions of soil and climate upon the product of the groves, and also gives information as to the appropriate fertilizers to be used in each case. The physical data—that is, the per cent. of rind, pulp, juice and the like—are of interest from a commercial standpoint because they show the true quality of the fruit. The difference between an orange or a lemon which has such a thickness of rind and such a percentage of pulp and juice as characterize the best kinds of these fruits, and one whose weight is more than one-third rind and more than one-quarter dry pulp, is very apparent. And yet such differences exist. Besides this, although fruit is generally considered a pure luxury, consumers may find much valuable knowledge from studying the relative food-values of different varieties. The nourishing portions, which are especially shown in the saccha-

rine and nitrogenous contents, vary greatly among different kinds and under different conditions of growth. It is therefore an important question of domestic economy to the consumer to know what fruit he is using. The ash analysis, together with the nitrogenous contents of the standard varieties, show that the ingredients which the soil loses by an ordinary crop are a serious drain upon its supporting value, and what particular plant-foods suffer the greatest loss can only be known by determining the actual constituents that are withdrawn.

The body of the bulletin is taken up with a description of various varieties of oranges received from different places, together with a physical analysis, a proximate general analysis, and an analysis of the ash. For example, eight specimens of the Navel Orange, taken from different parts of the state, were investigated, and a similar analysis was made of several specimens of Mediterranean Sweet, Saint Michael's, Valencia, Malta Blood, Tangerine and some seedlings. Of course, it would not be of interest to quote all these details, but some of the prominent points of similarity and difference which have been brought out in the tables are interesting. In comparing the oranges as to their proportion of rind to flesh, the Navel, although the choicest of oranges, has, contrary to popular impression, no advantage in this respect over the Mediterranean Sweet or Saint Michael's. The average Navel contains about seventy-two per cent. of flesh, while the average Mediterranean Sweet shows seventy-three per cent., and the Saint Michael's eighty-one per cent.

In regard to the proportion of juice to flesh the Navel seems to be the driest, while Saint Michael's is the juiciest. The skin of the Navel, although thin, is hard and solid and weighs heavier than the more corky skins of the Mediterranean Sweet. As to the sugar contents of the juice, the maximum of sugar appears in the Navel orange grown on the hills, but it is approached very closely by other Navels, by the Mediterranean Sweet, the Malta Blood, the Pomona, and the Tangerine from San Gabriel. This Tangerine shows the highest proportion of cane-sugar in the whole series, but to what extent the cane-sugar determines the sweetness to the taste is a matter not fully understood. The proportion between the grape-sugar and the fruit-sugar is not yet determined, and is, of course, an essential factor in the case. The average sugar-content of fully ripe Navels, from all localities, is 10.8 per cent., which is more than that of the other varieties. A Valencia orange from Pomona shows a much lower sugar percentage. In respect to acid in the juice, the Malta Blood contains a maximum of more than two per cent., with an average of one-sixth per cent. in three samples examined. In contrast with the Malta Blood, Saint Michael's has a low acid-content, but this is combined with a low sugar percentage.

In discussing the nutritive value of the fruit the flesh-forming ingredients are the most important, and it is, therefore, of interest to compare the albuminoids of oranges with those of other fruits, and of different varieties among themselves. According to European data, oranges stand first among fruits in this regard, followed by prunes second, peaches and apricots third, bananas and grapes fourth, while apples and pears stand nearly the lowest on the list. The determinations of albuminoids in California oranges show smaller percentages, so that it must be concluded that the California fruit is less nourishing than that of Sicily. The difference observed, however, may be due to the age of the trees which bear the fruit, as California trees are usually young.

Referring to the composition of the ash and nitrogen contents of fruits, it is said that grapes stand first and oranges stand second in the quantity of mineral matter withdrawn from the soil. Heretofore, all conclusions bearing upon the ash and nitrogen of oranges and lemons have been based on European data, but from the comparative exhibit made here it seems, so far as oranges are concerned, that the California fruit draws much less upon all the ingredients that have to be replaced by fertilization, while the California lemon draws about the same amount of mineral from the soil as the European orange. Potash is the predominating ingredient in the ash, amounting to quite half its weight, and it is, therefore, highly important that the supply of this substance should be kept up. Fortunately, it has been shown, by previous investigation, that the potash supply in California soils and irrigation waters is exceptionally large, so that in many cases the demand of the fruit upon this element will be amply supplied in the course of cultivation. Phosphoric acid is not drawn upon so heavily, but, since the supply of this element is usually limited in California soils, it is probable that it would be prudent to use fertilizers containing it in large proportion. The natural supply of nitrogen, especially in southern mesa soils, is not large, and, as the draft made by the Orange on this substance is very heavy, it should be always among the first elements of plant-food supplied. Next to potash, lime is the ingredient most abundantly taken from the soil, although its percentage varies very widely, but the supply of lime in California soils is so universally ample within the orange-growing region that no replacement of this substance in fertilization will be called for. The large amount of sulphuric acid found in this fruit suggests gypsum as an acceptable fertilizing agent.

In regard to lemons, it can only be said, from the incompleteness of the investigation, that the acid, or the most important ingredient of this fruit, exceeds the commonly assumed average, and this point should ensure to California-grown lemons a high position in commerce. The relatively large proportion of sugar shown by the analysis is a feature which will further commend them to the consumer's taste, but there are very great differences among varieties in the proportion of rind to flesh and to extractable juice.

Bulletin 82 of the New Jersey Experiment Station gives a carefully illustrated account of the history and habits of the Rose-chafer, together with the details of some experiments for destroying this insect, which, upon the whole, are rather depressing. Careful trials were made with the arsenites, copper mixtures, pyrethrum, kerosene, lime, tobacco, ascetic acid, quassia, digitalis, corrosive sublimate, muriate of ammonia, cyanide of potassium, sludgite, kainit, alum, white hellebore, carbolic acid, Ailanthus-blossoms, and other alleged repellants and poisons with very unsatisfactory results. The hot-water cure, suggested by Mr. Kellogg, of Vineland, and at a later date recommended by Mr. E. S. Carman, was tried, and it showed that water heated to 125° Fahrenheit will kill the insect, but in practice it was found impossible to get the spray hot enough to kill at any considerable distance from the nozzle of the force-pump. It seemed to Professor Smith that only a solid jet of water could be kept hot if carried even eight or ten feet, and then would follow the practical difficulty of securing a large and continuous supply.

Mr. A. S. Fuller suggests that the species of Spiræa are very attractive to these insects, and that in small gardens, if a full supply of food from Spiræas was afforded, they might leave other plants. Following this line of suggestion, Professor Smith thinks it is possible to prevent in part the development of the insects in cultivated ground, and the outside of vineyards can often be defended by the counter-attraction of a few rows of Blackberries. The blossoms of these plants are great favorites with the beetles, and they would be likely to arrest the incoming crowds. If they were collected from these plants the injury to the vineyard might be largely averted. This matter of collecting seems, after all, to Professor Smith the most practicable method of dealing with the pest, and various mechanical devices similar to an entomologist's umbrella are figured. By shaking the vines the insects can be caught in these receptacles, and if the collecting is done once or twice a day for three weeks the crop may be saved. The Rose-chafer has no day of rest, and the collecting must be done on Sundays as well as other days, for a single twenty-four hours' neglect may result in as much injury as is prevented by six days' work. The insects come in such numbers that they cover everything—acres of Grape-vines, Strawberries and Blackberries, with thousands of fruit and other trees, and the best that Professor Smith hopes from persistent collecting, if carried on generally, is that, after some years, their number may be lessened so as to bring, for a time, comparative exemption from their attacks. At present, however, there are too many abandoned fields to make this appear sanguine, as the best of their breeding-places are left undisturbed, and no method of killing them before they come out of the ground has yet been devised.

Notes.

A basket of rare and costly Orchids, presented to the Empress of Germany by Messrs. Sander & Co., was the subject of a supplementary illustration in a late number of the *Gardeners' Chronicle*.

It is stated in *Fruits and Flowers of Oregon and Washington* —the new horticultural monthly of the north-west—that Peach-trees in Oregon measure fifteen inches in girth at three years old, with a spread of branches sixteen feet in diameter.

Perhaps few persons who visit the Botanical Gardens in Liverpool know that they were founded by William Roscoe, the celebrated historian. His name is preserved in the annals of science by that of the genus Roscœa, which includes half a

dozen species of herbaceous Himalayan plants, sometimes cultivated in greenhouses.

Decumaria barbara is quite at home in the neigborhood of Philadelphia, and in Laurel Hill Cemetery it is quite largely planted, and clings to walls as closely as English Ivy. Its leaves are large and lustrous, and it will certainly be used more generally when its good qualities are appreciated as they should be.

"The total number of trees and shrubs indigenous to this country," wrote Downing in the year 1846, "is about 530." How largely our knowledge of the products of the United States has advanced since this time will be seen when we note that 420 indigenous species of trees are now recognized within their area, while the number of indigenous shrubs must be nearly a thousand.

The old saying, that "language is a bundle of fossil metaphors," is well illustrated by the word disseminate, which, etymologically, means "to scatter seed," and, as a writer on plant-life recently remarked, "points to the fact that everywhere in nature seeds are scattered broadcast, infinite pains being taken by the mother-plant for their general diffusion over wide areas of woodland, plain or prairie."

We have received from our correspondent, Monsieur Charles Naudin, a photograph of a noble flowering specimen of *Yucca filifera* (see Garden and Forest, vol. i., pp. 78 and 79), taken in the gardens of the Villa Thuret. Judged by the height of the man standing by the tree, it must be from twenty to thirty feet high, and forms one of a group of five specimens, all about equal in height.

"The principle which would govern us," wrote Downing nearly fifty years ago, "if we were planting the streets of rural towns is this: Select the finest indigenous tree or trees, such as the soil and climate of the place will bring to the highest perfection." Unfortunately, the sound and sensible advice thus briefly conveyed is almost as sorely needed to-day as when Downing's words were written.

"Midway between Fifteenth and Sixteenth Streets," says the *New York Sun*, "at the curb lies a broken brown stone which bears the inscription, 'Union Square. Founded 1832.' It is a part of the pavement, and yet New Yorkers have walked that way for forty years without noticing this modest official record. This was a wild locality in 1832. A farm-house stood at the junction of the Bowery road and the road to Bloomingdale in the upper part of the present little park, and dust and blackberries abounded at the road-sides. The city straightened out the streets at that time into a square, and the park was an afterthought. The Hon. Walter Bowne was Mayor at the time."

A dispatch to *The Tribune* states that "next winter will see the shipment of an enormous quantity of fresh vegetables from southern California to New York and other eastern cities. The railroads have given a rate of three cents per pound, which allows a big profit on all vegetables that will bear transportation. Tomatoes, peas, beans, new potatoes, cauliflower and other vegetables can be supplied by southern California from the 1st of December to the 1st of March, during which time there is practically no competition from Florida. It is claimed that this industry will eclipse fruit-growing, as it will stimulate a demand for fresh vegetables where canned goods are now used."

The botanical name of the Carnation, Dianthus, signifies Jove's flower, being a contraction of *Dios anthos*, while the English name seems to have been bestowed to characterize the flesh-colored hue of some of the commoner kinds. Its earliest form appears to have been "Carnadine," and Drayton long ago wrote: "The brave Carnation . . . so of his color called." In the last century Carnations were in special favor in Holland and England, and we may read in a number of the *Spectator* that "now and then a few fanciful people spend all their time in the cultivation of a single Tulip or a Carnation." Fifty years ago between three and four hundred varieties of the Carnation were already noted in English catalogues.

Mr. Sereno Watson's eighteenth contribution to American botany, reprinted from the twenty-sixth volume of the *Proceedings of the American Academy of Arts and Sciences*, has appeared. It contains descriptions of some new North American plants, chiefly of the United States, with a revision of the American species of the genus Erythronium, in which Mr. Watson now recognizes thirteen North American species; descriptions of new Mexican plants collected chiefly by Mr. C. G. Pringle in 1889 and 1890, and including a few new genera and several new species; a note upon a wild species of Zea, from Mexico, and upon a small collection of plants made in the island of Ascension by Mr. E. G. Loomis, of the Nautical Almanac Bureau, during the visit of the United States Eclipse Expedition to the island in 1889.

The editor of the *Country Gentleman* says that he once received some Peach-cions in summer, and the sender had left their leaves on to shade them and to keep them from drying up. Of course, these leaves sent a great deal of watery vapor into the dry summer air, and in a few hours the shoots were withered. If he had cut all the leaves off, leaving only the stumps of the leaf-stalks, they would have remained plump and fresh. We often see radishes offered for sale in grocery-windows with all the leaves on, and in a few hours they are shrunk and withered. If the leaves of radishes, beets and similar vegetables are cut off at once as soon as the roots are taken from the ground they will keep plump and fresh. If the leaves are left on trees which are cut down in summer they will pump the sap out of the timber and hasten the seasoning of the wood, which might otherwise become sap-rotten.

A photograph recently reproduced in the *North-western Lumberman* showed a redwood plank of extraordinary size, measuring sixteen feet five inches in width by twelve feet nine inches in length and five inches in thickness. It was cut from a tree thirty-five feet in diameter and three hundred feet tall, being hewn out of the stump after the tree was cut at about twenty-eight feet above the ground. A locomotive, attached to a block and tackle, was needed to lower it, and two men were occupied for a month in roughly preparing it for shipment. The price of this labor, added to the cost of transportation, amounted to some $3,000, after the plank had been taken by water to San Francisco. The tree stood in Humboldt County, California, and the plank, after being exhibited in various cities, will probably be a feature of the World's Fair at Chicago. A specially constructed car is required for its transportation.

"After some trouble," wrote Fortune, in his account of his travels in the Malay Archipelago in 1845, "I discovered the locality of the beautiful *Phalænopsis amabilis*. I was in the habit of making an Indian's hut in the wood my headquarters for a certain time, where I held a sort of market for the purchase of orchidaceous plants. The ground in front of the hut was usually strewed with these plants in the state in which they had been cut from the trees, and often covered with flowers. The Phalænopsis in particular was very beautiful at this time. I was most anxious to get large specimens of this plant, and offered a dollar, which was a high sum in an Indian forest, for the largest specimen which should be brought to me. The lover of this beautiful tribe of plants will easily imagine the delight I felt when I saw two Indians approaching with a plant of extraordinary size, having ten or twelve branching flower-stalks upon it and upward of a hundred flowers in full bloom." This plant was successfully transported to England and established in the garden of the Horticultural Society, and, although it had been somewhat cut to get it into the packing-case, was by far the largest specimen then to be seen in Europe.

In his *Sylva*, written two centuries ago, Evelyn notes, among other giant Linden-trees in Germany, one of such size and antiquity that it was recognized in the name of the town in Wurtemberg where it grew, this being called Neustadt-an-der-Linden. He describes it as measuring more than twenty-seven feet in circumference, and covering, with the spread of its branches, a space four hundred and three feet in diameter, and says that it was "set about with divers columns and monuments of stone (now eighty-two in number and formerly above a hundred more) which several princes and noble persons have adorned, and which, as so many pillars, serve likewise to support the umbrageous and venerable boughs." Even then, Evelyn continues, the tree had once been "much ampler, as the ruins and distances of the columns declare, which the rude soldiers have greatly impared." Some of the inscriptions on the stones were copied by him, the oldest, bearing a date, having been cut in the year 1550. In 1837 this giant still survived, and a drawing then made of it, for Loudon's Arboretum, showed its trunk surrounded by a wooden balustrade raised on a coping of stone, and its limbs supported by no less than 108 columns. The people of the village being in the habit of sitting in the tree and eating, several Gooseberry-bushes had sprung up in the crevices of the bark, and their fruit was gathered and sold to visitors. It would be interesting to know whether this tree still survives in the year 1891.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by . . . . . Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, AUGUST 26, 1891.

TABLE OF CONTENTS.

The Northern Pitch Pine.

INQUIRIES about this tree often reach us from Europe, especially from France and Germany, where the impression prevails that it is the species which produces the pitch pine of commerce, generally known in this country as southern pine or Georgia pine, and now exported from the maritime region of the southern Atlantic and Gulf-states to Europe and South America in large quantities. The vernacular name is, in part at least, responsible for this confusion. It should be remembered that all our Pines on which the leaves appear in twos or in threes in the same cluster, and which produce coarse resinous wood distinctly marked by broad bands of dark-colored cells, are called Pitch Pines, and that the Pitch Pine in New England and in New Jersey is an entirely different tree from the Pitch Pine in Georgia, or from the Pitch Pine in California; and that there are more than a dozen different trees in the United States to which this name is applied by the people living in the regions which these trees inhabit.

The northern Pitch Pine is the *Pinus rigida* of botanists. The wood of this tree was formerly used in building in those parts of the country where it was found before cheap transportation brought the more valuable material of the southern Pine-forests to northern markets. Now it is rarely manufactured into lumber, and during the last twenty years it is not probable that a single foot of it has been exported from the United States. The two Pitch Pines of North America, which now possess commercial importance, are the Pine of the south, *Pinus palustris*, and the western or Oregon Pine, *Pinus ponderosa;* and it is from the forests of the former that the pitch pine so largely used in the north is derived, and that furnish all the American hard pine sold in Europe.

The northern Pitch Pine is a valuable and interesting tree in spite of the fact that the lumber it yields is not of the best quality. It grows naturally on poor and sterile land, usually on sandy barrens, and less frequently in sour swampy soil. Its presence is a good indication that the soil which bears it is too poor to supply other trees with sufficient plant-food to compete successfully with this tree. Once in possession of a sandy plain on our northern seaboard no other tree can wrest this advantage from the Pitch Pine, and its hold upon existence is strengthened by the peculiar power it possesses of reproducing itself from seed. Seedlings spring up in great quantities in the neighborhood of seed-bearing trees, and grow rapidly in what would appear to be most unfavorable situations; and it can be raised from seed sown in the open ground more easily and with greater certainty than any other tree which is hardy in the northern states. In this capacity of the seed to germinate readily will be found the greatest value of this tree, which seems destined sooner or later to be used in covering the great tracts of unproductive land which occur in the neighborhood of our northern seaboard. Its value and adaptability for this purpose has already been proved. Thousands of acres of the New England coast have been covered with forests of this tree, raised from seed at a mere nominal cost, and nothing but the dread of fire prevents the extension of these forests over still larger areas. What appears to be barren soil, such as occurs on some parts of Cape Cod, in Massachusetts, and in southern New Jersey, will in forty or fifty years produce a forest of Pitch Pine of considerable money value for the fuel which it contains. No other method has yet been found by which such waste lands can be made to yield any return whatever, and any comprehensive system of agriculture must look to covering sooner or later these lands with trees. The Pitch Pine planted on barren soil will not grow to a large size or produce anything more valuable than fire-wood. It will, however, in a comparatively short time yield on the poorest land several cords of fuel to the acre; and the fuel value of this wood is unsurpassed by that of any other inhabitant of our northern forests, and for many purposes, such as brick-making and for charcoal, it is extremely valuable. When individual specimens have happened to grow in good soil they have sent up tall stout stems two or three feet in diameter. These trunks were eagerly sought for in the early settlement of the country, and were manufactured into timber and flooring of excellent quality and remarkable durability. In some parts of New Jersey houses timbered and floored with this wood a hundred years ago are still standing, and are in a perfect state of preservation. Such trees have now almost entirely disappeared, however, and there will probably never be a question of planting the Pitch Pine for timber, for where the soil is good enough to produce large individuals with straight clean trunks it will support a forest of more valuable species.

As an ornamental tree *Pinus rigida*, although it is not suited to decorate a trim lawn, can be used sometimes to advantage when it is desired to produce bold, picturesque effects or to clothe a barren knoll with verdure. It grows rapidly; the trunk, covered with dark, deeply furrowed bark, broken into large, square plates, is always a handsome object, and the color of the coarse, pale-green foliage makes a good contrast with the other trees of our woods and plantations.

The form this tree assumes, when it stands by itself and has the opportunity to develop the stout branches which are characteristic of single individuals, is well shown in the picture on page 402, made from a photograph of a peculiarly picturesque Massachusetts tree, for which we are indebted to Dr. W. H. Rollins, of Boston.

Monuments in Public Places.—I.

MORE and more, as the years go by, the questions involved in the placing of statues and other monuments in our parks, streets and city squares must attract serious attention from all who have the artistic interests of the community at heart. These questions are three in number: Is the person or event to be commemorated

deserving of such conspicuous and lasting honor? Is the monument sufficiently excellent as a work of art to be worthy of its subject, to satisfy the eyes of those qualified to judge in such matters, and to aid in forming a correct public taste? And is it so placed that it appears to the best advantage itself and in harmony with its surroundings, so as to increase the general attractiveness of the spot where it stands?

With the first of these three questions we need not greatly concern ourselves. Public monuments have very rarely been proposed to do honor to persons or causes whose commemoration would have a bad influence upon the community. We think that no such monument has ever been actually erected in this country, and if a number have been erected which record the existence of men in whom the public take small interest, no one need object to their presence for this cause alone. If a work of art is good as such, we may be glad to possess it, no matter how feebly our minds are impressed by the personality it portrays, or the idea it expresses.

But the question whether or no the work of art is good as such is very important, and not alone from the purely artistic point of view. It is a misfortune if the eyes of the people are offended, and their taste corrupted, by the constant sight of bad works of art, but it is also a misfortune when such a work persistently imprints upon the public mind a weak, false, or grotesque impression of a man entitled to reverence and respect. Bad monuments, in short, injure both those who look at them and those whom they profess to honor. And there are many such in all our cities. Who, for example, can be won to admiration of the poet by the contorted, ridiculous figure which, at the entrance of the Mall in the Central Park, bears the name of Burns? Or who can gain a fresh sense of the services that Seward rendered to the Republic by contemplating his statue on Madison Square? Farragut is really commemorated, really honored, by the figure which stands not far away from this Seward. Each time we pass it we think with gratitude and admiration of him, while we receive a never-failing impression of pleasure from the sight of the work of art as such. Nor need it be thought that the humblest among the populace are blind and deaf to the difference between the aspect and message of such works as these two. Hundreds of persons of all classes daily stop to study the Farragut statue, while, if one watches at the other end of the park, he will find that scarcely a glance is ever directed to the Seward. No one points out the Dodge monument on Sixth Avenue to the passing stranger, and, probably, few people know even that there is a bust of Washington Irving in Bryant Park, though, if these were really fine works, they would be recognized, like the Farragut, as among the things every visitor to New York should see. St. Gaudens' statue of Lincoln not only adorns the city of Chicago, and daily teaches its people what sculptor's work should be, but it helps to interpret our greatest man to the rising generation. But what lessons are inculcated by the statue of Lincoln in Union Square? And who will ever care to inform himself about Bolivar after seeing his equestrian figure in the Central Park?

The proportion of bad monuments to good ones in any American city to-day is probably at least ten to one. The collective effect of so many poor ones in deforming our public places and in discouraging, if not corrupting, the people's taste for art can hardly be overestimated, and surely the time has come when a more serious sense of responsibility should be impressed upon those who have such matters under their control. Whatever is now admitted to our parks and streets is almost certain to stand there for centuries. We cannot hope for many successful efforts like that of General Custer's widow, who, a few years ago, secured the removal of a ridiculous statue of her husband from the Government grounds at West Point. The only sure and sensible way to avoid bequeathing monstrosities to our children is to prevent their erection.

Adequate means toward this end have been provided as regards the Central Park at least, for no monument can be erected there without the permission of a committee of three persons well qualified to choose among good and bad works of art. Until lately, it must be said, this committee has consistently erred on the side of leniency. All lovers of art, therefore, were gratified to learn last spring that it had refused permission for the erection of a statue already completed, but judged of insufficient merit. They may regret that this same statue has since been set up in one of our small city squares; but it had better be there than in the park, and the precedent established by its rejection will surely work for future good. There is no danger, we believe, of over-severity in the matter. It is a painful task to refuse a work which is offered by generous, well-meaning citizens, and a task certain to bring a measure of unreasoning public condemnation upon those who are prominent in its performance. It is not likely that our park will ever be deprived of a work of even a reasonable degree of excellence, while it is likely that for many years to come foolish and grotesque monuments will be offered to it in ever-increasing numbers. We feel, therefore, that this is a subject with regard to which public sentiment of the right sort should be appealed to, and that the press and the people ought to encourage those in charge of our public places consistently to temper mercy to the artist and would-be donor with justice to the people at large and the cause of art. The streets and parks of a great city ought to be guarded against the intrusion of bad works of art even more carefully than the apartments of a public museum; for while hundreds or even thousands of persons may daily visit the museum, tens of thousands must, whether they will or not, daily look on objects set under the open sky.

Black Tea and Green.

WHAT is the difference between black tea and green tea? Are they produced by different plants or merely by different methods of treating the leaves? And are the Oolong and Japanese teas, so popular in this country, really green teas or black? One so often hears these questions asked, and so seldom gets a reliable answer, that our readers may be interested in the following account of Japanese tea-production which we quote from Mrs. Scidmore's "Jinrikisha Days in Japan."

The Tea-plant, as every one knows, is a hardy evergreen of the Camellia family. It grows a thick and solidly massed bush, and, at first glance at a field regularly dotted and bordered with the round bushes setting close to the ground, one might easily mistake it for Box. In the spring the young leaves crop out at the ends of the shoots and branches, and when the whole top of the bush is covered with pale, golden-green tips, generally in May, the first picking takes place. The second picking belongs to the fire-fly season in June, and after that great festival tea comes in from the plantations in decreasing quantities, until the end of August. The choicer qualities of tea are never exported, but consumed at home. Choice basket-fired tea, such as is used in the homes of the rich and well-to-do Japanese, sells for one or two dollars a pound. There are choicer, more carefully grown and prepared teas, which cost as high as from seven to ten dollars a pound, but such teas are shaded from the hot suns by matted awnings, and the picker, going down lines of these carefully tended bushes, nips off only the youngest leaves or buds at the tip of each shoot. The average tea, bought by the exporters for shipment to the United States and Canada, is of the commonest quality, and, according to Japanese trade statistics, the average value is eleven cents a pound, as it stands, subject to the export duty and ready for shipment abroad.

Japan tea came into market as a cheaper substitute for the green teas of China, those carefully rolled Young Hysons and Gunpowders of our grandmothers' fancy. Europe has never received the Japan teas with favor, but the bulk of American importations is Japanese. . . . For green tea, the leaves are dried over hot fires almost immediately after picking, leaving the *theine* or active principle of the leaf in full strength. For black tea, the leaves are allowed to wilt and ferment in heaps for from five to fourteen days, or until the leaf turns red and the harmful properties of the *theine* have been partly destroyed.

The Oolong tea of south China is nearest to green tea, its fermentation being limited to three or five days only, while the richly flavored black teas of north China are allowed to ferment for twice that period, to prepare them for the Russian and English markets. . . . The Japanese government made experiments in the manufacture of black tea in the province of Ise, but the results were not satisfactory, and no further efforts have been made to compete in that line with China. Japan will continue to furnish the world's supply of green tea. . . . The young tea-leaves, picked in May and early June, comprise more than half the whole season's crop, succeeding growths of leaves being coarser and having less flavor. Tea which is to be exported is treated to an extra firing, to dry it thoroughly before the voyage, and, at the same time, it is "polished," or coated with indigo, Prussian blue, gypsum and other things, which give it the gray lustre that no dried tea-leaf ever naturally wore, but that American tea-drinkers insist on having. Before the tea-leaves are put in the pans for the second firing, men, whose arms are dyed with indigo to the elbows, go down the lines and dust a little of the powder into each pan. Then the tossing and stirring of the leaves follows, and the dye is worked thoroughly into them. . . . This skilled labor is paid for at rates to make the Knights of Labor groan, the wage-list showing how impossible Tea-culture is for the United States until protectionist tea-drinkers are ready to pay ten dollars a pound for the commonest grades. During the four busy months of the tea-season the firers are paid the equivalent of eleven and four-tenths cents, United States gold, for a day's work of thirteen hours. Less expert hands, who give the second firing, or polishing, receive nine and six-tenths cents a day. Those who sort and finally pack the tea and who work as rapidly and automatically as machines, get the immense sum of fifteen cents. . . . Each year the United States pays over $7,000,000 for the nerve-racking green tea of Japan.

How We Renewed an Old Place.

XVII.—DISCOURAGEMENTS.

IT was, I believe, Sir George Cornewall Lewis who declared that life would be a very enjoyable thing were it not for its pleasures, which is convincing proof that he must at some time or other have interested himself in gardening, since this pursuit, which at first seems, of all others, the most gentle and enticing, leads the unwary dilettante from woe to woe before it has done with him.

As soon as our forest is tall enough to show above it, we are talking of erecting an arch at its most obvious point of entrance, with the appropriate inscription,

Abandon hope, all ye who enter here!

our experience leading us to think that the only true way to enjoy a prospective wilderness is to find one's blessedness in being among the happy few who expect nothing, and therefore can never have any but agreeable surprises. This arch, which perhaps will more appropriately take the form of a lich-gate, is to be sculptured with high-reliefs of the woodchuck and the field-mouse, while the rose-bug and the borer are to find a prominent place in the general decoration. This architectural step has been suggested by the appearance of a new enemy, which has destroyed the last vestige of our confidence in conifers, and is a new proof of that perversity in trees to which I have before reluctantly called attention.

Early in July we noticed a tendency to droop in the leaders of some of the Pines and Spruces, but concluded it might be the dry hot weather which had affected their uprightness. A week or two more passed, and the new tassels of the year's growth all began to turn yellow and to hang down disconsolately. We then supposed that some one in passing might have given the tops of the little trees an unfriendly twitch, from which they were suffering; but as the days went by and a stout little Norway Spruce near the house began to lose its top-knot, and Episcopus himself showed a bad kink in his mitre, we thought it worth while to look into the matter more closely, so we chopped off the head of one of the sufferers and gave it a post-mortem examination. Dissection revealed ravages, and the fatal secret was out. There was a worm at the core!

And not one worm, but many, small, white, plump and persevering, indifferent to resin, and coolly tunneling their way down the inside of the stem toward the ground. Certain leaks on the outside, and port-holes of their own construction, showed the exact length to which they had gone, so that by cutting just where these signs disappeared, we had the satisfaction of ending the earthly career of the leading invader by snipping his fat unpleasant carcass neatly in two.

We pursued our insidious foe from tree to tree with the shears, and beheaded him with great slaughter. But, alas! it was only a realization of the old nursery sneer, about cutting off your nose to spite your face, for when we had decapitated the worm we left a headless tree to serve as his monument, and, in some cases, the wretched little monster compelled the destruction of three years' slow growth.

The parent of the worm, being a fly of ambition and taste, invariably picked out the biggest and showiest of the poor little struggling trees to lay her eggs in, so that after the day of judgment was over and the ins(ect)urrection crushed, our pride was crushed with it, for the borer, not being, alack! the baseless fabric of a vision, left an awful wrack behind, both of our Pines and our vainglory.

Small comfort do we find in the assurance that the Pines will be none the worse for topping, for, with a life and trees so short as ours, "a few years" are not to be lightly regarded, and the poor hill had precious little good looks to lose, and has been waiting for its beauty already quite long enough. Moreover, what assurance can we have that every summer will not bring with it fresh devastation? It takes a year or two for insects to find you out; but their first call is never their last. If the borers have intelligence of the existence of Pines on "Doctor's Hill," they will come again as sure as the tax-collector, and new woes are in store for us from their visitations.

Moved by that desire to find consolation in our neighbor's ills, to which La Rochefoucauld cynically alludes, we go about spying at the tops of other people's evergreens, and find that this is the borer's year. Driving, a few days since, in a neighboring village, I saw, with concern, a long row of tall Norway Spruces at least forty feet high, that enclose a public garden, all suffering from the attacks of our fell marauder. Luckily, their tops will hardly be missed, while ours—Wae's me! as Carlyle would moan.

Now the question arises, Is there any prevention as well as cure for this infliction? Is there any application obnoxious to the borer's mamma that can be put where she would lay her eggs, and so induce her to move on? Has she any avowed distaste for whale-oil soap or coal-tar or kerosene emulsion, or any other unpleasant odor? And if there is such a deterrent, where should it be applied—on the very top of the leader, or at the place where the new shoots start from the old year's growth?

When a person sets out to plant a tree or two he scarcely bargains for having the study of entomology thrown in, with a course of chemistry into the bargain, not to mention toxicology and the trade of wholesale murder, until he might as well begin the career of gardener by serving an apprenticeship to the Czar of Russia. I am horrified by the bloodthirstiness developed by this seemingly innocent diversion; still, this but confirms the view of pleasures before quoted. Indeed, I am not sure but there is opening for an essay on the Dangerous Moral Tendencies of Gardening. The only objection to it is, that if the Legislature of Massachusetts got wind of such a thing it would pass a law which might prove inconvenient. There are advantages in having your morals legislated about by a paternal, not to say Puritanically paternal, government, but there are drawbacks also—one does not always wish to be virtuous by act of Parliament. Still, if the legislation can be brought to bear upon worms, we will not complain.

An eminent Philadelphia physician, visiting Boston, was struck with an inscription in the Public Garden, "Dogs forbidden to swim in this pond on Sunday," and remarked that he knew that education had been carried to an advanced stage in Massachusetts, but he had not learned before that even the dogs had been taught to read! How delighted we should be to learn that the Gypsey Moth has been warned off by the General Court. So far we of the South Shore have been left to cope, somewhat ineffectively, I admit, with our own insects, but if the famous moth finds us out we may expect the government myrmidons at its heels, and let us hope that they will carry the Web-worms with them. But a commission ramping about the fields, even for so praiseworthy a purpose, has its terrors.

Another discouragement comes in the worm which saws off the small branches of the Oaks and leaves the ground strewn with twigs, as after a storm, but that supercilious insect disdains trees the size of ours, and he is still to be anticipated.

Upon some of the dwarf evergreens we have discovered a white scale insect, something like a Mealy-bug, which covers the trunks and branches with its white spots, but that seems to yield to the dissuasive effects of soap and water, and disappears after a good scrubbing.

The Hemlocks are to be watched with a new anxiety since the newspapers tell us of a worm that is destroying the foliage and killing the timber in Potter County, Pennsylvania. This creature infests the trees in great quantities, to the dismay of the lumbermen, who are unable to destroy them. It is hard enough to persuade a Hemlock to grow anyway, but if a beast is lying in wait to devour it, we may as well give up altogether. I am told that there is a book as big as the Bible, published by the Agricultural Department in Washington, about nothing in the world but the insects injurious to forest-trees, which seems enough to discourage the planters, even of a wood that can be covered by a pocket-handkerchief like our own; but, to crown all, we rashly took a Brobdignaggian in the tree-line to walk in our Lilliput one day—a Brobdignaggian to whom the largest Elm in Hingham is but a walking-stick—and, looking down upon our three-inch Oaks, he complained that there were not trees enough! *Lucus a non lucendo*—fancy a forest with that deficiency! Having, moreover, discovered that our favorite Beeches were Black Birches, he contrived to impress us with the fact that the best of our forest was the prospect, and that, when the trees were grown, we should not even have that! That Brobdignaggian was a terror! Luckily he had not much daylight to see the place in, or we should never have the courage to go on, for, wherever we had a good-sized tree he advised that it should be cut down, and if there was a square inch of territory without a seedling he thought it would be a good plan to put in a handful; and he even showed a disposition to discredit our crack story about a yield of forty bushels in the palmy days of our great Pear-tree, Methuseleh, but that may have been because we tried to make him believe they were barrels.

So much for taking a Man-Mountain into Lilliput. I would not have trusted that one alone upon the premises with a pair of scissors, for there is nothing less to be depended on than the cutting mania. Granted that one ultimately accepts the situation, the moment when your tree comes down is always one of anguish. It takes so long to grow, and is so easily destroyed. Our Brobdignaggian took his toll at last, for he pointed out the fact that the flourishing little Elm I have been cherishing to shade the seat in the Box-arbor from the noon-day heat, was really injuring the Box, and should come down, which it did forthwith, as a tribute to his superior knowledge, a nice little tree, too, that it would take ten years and more to grow again.

We have another disturbing visitor who insists upon a vista, which involves the sacrifice of a fine clump of Lilacs and Buckthorn that shuts off a view of the northern part of the place. We are disposed to think that it would be an improvement to get a glimpse of the great Elm-trunk and the green grass beyond; but, suppose we do not like it when the bushes are down, what then?

Even given on his part the best artistic perception, does it follow that another man's views of what you ought to like always suit your own?

May it not perhaps be wiser to work out your own problems in your own way? Human nature is so constituted that it yearns for authority, and when it gets authority it chafes thereat, and each man cherishes his own unwisdom as dearer than the knowledge of another. Such contrary beings are we that it is always what we have not that seems the greater blessing, and we seldom know when we are well off. The hardest state of mind to attain is content, and so little do we know the essence of happiness that finding the contented man we forthwith compassionate him for his lack of ambition, or gird at him for supineness, and pride ourselves upon our own divine unrest.

Even thus do the educating influences of the garden lead us round to philosophy, and the vista through the bushes opens out a moral perspective.

It is only by what we suffer that we learn what is worth while, and, judging by the amount of suffering our amateur gardening gives us, we ought in time to have the wisdom of Solomon, which, ranging from the Cedar of Lebanon to the Hyssop on the wall, must have given him a good deal to undergo. No wonder that he discovered that "all is vanity." Probably it was borne in upon him by finding a borer in his own pet Cedar, or a caterpillar crawling over the remains of his last Hyssop.

We, struggling along after that illustrious gardener of Israel, have at least mastered one lesson, the important one that Nature, the rudest of task-mistresses, takes pains early to impress upon her pupils, sternly reiterating,

I teach by killing, let the others learn!

Hingham, Mass. *M. C. Robbins.*

Dijon.—II.

THERE is but one real park at Dijon, and the fact is shown by its name, which is simply "The Park." It was begun in the year 1610 as a private pleasure-ground for the "Great Condé," who was then Governor of Burgundy, and was designed by Le Nôtre. Thus the memories of two men, each the greatest of his time in his own path, unite to give it unusual historical interest; and it also has peculiar artistic interest from its unlikeness to the designs with which we generally associate the name of Le Nôtre. Here are no marble terraces and sculptured fountains, no clipped avenues and arbors, no formal yet intricate paths and ornamental beds of color. Regular though the design is, it is extremely simple, and now that the trees have attained gigantic size and the picturesque outlines of age, the park gives, as a whole, an impression of peacefulness and sober but almost artless charm. This impression is enhanced by the fact that, as is the case with most parks in provincial towns which lie at a distance from the busy streets, it is almost always empty except on fine Sunday afternoons and holidays. Even when we visited it, on a lovely Sunday morning in July, no carriage-wheels but our own were heard, and only two isolated pedestrians broke the wide stillness by a footfall on the gravel paths. I doubt whether at the most favorable times this park is very full of life; for it is so far away from the centre of the city that only energetic walkers can reach it on foot; and, moreover, the natural environs of Dijon are so lovely that such walkers may well seek refreshment there rather than in the place which, while thinking only of his own pleasure, *le grand Condé* was preparing for the populace of to-day.

An avenue of about three-quarters of a mile in length leads to the only entrance of the park from the south-western gate of the town. It is planted with four rows of trees, of no great age, and, unfortunately, unsymmetrical aspect. Among them I noticed Lindens, Horse-chestnuts, Ashes, Locusts and two kinds of Maple, *Acer campestre* and *A. platanoides*. But about midway of its length occurs a large rond-point, with a big basin in the centre, and from this point on the planting has been done with Elms alone, and the effect is consequently better. All this, however, is modern work—*le grand Condé* felt no impulse to join the city to his park by a wide public highway. It is only when we approach a great monumental gate-way, opening in a high wall, that we see traces of the work of the great seventeenth-century gardener. From this gate-way runs a very wide, straight avenue, at the far, dim end of which we barely discern the shape of a picturesque little château. This avenue, half a mile or more in length, is forbidden to wheels, although on each side of its broad central strip of turf runs a road quite wide enough to receive them. Carriages may follow the road which, under thickly overhanging trees, encircles the park at its outer edge, but all other portions must be visited on foot. However, it is no hardship to walk in weather such as central France can give us in July, and the sunny quietude of the stately scene is so enchanting that one hardly wishes for the gay coaches that in Condé's time doubtless enlivened all parts of the enclosure. After walking a while we begin to feel, too, that in Condé's time the place itself cannot have been nearly so beautiful as now. For we see that it is rather a wood traversed by straight roads than a park in the modern sense of the word; and, of course, a wood in its youth has little of the beauty, and none of the majesty, which characterize one where two centuries have developed the trees to magnificent proportions, and yet have broken few gaps through their ranks. The full sense of the special character of this park is not obtained, however, until one reaches a great circular space, half-way up the avenue, whence twelve straight roads diverge in as many different directions. Often in other old parks, as notably in the one at Dresden, we find a central avenue flanked by masses of trees too close for the eye to penetrate, beyond which might lie a genuine forest, but beyond which really do lie open lawns and sunny paths and flower-beds. From the central space in the park at Dijon, however, we see down the twelve radiating roads nothing but unbroken walls of foliage supported by gigantic trunks sheathed with luxuriant Ivy. Only a bit of blue sky shows at the end of each perspective, and the forest-aspect is enhanced by the fact that all the roads are turfed. Twelve great stone seats encircle the open space, alternating with the debouchments of the roads. Thus, the design of the park may be compared to that of a great wheel, with the outer drive for the tire, the twelve grass-roads for spokes, the central area for the hub, and all the spaces filled by a thick growth of ancient trees. Otherwise there is nothing to be described, save a few small paths, which, on the side by the river, run from the outer drive toward the twelve

roads, and here and there open into little irregular glades which cannot be dignified by the name of lawns.

But there is a river-side to the park, and this is really its main point of interest, giving it a variety and charm so great that one never thinks of its design as being monotonous or tame. From the beginning the little far-off château has asserted its importance in the scheme, attracting the foot as well as the eye, and giving an artistic reason for the long avenue perspective; and, as we approach it, curiosity is whetted by the discovery that it cannot be reached—it lies on the other side of the narrow river Ouche. But, to emphasize the fact that this is the picture we have been brought to see, the encircling drive here widens out into a fine terrace, over the edge of which we may look down along a massive water-wall, fringed with flowering plants, into the yellow stream below. Condé called the château *La Colombière*—the "Dove-cote"—and, to enhance its attractions, caused the park to be laid out, probably using it as a hunting-lodge or summer villa in agreeable contrast to the tall, grim, medieval pile which was his official residence within the town. Just what it is to-day I cannot tell, or whether tourists, more enterprising than we, could have found an easy way to it and a pass-word to unlock its doors. In that golden Sabbath stillness it seemed pleasantest to think of it as a sort of enchanted home of sleeping princesses, ignoring certain prosaic signs which seemed to imply some not very dignified sort of modern serviceableness. A little to the right of the château lies a little island in midstream, crowded with those tall spiring Poplars—not Lombardys, but Black Poplars lopped of their large branches, and feathery to their lofty tops—without which no scene would look truly French. The clipped hedges too, which are almost equally characteristic of the land, although they do not occur in the park itself, surround the château and give it dignity and charm together. And right and left, as we lean over the low balustrade, the eye can follow the pretty stream lying deep between its verdant banks, and see, off the soft, blue hills beneath, a sky almost as brightly blue as our own country shows us in July.

A great majority of the trees within the park itself are Horse-chestnuts and Elms, and it was here that I first discovered what a Horse-chestnut might become. "A symmetrical tree with a compact round head"—thus it is described for us in botany-books and horticulturists' catalogues, and thus we usually see it, not only in America but in Europe too. But here, where it has grown in masses, and for generations, its aspect is so entirely different that no one, seeing the size and outlines of these Dijon trees, and not seeing their foliage, would be likely to fit them with their proper name. Along the grass-roads especially, as one viewed them from the central space, they rose to an enormous height, with broken outlines and huge pendent branches, now revealing a great reach of massive trunk, and again concealing it by luxuriant irregular cascades of foliage. No more unpicturesque tree could be imagined than a "fine Horse-chestnut," as we commonly understand the term; but I have never seen trees more picturesque than the old Horse-chestnuts here.

New York. *M. G. Van Rensselaer.*

Foreign Correspondence.

London Letter.

Aristolochia grandiflora is now finely in flower at Kew, a plant of it having been kindly presented by Mr. Sturtevant, who found it two years ago in a garden on the Hudson River under the name of *A. pelicana* (see Garden and Forest, vol. iii., p. 596). Until Mr. Sturtevant's plants came I do not believe the true *A. grandiflora* had been in cultivation in England for many years, the commoner *A. ornithocephala* being generally grown under that name.

In the house here devoted to *Victoria regia* there is a very vigorous plant of *A. grandiflora* with about twenty flowers and buds upon it, and the large, long-tailed, extraordinary-looking blooms hanging from the roof over the great tray-like leaves of the Victoria have a particularly striking effect. As a stove-climber for large houses this Aristolochia has quite exceptional claims. It grows very freely in a moist, unshaded house.

Mucuna atropurpurea is an annual attraction in the large Palm-house at Kew, where it is now at its best. Like the majority of the perennial species of this genus, it grows very vigorously, its Bean-like shoots extending many yards along wires or anything else that they can entwine themselves round. The leaves are large, ternate, and covered with a silky tomentum; the racemes are axillary, pendulous on cord-like stalks a foot long. Each raceme is about as large as a pound-bunch of grapes, and is made up of about twenty flowers, each two and a half inches long and colored blackish purple. They last a long time, and are copiously produced by healthy plants. The bean-like pods of this species are coated with prurient hairs, which are celebrated as an anthelmintic known as cowage or cow-itch. The species is a native of the East Indies.

Gourds as Stove-climbers.—The attractiveness of the Water-lily house at Kew at this time of year is largely due to the tropical Gourds, which are planted in a shallow border all round the house and trained along under the roof, from which the fruits now hang in great profusion. Luffas, including *L. gigantea*, which has a cucumber-like fruit five feet long; the large Bottle Gourds; the Trichosanthes (Snake Gourds); the brown reticulated Sikkim Cucumber, with yellow, crimson, orange and variegated Cucumis and Momordicas, are now at their best. They are as attractive in colors as the most brilliant flowers, and they are a novelty to many of the thousands of visitors who come to Kew daily, and who "have never seen such queer-looking cucumber things before."

Aerides Lawrenciæ and *A. Sanderianum* are merely forms of one species, and that a very beautiful one. The flowers are the largest of all Aerides, and their colors are pretty. Both kinds grow as freely as their ally, *A. odoratum*, and flower as regularly. Frequent importations of them are made chiefly by the Messrs. Sander & Co., in whose nursery a fine lot are now in bloom. Each flower is at least twice as large as the flower of *A. odoratum*, and colored white or cream-yellow, with the segments tipped with bright amethyst. The form named *A. Lawrenciæ* by Professor Ruchenbach was described by him in 1883 as "the best and most beautiful Aerides ever introduced," and it was shortly afterward sold by auction for thirty-five guineas, the purchaser being Sir Trevor Lawrence.

Lemoine's New Gladioli.—These are now a handsome feature in our bulb-border, and promise to remain an attraction for some weeks to come. They are fulfilling all that their raiser predicted for them—namely, hardiness sufficient to enable them to withstand the cold of an English winter, floriferousness, and constitution which is easily accommodated by the most ordinary soil. That their flowers are large, distinct and beautiful goes without saying, and the question, Are they equal in beauty to the Brenchleyensis section of Gladioli? is answered differently by different cultivators. Certainly the two sections fully merit favor just as Tea Roses and Hybrid Perpetuals do. We grow a representative collection of both, and now that we know the good qualities of Lemoine's Nanceianus seedlings we should not willingly discard one of them.

Interesting Combinations.—An attractive large bed along one of the principal walks at Kew is made up of compact bushes of *Olearia Haastii* and Tiger Lilies. They are in flower together, and the gray foliage and white flowers of the Olearia are a capital foil to the bright orange of the Lilies. Another bed is formed of small bush Rhododendrons and *Lilium Canadense;* another of American Azaleas and *L. superbum*, while *L. auratum* is grown in large quantities among various kinds of shrubs. The effect of these large masses of Lily-flowers could not be easily surpassed, and their perfume makes the whole garden pleasant. *L. candidum*, which is usually a failure at Kew, has done well here this year. *L. longiflorum* is also very fine; in fact, the Lilies generally are better than they have ever been. This is probably due to the moisture and coolness of the present summer.

Carnations are now more popular than ever before. The number of named kinds in English gardens is legion, and it is somewhat remarkable that fanciers of these plants can find marks of distinction in every one of them. They are not every man's plant, or rather it would be more cor-

Fig. 65.—Northern Pitch Pine (*Pinus rigida*).—See page 397.

rect to say the different varieties cannot be cultivated in the same garden—those kinds which thrive in one place failing in another. A remarkable fact in relation to seedling Carnations is their dying out after a few years' cultivation, or, if they do not die out, they revert to some inferior form. Of course, many are stable enough in character. The raisers of new seedling Carnations send their most promising kinds to be cultivated in the trial grounds at Chiswick, side by side with those of established reputation. These are examined annually by a committee of experts, who award marks or certificates to the best. The list of certificated new kinds is published in the *Journal of the Royal Horticultural Society*, and in this way growers are made acquainted with the best new seedlings as tried at Chiswick. The examination of Carnations, Annuals, Peas, Beans and several other classes was completed last week. Tomatoes will be examined shortly. Meanwhile, the exhibition of these plants under first-rate cultivation, in a large house set apart for them, is both interesting and instructive. A house over a hundred feet long by thirty feet wide is entirely filled with Tomatoes, two of each kind being grown and labeled with the raiser's name. The gardens in which these trials take place are open to the public as well as to the Fellows of the Royal Horticultural Society.

Cultural Department.

Some Hybrid Gladioli.

MANY years ago I obtained bulbs of *Gladiolus purpureo-auratus*, and at once began to raise hybrids between this species, then new, and the Gandavensis varieties, and had several sorts when Monsieur Lemoine first offered his hybrids for sale. Among the first seedlings were Alguacil and Corporal, which I still regard as worthy of a name and place though raised so long ago; indeed, Corporal, to which the Massachusetts Horticultural Society awarded a first-class certificate in 1884, is still the brightest of all my varieties. I mention this to show that there is a strong element of chance in hybridizing operations; the first attempt may produce results which thousands of subsequent seedlings may not surpass. Nevertheless, every year has added to my collection, which now numbers, of the Lemoinei strain, sixty-four varieties, all sufficiently distinct to be recognized. Not all which have been named have been preserved, for when a seedling has appeared of the same general appearance as a named kind, the stock of the latter has been sacrificed and its name and number given to the new-comer.

Of a lot of seedlings more than half will have the form of *G. purpureo-auratus*, that is, hooded over at the top by the strong curvature of the upper petal. This form is generally accompanied by a uniformity of color, red or purplish red, with a crimson blotch on the lower petal, which is tipped with a greenish yellow. Yet I have seen three of this shape which I think are good enough for any collection: Lemoine's Sceptre d'Or, which is a fine, clear, yellow flower; Lemoine's Masque de Fer, a bright red flower whose two lower lateral petals are black, with a bright yellow point in the centre of each; and a seedling, probably from the latter, which appeared among my plants two years ago; it is exactly like its supposed parent, except that every division of the flower is edged with a fine white line.

A great many of the seedlings produce flowers of a broad open shape, which, combined with their color, has caused them to be compared to magnolias, not, I think, a very close comparison. These are mostly of a pink, red or purple color. Some of the best I have of these are Condesa (F. C. C., 1884), a large flower whose color is much like that of a well-ripened water-melon, and Centurion, which is deep red, of an orange cast, the lower petals being crimson and black.

Another class combines the colors of the first section with a much more open shape. Many of these are very good, as their tints are brighter and the yellow of their lower petals is devoid of greenness and is sometimes changed for pure white, as in Prince Regent (F. C. C., 1886). Admiral is another good one of this class and is a remarkably strong grower. Autocrat and Steward are also worth growing.

A fourth class has flowers about as widely opened as the Gandavensis kinds, and a ground color of light buff or salmon (I have never seen a Lemoinei variety with white ground), blotched heavily on the lower central petal or the lower lateral one. Many of these may be seen at horticultural exhibitions, and I raise a large number every year. Of this class I have added to my list Principessa, which is a tall variety with a purple throat, La Duquesa, with cherry and yellow blotch, and Umpire (F. C. C., 1887), whose two lower laterals are brownish red. It is, perhaps, worthy of remark, that the stems in classes one and four are usually tall and slender, and in the others more like those of the Gandavensis sorts.

These four classes will be found to include over ninety per cent. of every large collection of seedlings of the Lemoinei strain. Anything really new and striking must come from the small residue, such as Suffragan, a very small red and yellow flower, which most people would not like, but so brilliant that I still keep it; Pontiff, which frequently has all six segments tipped with yellow and the lower one grained with narrow parallel violet lines, and M. Levèque (Lemoine's), deep crimson-purple throughout. I sow the seed of well-opened flowers only, yet more than fifty per cent. of the seedlings prove to be of the *purpureo-auratus* type; how strong and vigorous must the influence of that species be to appear so abundantly for nearly twenty years, though not but once in all that time has a flower of that shape furnished seed for my sowing.

My experience with Monsieur Lemoine's Nanceianus strain has not been great, but from my observation I should say that their value lies more in what they promise to be than in what they are. The complaint that they have but one flower in perfection at a time does not appear to me to be well founded, for I have to-day counted six perfect and gigantic flowers on the variety Comte Horace de Choiseul, and three pale-pink flowers, not yet withered, occupied the lower part of the same spike; fading is the defect of this otherwise fine flower. President Carnot also fades, though not so badly; but the graining and mottling, which is delicate and beautiful in the parent Saundersi, becomes coarse and displeasing in this. In others the shape is objectionable, being too wide for its height. No doubt, these and other defects will be absent in seedlings yet to come, but I do not believe that Nanceianus or Lemoinei, or any other strain, will ever attain the excellence of the Gandavensis tribe.

Canton, Mass. *W. E. Endicott.*

Spring-flowering Bulbs.

THE first spring-flowering bulbs are now making growth in the border, and this may be considered a warning to plant this class of bulbs as soon as possible. None of my other bulbs rest for so short a season as those of the Taurian Muscari, which, having remained dormant scarcely a month, in the middle of August have made leaves some three inches long. An examination will soon show that many bulbous plants are slowly commencing to move, and, of course, if such bulbs are kept unplanted valuable time is lost to their detriment. Bulbs, corms and rhizomes are always rather mysterious things, and a general collection proves of constant interest, and is no small care, until their habits are well known. Between the accommodating ones which can be persuaded into growth and flower by a little moisture at any season, and the obstinate ones which refuse to grow until a certain season of the year, there is a wide difference with many variations and with all manner of vagaries.

However satisfactory those plants are which grow and bloom with regularity and small care, to one with a spirit of garden adventure in his veins there is great fascination in the cultivation of unreliable and difficult subjects, such as the Oncocyclus Irises of which Mr. Orpet wrote last week. This fascinating group interests me very much, and after some experience I have sometimes thought I knew how to grow them, and then again I have concluded that they are capital subjects to humble one's pride in his cultural skill. It is very well understood that, given certain protection, so that conditions of growth may be controlled, a fair proportion of these plants may be expected to bloom, but some of us have too little time in the garden to watch pots and frames, and we wish to grow hardy subjects in the open. Certainly the Oncocyclus Irises are hardy and do bloom well in the open sometimes, and it would be interesting to know, in a general way, the proper conditions. The first *I. Susiana* I planted made a strong growth in the fall, and with other things in a south border was covered with hard forest-leaves, and in the spring flowered strongly. Since then I have grown numbers of them by the most approved advice, and the result is generally unsatisfactory. Pots were tried last season, an experiment I shall not repeat. I grow about a dozen kinds of Oncocyclus Irises, and they are all equally uncertain as far as culture is concerned. They are all beautiful in flower, however, and well worth

growing, though, like the fisherman's trout, their beauty is somewhat enhanced by the difficulty of securing them. The reign of *I. Gatesii* as the finest of this family was rather short, as we already have a successor in *I. Lorteti*, which is now said to be "the most beautiful Iris ever introduced." It is something like *I. Gatesii*, but with lovelier tints.

Not every one is willing to devote time to plants which require care, and, fortunately, the general run of commercial bulbs, as Daffodils, Tulips and Hyacinths, require little or none. This note may serve to remind some reader to secure at once a liberal supply for the coming year, for the planting season is over all too soon.

Elizabeth, N. J. *J. N. Gerard.*

Cycads.

MANY of these plants are valuable for a certain boldness of effect, some singularity in growth, and they often have tough foliage, which stands well under rough usage. In general, the Cycads grow better in a warm house, but this is not essential for all of them; the well-known *Cycas revoluta*, for example, will flourish under ordinary conservatory treatment in winter, and through the summer it can be used for out-door decoration. Nor are they exacting as to soil. A good loam, somewhat sandy and slightly enriched with old manure, will satisfy them, and they should be potted firmly. They should be drained well, watered freely while they grow, and less abundantly, of course, in winter. They are not very liable to insect pests unless much neglected, their chief enemy being scale; this may be readily removed by the usual methods.

C. revoluta, popularly, though erroneously, known as the "Sago Palm," is, doubtless, the most frequently seen in cultivation, since it has been imported from Japan and China in very large quantities of late years. The stems, of various sizes, from six inches to six feet in height, are denuded of leaves and roots and then boxed up like so many logs of wood, and thus shipped to large dealers in the United States and Europe. These stems possess much vitality and seldom fail to grow after such harsh treatment, unless they have been exposed to frost or otherwise ill-treated in transit. Our recent fashion of using the leaves of this plant in funeral decorations is not a novel one. A similar custom was popular in Saxony fifteen or twenty years ago.

C. circinalis, though not nearly so often seen as the foregoing species, is perhaps the handsomest member of the genus. It has long, graceful, pinnate leaves, which sometimes attain eight to ten feet in extreme length, the pinnæ being falcate and from six to twelve inches in length, dark green and glossy on the upper side and paler beneath. The stem is stout and somewhat similar to that of *C. revoluta*, and it seldom branches, except when extremely old, the branching habit being said to be more common in the male plant than the female.

Another handsome species is *C. Rumphii*, which, when small, bears some resemblance to *C. circinalis*, although it becomes more distinct as it attains age. *C. Rumphii* has a slender stem, from which is produced a crown of pinnate leaves that are from four to six feet long. The pinnæ are narrow, lanceolate and pale green, and rather thin in texture. This species is a native of the Indian Archipelago, and, though elegant in appearance, is hardly equal to the preceding.

Dion edule, another interesting member of the family, has a strong constitution, and is capable of withstanding much neglect. It is a native of Mexico, and has a stout, rough stem, from which are produced a number of stiff, pinnate fronds, the pinnæ being smooth, dark green and sharply pointed, and the lower part of the leaf-stalks being clothed with short, white, woolly hairs. This plant will grow in a cool house, and may also be used to advantage out-of-doors in summer, since the leaves are not easily injured.

Encephalartos villosus is also a fine plant, and in general characteristics has much in common with the Dion, but makes a finer specimen. All the species of Encephalartos make stout short stems, and make them slowly, too, and *E. villosus* produces a number of fronds at a growth, as is the habit of the Cycas. These leaves are from four to six feet long, pinnate, with pinnæ from six to eight inches long, the edges of the latter being spiny, and also terminating in a spine. The stem and crown of the plant are also more or less covered with tomentum of light color.

E. Altensteinii is another admirable member of the genus, and in a general way resembles the preceding, but the base of the petioles is much swollen and the leaves are more widely spread. *E. Altensteinii*, in common with the other members of this genus, is of African origin, and may be used out-of-doors in summer, though such treatment may retard its growth somewhat.

The Zamias, too, include several handsome plants among their thirty-odd species, one good species being *Z. furfuracea*, a stove-plant from Mexico, which bears pinnate leaves about three feet long, the pinnæ being broad and rather irregular in outline. The leaflets are stiff and leathery in texture, and, as the varietal name indicates, the plant is inclined to be scurfed with brownish tomentum. There are also some very handsome species among the Macrozamias, a genus closely allied to the above, notably fine sorts being *M. plumosa*, with slender semi-erect leaves and long pinnæ, *M. Miquelli* and *M. spiralis*, all of which are worthy of a place among select foliage plants.

Holmesburg, Pa. *W. H. Taplin.*

The Blackberry Crop.

FIVE years ago it was hardly possible to recommend any Blackberry as having the essential elements of a fruit good for market or home use. Now we have fairly well tested these first-rate berries, the Snyder, the Agawam and the Taylor. Perhaps our best plan would be to take this list and reverse it for planting. The Taylor is a noble berry. The Agawam is somewhat smaller and delicious. Both are sweet and both are hardy. Snyder is absolutely hardy and a fairly good berry. There is not much difference in these three sorts so far as prolific bearing is concerned. The quality of the two first named is decidedly best. I am also confident that Snyder needs a soil more moist and cool to give good crops. It dries up more easily in a time of drought. I find it gives me very fine crops at the foot of a slope in rich strong soil; whereas Taylor and Agawam give me fine returns from all soils. However, all Blackberries are easily injured by very dry weather. This must not be misinterpreted to imply that the Blackberry can be grown on wet lands, for it cannot.

In order to receive the largest and best crops I have adopted this plan of growth: For two years after setting I cultivate with harrow and hoe; then I let the berries take possession of the land. They will keep out the grass and weeds without help. I allow the canes in such a field to grow till fall, when I cut them back to five or six feet. The old canes are left till spring, as they help to prevent crushing with snow. This plan of culture is, I know, sharply criticised, but I have tried all ways, and am satisfied that it is best for me. I presume those who grow largely for market will find the difficulty of picking such a field too great. But the plan of growing in rows will be also formidable for home culture. The Blackberry is a ferocious plant.

Besides the three sorts named, I have experimented with Wilson and Wilson Junior, both of which are too tender north of New York, though both are delicious when they can be grown. The old Rochelle, or Lawton, is also useless at the north, although all improved sorts pass in market as Lawtons. Kittatinny is a fine berry in size and quality, earlier than Lawton, which was disseminated as long ago as 1865, but it cannot be relied on as hardy year after year. I get a crop once in three or four years. I have rooted out all but a corner where they are allowed to grow for sake of the good they tried to do. Wachusett's Thornless is small, fairly good, but not entitled to much space. Dorchester is so wholly superseded as to need no further reports. Erie is also to be set down as having no claims for general planting.

The Dewberry has so far failed to develop more than one or two sorts adapted to cultivation. The Lucretia is the best that I have tested. It is not quite hardy, but, for all that, generally furnishes a fair crop of superb berries. It begins to ripen July 20th, or a little earlier. This is two weeks before the High Bush. As a market fruit it is very taking, and if it can be obtained without too much trouble it is profitable.

The demand for blackberries is very large, and it is growing. The wild berry can now rarely be obtained. The chief trouble has been with the sourness of unripe Lawtons and Kittatinnys. When not dead-ripe, these berries are poor enough. As consumers get a taste of the sweet sorts, they ask for them and buy greedily. It is not, however, a crop to plant extensively, except on land which is unsuited for anything else. The best plan is to have a variety of small fruits; with Blackberries much less abundantly planted than Raspberries.

The crop this year is excellent, both in quality and in quantity. For home use, no fruit is more wholesome or delicious. It is first-class for cooking, canning and for dessert. The cultivation of the best sorts should be encouraged, from a sanitary point of view, as a most wholesome summer food.

Clinton, N. Y. *E. P. Powell.*

Correspondence.

"A Massachusetts Forest."

To the Editor of Garden and Forest:

Sir,—Mr. Baxter's enthusiastic article about the Blue Hills of Massachusetts (in your issue for August 5th) prompts me to urge again the creation of one general board of commissioners endowed with power to take lands for park purposes in any of the twenty municipalities which compose Greater Boston. These eight cities and twelve towns possess a million inhabitants and more than a thousand million dollars' worth of taxed property. The whole district needs to reserve at once numerous small plots of land for squares and breathing-places; and for country parks not the Blue Hills only, but the Fells and some other wild lands as well. These needed reservations will never be secured unless the several municipalities will unite for the purpose. Let the next Legislature frame an act naming a metropolitan park commission and giving it power to take lands regardless of town and city boundaries. Let the act provide money for the purchase of lands by means of a state loan to be repaid in fifty years by the interested towns. Then let the act provide that it shall take effect and the commission come into existence only when a majority of the votes cast at special elections held in the twenty municipalities shall be yes votes.

A tax levied on a growing thousand millions at the rate of a tenth of a mill on the dollar would in fifty years yield more than enough to pay off a loan of five millions spent in the purchase of lands to-day. Five millions would to-day buy sites for at least fifty squares averaging five acres, together with ten thousand acres of wild lands distributed between the Fells, the Blue Hills and other quarters. Another tenth of a mill on every dollar would provide a hundred thousand a year for road-building and maintenance. Thus easily can Greater Boston save, if she will, her reputation as the most beautiful and most enlightened city in America.

Boston. *Charles Eliot.*

[This letter should have appeared in last week's issue, which contains an editorial allusion to it.—Ed.]

The Florists' Convention.—I.

Extracts from Papers Read.

THE seventh annual convention of the Society of American Florists was held at Toronto last week. The society had never before met without the limits of the United States, and the courtesies extended to the members from this side of the boundary by the local clubs and the city authorities made the convention a most agreeable one in its social features. The addresses of welcome by the Mayor and Alderman Hallam were particularly happy, and the response by Judge Hoitt, of Nashua, New Hampshire, contained fitting allusion to the services rendered to horticulture by English societies and Englishmen. The visitors received the most cordial attentions, and the garden-party, with the accompanying banquet in the beautiful suburban grounds of Alderman Hallam at Chorley Park, 'deserves mention as an example of hearty hospitality. Mr. James Allison, Chief of the Department of Manufactures of the Columbian Exposition and acting head of the Department of Horticulture, was present throughout the meeting, having come at the request of Director-General Davis to report the progress made in organizing the World's Fair and to invite suggestions as to the best means of securing an appropriate representation of the horticulture of the country at the exposition. A committee was appointed to report on this subject, and they recommended the necessity of immediate action, as the time was already too short for securing the proper growth of plants for exhibition. They also recommended that arrangements should be made for ample out-door space for gardening, and they advised the managers to invite the owners of private conservatories to make contributions of specimen plants for the display. Mr. John Thorpe, the first President of the society, was unanimously recommended as a suitable man to take charge of the interests of floriculture at the exhibition.

The work of the year specially commended in the report of the Secretary was that of the Committee on Nomenclature, whose members have taken great pains to secure accuracy in the naming of garden-plants, and especially to reduce the number of synonyms. The officers elected for the ensuing year were James Dean, of Bay Ridge, Long Island, President; William R. Smith, of the Botanic Gardens, Washington, Vice-President; W. J. Stewart, Boston, Massachusetts, Secretary; Myron A. Hunt, Terre Haute, Indiana, Treasurer. The next annual meeting is to be held at Washington.

Extracts from some of the more important papers read at the meeting are given below:

THE PRESIDENT'S ADDRESS.

President Norton, in his opening address, stated, as a gratifying fact, that the membership of the Society was still increasing, and that there was more money in the treasury than there had been at any time since the organization of the Society, seven years ago. Nearly 1,000 names are found now on the roll of the Society, and the number of new members who have joined during the early part of this year is much larger than that of any previous year in its history. Mr. Norton alluded to the present tendency of growing specialties, and he attributed the excellence which had been attained in the growing of special plants like Roses, Carnations, Violets, Chrysanthemums and the like, to the devotion of florists to individual flowers. This excellence was more manifest in the market, because growers took care to reject poor blooms, culling them out and throwing them away, so that the improvement in the general quality of those plants which were sold has been very marked.

During a year or two past certain flowers have brought much higher prices than ever before, and this illustrates the truth that people are always willing to pay the highest price for good quality, so that the extra pains required in growing the best plants and in preparing them for the market always has its reward. Wholesale dealers have no trouble in disposing of such stock, and in spite of its high cost is more readily sold than flowers of inferior quality.

The President congratulated the Society upon the improved methods of arranging cut flowers. The loose, natural way of putting them together with long stems and healthy foliage and with an eye to soft harmonies and contrasts of color, and the habit of using only a few colors in each basket, is a vast improvement upon the style of a few years ago, when matches, corn-broom and wire were considered indispensable factors in making up designs, and when an infinite variety of flowers of all colors was packed stiffly together.

Mr. Norton recommended that ampler opportunities should be afforded to women for going into business as florists. In retail stores especially they have been found exceedingly useful, not only as book-keepers and cashiers, but in waiting upon customers and filling orders. Their correct taste and aptitude for recognizing the beautiful in form and color makes their services of value as artists and designers. Many women to-day throughout the country are doing profitable business on their own account, and there is room for many more in an occupation so pleasant and for which they are so admirably fitted in refinement and taste.

It was said to be an appropriate work of the Society to encourage in every way public exhibitions of plants and flowers. There is no better way of advertising for the trade than by displaying florists' productions at such exhibitions. It educates public taste and creates a demand for florists' products. Horticultural exhibitions which are supported mainly by contributions from private collections are very creditable, but the exhibitions are always better when they are supplemented by the stock of commercial growers.

REVIEW OF NEW PLANTS.

This was the subject of a long paper compiled by Mr. William Falconer, of Glen Cove, New York, from reports on various classes of garden-plants made by recognized experts in special fields. Thus the lists of Hardy Perennials were prepared by Mr. Edward Gillett, of Southwick, Massachusetts, and Mr. George C. Woolson, Superintendent of Planting in the New York City Parks. The best new Chrysanthemums were named by Mr. Edwin Lonsdale, Secretary of the National Chrysanthemum Society. The lists of new Begonias were made by John Saul, of Washington; J. N. Gerard, of Elizabeth, New Jersey; F. T. M'Fadden, of Cincinnati; Mr. E. G. Hill, of Richmond, Indiana; Henry A. Dreer, of Philadelphia; and Messrs. Pitcher & Manda, of the United States Nurseries,

Short Hills, New Jersey. Mr. E. V. Hallock, of Queens, Long Island, wrote of Bulbous Plants; Messrs. E. G. Hill and A. P. Simmons wrote of Fuchsias and Geraniums and so on. The plants named were not all new, but many of them are little known, and the catalogue, with descriptive notes on each plant, is a valuable one. The lists of some of the more important plants are given below.

New French Roses.—Most of these Roses tried last winter proved worthless for growing under glass. Out of nine varieties of Tea Roses I found only one which I considered worth another year's trial. Here are the names of the ones I found of no value: Souvenir de Clairvaux, Comtesse de Witzthum, Comtesse Eva de Starenburg, Jaune Nabonnaud, Maurice Bauvier, Princesse de Sarsina, Souvenir de Lady Ashburton and Souvenir de Madame Sableyrolles. Elisa Fugier, with a white flower somewhat resembling Niphetos, but stiffer-stemed, is the only one I shall try again. Among the hybrid Teas I imported four kinds and shall try three of them for another year. These are Madame Caroline Testout, a large pink Rose of good, firm petals and stiff stem, but not sufficiently double; Triomphe de Pernet Père, a sweet red Rose, but with too much purple in it for a good cut flower, with the form of General Jacqueminot, and a better color would have made it a good rose; Marquise de Salisbury, which only lacks size, and is otherwise an elegant rose; it is a free bloomer, and its flowers are a brilliant velvety red, but entirely too small.—*Ernest Asmus, Hoboken, N. J.*

Bedding Roses.—Etoile de Lyon is showing up well in the open ground. This beautiful Tea succeeds better outside than under glass, and is one of the hardiest of the Tea class. Madame Agatha Nabonnaud is one of the finest bedding Roses and a good grower; color, flesh-tinted rose; buds large and fine. Duchesse Marie Salviate is a beautiful new Tea Rose, and a free grower and bloomer; color, orange yellow, showing red. Madame Pierre Guillot is probably the finest of the new Teas, and is now blooming well in the open ground. The color of its flowers is richer than that of Madame Watteville. Snowflake and Lady Lambert seem to be identical, and so do Dinsmore and Madame Charles Wood. Mrs. Degraw and Henri Plantier are the same.—*Dingee & Conard Company.*

[Note.—As regards Mrs. Degraw: Mr. William Burgess, formerly of Glen Cove, Long Island, and now of Brooklyn, and well known as of Marechal Neil fame, told me that he raised this Rose from seed, perhaps thirty years ago, and named it in compliment to an ex-president of the New York Horticultural Society. Anyway, this Rose has been grown in quantity about Glen Cove for twenty years or more and generally known as Mrs. Degraw or the Burgess Rose, and as such Mr. Burgess exhibited it, year after year, for many years at the Queen's County, New York, agricultural fairs at Mineola. And many rosarians, John N. May among them, who have seen the Rose here, and to whom I sent plants of it, assured me that it was quite distinct from any other Rose. Notwithstanding all this, however, I claim nothing regarding its distinctness.—*Wm. Falconer.*]

New Roses.—Augustine Guinoisseau, a hybrid Tea, is a sport from La France, and similar to it except in color, which is white, faintly flushed with pale pink. In masses or bunches the flowers are admired by every one. Kaiser Frederick is a Tea Rose of the Gloire de Dijon type, producing freely large, very double flowers, with the same coloring as those of Malmaison. I consider this a decided break in climbing Teas, the yellowish salmon tinge common to this class being entirely eliminated. Climbing Perle and Climbing Niphetos, both genuine climbers, throw up strong, vigorous shoots eight to ten feet in length. The Gulf and Pacific states will find these roses great acquisitions.

Madelaine d'Aoust, Tea; color, coppery yellow; petals, heavily edged with white; buds, medium size; growth, moderate; an excellent and distinct bedding Rose. Madame Pierre Guillot, Tea; color, creamy white; petals, edged with rose; buds, large and of beautiful form. Compared with Madame de Watteville, the color is similar; buds larger, more double. Every shoot bears a bud, and has not the Watteville habit of throwing blind wood. Clotilde Soupert, Polyantha Tea: one of the most valuable Roses of recent introduction; it has endured ten degrees below zero planted in the open ground. Waban, a sport from Catharine Mermet; flowers, a very deep shade of rose, with a decided tinge of red on the outer petals; in an even temperature of fifty-five to fifty-eight degrees it produces fine buds; young growths and foliage darker than in the parent, but otherwise it is exactly similar. Our experience with it is limited to the growth and behavior of ten four-inch pot-plants, bedded out in January last.

In the latest European sorts our experience is limited to a few months' growth under glass. Madame Elis Lambert may be described as a medium-sized Marie Guillot, pure white, with an edge of rose on the inner petals, very double, free-blooming, distinct, and a good grower. Elisa Fugier; in form and color of bud very similar to Niphetos; every shoot produces a bud; growth, very vigorous, much more so than in Niphetos; promises well for forcing. Henri Brichard, hybrid Tea; produces very large, globular buds, in color similar to those of Captain Christy, with perhaps a deeper centre; thoroughly distinct, quite different from any in this section, good grower and free bloomer. Triomphe de Pernet Père, hybrid Tea, said to be a cross between General Jacqueminot and the Tea-rose Désir; buds, of fair size, and in style like those of Jacqueminot; fragrant; cherry red; constant bloomer and vigorous grower.—*J. C. Vaughan, Chicago.*

Rose Novelties.—Madame Pierre Guillot, Tea, a magnificent and distinct new Rose, equally good for forcing or for open-ground bedding. This Rose will rank with the finest of the Teas. J. B. Varrone, Tea, is a variety which may be classed as intermediate between Comtesse La Barthe and Luciole. It combines the free-flowering qualities of the former with the rich coloring of the latter. A most distinct and valuable new Rose. Miss Marston, Tea, a large open-shaped flower when fully developed, of the general make and style of Catherine Mermet; a promising new Rose, which will probably force well. Madame Marthe de Bourg, Tea, a distinct-shaped bud of considerable length, somewhat after the form of Niphetos, but differing in color and texture. This Rose blooms well, forces readily, and is of good, sturdy habit.

Other new varieties of the Tea section may be mentioned briefly: Souvenir de Dr. Passot, of very brilliant color, but too thin and scanty in petals, and not large enough; Souvenir de F. Gaulain, a fine, strong, free-flowering Rose, quite double and of good form, but with a decided purplish cast; Jeanne Guillaumez has flowers of beautiful apricot color, but scarcely large enough in bud, very showy when full blown, and quite free; Gustave Nadaud has a bud of bright carmine color, shaded with yellow, long-pointed, lacking in substance, however, and also in distinctness from other varieties; May Rivers and Madame Olga are both very similar to the old variety Ophelia, and not distinct enough from Cornelia Cook.

Georges Farber, Mademoiselle G. Goddard, Madame A. Tarle, Mademoiselle M. Fabisch, Mademoiselle M. Thezillat and Marquis de Foretan are novelties that should not have been put on the market, as they are of no value to any one.

Augustine Guinoisseau, the so-called White La France, is a hybrid Tea. It is admired by many and condemned by not a few as lacking in distinctness of color; it is not white, but it is quite distinct from both the Duchess of Albany and La France. In every respect but color it is a veritable La France, and worthy of culture. Bona Weillshott, another hybrid Tea, is a plant of good growth and great freedom of bloom, but the flower is lacking both in color and form; occasionally it is quite fine, but so few good blooms are produced that it cannot be recommended. La France of '89 is a most distinct and fine Rose. It, however, is not "perpetual" in its bloom, like the hybrid Teas generally. It is semi-climbing in habit and of vigorous constitution, and promises well in form, size and rich coloring. Madame Hortense Montefiore, hybrid Tea, is weak in growth, and the flower lacks size; undesirable. Madame Zea Collogne, of La France type, has a more distinct combination of colors than most others of this type.

Hybrid Perpetuals.—Gustave Piganeau is most distinct and valuable on account of its fine form, large size and good color. These points, together with its great freedom of bloom, place it among the finest of its class. Gloire de l'Exposition de Bruxelles—a very dark crimson-maroon colored Rose, with scarlet shadings. Very full and double and free and fine in habit. Oscar II. Roi de Suede is a very pronounced and distinct Rose; color, cinnabar-crimson, with maroon shadings; of strong growth, and bearing large, handsome flowers. Lady Arthur Hill, James Brownlow, Martin Cahuzac and Maurice de Vilmorin are Roses of promise in this section, and can be commended for trial.

The above hybrids are the most noted ones of the many sent out last year, but the judging has all been done from blooms produced under glass.

Pink Rover.—A Bourbon of the general type and color of Malmaison, but somewhat darker in its shadings; will doubtless prove a useful variety.—*E. G. Hill, Richmond, Indiana.*

New Hardy Roses.—My observations upon the Rose are chiefly with a view to their adaptation for garden-purposes. I can speak of but few this season. Augustine Guinoisseau seems to me an acquisition to the La France group, and likely to prove a valuable addition to this class of Roses. The color is a pale rose or cream, and apparently it flowers as freely as La France, the plant making a similar growth. We have now a trio of beautiful flowers, namely, La France, Duchess of Albany and the above, that will undoubtedly prove of great value for summer-bedding purposes. If we could add to these a pure white, the group would supply a fine quantity of color for the garden. Gustave Piganeau has a flower of the largest size; color, bright carmine lake; habit, good; petal, firm; I confidently expect this Rose to prove an acquisition. The flower is similar to that of the Countess of Oxford. Jeannie Dickson has a striking flower of a bright cheerful color, rosy pink, and, from a single bloom, I am favorably impressed with it. It is another addition to the scentless class of Roses, and, like the Baroness Rothschild, its strength will make it a fine exhibition rose. Lady Arthur Hill is another of Dickson's new Roses; the form of the flower is rarely equaled, the color rosy lilac, and it appears to be a free bloomer.—*Wm. H. Spooner, President of the Massachusetts Horticultural Society.*

Azaleas for Forcing.—Vervæneana bears a large double flower of a rich rosy pink color, broadly margined with white and with a carmine blotch. It is very distinct and free-flowering, and it forces well; indeed, it is one of the best of its class. Imperatrice Victoria is perhaps the most beautiful of the double-flowering Azaleas, with flowers of rosy pink, banded with pure white. The plant requires careful attention during the hot summer months, or the foliage will turn brown and drop. Madame Louis Vervæne is a most distinct variety, with flowers pure white, striped and spotted with rosy carnation tints. Triomphe de Mont St. Amand bears very large double flowers of a clear rose color, with pure white ribbon and a bright carmine spot on the upper segment. The best of the older varieties are Madame Vandercruysen, Simon Mardner, Empress of India, Emperor of Brazil, Bernhard Andreas Sakuntala (if Easter is late), and Deutsche Perle (if Easter is early).—*James Dean, Bay Ridge, N. Y.*

New Pansies.—The old English and Scotch strains that the German seedsmen have taken hold of and subdivided into ever so many varieties remain practically the same under their new names, and I do not see that any improvement has been made in them except in the catalogues where they are rechristened. A really new strain is the Trimardeaux, originated by a florist near Paris, France, but it has been greatly improved since its first production. These Pansies are very large in every way, with very hardy flowers and foliage, enduring well the extremes of heat and cold, and they give general satisfaction all over the country. Another new strain, also of French origin, is the Odier, or fine spotted varieties, which of late years have been greatly improved by the well-known specialists, Cassier and Bugnot, the latter especially introducing new shades of color and flowers which would have been thought impossible a few years ago. These last strains, however, are by no means as hardy as others, owing, I suppose, to closer breeding. These two races are the only really new varieties that have been introduced within the past few years, and that are, in my opinion, of any merit, and I have come to this conclusion after having tried within the past five years everything of note in the Pansy line.—*Denys Zirngiebel, Needham, Mass.*

The Construction and Heating of Greenhouses.

Essays were read on this subject by Mr. John N. May, of Summit, New Jersey; Mr. E. G. Hill, of Richmond, Indiana, and Mr. F. R. Pearson, of Tarrytown, New York. Mr. Pearson insisted especially on durability as an essential quality of such structures, and considered the constant expense for repairing one of the most serious drawbacks to commercial success. He advised the use of a continuous iron rafter, from the ridge to the ground and set in concrete, so that the frame of the house will contain nothing perishable. After explaining elaborately the construction of such a house, Mr. Pearson spoke of certain conveniences, and from this part of his paper we quote the following:

Devices which save labor are matters of prime importance in the greenhouses of commercial florists. In arranging for the application of liquid manure, for example, we have large vats out-of-doors that can be reached readily by carts, so that the labor in handling the manure is small. The manure is dumped into these vats from carts, and water is pumped into them by steam. After soaking for twenty-four hours or more the liquid is drawn off into a side vat lower than the first; two valves close the pipes, one leading to the first vat, and one from the well from which our water-supply is obtained, and the same pipes and the same pump are used to distribute the liquid manure. We have such perfect control of it that we use weak liquid manure regularly once a week, and sometimes oftener, and no more time is occupied than in the regular watering. The amount of labor saved by this will be best appreciated when we state that we can now water the place with four men with liquid manure in two hours, whereas by using cans it formerly took four men two days to go over the place. The difference in cost between the two methods would make a substantial profit alone in twelve months.

In Rose-growing a large item of cost is the annual removing and refilling of the soil in which the Roses are grown. We use small tram car-wheels and dump-cars, the sides of the benches being used as tracks. These cars are made large, and run through the centre of the houses, carrying as much soil as a good stout boy can push, which is more than four boys could carry. When emptying a house, several cars are used, and two or three men are employed filling the cars. As fast as a car is loaded a boy propels it to the end of the house, where it is dumped into a cart in waiting and brought back; during the time occupied in running down the first car a second car is filled up by the same gang of men, which keeps them constantly employed. By the time the second car is filled the first has been emptied and returned, so by the use of two carts to carry the soil away, and two or three cars in a house, the men are occupied constantly, and the greatest economy in labor is secured. Our houses are 304 feet in length, with doors at either end, which necessitates carrying the soil only 150 feet to the farthest point, and this is rapidly reduced as the houses are emptied.

An idea seldom thought of is the location of the walks and the purlines with reference one to the other. We use drip bars, which we consider a decided advantage, as they reduce the drip in a house very much, but the location of the purlines is still a matter of vital importance, especially where high grade Roses are grown. Drip, in midwinter, on such Roses as La France or American Beauty, will often destroy flowers worth fifty cents to one dollar each. By locating the purlines over the walks almost every atom of drip in the house that would do damage can be obviated, and in our new houses none of the purlines are over the benches. Some will say there should be no drip in a properly constructed house, but we find the drip that causes the damage is that produced from condensation in midwinter weather, and not that which comes in from out-of-doors, and which never occurs when a roof is in proper condition.

A point worth considering is the destruction of green-fly. We have been skeptical as to the advisability of evaporating tobacco-juice, fearing that the moisture generated would tend to bleach American Beauty Roses, of which we are very large growers, and for that reason we experimented some time before using it on a large scale. Our experiments were satisfactory, and we furnished our whole place with pans or galvanized iron troughs, about three feet in length and four inches in width and depth, fitted to the steam-pipes, the steam-pipes running through the troughs. By setting the steam-pipes close to the bottom of the troughs the liquid is evaporated in about two hours, or much more quickly than if the troughs were placed on the pipes. This device should be used more as a preventive than a cure, for if the house is badly infested with green-flies it will take some time to remove them, but when the tobacco-extract is evaporated regularly and constantly no green-fly will ever appear. We have saved hundreds of dollars by the use of this simple remedy, and have demonstrated its desirability beyond all question.

We consider it a great advantage to take the chill from water before it is used on plants in midwinter. In watering we use a steam-pump. The distribution pipe, after it leaves the pump, is thrown into an ordinary galvanized hot-water boiler, such as is used in kitchens, entering at the bottom, the outlet being at the top. Through the centre of this heater or boiler a coil of one and a quarter inch pipe has been introduced containing about fifty or sixty feet. The exhaust steam from the pump is thrown into this coil, and, in passing through it, completely condenses, heating the water to a temperature of about fifty-five or sixty degrees in the coldest weather, which is about the normal temperature of the house. The advantage of this scheme lies in the fact that exhaust steam is absolute waste, and the lost heat is thus utilized. It is a very practical adaptation, from the fact that there is no exhaust steam unless the pump is working, and then the water is cir-

culating, so that the two conditions are inseparable. The danger in putting steam-heating pipes through the heater is that when the water had stopped passing through the heater it would soon become too hot to use. It would not be as economical as our plan, where nothing but waste steam is used.

The question, What twelve plants are the best companions of *Ficus elastica* and *Latania* (*Livistona*) *Borbonica* for house decoration? was submitted to Mr. Robert Craig, of Philadelphia; Mr. Charles D. Ball, of Holmesburg, Pennsylvania; Mr. W. K. Harris, of Philadelphia; Mr. F. G. Foster, of Hamilton, Ontario; and Mr. William R. Smith, of the Botanical Gardens at Washington, D. C.

In the lists presented by these gentlemen, from which rare and expensive plants were omitted, *Areca lutescens*, *Kentia Belmoreana*, *Dracæna fragrans*, *Pandanus Veitchii* and *P. utilis* were named five times; *Aspidistra lurida* and its variegated form and *Cocos Weddelliana* four times; *Phœnix rupicola* and *Ficus elastica variegata*, three times; *Araucaria excelsa*, *Dracæna terminalis*, *Aralia Sieboldii variegata*, *Kentia Forsteriana*, *Phœnix reclinata*, *Raphis flabelliformis* twice; *Seaforthia elegans*, *Cyperus alternifolius* and its variegated form, *Caryota urens*, *Cycas revoluta*, *Phormium tenax variegatum*, *Cordyline terminalis* and *Dracæna Goldieana*, once each.

Notes.

A. Lietze, a florist of Rio de Janeiro, Brazil, has written to a Chicago correspondent asking him to take charge of an exhibit for the World's Fair of 400 varieties of Caladium.

The raisin-crop in Fresno County, California, is the largest on record. Fully 4,000 Chinese are now engaged in the vineyards of that county picking grapes, and they have advanced the price fifty cents a day over prices last year.

A western paper recently stated that a citizen of the town where it is published had "invented" a vine, to which he had given the name of Potomato, because it bears potatoes under ground and tomatoes above ground. This is not a new "invention," but probably a result achieved by grafting a Tomato-cion on a Potato-stock.

Many of the visitors at Toronto last week remarked the thrifty condition of the street-trees. The American Mountain Ash trees were conspicuously good, and were loaded with fruit. The practice of cutting back the Lombardy Poplars seems to give freshness and vigor to these trees, and they appear to be longer-lived than they are in the cities of the United States.

Mr. Frederick McMonnies, a young sculptor who has recently been studying in Paris, has completed a statue of Nathan Hale, the famous Revolutionary spy, which will be set up in the City Hall Park in this city. He has also received a commission to design the statue of Victory, which will be the crowning ornament of the soldiers' monument to be built on the government grounds at West Point by Messrs. McKim, Mead & White, and he will be the sculptor of the large Columbus fountain for the Exposition grounds at Chicago.

The death is announced, in his seventy-fifth year, of Dr. Henry Bennet, an English physician long established on the Riviera, where his garden at Mentone had become, under his zealous and intelligent care, one of the richest and most interesting in Europe. He is remembered as the author of a delightful book entitled "Winter and Spring on the Shores of the Mediterranean," by means of which he brought the Riviera, and especially Mentone, into wide repute as a winter residence for invalids. He found Mentone, a contemporary remarks, "an obscure hamlet; he left it the resort of thousands of invalids from all countries, with all the luxuries and appliances suited to their condition."

The most striking feature in the attractive public garden at Dijon, known as *L'Arquebuse*, is the so-called *Gros Arbre*, an immense Black Poplar, for which an antiquity of more than four centuries is claimed. Its trunk is said to be fifty feet in circumference, and despite the fact that it has lost its larger branches, it is still well clothed with leaves and is a stately as well as an interesting object. One can hardly realize that it is a tree of the same species as the myriads of slight feathery Poplars which grow in almost every field in these parts of France.

General Vincenzo Ricasoli, a distinguished Italian soldier who fought as a volunteer in Lombardy in 1848 and 1849, and later was the companion of Lamarmora in Sardinia and in the Crimea, and who in his old age came to be called the father of horticulture in Italy, has recently died. His garden at Casa Bianca, near Port Ercole, was one of the richest in the peninsula, and famous for the experiments its owner made there with Eucalyptus, Acacia, Palms, Cycads and other semi-tropical plants of which he was one of the first and most successful cultivators in Italy. He was particularly interested in the *Bulletin of the Royal Horticultural Society of Tuscany*, which he helped to found, and to which he made frequent and important contributions, describing in its pages the results of his experiments and explaining his broad and catholic views on all matters relating to agriculture and horticulture.

Professor Goodale, in his address as the retiring President of the American Association for the Advancement of Science, in speaking of the possibilities of Economic Botany, said that the methods of improving plants are already known so well that "if all our present cereals were swept out of existence our experiment stations could probably replace them by other grasses within half a century. New vegetables may be reasonably expected from Japan, which has already sent us many choice plants in all departments, and it is likely that some of our present vegetables, which are now much neglected, will come into greater favor and be improved. The fruits of the future will tend more and more toward becoming seedless, just as pine-apples, bananas and some oranges are now. There is no good reason why we should not have seedless raspberries, strawberries and blackberries, and also raise, by cuttings, plums, cherries and peaches free from stones."

A writer in Downing's *Horticulturist*, in the year 1846, stated that the Baldwin Apple "originated in Wilmington, near Boston, in that part which now makes a portion of the new town of Sommerville, in the county of Middlesex. The original tree grew on the farm of a Mr. Butters and was known for a time as the Butters Apple. This tree was frequented by woodpeckers, and Mr. Butters called it the Woodpecker Apple, which was soon abbreviated to the Pecker Apple. My trees, which I set out twenty-eight years ago, are registered 'Peckers.' This fruit must have been known about a century. Orchards were propagated from Mr. Butters' tree pretty freely, about seventy-five years since, by Dr. Jabez Brown, of Wilmington, and Colonel Baldwin, of Woburn, and their sons, to whom the public are principally indebted for bringing the fruit so generally into notice. From Colonel Baldwin and his family it took the name of 'Baldwin,' by which the fruit is now everywhere known."

Last week Professor J. L. Edwards delivered a lecture at Chautauqua on the Arboretum at that place. Among other interesting statements he said that there are found there fifty-six different species of native trees, or half the number of species in the state. The tallest is a Hickory, 132 feet high. The largest is a Red Oak, twenty-three feet in girth and 110 feet high. Twenty trees average seventeen feet in girth. The largest stump is that of a Chestnut, over which was built the original Chautauqua platform; it measures twenty-seven feet around. The speaker said that all people, and especially young people, should become interested in trees for the following reasons: Such a study cultivates habits of observation; the knowledge gained is intrinsically valuable; trees have interesting historic and patriotic associations; communion with nature is wholesome, cheering and ennobling; literature is permeated with the spirit and imagery of the forest. The very terms employed in literary work are redolent of the woods. Paper from Papyrus, book from Beech, library from liber, the inside bark, and leaf from leaves of the trees.

The famous Grape-vine at Hampton Court, near London, was formally referred to as the largest whose size has been recorded. But in the volume of Downing's *Horticulturist* for 1846–1847 we find a letter, signed "J. J. S., Philadelphia," which runs: "I have lately made an excursion to Burlington, New Jersey, for the purpose of obtaining the exact measurement of the most extraordinary Grape-vine I have ever heard of. It stands on a farm called West Hill, belonging to my late brother, two miles from the city of Burlington. . . . At three feet from the ground it measures six feet one inch round the trunk, and at ten feet high it is positively three feet in circumference. It is a native male Grape, and has been the wonder of the neighborhood as long back as the memory of man reaches. It is still healthy, and its giant folds run over and cover four trees, one of which is a full-sized White Oak, while the others are quite large. . . . This vine grows near a springy soil on upland, its roots, no doubt, penetrating to the water." To this Downing adds: "The celebrated vine at Hampton Court . . . does not, as regards size, deserve to be mentioned in the same paragraph."

TABLE OF CONTENTS.

The Responsibilities of Florists.

We have heretofore alluded to the controlling influence exerted by florists and nurserymen in forming public taste in matters relating to horticulture. Many Americans, it is true, who own country places have a considerable knowledge of trees, shrubs and herbaceous plants, and give personal attention and study to the adornment of their home-grounds. Such places are not always planted in the most artistic manner, but the planting invariably shows individuality and more or less skill. Certainly their owners derive from them a satisfaction which can never be gained by those who have no knowledge of plants, and who therefore can give no intelligent attention to the work of their gardeners. There are many persons, too, who have clear and correct ideas about the plants and flowers which should be used for decorative purposes in-doors; and to them a vase of cut flowers, properly arranged and placed, will afford a much keener delight than it can possibly do to those who buy flowers simply because it is the fashion. And yet it must be confessed that a great majority of those who plant trees and buy flowers get all their ideas at second hand, and it is the nurseryman or florist who practically chooses for them where any choice is made. Generally it may be said that this duty devolves upon the local florist; for a florist can now be found in every well-settled neighborhood, and the bright display of his stock in the principal street advertises his business to every passer-by, while the grower of ornamental trees and shrubs is usually located in the country. In this way it happens that the florists of the country do by far the greater part of what is done toward forming and directing the taste of the people in horticultural affairs.

The thought naturally suggested by considerations of this kind is, that a grave responsibility must accompany such a power; or, in other words, that florists who exert such an influence upon public taste are bound by a corresponding duty to take heed that the public taste is elevated to an appreciation of the beautiful in its simplicity and genuineness, and not degraded by being familiarized with what is tawdry or false. On the other hand, it must be said that florists do business primarily for profit; and if buyers demand monstrosities in the way of floral designs, or ask for plants which have gained a fictitious reputation from highly colored pictures, but have no genuine merit, why should not this demand be met, especially when it is to the dealer's pecuniary interest to offer such supplies? Other tradesmen who furnish us with articles of clothing or jewelry or house furniture provide what fashion demands, without regard to the intrinsic beauty or ugliness of their wares, and why should a separate rule be laid down for florists? Really the obligation in one case is quite as binding as in the other. One of the essayists at the recent convention in Toronto characterized horticulture as a profession rather than a trade, and he probably meant by this that the cultivation of beautiful natural objects was a more dignified and responsible calling than other material occupations. But, after all, every man is under equal obligations to society to do all that in him lies for the general education in taste and morals. The conflict between personal advantage and the general good is not confined to any business or trade or profession. One calling, so long as it is a legitimate and useful one, is quite as honorable, intrinsically, as another. It is the conscience and intelligence with which work is done that gives dignity to the worker, whether he be artist or artisan.

Fortunately, as a matter of fact, there is little real conflict between the business interests of the florists and the claims of good taste. American buyers are quick to recognize the superiority of what is genuine over what is meretricious, so that American florists need have little fear of doing work that is too refined and artistic to win public appreciation. In our large cities the florists' windows which are most artistically decorated attract the most attention, and those florists who have made the greatest progress in the direction of naturalness and simplicity are doing the most prosperous business. That the florists themselves have made a conspicuous advance in the quality of their work is well known, and President Norton stated this fact with emphasis in his address at Toronto a fortnight ago. Of course, there are some growers who estimate the worth of a rose according to its bigness only, and there are others who value flowers for their novelty or singularity rather than for their beauty or sweetness. Many stiff "set pieces" are yet constructed, and reliance is still placed by some floral designers on stuffed birds and artificial insects. There are many things yet to be learned of color-harmonies and contrasts, and of the proper use of foliage. Much of the bedding out in public parks and private grounds offends cultivated taste by its violent color, and equally offends good morals by its needless extravagance. But, after all, there is no country in the world where the florists show such good taste as those of the United States, and nowhere in the world where floral work of genuine merit receives such ready and such hearty recognition. Indeed, it is the quick appreciation of American buyers which has reacted to school the florists and train them to work of higher excellence.

The sum of the matter is, that every conscientious florist must feel that within his sphere, and to the extent of his personal ability, he has some responsibility for the influence of his craft upon the horticultural taste of the community. He can do much to develop correct taste; he can do something to retard this development. A devotion to the duty which devolves upon him as a public-spirited member of society does not, however, demand any business sacrifice. Enlightened self-interest, as well as loyalty to his calling and to art, should prompt him to avoid everything insincere and affected with all tricks and deceptions for gaining temporary applause, until all his work is characterized by truthfulness, simplicity and naturalness. Of course, no one but a genuine artist can do work of such quality, and the

acquisition of such skill as invests its possessor with the rank of an artist means patient study and long training, added to original good taste. No business men, as a class, are more alert than American florists to catch new ideas, to adopt new devices in cultivation, in buildings, or in mechanical appliances for saving labor. If to this spirit of enterprise is added a thorough training and a conscientious devotion to the highest ideals on the æsthetic side of horticulture, the country will have reason to be grateful for the influence exerted by its florists.

Monuments in Public Places.—II.

OUR public monuments might, as a rule, be much more successful but for a common mistake in their first conception. Nine times out of ten a statue is insisted upon, when a bust or an architectural monument, with a fitting inscription and, perhaps, a profile-portrait, would be all-sufficient, and, indeed, distinctly more appropriate. This perpetual demand for full-length figures works in two ways against the sculptor's success. In the first place, the average of physical dignity and beauty in our race is not very high; many men since Saint Paul have been weak in their bodily presence, though giants in moral and intellectual respects; and since the time of Saint Paul there has been a great change for the worse in masculine costume, judged from the artistic standpoint. The modern portrait-sculptor has fallen upon hard times; why make his trouble greater by insisting that he shall portray the whole body in cases where not the body but the mind of the subject is the thing we really want to commemorate?

In the second place, it is as difficult in cases such as this to evolve an appropriate conception as to execute it beautifully when arrived at. Unless a man's physical presence has been prominently associated with his services to the public, how shall it be posed and presented so as to express any clear and dignified idea? The broad rule seems to be that a man of action should be portrayed at full length, standing or mounted, as the case may be, and that for men who have labored rather with the brain alone than with brain and body both, a seated figure is at times desirable, while most often a portrait of the head alone will be best. No one would be satisfied with a figure of Sherman except on horseback; a bust of Farragut could never have expressed him as Saint Gaudens has done, placing him in a bold attitude on his quarter-deck; nor could a great orator, whether statesman like Webster or clergyman like Beecher, be fully characterized except upon his feet. But we can fancy a chief-justice, for example, best portrayed in a sitting posture; and it might seem as though this were the most natural aspect to choose for Lincoln, did not the Chicago statue prove that a great artist may see deeper than ordinary mortals, and, working more boldly than they might counsel, may treat his theme more clearly and fully. In this monument the chair of state behind the figure explains one phase of Lincoln's responsibilities and services, while the erect, yet reflective, pose of the figure itself declares that the man who filled the chair was likewise an orator, and was not only the people's executive, but their actual leader in a crisis demanding the most energetic action.

Thus we see that two things should be considered in the conception of a memorial. We should reflect upon the character of the services rendered by him who is to be its subject and also upon the bodily presence Providence had bestowed upon him, and then decide whether a statue, a bust or some still less personal kind of monument should be erected. William E. Dodge, for instance, was a good and useful citizen, but a statue in his honor was less appropriate than would have been a drinking-fountain suitably inscribed. A bust of Holmes or Whittier would be better than a statue; but Carlyle's more strongly marked personality, more energetic cast of mind, needed to be shown, as they are in the seated statue near his old home in Chelsea, through a rendering of his tall gaunt form and familiar voluminous cloak. An intelligent artist will not find great difficulty in deciding this question of appropriateness in the character of a monument; but, unfortunately, the artist is often the person who has the least to say in the matter.

Even in the interests of mere variety we might well wish for a wider difference in the conception of our monuments. But to bring it about in satisfactory ways we must realize that we should depend less exclusively than hitherto upon the sculptor. We should sometimes leave the work entirely in the architect's hands, and should always associate architect and sculptor together. All who have seen the Chicago Lincoln know how vastly the effect of the admirable figure is increased by the striking, yet quiet and dignified, character of the substructure on which it stands; and a large part of the impressiveness of the Farragut figure in Madison Square depends upon its base, although this, from the purely architectural point of view, is not wholly satisfactory. It seems to us that, in always insisting upon the assistance of an architect, St. Gaudens has rendered a service to the cause of monumental art scarcely inferior to that performed by his own creations. His example is being more widely followed year by year, but poor or inappropriate bases are still the rule, and occasionally we see an instance of their total abolition, in curious disregard of that fundamental rule of criticism and common sense which says that a work of art must always be confessed and emphasized as such. In the Central Park, for instance, Mr. Kemys' fine figure of an American panther crouching for its spring is set, without any pedestal, on the top of a vine-covered rock overhanging the drive-way. We believe that this was done against the sculptor's protest, and certainly no true artist would consent to so puerile and mistaken an effort to pretend that a bronze figure is an actual animal. A worse example of this kind of folly came to our notice recently in the photograph of a statue to some military commander which has been erected at Gettysburg. The figure is standing, field-glass in hand, and is placed on the edge of an abrupt low rocky hill without any base, except the necessary thin plate of bronze beneath the feet. To persons looking from below it may well appear like the figure of a living man. But is this a worthy aim in the placing of a work of art? Could even the best statue in the world fail to seem cheap and trivial thus deprived of proper station and emphasis? We are still in the very infancy of art when we can tolerate blunders so gross and self-apparent.

Only a Fence-corner.

THE difficulty of mowing in an angle saves some charming bits for the artist, and the eye of the country stroller is often caught by some such graceful grouping as is shown in the photograph of a fence-corner in Illinois, taken by Mr. D. Burnett, of Olney, in that state, and reproduced in this number (page 415).

In the foreground are to be seen the rosy blossoms of *Hibiscus lasiocarpus*, which grows abundantly in moist portions of the prairies in parts of Illinois and southward. It has soft, downy leaves, and blossoms resembling those of the Rose Mallow, which grows on the borders of the salt-marshes of New England. Behind the Hibiscus a tall wild Sunflower is leaning up against the fence, while a tangle of Ferns and Golden-rods veils the lower stalks of the flowers. In the foreground are some distinct leaf-forms such as the old masters loved to delineate in their carefully studied pictures, and the outline of the group of plants is free and graceful.

So prodigal is Nature of her wealth that she clothes the edges of even the dusty highway with beauty, and, given the unmolested corner of a field, this greatest of artists will weave an embroidery of varied color and exquisite design that baffles the hand of man to imitate. Sometimes her tapestry is woven of the delicate fronds of Ferns, and again she dapples her greens with the sky-blue flowers of the Succory, or, perhaps, a clump of Fire-lilies glows amid the long grass, or a Morning-glory festoons the rails,

and opens its dewy cups to catch the first kiss of the sunlight.

In other corners the wild Rose clusters, thorny and sweet, and, if the ground be damp and sedgy, one may find Cardinal-flowers, and the sculptured white petals of the Arrowhead, mingling with the blue of Pickerel Weed, and the pink blooms of the Milkwort.

In drier places little seedling trees are apt to spring up, kept warm and shaded by embracing Jewel-weeds, till their roots gain vigor enough to force the strong young shoots up into the sunlight, or, perhaps, a Clethra may have strayed away, with a sweet Fern for a companion, from neighboring woods, filling the air with a forest-fragrance.

No matter how rough and ugly a field may be, its fence-corners, if neglected, become its redeeming feature, so that one is grateful to the careless farmer whose sense of duty does not drive him to clear up what he considers rubbish, but allows the wild things to gladden us in their own way, with their dainty forms and graceful attitudes, as they hide the coarse rails with their soft leaflets, or wreathe the rough surfaces with garlands of flowers and festoons of foliage. Such little pictures as this are to be seen on every hand by all who will look for them by the way-side. Free, indeed, is the gift of beauty to man, when from neglect he can reap loveliness, and from disorder, grace.

Winter Beauty in the Home Grounds.

A LETTER in *Downing's Horticulturist* for 1851 shows that, forty years ago, there were some persons who appreciated the charm of a garden outlook especially prepared to be beautiful in winter. "I saw, not long since," this letter runs, "a country house where there was a novel feature that delighted me. This was a winter landscape or scene on one side of the house upon which the two rooms occupied by the family in winter looked. A broad glade of lawn was agreeably varied and quite surrounded by beautiful evergreen trees and shrubs. From the windows commanding this scene not a leafless tree was in sight, nor any other feature which reminded you that the leaves had fallen. The grass still green, and the White Pines, Spruces, Firs, Hemlocks, Junipers and Laurels, from large trees to small shrubs, were all arrayed in the richest green—so as fairly to belie the season. Even when the lawn is covered with snow the evergreens are still cheerful, and their verdure is heightened by the contrast. I have seldom seen a happier idea, or one better carried out. It seems to me particularly well suited to country houses in which the family passes the whole year." To this Downing himself added: "An excellent arrangement, and one which may be heightened in the execution. With the American Holly and the Winter-berry to decorate it by their brilliant berries, and such plants as the Yucca and Chinese Honeysuckle, which hold their foliage all winter, to give it variety, a winter garden might be a gay and agreeable thing to look upon when January is at its bleakest."

Perhaps country homes may now be found here and there where careful provision has been made for the pleasure of the eye in winter as well as summer. But certainly they are not common. Coniferous evergreens are not so generally planted now as they were some forty years ago, when the rage for them in England, like other horticultural fashions before and since, extended to this country also. The results of this fashion are, of course, still everywhere conspicuous, and we often see plantations around houses where the family resides only in summer almost entirely composed of dark and heavy conifers. Conversely, now that deciduous trees are more generally liked, we frequently see houses that are inhabited all the year round encircled by grounds which, as winter approaches, show only bare trunks and leafless masses of shrubbery.

No rule, even of the broadest sort, can be laid down to determine where evergreens should be planted, in what numbers, or in what combinations. The very essence and interest of gardening lie in the fact that each problem is a new one which must be solved in accordance with the habits and tastes of the family in question, as well as with regard to the size, situation and character of the grounds. But we can at least assert that there is no reason why the owner of a house occupied in summer only should prepare for beautiful winter effects. His aim should be to attain a special, temporary effect, and he can secure this more completely than his neighbor who is obliged to provide for the whole circle of the seasons. But if it would be foolish for him to think of winter beauty, it is still more foolish for those who must look at their grounds in winter also, to think only of the summer, or, as we sometimes find to be the case, almost exclusively of the spring. The letter we have quoted hints at the right scheme—a comparatively small reserved portion of the grounds, commanded by rooms appropriated to winter use, and specially planted with this season in view.

Even here, however, too vigorous an effort ought not to be made to "belie the season." In our climate this cannot be done so successfully as, for example, in the southern parts of England, where the grass remains green all winter, and many broad-leaved evergreens flourish which would die with us. In such a climate as that of our northern states winter will strongly assert itself, no matter what we do to combat its supremacy. And therefore our aim should be not to disguise its presence, not to pretend we are still in the autumn or already in the spring, but to show how beautiful winter itself may be in its own proper character. For this reason we could hardly commend an arrangement where "not a leafless tree was in sight." A true lover of nature takes especial delight in the beauty that most trees display when stripped of their leaves. In winter we see the structure of a tree in its sturdy trunk, diverging branches and feathery spray, and this structure varies perpetually as we pass from species to species. Moreover, the effect of a plantation of evergreens, whether laden with snow or not, is too heavy and monotonous unless lightened by some intermixture of leafless branches. Therefore, instead of altogether banishing deciduous trees, at least a few such should be selected for the winter plantation with special reference to their comparative beauty when leafless. A sturdy rugged Oak, for instance, with its wide-stretching branches; a Dogwood, with its horizontal layers of branchlets; a group of tall, narrow, fragile, light-sprayed Gray Birches, and an American Beech, isolated perhaps so that the symmetrical beauty of its shape may fully appear, will greatly increase the beauty of a winter plantation. And the gain will be in effects of color as well as in effects of form. The Oak will keep a large part of its yellow or reddish leaves throughout the winter, and the Dogwood some of its scarlet berries; the trunks of the Birches will shine like silver against the dark green background, and the pale gray color of the Beech will be as attractive as the extraordinary grace of its ramification. Finally, these trees will vastly increase the beauty of the scene when summer comes; and we should not forget that even the winter plantation ought to be beautiful in summer too.

The Oak, the Birch, the Dogwood and the Beech are only four among many deciduous trees which may be selected for conspicuous beauty in winter, while the list of deciduous shrubs of similar value is very long. A shrubbery composed entirely of evergreens, even though many broad-leaved forms are mingled with the coniferous species, can never be so beautiful as one which is enlivened by such plants as the Scarlet-twigged Dogwoods, the Golden-barked Willows, the Kerria, with its shining green branchlets, by the Carolina Rose, the High-bush Cranberry, the Cockspur Thorn, the Black Alder, and the Snowberries, each carrying well into the winter its load of fruit, now black, now white and now a vivid red, and by the Bittersweets, with their contingent of still more brilliant orange and scarlet berries. Then, too, one might recommend the planting in a winter landscape of a few very early-flowering shrubs like the Forsythias and the Shad-bush, which, though they will not add distinctly to the actual winter effect, will prove spring's arrival at the earliest moment.

As regards the choice of the evergreens to be used in winter plantations we merely note that, since Downing's day, the list of available exotics for this purpose has vastly increased, while more attention is paid to those native plants for whose use he so persistently and earnestly pleaded. We will, however, recommend one single plant of the latter kind, common along our eastern shores but not nearly so well known as many costly exotics of far inferior beauty. This is the Inkberry (*Ilex glabra*), which, in its native woods, grows tall and rather straggling, but, under cultivation, assumes a compacter form while losing none of its grace. Its beautifully shaped, long, narrow leaves, delicately toothed at the apex, recall the Laurel-leaves one sees so constantly in Grecian decoration; they remain bright green and glossy throughout the winter, while an added attraction is offered by the clusters of small black berries. This is one of the most beautiful of North American shrubs, even when compared with others which carry their leaves throughout the winter; and in winter the lightness of its spray and small size of its leaves contrast favorably with the broad-leaved evergreens more generally planted.

New or Little-known Plants.

Protea nana.*

ALTHOUGH this plant was cultivated at Kew in 1787, whither it had been sent from the Cape by the collector Masson, it had disappeared from cultivation, and had been forgotten long ere it was reintroduced to Kew, where it flowered in a cool greenhouse two years ago. Fifty years ago there were about thirty species of Protea included among popular greenhouse plants in England; now one may safely say there is not one, the few really under cultivation being only in botanical collections. Writing of these plants exactly ten years ago, Sir Joseph Hooker observes: "The Cape *Proteaceæ*, the favorites of our grandfathers, may be said to have gone out of cultivation, so completely have they been replaced by other tribes of more or less deservedly popular, but neither more interesting nor more curious, plants. . . . This neglect of a whole genus of most conspicuous plants, which forms a grand feature of one of England's greatest colonies, is not due to want of beauty, for some of them are among the handsomest of plants, whether for size, form, or color of inflorescence; and would carry away the first prize at any horticultural show. . . . Of these, however, the present, and even past, generation of horticulturists know absolutely nothing. Nevertheless, that these and many other plants requiring like treatment will be reintroduced, and will be the wonders of the shows for many successive seasons, is as certain as that they were once the glories of the old flue-heated houses that our forefathers called stoves, in which Orchids quickly perished, and Banksias and Proteas throve magnificently."

Although this prediction has not yet been realized, at least two species of Protea have recently been exhibited in London and won considerable attention, namely, *P. cynarioides*, which some thought was a glorified Artichoke, and *P. nana*, the species represented in the illustration on page 413. The plant is scarcely two feet in height, the branches are hard and wiry when mature, the leaves are rather rigid and pine-like, and the nodding terminal flower-heads are in the form of shallow cups, two inches in diameter, and composed of several rows of rigid petaloid bracts, the lower ones colored green, the upper deep crimson. The true flowers are packed closely together in the form of a disk, which occupies the greater part of the cup inside and is colored yellow, the exserted stigmas being pink. The flower-heads remain about a month in perfection.

The Kew plant is nine years old, having been raised from seeds received from Professor MacOwen, of Cape Town, in 1882. It has been grown in an airy, sunny greenhouse, and is planted in very sandy peat. The one great danger to cultivated Proteads is excessive watering, and to guard against this it is found to be a good plan, in the case of delicate species, to place the pot in which the plant is growing inside a larger one, filling up the space between with silver sand. The latter is always kept moist. By this means we have been able to keep and grow such Proteads as the Cape Silver Tree (*Leucadendron argenteum*), *Protea nana* and other delicate species. Beside the two already named, the following Proteas are now in cultivation at Kew, *P. longifolia*, *P. marginata*, *P. grandiflora*, *P. mellifera* and several undetermined species. These plants are easily raised from seeds, which may be obtained in quantity from the Cape. I have seen huge bushes of *P. speciosa* growing among the rocks near Grahamstown, and as thickly clothed with large heads of rosy red, deliciously fragrant, cup-like flowers, as a big specimen Rhododendron is with flowers when it is at its best. *P. cynarioides* is very abundant in some parts of the eastern division of the Cape. It grows to a height of from three to five feet, and, when in flower, its enormous rosy red cups, not unlike the heads of Artichokes in size and shape, are such an attraction that the colonists are wont to devote a special holiday to a picnic among the "honey-pots," as the flowers of this Protea and others are called. Proteas certainly are deserving of the attention of every cultivator interested in plants remarkable not only for beauty of flower but also for singularity of form and color.

There are about sixty species of Protea known, and, with the exception of one or two found in Abyssinia, they are all natives of south Africa.

Foreign Correspondence.

London Letter.

LONDON is now supposed to be taking its holiday, and the exodus of the rich patrons of horticulture to their country-seats has a marked effect upon the attendance at the metropolitan gatherings. But the actual workers in horticulture know no rest, for the seasons of the various classes of popular plants and fruits succeed and overlap each other without interval. At the last fortnightly meeting of the Royal Horticultural Society at Westminster, now the centre of horticultural activity, no one would have supposed that it was holiday-time to see such an assemblage from all parts of our little country, for one could hold converse with a hundred of the best and most representative men in every branch of gardening, both scientific and practical.

The popular flower of the season is still the Carnation, which seems to take a firmer hold of the public taste year after year. This season its flowering time has been much lengthened owing to the dull and rainy weather of the past month. The favorite flower of the Rothschilds is now the flower of everybody, and since raisers have turned their efforts upon the extension of the sturdy border sorts, with well-defined self-colors, both delicate and brilliant, there is not a good garden in the country where the Carnation does not receive special attention, just as the Rose, Chrysanthemum and Dahlia do. While the strictly florists' type has not been improved upon from what it was thirty years ago, we have now such a multitude of self-colors of sturdy constitution that it is quite a business to select even the best twenty sorts. Among new sorts shown by Turner, of Slough, some of which captivated the specialists, my choice would be one named Queen of Bedders, which not only has large full flowers of a soft crimson, but has such vigorous grass and is so dwarf that it is exceptionally valuable for the open border. This variety, of which a dozen large bunches were exhibited, took, in its class, the first prize by an amateur for "flowers cut from plants which have been wintered in the open garden and staged without 'dressing,' and exactly as they were cut from the plants." This class is quite an innovation and in the right direction, the object being to develop excellence as decorative flowers in the open border and to encourage varieties that yield abundant heads of flowers. The schedule, moreover, stipulates that the flowers are to be shown in bunches, with their own foliage and buds. No bands or ties round the calyx are allowable, and no wire-supports or paper-collars are allowed, and a split calyx is a disqualification of the bloom. This is a long list of restrictions, but the Queen of Bedders fulfills all the conditions, and, no doubt, it is the forerunner of a race that will satisfy the most exacting. A few years ago such a high standard would have been thought wholly unattainable, but now we are developing a dwarf race which needs no special attention to make their flowers respectable.

The flower-loving people welcome this change from artificiality to naturalness, not only in Carnations but in other flowers, for we are gradually throwing aside the conventionalism of the old school at the metropolitan shows. I have mentioned only one sort of Carnation of the multitude that were shown, and I doubt if your readers would care to have a full list, but a dozen of the very best

would include the following, and most of these were distinguished by awards of merit from the judges. Of the finest yellow ground sorts were: Countess of Jersey, edged with bright rose; Edith Wynne, heavily marked with deep maroon; Victory, edged and flaked bright red; Mrs. Harwood, scarlet-edged. Among self-colored flowers were: Ruby, clear carmine-crimson; Ketton Rose, bright rose-pink; King of Scarlets, vivid scarlet; Pride of Sevenoaks, pure white; Golden Fleece, bright yellow; Mrs. Walford, yellow striped rose; Hotspur, clear, soft rose; and Mrs. Apsley Smith, very bright scarlet. These are the best of the new sorts which combine all the good qualities which the specialists discover before they certificate them, and it may be assumed that they are improvements upon older sorts of a similar color.

Besides the Carnations, there were exhibits of interest to the specialist in Orchids, Roses, and hardy plants. The most remarkable Orchids were three new hybrid Cypripediums shown by Messrs. Veitch, of Chelsea. *C. Corningianum*, named in compliment to one of your great collectors, is a cross between *C. superbiens* (*C. Veitchii*) and *C. Philippinense* (*C. lævigatum*). It is intermediate in

Fig. 66.—Protea nana.—See page 412.

character between the parents, the flower being of the same size as *C. superbiens*, with a similar pouch, but the lateral sepals are much deflexed, as in *C. Philippinense*, but shorter and broader, and are copiously dotted with minute black spots on a purplish ground. This is the nearest approach to the rare *C. Morganæ* that I have seen. Cleola is a cross between *C. reticulatum* and the little *C. Schlimii album* as the seed-bearing parent. The progeny recalls the beautiful *C. caudatum* of the Sedeni group, but the flowers are smaller and whiter; indeed, there is only a suggestion of pink to mar the chaste purity of its ivory whiteness. The form of the flower is exquisite. It is of vigorous growth, inheriting that character from *C. Schlimii album*. *C. macrochilum* is a remarkable hybrid, as it is the first instance of the strange *Uropedium Lindeni* being crossed with a true Cypripedium, the parent being *C. longifolium*, which gave us the Sedeni hybrids. At first sight one would think the hybrid a large-tipped form of *C. caudatum*, so alike are the flowers in general appearance. The lateral sepals are pale purple, long, and hang like strings; the back sepals are green striped, as in Uropedium, but the lip is different, being large and long, of similar color to that of *C. caudatum*, and the inturned edges at the top have the same ivory appearance. This hybrid tends to prove what some specialists have always maintained, that Uropedium is but a deformed variety of Cypripedium, possibly of *C. caudatum*. It is singular that, from the result of intercrossing, it should have so completely recovered its lost pouch. Other Orchids of interest shown were *Odontoglossum Hennisii*, a new species which Mr. Rolfe describes as having affinity with *O. odoratum*, but cultivators will compare it with *O. constrictum* and *O. Lindleyanum*, from its general appearance; but it is different, as may be seen by the much broader lip. The plant shown was a poor representative of what Mr. Shuttleworth considers a really pretty cool Orchid. The splendid new *Dendrobium Statterianum* is a gain and won much admiration. It may be described as having the growth and flowers of *D. crystallinum*, with the color of *D. crassinode Barberianum*, and the flowers are as thickly set on the slender stems as in that variety. As a late summer-blooming Dendrobium it has no rival. *Phajus Humbloti rubescens* possesses, as its name implies, a deeper color than the type, and is a first-rate Orchid. *Lælia elegans Turneri*, the best variety of the species, was shown finely, and so was *Angræcum Ellisi*, with spikes a foot long. Besides these was a grand group of *Disa grandiflora* from Chatsworth, where its cultivation is plainly well understood. Some of the spikes bore ten open flowers, which, as every orchid-grower knows, are produced only on strong plants.

Among the new Caladiums was a remarkable group shown by Mr. Bausé, well known in earlier days as a raiser of Coleuses and Dracænas. But most of his Caladiums had their origin in France, and the raisers there have apparently turned their attention to the production of those sorts only that have very rich-colored leaves, for most of the new ones have pink, carmine and crimson foliage. There were quite half a hundred shown, and a dozen of the best I picked out were Madame Leon Say, M. Leon Say, Comte de Germiny, Raymond Lemoinier, Ibis Rose, Madame Alfred Magne, Comtesse de Brouses, Marie Freeman, Oriflamme, Mrs. Harry Veitch, Louis Van Houtte and Le Nain Rouge (dwarf). All these are first-rate.

Among new Roses shown by Messrs. Paul, of Cheshunt, the finest were Charles Gater, a brilliant scarlet-crimson, good in form and luxuriant in foliage; T. B. Haywood, combining the qualities of the old Alfred Colomb and the brilliancy of the Duke of Edinburgh; Duke of Marlborough, in the way of Auguste Mie, but more powerfully scented, and Kaiser Friedrich, one of the Gloire de Dijon type, but with a more conical and better-shaped flower in the open state. None of these novelties, however, took the fancy of the committee shown in their present condition after such rain-storms as we have had.

A new race of the annual *Chrysanthemum carinatum* was shown by the Messrs. Hurst. The flowers are as double and as large as double Pyrethrums, and varying in color from bright golden yellow through deep bronze maroons to the richest crimsons. These beautiful varieties are destined to become popular as they are so easily grown, and no doubt they will be improved upon still further now that a distinct break has been made.

Dahlias have made their appearance at the show-table, and Messrs. Cannell showed some Cactus varieties of the true Yuarezi type, not the spurious kinds which sometimes pass for Cactus Dahlias. The best were Panthea, orange-scarlet; Oban, bronzy crimson, and Duke of Clarence, deep crimson. These, together with Cannell's double Begonias, which look more like double Hollyhocks in size and form than the Begonias of a few seasons back, made a brilliant display.

Midsummer Flowers.

China Asters.—The flowering of these plants marks the culmination of the summer garden. At this time the annuals have about reached their best state; the summer-flowering perennials are making their second growths, and the first of the multitude of fall-flowering composites are rapidly coming into bloom. Each season brings its novelties, and among the spring offerings of the seedsmen few are usually so well worth trial as the Asters. Easily grown, they produce a large crop of the most useful and lasting flowers, such flowers as are never in too great abundance in any garden. Not all the varieties are improvements on the old favorites, but each year there are found some kinds with valuable distinctions entitling them to a permanent place in the annual border. The Comet Asters of the last few seasons were a great acquisition, the Rose variety being especially charming. This season we have a new strain in the Jewel Asters, which prove to be finely formed flowers, well incurved, though I have grown no nine-inch specimens, which size they are said to attain. The Apple-blossom is of the faintest flush of pink, and very attractive. The Deep Rose, as its name implies, is dark pink and of the same form. The Snowball and other white Asters do not seem to be any distinct advance on old forms. One cannot have too many white and pink flowers in a garden where flowers are in demand. For some reason, I suspect not unconnected with the prevailing shades of dress goods, there has been a rather unusual draft on my pink flowers this season. I grow during the year a fair number of flowers, but until this experience I had not noted specially the comparative scarcity of good pink flowers of a satisfactory shade.

Hardy Sunflowers.—Among the single flowers of these I have seen none more satisfactory, in substance, form, and color, than *Helianthus rigidus*. They are about three inches in diameter, a rich golden yellow of pure tone, with a dark-brown centre. The plant has a stiff habit, with sparse foliage. It has an objectionable way of spreading through the borders by underground stolons, the old crowns dying off. Unless one is familiar with this habit he may think the plant is lost, or he may lose it by digging up the border around old crowns. *H. Japonicus* (or *præcox*) is a form of *H. rigidus* sent out by Ware, but it does not seem distinct enough for name, especially for a misleading one—Japan, I believe, not having any species of Helianthus. With me it is no earlier than *H. rigidus*. After, or with *H. rigidus*, I should say that *H. lætiflorus* is the most satisfactory. This has more abundant foliage, the same root-action, and the flowers are perhaps a trifle deeper in color, with yellow eyes. The petals are also more abundant, and the flowers are sometimes semi-double. I have a third variety, the name undetermined, which came from seeds supposed to be of *H. rigidus*. This has flowers of a lighter yellow, and is not a wanderer at the root. My double Sunflowers have mostly drifted into my neighbors' gardens, where I enjoy them. They are fine bits of color at a distance; near by they are a trifle lumpy, and the leaves gather all the floating mildew.

Clematis paniculata and Schubertia grandiflora.—These two plants, now in bloom on the same trellis, form a charming picture. The large glossy leaves and clusters of large waxen white flowers of the Schubertia enhance the grace of this most lovely Clematis. The figure of a flowering branch of this plant in Garden and Forest, although accurate, did but scant justice to its graceful, dainty, spray-like blooming habit, which can only be shown by the entire vine. In any stage, the plant is one of the most valuable climbers of recent

introduction. Against a south wall this was one of the earliest plants in my garden to start, making growth in late January.

Phytolacca decandra.—This is a truly regal plant, with smooth, erect crimson and purple stem, branching upward at the top, with ovate leaves and white flowers, followed by racemes of purple berries, and yet it is only the Pokeweed! Never until some bird dropped the seed at the side of my water garden, where it has grown into a large specimen, had I noticed the beauty of this common wayside weed; but there it stands, growing out of the Irises, quite holding its own, in stateliness and distinction, among the best exotics.

Experiences with the Rose-bug in 1891.

This insect (*Macrodactylus subspinosus*), of which much has been already said in Garden and Forest, appears here in annually increasing numbers, and seriously threatens our fruit-crops, and especially the grape. Over a wide area in southern New Jersey it has this year devoured the grapes, the blackberries and several other fruits. In the autumn of 1890 I undertook to trace its life-history. In October and November I dug in the soil of my farm and found the larvæ there at a depth of some three inches, and disposed to burrow more deeply. When a number of larvæ were placed on loose soil in a quart-can they soon went beneath the surface, and continued until they reached the bottom of the can. Instinct carries them below reach of frost, and possibly the alarming increase of these bugs for the past three years is due to a succession of mild winters; the ground never having been frozen more than two inches in depth. Almost weekly during the winter of 1890–1891 I renewed search for the larvæ and found them always a little deeper, until they had reached a depth of five or six inches.

The larva resembles a small white grub, is about a half-inch in length, and is coiled into a ring, with head and tail meeting. I do not find them in wet and heavy ground.

On Monday, May 25th, 1891, Professor John B. Smith, Entomologist of New Jersey Experiment Station, came here, and we dug for the rose-bugs and found, in the same square yard of soil, the larva, the pupa and the fully developed insect. This explains the constant increase of rose-bugs during their term. They do not all appear at once, but come out in succession.

On May 27th my diary notes: "Found the first rose-bug to-

day." To complete this part of its history I quote again from the diary, June 26th: "Rose-bugs nearly gone; can find only a few, which appear moribund." On June 28th: "Can find no more rose-bugs." This agrees with observations of former years. The rose-bugs continue here for about one month.

On June 4th Professor Smith came here again, provided with various chemicals which we hoped might be destructive or repellent of the insects, but we found nothing destructive to the bugs which was not ruinous to the plant. In Bulletin 82 of the New Jersey Experiment Station, Professor Smith tells more of the life-history of the rose-bug than has been known to entomologists. He confined a number of the insects in a glass fruit-jar, partly filled with loose sand. They burrowed down in this several inches, where they built a cell, laid their eggs and then returned to the surface.

Whether they again go down to deposit another batch of eggs is yet not known. It has hitherto been believed that the rose-bug oviposited near the surface of the ground, and that the larvæ burrowed, as do those of the potato-bug. Observations this year prove this belief to be wrong. The mature beetle burrows some inches below the surface, there lays her eggs, and then the larvæ, when hatched, continue to go deeper. Perhaps the insect does not begin to reappear until developed into the fully matured beetle. Then these come forth in constantly increasing numbers for about two weeks, when the rose-bug invasion may be considered at its height. From this time the older bugs seem to be nearing their limit of life, and doubtless the death-rate increases till the last bug dies. The life of an individual bug does not endure for a whole month. This is the length of time from the appearance of the first specimen to the disappearance of the last one. Professor Smith's bulletin enumerates a long list of chemical poisons which proved of no use against the enemy, and the experience here of Dr. Kellogg and myself with pyrethrum, sludgite, hot water, and many other remedies, if fully written out, would make an entertaining story. Up to this time, however, no practical way of combating these pests is known to me—that is, I am not yet sure of any way, but I will venture to suggest a plan which offers some promise of success.

When, as Special Agent for Department of Agriculture, I began experiments for the prevention of grape-diseases, I observed that where the "Bordeaux mixture was used the rose-bugs departed." I think Professor Riley mentioned this in one of his bulletins. Subsequent observations did not confirm this statement; but, per contra, these applications of the copper solutions were made a little too late to be protective against the insects. I was called away, and did not spray my vines until they were nearly out of blossom. During this time the rose-bugs did most of their damage.

This year I made the application of the copper mixtures as complete as might be. I bought two Eureka sprayers, and sprayed my vines every ten days from the time the buds opened until August 23d.

The north section of my vineyard was left unsprayed, because I had not time to go over it. The rose-bugs pervaded my vines, but only on the unsprayed section is the loss total. No grapes are left there, but on the sprayed vines there is a full crop, free from harm of rose-bugs or of rot.

But these trials must be made for successive years before we can be sure that we have a real preventive. The rose-bug is capricious. It may bring ruin to a vineyard this year, and leave the same unharmed the next year. Yet, I am strongly disposed to believe in the Bordeaux mixture, early applied, as a repellent to the rose-bug.

I find the Eureka sprayer the best machine to use. Other Knapsack sprayers are nearly as good. Any of them are better than the horse-power machines.

Vineland, N. J. *A. W. Pearson.*

Notes on American Plants.

THE Monardas, or Horse-mints, of which we have several species, are quite attractive plants when in flower, and their flowering season is usually a long one. They are erect in habit, usually more or less branched toward their summits, and quite odorous. *M. didyma*, commonly called Oswego Tea or Bee Balm, is by far the handsomest species, having large heads of cardinal-red flowers, which, in some forms, are quite as rich in color as the Cardinal Flower (*Lobelia cardinalis*). I doubt if this species is anywhere so abundant as *M. fistulosa* (Wild Bergamot), which, in some portions of Illinois and Missouri, is very common along the railroads and in fallow fields. Though this is not so attractive a plant as the Bee Balm, it is well worthy of cultivation, bearing an abundance of light purple flowers, which are durable and pretty. It had commenced to bloom in favored situations by the 3d of July, and now, more than a month later, it appears to be in its prime. Some plants are not yet in flower, and it seems as if its season of bloom would extend over a period of eight or nine weeks.

Sabbatia angularis, which flowers the last of July, is one of our handsomest wild flowers. It usually grows about eighteen inches high, is much branched, and bears an abundance of rose-pink flowers a little less than an inch across and deliciously fragrant. It is a variable plant in size, sometimes only six or eight inches high, and bearing a single flower, and, again, at the other extreme, it may be nearly three feet high, much branched, and with an abundance of bloom. Its natural home seems to be in rich moist soil.

Lepachys columnaris is a pretty species of the Composite family. Its height is about eighteen inches, and it branches from near the base. The disk or centre of the flower is columnar, nearly or quite an inch long. From its base project the numerous bright yellow rays which, though shorter than in the other species (*L. pinnata*), have the same half-drooping habit which gives the flower a peculiar and attractive appearance.

Helianthus mollis, a species of Sunflower scarcely three feet high, with simple leafy stems and large yellow flowers three inches wide, is common in dry soil in western Illinois and Missouri. The flowers when open usually face the horizon, which makes them more conspicuous. It is quite attractive when in bloom, and will live in any ordinary soil in the sun.

Primula Mistassinica, one of our rarest and most delicate little Primroses, is proving a fine plant in cultivation, where it attains a much larger size and produces larger and handsomer flowers than when growing wild. It is an early bloomer, and is, I believe, usually past flower by the middle of June, but in our nursery the past season it not only began blooming early, but continued to flower at intervals all summer, and several plants are now blooming in the middle of August. It needs a light loamy or sandy soil, with partial shade.

Habenaria ciliaris (Yellow-fringed Orchis), a native of wet sandy soil from New England to Florida, is one of the most attractive of this genus, and flowers about the middle of August. It grows from one to two feet high and bears a thick spike of orange-yellow blossoms. It is a good plant for the drier portions of the sand-bog.

Calochortus Bonplandianus is a Mexican species, which attains a height of a little more than a foot, and bears in long succession four to eight handsome bell-shaped pendent flowers, dark purple and light green outside, and yellowish purple within. The flowers are over an inch long by nearly three-fourths of an inch in diameter. It is a strong and healthy-growing species, though probably not hardy, and should be wintered in the cellar. Unlike any other Calochortus I have seen, it bears numerous little bulblets in the axils of its leaves, like the Tiger Lily, by which it evidently propagates itself.

Charlotte, Vt. *F. H. Horsford.*

Garden Phloxes.

VARIETIES of *P. maculata* and *P. paniculata*, and commonly known as the Decussata varieties, are indispensable at this season of the year, and they, together with Sunflowers—perennial and annual—are now among the showiest border-plants. Owing to the ease with which they may be propagated, and the thoroughness with which they take care of themselves, gardeners often become careless about preserving the best varieties true to name. Seedlings spring up profusely about old plants, which, if not carefully watched, will gradually crowd out the parent plant, and, as seedling varieties rapidly revert to the purple-colored type, one not infrequently sees, in neglected borders, masses of Phloxes of this color alone. On the grounds of Mr. Fewkes, of Newton Highlands, Massachusetts, I lately saw some particularly fine Phloxes among fifty or more varieties in his trial grounds. I selected, as very distinct, Panama, Snowflake, Josephine Gerbeaux, Beldonville, Saison, Liervalle, Superba and Delicata. Fifty years ago Phloxes were grown as pot-plants for conservatory decoration, but, while beautiful, their period of usefulness was of short duration, owing to the fugacious character of the corollas. Where Phloxes are made a specialty, and grown in masses, frequently of one color, the practice is to strike cuttings in spring and grow the plants in six-inch pots until they attain considerable size. It is easy then to plant and so arrange them to have a good even-surfaced bed when in bloom. Raising Phloxes from seed is a very interesting pastime and should be popular with amateurs. They self-fertilize

so easily that it is rather difficult to get what result you desire, but out of a batch of fifty seedlings there will usually be a few worth selecting.

Flowers for Late Summer.—A bed of Ghent Azaleas below the pavilion in Mr. Walter Hunnewell's garden makes a lovely picture in spring, with a few blue-flowered German Iris and Columbines dotted among them, as their colors harmonize admirably with the yellow-orange and the pink of the Azaleas. Though gorgeous while they last, their blooming is short and so early in the season that we fill out the bed with Dahlias, Gladioluses, Tritomas, Crocosmias, Galtonias, Sunflowers and various other summer-blooming annuals, which keep up a continuity of bloom and furnish abundant flowers for cutting. The bed is thus kept gay when otherwise it would remain dull and unattractive through the long summer. While the rock garden shows to better advantage in spring than at any later season, we nevertheless have a few flowers at all times. Conspicuous for a long time have been *Campanula grandiflora*, var. *pumila* (*Mariesii*), the best of all the Chinese Bellflowers; *Œnothera Missouriensis; Clematis Davidiana*, a lovely bush-Clematis, with small, tubular, light blue flowers, which are fragrant; *C. tubulosa*, of similar habit, but dark blue flowers, and a neat trailing Rose, *R. bracteata*, with large white flowers. *Campanula rotundifolia*, the true Blue Bell of Scotland, and *Geranium sanguineum* are all worthy of note at this season.

Wellesley, Mass. *T. D. Hatfield.*

Baptisias.—Some of these native plants are worthy of a place in the garden. They are all herbaceous perennials, and useful for filling-in large mixed beds or borders and for dotting among shrubs of dwarf growth. *B. australis*, the Blue False Indigo, is perhaps the best species. It is found wild from Pennsylvania westward to Arkansas. The growth is dense, and the numerous stems and branches are thickly clothed with ternate leaves of milky-green color. The large flowers, like those of the ordinary pea in form, are borne in racemes from eighteen to twenty-four inches long, the largest of which carry from thirty to forty flowers during the month of June. *B. leucantha* is a foot taller, with larger leaves, but less compact in habit, the stems branching only at the top. The flowers are white, and the plant, which also blooms in June, is common in the south. *B. tinctoria*, Wild Indigo, the common way-side plant, is the most floriferous species. It resembles *B. australis* in general habit, but is smaller in every respect, and bears quantities of yellow flowers in June and July. These plants thrive luxuriantly in any ordinary garden soil, and in any position not exceptionally dry or too much shaded by overhanging trees. They stand severe drought much better than a great many of our herbaceous plants, and that is a matter of some importance in dry seasons. Propagation is readily effected by division of established clumps early in spring, or by the seeds, which ripen freely.

Cambridge, Mass. *M. Barker.*

Correspondence.

What is a "Garden"?

To the Editor of GARDEN AND FOREST:

Sir,—I wish I always had time to thank you fully for your various references to my words, but I cut the following from your number for July 24th, and wonder a little at it:

> For example, Mr. William Robinson, writing recently in *The Garden*, used the word "garden" to indicate the grounds forming the immediate ornamental environment of the house, though this word is commonly employed to designate a place in which flowers are grown. He explained, however, that the lawn must be "the heart of an English garden." To indicate these same grounds Mr. Parsons uses the word "lawn," although the very first sentence of his first chapter explains that "to the minds of most readers the lawn suggests simply grass." He might better have employed the term "home grounds," a term that once was generally used, but now appears to have gone somewhat out of fashion.

Country places and gardens are so different in America that these may explain your writer's doubt, but to us there is no confusion, and as gardening is of such long-standing importance with us we may perhaps be allowed to define a garden! Certainly it is not confined in any such way as this paragraph suggests, but broadly means the whole of the grounds given to gardening of whatever kind it be. There are all sorts of gardens. Of course the lawn is generally a part of the garden, save in few cases, where very large lawns would be formed for archery or any like game. "Home grounds"—home lands—may be rightly used as regards the ornamental parts of the garden, but the grand old name of garden covers all. In this country, where there are inconceivable degrees in the size and nature of gardens, any kind of classification of them is not possible or desirable, but we agree in the term garden for all. We say Glasnevin is a fine garden, and of Longleat, the gardens—two wholly different kinds of garden—are beautiful.

The way you use the term landscape-gardener shows the range of the word, and, of course, his work has more to do with the ornamental parts than with the gardens for fruit or flowers.

Office of *The Garden*, London. *W. Robinson.*

How the Red Cedar Grows in New England.

To the Editor of GARDEN AND FOREST:

Sir,—I recently purchased nine extra large Red Cedar posts to support the floor-timbers under a new barn. These averaged three feet in circumference near the ground. On counting the rings of growth, I was surprised to find that there were but seventy-six in the largest of them, and that a third of these were in the inch and a half of white sap-wood which surrounded the heart-wood. These Cedars grew among other large trees, on a strong loamy soil in the town of Danvers, Massachusetts.

Marblehead, Mass. *J. J. H. Gregory.*

Periodical Literature.

A Ride Through the Caucasian Mountains.—I.

DR. DIECK, the well-known German dendrologist, has begun to publish in *Gartenflora* an account of the journeys he made last summer in the Transcaspian provinces, and we have thought that an abbreviated translation of his first article, which is called "The Primeval Abchasian Forest," might interest our readers.

Going by steamer from Odessa the author landed at Suchum Kale, where he found both a public and a private botanical garden. Here, as well as in the town parks and avenues, a subtropical vegetation predominates, so that one might almost think one's self in Palermo or Alexandria. The Albizzia and the Sterculia are the favorite trees, but the Diospyros, the Eucalyptus and the Paulownia also occur with many Palms, and what Dr. Dieck, pursued by memories of prevailing European fashions, rather plaintively calls "the unescapable variegated Negundo." Mexican, Californian and Indian conifers flourish admirably, and one of the most beautiful objects near the shore is a fine group of *Pinus insignis*. Indigenous plants are, indeed, almost wholly neglected, for only the Cherry Laurel and the Date Palm appear in any quantity, mingled with acclimatized Pittosporums and Escallonias, Evonymus and Magnolias, Myrtles and Pomegranates. The Tea-plant also grows so well that Dr. Dieck believes Russia might supply itself with the greater part of the enormous quantity of tea it consumes if the many hundred square miles of now unused land in the Transcaucasian region were to be devoted to its cultivation.

But the traveler's chief wish was to explore the virgin forests of the Caucasus where "uncontrolled nature reigns in mountain regions which have been almost depopulated by emigration, and where only on the borders of the sea is the axe of the wood-cutter beginning its work of destruction." Accompanied for a time by a number of companions, some of whom were scientific students, he noticed first, as the road from Suchum skirted the water, impenetrable thickets formed by *Paliurus aculeatus*, *Hippophae rhamnoides* and a high-growing Rubus with pale blue-green branchlets and gray-green leaves resembling *R. tomentosus*, which is one of the most characteristic plants of the Pontine coast.

After passing the Kelasuri and Madschara Rivers a fruitful, and, in places, marshy region was reached, the region of Alders and Pterocarya, of Smilax and wild Grapes. In the distance little appeared except *Salix alba* in a form peculiar to the Orient, which has very sparse foliage, so that though the trees are finely developed they have a thin appearance. Among these Alders and Willows the *Pterocarya fraxinifolia* made a fine effect, although the author says that he seldom found it growing as well as it does in Germany, the trees having a tendency to branch at or near the ground and assume a shrubby habit.

Carpinus Betulus, *Quercus sessiliflora* and *Diospyros Lotus* appear as the road turns inland, accompanied by *Rubus meridionalis; Smilax excelsa* and *Clematis vitalba* swing themselves from tree to tree, and, with the Brambles, make a jungle of the forest whence the trees valuable for timber have been cut away. Among the shrubs almost everything else is crowded out by a European Elder and Fern (*Sambucus Ebulus*

and *Pteris aquilina*) and an American immigrant, *Phytolacca decandra*, which "has taken southern Europe and the Orient by storm." This plant, although it was only the middle of August, had partially assumed its beautiful red autumn coloring; its dark purple fruit was attractive to the eye, and, although only a Caucasian stomach, says the author, can long endure it as food, its juice is consumed even by the most civilized, as it is now the chief material used in the south for coloring wine. "Where these three plants have established themselves, and, unfortunately, this means in almost all the low portions and middle ranges of the Caucasian mountains, every other plant is crowded out, and agriculture can be pursued only with indescribable difficulty."

At a height of about 300 metres above the sea-level the vegetation changes. The delicate *Carpinus Duinensis* mingles with *C. Betulus* and *Tilia rubra* and *T. platyphyllos*, *Alnus incana* and *Ulmus elliptica* (largely cultivated in European gardens as *U. Sibirica*) associate themselves with the Oaks. With this dark-leaved Elm stands a light green Maple, *Acer Lobeli*, Ten., var. *colchicum*, and the undergrowth of the wood is richly varied, forms which have immigrated from the north mingling with the children of the south. Near the wild Fig-tree grows the European Buckthorn (*Rhamnus Frangula*), and beside *Rhododendron Ponticum* the common Hazel. The Cherry Laurel mixes with Willows, and the common with the Colchican Ivy; and with the Poet's Laurel stand the Spindle-tree and *Cornus sanguinea*, the berries of which in this rich soil and warm climate attain the size of small cherries. *Staphylæa Colchica* shows both the three-foliate and the five-foliate leaves which have puzzled botanists to decide which is the characteristic form.

As the mountains are penetrated the road becomes steeper, so that carriages are exchanged for saddles; the country grows more romantic, the soil richer, and vegetation ever more and more luxuriant. Azaleas now accompany the Rhododendrons, and the Colchican Ivy and the Wild Grape seem endeavoring to smother the trees and shrubs in their embrace, or hang in garlands from the beetling rocks. Deep below in a ravine rushes the river, half overgrown with Ferns and large-leaved shrubs and fringed by the ubiquitous Alder. Crossing this by a rickety bridge, travelers emerge from the fresh dampness of the forest on to a sun-burned highland with vegetation of a wholly different character. *Rubus meridionalis*, which had been seen on the sea-shore, reappears with the Burning-bush (*Cotoneaster Pyracantha*), luxuriant wild fruits, and various Roses, which seem to feel very happy on this soil. Here is a newly established agricultural colony, where fruit-trees offer grateful shade, but give fruit of no very delightful quality; hence the way leads for many hours through thickets of Alders, and near Antkjel may be seen the remains of an old Box-tree forest. This tree is now rare even in the Caucasus; a wood containing about 20,000 trees, ranging up to two feet in diameter, still stands at a higher elevation near Bsipp, but has recently been purchased by an English company for nearly one million dollars. A Box-forest, says Dr. Dieck, is the genuine forest of the fairy-tales. "No soul can be so dull as not to feel its influence. Hardly a ray of sun can penetrate its thick roof of foliage; perpetual twilight and solemn silence reign within it. All the trunks, all the knotted branches, all the twigs are thickly covered with long trails of moss, while the dark soil beneath bears only a rare tuft of Ferns or group of shrinking Fungi. No bird's voice is heard, no insect whirs through the air; only the rustling of the tree-tops and the moaning of the wind-twisted boughs breaks the church-yard stillness of this ghostly wood."

The Florists' Convention.—II.

Extracts from Papers Read.

WE herewith offer, in addition to our report of last week, a few more extracts from the more important papers read at the Convention of American Florists, held in Toronto a fortnight ago.

THE FUTURE OF HORTICULTURE IN AMERICA.

In treating this subject Mr. W. A. Manda, of Short Hills, New Jersey, began by quoting the statistics from the census bulletin on floriculture to show the remarkable growth of this industry, which had largely come into existence during the last quarter of a century. The business establishments devoted to floriculture now use more than 38,000,000 square feet of glass and cover about 900 acres of ground, and their total value amounts to forty millions of dollars, while the annual sale of plants and flowers amounts to nearly thirty millions of dollars. It is a mistake, however, to measure the standard of excellence in horticulture by financial success alone, for this ought not to be considered a trade but a profession, which is connected with science on the one hand and art on the other. It is a fact that the very ablest horticulturists of the past and the present, the men to whom the public owes a debt of the highest gratitude, have not generally amassed fortunes. This is hardly an encouraging business statement, and yet the speaker hoped that commercial florists would continue to devote more labor and study to matters which would benefit posterity. A florist, for example, who has six greenhouses filled with plants which bring a remunerative income, might afford to have a seventh for a special class of plants which he favored and which he might improve by cultivation and bring up to such a standard of excellence as has been reached by several classes of plants already. When we see the original forms from which the Rose, the Pansy, the Carnation, the Chrysanthemum and the tuberous-rooted Begonia have been developed, and compare them with the present condition of the plants, we are filled with wonder, and we cannot doubt that many other plants, by careful cultivation, selection and cross-fertilizing, can be brought to the same state of perfection. Work of this sort might re-imburse the raiser for his trouble, and it would certainly entitle him to a name and a high rank among horticulturists.

As the population of the country grows, and after the bare necessities of life are secured, the next thing which people demand is the beautifying of their homes with trees and shrubs and plants. As wealth accumulates and the leisure-class multiplies, conservatories and greenhouses will be demanded at all the large mansions near towns and cities, and the demand for fine tropical plants will grow year after year. Clubs and societies where flower-loving people meet to hear essays on topics connected with the art of horticulture, are centres of good influence, and as new members are attracted they are fired with enthusiasm. Public and private exhibitions, too, are the means of interesting the public, and, probably, half the amateurs who have fine collections of plants have begun to collect them after visiting an exhibition of this kind. Public gardens and parks are also potent means of increasing the love for beautiful plants. Such parks and gardens not only afford rest and recreation to the weary, but they instruct visitors, and many of these will here begin to have a longing for the possession of plants and the pleasant experience of cultivating them.

The flora of this country furnishes an ample field for years of study. Its large area, reaching from the cold north to the tropics, furnishes varieties of soil and conditions which, by judicious selection, will suit any plant. It will be only a few years before the tide of traffic will turn, and more plants will be exported from this country than are imported. With our proximity to tropical South America, and communication with the East Indies, we shall be able to introduce and establish tropical plants and compete favorably with any producers in the world. It has been said that the comparatively high wages in this country prevent the successful growing of plants for competition in the markets of the world. But Nature helps us here. We have a more favorable climate, so that many plants make as much growth in one season here as they will make in two seasons in Europe. The methods of cultivation used here are far simpler and better than those abroad, and this will help to neutralize the expense of higher wages. And while we are now exporting only Tuberoses, Orchids and a few bulbs and seeds, we shall in time grow all our own Azaleas, Tulips, Hyacinths, Lilies-of-the-valley, and many other plants, not only for home consumption, but for export; for we are sure to find in various parts of this large country the climate and soil adapted to plants which thrive in Holland, Belgium, the south of France, and in England.

FLOWERING PLANTS FOR DECORATIVE USE IN WINTER.

W. H. Taplin, of Holmesburg, Pennsylvania, read an essay on this subject, which he said might be conveniently divided into three heads: (1) Plants that bloom naturally during the winter season; (2) plants forced into flower during the winter; and (3) bulbous plants suitable for decoration, the first section, perhaps, being the smallest. There are a few special qualifications necessary to render a plant valuable for this particular use, such as graceful form, decided color, moderate rapidity of growth and ease of culture under ordinary conditions; the latter point being of special importance.

Among the plants of the first section the Poinsettias deserve a prominent place, for where vivid color is wanted they meet all requirements, and as the colored bracts of these plants

keep in good condition for several weeks there need be but little loss from waste of flowers. The original species, known in catalogues as *P. pulcherima*, is perhaps the most satisfactory for all purposes, though the double form of this is showy, and keeps well if water is not allowed to lodge among the bracts. The variety Major is also pretty, the color being crimson rather than scarlet, like those of the type. Either of these, to be useful for decorations, should be stocky, well-grown young plants from summer cuttings of soft wood. They may be made to produce one large head of bloom on a well-furnished plant in a five or six-inch pot. *Plumbago rosea coccinea* is another brilliantly colored winter-flowering plant, whose terminal spikes are clothed with red flowers about an inch in diameter. It is not new, by any means, but it deserves a more extended use. It is easy to propagate and it flowers with the least encouragement.

The flowers of Cinerarias have of late been wonderfully improved in size and color as well as in methods of cultivating them. A cool, moist atmosphere and generous supplies of fertilizers seem to be all they need. To keep up a succession of bloom more than one sowing of seed should be made.

Usually, yellow flowers (except Chrysanthemums) are somewhat scarce, so that old-fashioned plants with yellow bloom, like *Reinwardtia* (*Linum*) *trigyna*, ought not to be overlooked; these may be grown into bushy little plants in five or six-inch pots with but little trouble. *Erica hyemalis*, now quite frequently seen in our larger cities, is the most useful of its genus in winter; it is of free growth, when given reasonable care, while the long sprays of rosy tinted flowers give an additional charm to many tasteful decorations. Although the red and yellow flowers of *Libonia floribunda* are small, they are produced in such profusion as to render the plant quite showy. Another point in favor of this plant is its ability to endure neglect without showing signs of injury.

Chrysanthemums should, of course, be included in the decorative list, but all that needs to be said of them here is, to use only those with distinct colors, and to grow only enough varieties to secure a succession of bloom for as long a period as possible. Pot-plants of Carnations, Bouvardias, Roses and the well-known subjects suggest themselves naturally.

Primula Sinensis, in variety, are most useful for winter work, one of the best being the double white sort. Among the single-flowered forms a range of color, from white to dark red, including lilac shades, from the palest to deep purple, is wide enough to satisfy all tastes.

At the head of the list of plants which can be forced into flower the best varieties among the Indian Azaleas are Deutsch Perle, Fielder's White and Borsig, for white, with Madame Vandercruyssem, Eugène Mazel, Vervæniana and Bernhard Andreas for colored flowers. Some of the hardy Rhododendrons are easily forced, while hybrids from the East Indian species bloom at almost all seasons. Many of these are singularly beautiful, and, if they could be reproduced in quantity at a reasonable cost, would doubtless find a ready market.

Prominent among hardy shrubs for forcing come the Lilacs, which are the most popular, both because of their beauty and the ease with which they may be flowered. The Japan Quince has also proved easy to force into bloom, although the flowers are much paler in tint than when naturally produced. Some of the shrubby Spiræas, like *S. Thunbergii*, will bloom in winter as readily as *Deutzia gracilis*. *S. Van Houttei* is better still. Some of the Hydrangeas produced within recent years are admirable, but are, perhaps, more satisfactory toward spring. The practice of growing on summer-rooted cuttings of Hydrangeas into nice small plants in four or five inch pots, and bearing one head of bloom, gives good material for winter and spring work.

It would be worth while to try either white or pink Crape Myrtle for winter forcing, for, if successful, they would prove admirable additions to the stock of decorative plants. *Acacia pubescens* and other species are valuable for their pale yellow flowers, and no plants excel them in graceful habit. *Cytisus Canariensis* and *C. racemosus* furnish a deep shade of yellow, and are invaluable in other respects.

Among bulbous plants for winter decorations *Cyclamen Persicum* deserves first mention, especially since it has been so much improved by careful crossing. The most approved method of cultivation is to grow the plants on from the seed to flowering size without any period of rest or drying off, the whole operation being completed in fifteen to eighteen months.

"The best is the cheapest," is a proverb which applies with full force to Cyclamen-seed. By starting with a good strain, and then carefully selecting some of the best plants for seed-bearing, it is possible to still improve the stock to a wonderful degree.

There is no need to name the various useful Lilies and Amaryllises; and of the Dutch bulbs the only point worth emphasizing now is to grow only those with flowers of clear, distinct shades of color, as no others will prove satisfactory in combinations.

BEGONIAS.

Mr. John Chambers, Superintendent of Parks of the City of Toronto, read an essay on the value of these plants for bedding and for in-door decoration, with notes on the cultivation of the different classes. We quote, in part, his remarks on the tuberous-rooted section:

Both the double and single varieties include all known colors except black and blue; we have the purest white to the darkest maroon; all shades of yellow, from straw-color to old gold; reds, pinks, and salmons of every shade, and many that take on two or even three distinct tints. Flowers of the single sorts that will cover my hands are not uncommon, and the double ones attain almost the same size. In cultivating the tuberous Begonia you may start with seed or bulbs, or both. The seeds should be new. If you have any shallow pans clean them thoroughly, use plenty of crocks at the bottom, mix a light compost of peat with a little well-decayed leaf-mold and sharp sand, after covering crocks with dry moss to keep the soil from running amongst them. Fill the pan to within half-an-inch of the top, press lightly, sow your seed very thin (this is an important point), and cover with a thin layer of silver sand; water well, cover with a piece of glass, and shade from the direct rays of the sun. As soon as the plants are large enough to handle, prick out immediately into shallow pans, with as little delay as possible, as this is one of the secrets of success. Keep shifting into larger pots until the time for rest, then gradually dry off and place in a dry shed or cellar. The seed should have been sown as early in the spring as possible. Now that you have nice young tubers knock them out of the pots carefully, throwing away those that have been attacked with dry-rot.

Procure a few shallow propagating-boxes and some leaf-mold, and place the tubers in this about one inch apart, till they commence to make a few roots, by which time you will have had some clean five-inch pots ready for their reception. A light potting soil will do for this shift, but when it comes to seven, ten and twelve-inch pots, into which you can easily shift them in one season, the following is a good mixture: Say to fifty parts of fibrous turf add twenty-five of good peat, ten of leaf-mold, ten of sharp sand, and five of rotted manure or bone-dust. Mix thoroughly and pot lightly. Begonias of this section are gross feeders, so when they have had their last shift and the pots are full of roots, a good top-dressing and a liberal supply of liquid cow-manure, applied three times a week, will help them. Some varieties will require pinching, but one must be guided by common sense in this respect. A light, airy, span-roofed house is the best place to grow them, with plenty of shading on sunny days. Syringing in the early part of the day is also very beneficial. Tobacco-stems placed around the pots will help to keep down green-fly. For bedding, a partially shaded situation is most suitable, and they should be planted in from four to five-inch pots. Keep well watered, and they will well repay any trouble in that direction.

Mr. David Allan's paper on the Possibilities of Subtropical Gardening was carefully prepared, and gave a list of the best Palms, Cycads, Tree-ferns, Musas and Dracænas which could be used with Castor Beans, Cannas, the ornamental grasses, and other less costly plants. He considered as favorable places for subtropical planting the open squares or courtyards of large hotels and other buildings. There the Banana would make a perfect leaf without being torn with the wind. In such places Palms, Dracænas, Cannas, Caladiums and Musas would be appropriate. The same space could be filled in autumn with Retinosporas in variety, and other conifers.

Of new Fuchsias Mr. Hill mentioned the Countess of Aberdeen as worthy of note on account of its near approach to a pure white in color. When grown in a slight shade both the sepals and the corolla are absolutely white, but in sunshine it turns slightly pink. It is an interesting novelty, and will probably prove the forerunner of a race of Fuchsias of quite a distinct color.

The essay of Mr. Benjamin Grey, of Walden, Massachusetts, contained a brief history of the use of aquatics as garden-plants, with notes on the cultivation of some of the best varieties for planting in natural ponds or artificial basins.

Notes.

At this season, when comparatively few good shrubs or trees are in bloom, the large white flowers of *Gordonia Altamaha* make a striking display. They bear some resemblance to those of the smaller Magnolias, while the plant thrives in Philadelphia and southward under the conditions favorable for Rhododendrons.

The Florida Fibre Company have secured a tract of more than 1,300 acres of land fifty miles south of Jupiter Inlet, in the latitude of the northern Bahamas, and they are setting out 200,000 plants of Sisal Hemp. The company have erected houses, provided boats and implements, and will be prepared to begin to manufacture whenever the growth of the plant warrants it.

Warm weather and frequent rains have encouraged a most vigorous growth in the large Croton-beds in Fairmount Park, Philadelphia, and they are now exceptionally brilliant. There are four circular beds that are each more than twenty feet in diameter, and also one rectangular bed about thirty-five feet in length, all of which are filled with various-colored Crotons, and edged with a line of golden Coleus.

Many of the famous trees of Laurel Hill Cemetery have been lost because the owners of lots have the privilege of cutting as they will on their own ground. Mr. Joseph Meehan, however, writes that there is still standing there a Cedar of Lebanon which is probably the best specimen in the vicinity of Philadelphia. It is some seven feet in circumference, and from sixty to seventy feet high. A large number of cones which hang from its branches make it an exceptionally interesting and uncommon object.

In a paper on Blackberries, recently read before the Wisconsin Horticultural Society, Professor E. S. Goff said that in our so-called improvement of fruits we have generally failed to improve the quality. Our most productive blackberries are large and beautiful, but they are inferior in flavor when compared with the wild ones found along the fence-rows of back pasture lots. Imagination and association have some influence on our sensations, but, after due allowance is made, the perfume and flavor of a wild meadow strawberry will put to shame our Jessies and Warfields. Perhaps the richest field before experimental horticulturists in America is in the direction of improving our native fruits, and of these fruits the blackberry is one of the most promising. The Dewberry has low habit and delicious, juicy fruit, characters that may be profitably combined with those of our Blackberries. Professor Goff esteems the old Dorchester, now almost entirely neglected, as the variety most closely approaching the wild blackberry in flavor. This should be revived, and crosses should be made with it upon our more hardy and productive varieties.

In *Scribner's Magazine* for September there is a picture of the sacred Bo-tree of Ceylon, from a photograph by Mr. James Ricalton, who states that it has stood for 2,130 years, according to authentic records, and is probably the oldest historical tree in the world. The Bo-tree (*Ficus religiosa*), in all countries where Buddhism prevails, has become a consecrated object, and may be seen on the road-side, about houses and temples and in towns, protected by masonry, over which shrines are placed for homage-offerings. This particular tree in Anuradhapura crowns the uppermost of three successive terraces; it has a multiple trunk, and its several divisions are feeble and gnarled, while its leaves lack verdancy and vigor and show the pallor of decrepitude. The soil about its roots is almost saturated with the oil of its anointment, and yet it spreads its protecting arms over its devotees while they deposit their offerings about it. All of them are eager for a single leaf, but no one would dare pluck it from the tree, for it must fall in full maturity to yield its highest merit. When one of these withered leaves loosens from its branch and comes sailing down there is a pious scramble among the multitude, a collision of zealous heads and hands, and then the solitary leaf is borne away in the happy bosom of the successful competitor.

We learn from foreign journals that the plants cultivated in Italy and the south of France for the yield of essential oils have suffered so from the severity of the last winter as to considerably impair the market supplies. Oil of Bergamot is exceedingly scarce in Italy and brings higher prices after every transaction. The principal plants cultivated in France for essential oils, which have been most damaged by last winter's frosts, are Thyme, Rosemary, Lavender and Pennyroyal, and the output of Geranium oil in Spain will this year be very small. The Peppermint crop in England has been winter-damaged, especially on the heavy damp soils and on the more exposed positions, so that some of the plants were taken up. Lavender, also, has suffered severely, especially the old plants, of which the frosts have apparently made short work, nearly all being killed. During the closing week of April the price of the oil advanced from about thirty-five shillings to forty shillings per pound. The Camomile plants have also suffered. It is worth noting that the first consignment of Cassia pomade shipped from British India was recently received in London. It was only a sample shipment, but, if successful, it may be the precursor of large quantities, as the flowers (*Acacia Farnesiana*) are found growing wild in abundance. It is claimed for the Indian pomade that it is very considerably stronger than the strongest French.

Mr. Edward Whittal writes to *The Mayflower* from Smyrna very pleasantly of his excursions to the mountains, where he has been collecting Chionodoxas. Besides the original *C. Luciliæ*, discovered by Mr. Maw, he found the first variety of this plant on the Mahmout Dagh, and named it Sardensis, from the beautiful plains of Sardis, which lay before him. This plant is of a darker tint than *C. Luciliæ*, and the intenseness of its color where many plants were grouped together, with a background of rocks, made a picture not to be forgotten. This variety of the Chionodoxa has white and pink sports, and it is an acquisition for the rockery or wild garden. Mr. Whittal found the third Chionodoxa on the Tmolus range of mountains. It is a smaller, but brighter-colored, plant than *C. Luciliæ*, and he named it *C. Tmolusi*. It has been considered by some botanists as identical to the one discovered by Mr. Maw, but in its wild state the difference between the flowers is very marked. No white or pink sports of this plant have been found. It was near this third Chionodoxa that Mr. Whittal found the variety which he named Gigantea, from its more massive flowers. The coloring of this plant is not so brilliant as in the type, but this deficiency is made up by its size and by the erectness of its flower-scape. It varies in color more than the other Glories of the Snow, and when well established it will be sure to attract attention.

A recent bulletin of the Chicago Academy of Sciences is devoted to the flora of Cook County, Illinois, and a part of Lake County, Indiana. It has been prepared by W. K. Higley and Charles S. Rudden, and includes 1,336 species and varieties, of which 177 species and five varieties have been introduced. From a brief chapter treating of plants which merit special attention by reason of some peculiarities in form or habit, we quote the following: "Situated along the shore of Lake Michigan is a class of alien plants whose natural habitat is in the vicinity of salt-water. Of these saline forms the Beach Plum, among the trees, is most interesting. All along the shores of the lake the bright flowers of the Beach Pea (*Lathyrus maritimus*) can be seen during the summer months lifting their heads above the sand, while among them at Evanston, and also at Wolf Lake and Clarke, Indiana, the Saltwort (*Salsola Kali*) is sparingly found. Leaving the lake-shore for the more marshy districts inland, several parasitic forms are found. Under foot the Corpse-plant and Cancer-root rear their pale forms above decaying vegetable matter on the roots of other plants, while three species of the Dodder twine their waxy stems around the stalks of the Helianthus and other species of *Compositæ*. Occasionally exceptional forms, such flowers differing in color from the characteristic hue and double forms, are recorded. A number of albino forms are included, among which may be mentioned the Cranesbill, Red Clover, Columbine, Blazing Star, etc. Many double forms among the species of Helianthus, Coreopsis, etc., have also been found in all stages of development."

Catalogues Received.

Wm. C. Breck, Allegheny, Pa.; Autumn Bulbs.—William Bull, 536 King's Road, Chelsea, London, S. W., England; Tuberous-rooted Plants and Bulbs.—Haage & Schmidt, Erfurt, Germany; Autumn Flower Bulbs and Roots.—William Baylor Hartland, 24 Patrick Street, Cork, Ireland; Key to Hartland's Floral Album of Daffodils and General Bulb List for 1891–92.—Hitchings & Co., 233 Mercer Street, New York, N. Y.; Water Heaters for Baths and Laundries; also Hot-water Heating Apparatus for greenhouses, graperies and all glass structures, and dwellings.—E. H. Krelage & Son, Haarlem, Holland; Dutch Flower Bulbs.—E. W. Reid, Bridgeport, Ohio; Pot-grown Strawberries, Small Fruits, Ornamental Shrubs, Roses, Grape-vines, etc.—Lewis Roesch, Fredonia, N. Y.; Fall Trade Price List of Grape-vines, Small-fruit Plants, etc.—Vilmorin-Andrieux et Cie., 4 Quai de la Megisserie, Paris, France; Flowering Bulbs and Flower Seeds for Autumn Planting.—Thomas W. Weathered's Sons, 244 Canal Street, New York, N. Y.; Hot-water Heaters for Dwellings, Conservatories, Greenhouses, Graperies, Poultry Houses, etc.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by . . . . . Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, SEPTEMBER 9, 1891.

TABLE OF CONTENTS.

Suggestions to Tree-planters.

INSTRUCTIONS for planting trees may seem untimely at this season, but really this is the time of year when preparation for next year's planting should be made if such preparation has not been largely completed already. Our springs are so short that if any work at all is accomplished at that season it must be hurried through, and planting cannot be thoroughly done in the trying weather which then prevails unless everything is made ready for it in advance. Of course, all planning and mapping should be completed before actual work in the ground begins, and since an essential part of this work is deep digging or trenching in time to allow the ground to settle during the winter, there is little danger that the work will begin too early. There are few labors in which men engage where the difference between the results of thorough work and of careless work is so striking. A little well-directed effort may insure health and vigor to a tree and make it an object of pride and beauty for a century, while the same tree hastily planted will prove feeble and short-lived, and therefore a disappointment, for no tree is beautiful which is not full of lusty life.

One point too often neglected is a consideration of the situation in which various trees are to stand. A so-called ornamental tree, which is feeble or sickly, is always a blot upon the landscape, and no tree can be thoroughly healthy for a long time unless it grows in a soil and situation peculiarly suited to its needs. A Pine-tree will thrive on a gravelly bank, but people who try to grow Maples or Hickories in such a situation will find their labor wasted. Equally futile will it be to plant Chestnut-trees where there is a substratum of solid rock, or ericaceous plants where there is much lime in the land. Of course, it is true that some trees, like the Red Maple and the Bald Cypress, which are usually found in wet ground, will grow when transplanted to uplands; but the best rule for a planter to follow is the one which is set by Nature, and he will be likely to plant with the greatest success who observes most carefully the positions in which the trees he plants are found when growing naturally. It is too often the case that landscape-gardeners or other planters, having been charmed with the beauty of some tree, attempt to use it without considering its special requirements, and this is one reason why so many short-lived and sickly trees are found in elaborately planted parks and private grounds.

Fortunately, this law does not restrict the planter to any troublesome degree, nor does it deprive him of the use of materials needed to produce the best effects. As a rule, swamp-trees appear to better advantage when their feet are in the water. Alders never look so well as they do by a brook-side, so that the planter who considers the wants of his trees, with a view to their health and vigor, will find that by following these rules he is gaining also greater naturalness and beauty in his combinations. Of course, these same rules apply to shrubs and herbaceous plants as to trees, for although the Cardinal-flower and Rose Mallow will bloom when transplanted from the marshes into a dry border, yet the most healthy and beautiful plants are those which are placed in the positions where they are found at home.

There ought to be no need of insisting on the necessity of a thorough enrichment of the soil, for every one knows that, in addition to its proper mechanical preparation, the soil must furnish plant-food of the proper quality. Here, too, a study of trees as they appear under natural conditions will teach a useful lesson. Let any one note the insignificant size and meagre foliage of a tree growing in a thin soil, or on a hungry ridge, and compare it with a specimen of the same species standing in deep, rich, moist loam, and he will have an object-lesson in the value of thorough enrichment of the soil for ornamental planting. An effort to produce immediate effect, as it is called, is often made by planting large specimens, or by grouping them close together, but the best way to secure early effect, as well as lasting effect, is to feed trees well and encourage them to a speedy growth, which is, as a rule, the most healthful growth.

Monuments in Public Places.—III.

THE right placing of out-door monuments can scarcely be called a less important question than their intrinsic excellence. A beautiful statue may be shorn of half its effect if badly stationed, and a good substructure can very seldom be designed unless the destined station is exactly known; while, on the other hand, a fine bit of landscape, or dignified open space in a city street, may be seriously injured by the inappropriate placing even of a work that is meritorious in itself.

We should first remember that, a monument being a palpably artificial thing, the best place for it is where other artificial elements are conspicuous; if in a park, for example, it should be placed at the intersection of roads or paths, on a terrace, or at the side of a formal avenue. No better situation for statues or other comparatively small monuments could be imagined than the Mall in the Central Park, where a long double row, alternating with the symmetrically spaced Elms, would greatly increase the stately beauty of the promenade, as well as its interest to the masses of people who daily frequent it. Commonwealth Avenue, in Boston, with its wide, open walk between doubled rows of trees, is another place which looks as though specially designed to offer hospitality to the sculptor; and it will be well indeed if the entrance avenue of Druid Park, in Baltimore, some day sees its rows of monotonous, ugly urns, suggestive of the "Forty Thieves," replaced by a varied, yet harmonious, series of works of art. In Washington excellent situations, especially for equestrian or other large monuments, are offered by the "reservations," circles or triangles which so frequently break the lines of radiating streets; and, of course, every city has certain little squares and open corners where, alone or in combination with trees and shrubs, monuments of one sort or another would be eminently appropriate.

The French show better taste than ourselves in the placing of their works of sculpture, and a study of their arrange-

ment in such places as the Luxembourg and Tuileries gardens might advantageously be made by our artists and those who have control of our pleasure-grounds. But the French are apt to be less skillful in dealing with a "natural" park than with formal gardens such as those we have named, and here even they sometimes make mistakes. In the Parc Monceau, in Paris, for instance, we see several bronze figures or groups set, at a distance from the road, in the centre of wide quiet stretches of lawn. Such an arrangement seems bad for two reasons. Not only is the repose of the lawn disturbed and its natural character injured by the presence of a conspicuous formal feature—the statue itself is placed too far from the eye to be thoroughly well appreciated.

But in addition to the broad rules which indicate the greater or lesser appropriateness in a general way of certain classes of situations, a number of special points must be considered before any monument can be well established.

One such point is scale, or the relation in size of the work of art to its environment. The figure of Webster in the Central Park stands in an excellent place, in the centre of a large circle where the West Drive is crossed by the road leading to Seventy-second Street. But it makes a poor effect, and not only because it is uninteresting and weak in conception and mechanical in execution; it is out of scale; it is so large that it dwarfs alike the neighboring trees and the passing figures of living men. In another situation it might not produce this effect, while, on the other hand, it would not be hard to point to statues which, if increased in size, would look much better where they chance to stand. Excessive size is a very common defect in the portrait busts we occasionally place out-of-doors, as, for instance, in the Schiller, in the Central Park, and the Irving, in Bryant Park. A bust should almost always be placed near the eye, and, if made very big, produces not an "heroic" impression, but simply one of unnatural and disagreeable bulk. If the situation chosen for a bust demands a comparatively large monument, then the architect should be called upon for an elaborate pedestal. The French appreciate this, and their architectural memorials, crowned by a bust little, if at all, larger than life, are among their happiest creations.

Nor is it only when busts are in question that the architect may help in giving a monument the proper scale. The circle where the Webster stands demands a large monument. An equestrian statue might well have been placed there, as bulk could thus have been secured without any undue exaggeration in scale; but a smaller standing figure on a more spreading and elaborate base might likewise have been eminently successful. Where such a circle is formed not by drive-ways, but by paths, it is usually smaller, and therefore demands a smaller monument for its completion; and every such spot should be supplied with its adornment only after a nice consideration of this question of scale, in full consciousness of the fact that a mistake will injure both the work of art as such and the general effect of the locality.

Another important point is the height above the eye at which a monument will stand. In city streets or squares this is determined simply by the pedestal; but in parks there are sometimes excellent situations elevated above the roads and walks. Statues placed here will be seen not against a background of buildings or foliage, but outlined against the sky, and their silhouette should therefore be considered with more than usual care. The Bolivar in the Central Park, on its little elevated plateau overlooking Eighth Avenue, proves that a bad statue may seem doubly bad when all its outlines are thus conspicuously lifted into prominence; but it also suggests, of course, how greatly the beauty of a good one might be increased by such a situation. Also in the Central Park, not far from the Webster statue, there is a figure of a falconer, which, if not a remarkable, is a pleasing work of art; and its effectiveness is certainly increased by its elevation on a rocky slope, although one might wish this slope had been a little less rural in character, a little better adapted for the reception of so artificial an ornament. A good place for a group or figure which demands a certain elevation to appear at its best is the top of a terrace or the balustrade of a bridge. In many European cities the old stone bridges are adorned with statues, which are themselves admirably shown, while the effect of the bridge is greatly improved; but we can remember no instance in America where the same thing has been done. For a large bridge great groups or equestrian figures are naturally desirable; but on a small one busts or other small works might be very beautiful. We should like to see a park bridge designed with especial reference to the sculptor's subsequent work, and then ornamented with the best that our sculptors now can achieve. Moreover, in such a place, or along the balustrade of a terrace, many men might be fittingly commemorated whose memory deserves to be perpetuated, yet who were hardly great enough to warrant the erection of a wholly independent monument of a more conspicuous sort.

A Brook in the Yosemite.

THE presence of water in some form almost always adds interest to a landscape. The distinct sea, with its suggestion of vastness and sublimity; a great river, flowing by in strength and silence; a placid lake, which mirrors back the light of the skies; the "still waters," which always unite with "green pastures," to form pictures of perfect peace; a running brook, with its sparkle and vivacity—each one of these reveals some of those distinctive qualities which in infinite variety finds expression in objects of natural grandeur or beauty. The brook in the illustration, page 426, which is foaming over a rocky bed, carries us at once into the solitude of a rugged forest-country. The scene might be on the flank of a New England mountain, but the trees along the borders of the stream are unfamiliar to eastern eyes. They are mainly Alders, it is true, but California Alders (*Alnus rhombifolia*), which are found widely distributed from British Columbia into Mexico. The great Alder of Oregon and the northwest Coast (*A. rubra*) becomes a still larger tree than this, often attaining the height of a hundred feet and more; the California Alder, however, not rarely grows to be fifty or sixty feet, although toward the northern and eastern limit of its range it is reduced to the form and size of a shrub. It is peculiar in the earliness of its flowers, which appear in central California in January, or just as soon as the leaves of the previous year fall. In his paper on the Pacific Coast Alders, Dr. Parry says that, "in spite of occasional sharp frosts, the process of fertilization proceeds steadily, and by the 1st of February, at least as far north as the lower Sacramento Valley, it is mainly completed, and the swollen winter streams, over which these trees lean, and the adjoining banks are conspicuously darkened by the effete male catkins, which resemble torpid caterpillars." It is a tree of neat habit, as the picture shows, and it adds to the beauty of many California streams upon whose banks it abounds.

This particular stream is in the Yosemite Valley, and is probably one of the tributaries of the Merced River. The illustration is from a photograph by Dr. H. W. Rollins, of Boston, to whom our readers are indebted for so many well-selected examples of American trees and American scenery.

How We Renewed an Old Place.

XVIII.—LANDSCAPE GARDENING.

WHEN we first purchased this old farm no dream of landscape-gardening crossed our minds. It was not to found a country-seat that we bought it, but simply to get a place to live in, a quiet village home, as indeed it is, where a lovely view would gladden our eyes, where we should have elbow-room, with enough land to cultivate to provide us with an interest, and where we could raise hay for our horses, and, perhaps, a few vegetables for ourselves. A tree or two to shade

us, and some Pines on the hill-side to relieve its dreariness, were in our programme, as well as the Willows along the street, but we felt that we had twice as much land as we needed, and should probably part with a lot on each side of us before very long, instead of wishing, as we now do, for a few acres more.

As in everything else that one begins in an amateurish way, we looked no further along the road we were to travel than the end of its first enticing curve, and little we recked where it was to lead us. To get rid of barrenness was our obvious business, but there was no method in our endeavor beyond the mere putting in of all the trees and shrubs we could muster from the resources of the place, or through the kindness of our friends.

For the first two years it required our best energies to make these live, and there was not much thought beyond digging around them, watering them when dry, and pruning them into shape. But the third summer, when the bare poles began to have perceptible tops on them, and the little shrubs to occupy a substantial space of the earth's surface, we began to be conscious of defects of arrangement, of a lack of meaning and purpose in the picture, and to feel the necessity of a more artistic disposition of our forces. The needs of the place, too, became apparent. The trees that had been planted for shade either showed that they would throw no shadows at all within the next ten years, at the proper hours, or else would throw them where they were not particularly needed. The shrubs in groups looked crowded, the single ones gave a spotty appearance to the lawn that was not to be borne, the drive-ways were too wide and their curves unsatisfactory, while the expanses of turf were too brief for beauty.

Each effort at improvement seemed but to make us the more conscious of our lacks, and while our neighbors were complimenting us upon the improved appearance of the farm, which no longer looked like an abandoned sand-hill, we ourselves were taking counsel together, and coming to the conclusion that the place was a schoolmaster to bring us unto knowledge by the painful road of ignorance and failure.

The conviction that you know nothing is always a hopeful, if a depressing, sign. When the painter feels that his finished picture is a wretched daub, when the writer knows that his last romance is but a thing of shreds and patches, it is a proof that he is still growing, that he has a stronger note to strike, and that his end is not yet.

One of our leading novelists says that his stories are to him like those tapestries wrought by the workman from behind, of which the weaver sees only the wrong side, the knots and ends of the worsted, the seams of the foundation, so that when the public views his finished work with delight, recognizing its sincerity and dramatic truth, the satisfaction of his readers is to him a wonder, since from his own point of view he knows not whether he has wrought well or ill.

All great successes, I fancy, must be surprises to the men who make them, for the discontent of the artist with his painting, of the poet with his verse, of the playwright with his play, is a penalty exacted by the ideal for which men strive, and which all the more surely eludes the greatest, whose imagination is the most far-reaching. When a man is satisfied with what he has done he has reached his limit; from that point he goes down-hill, imperceptibly it may be at first, but none the less surely.

Our own discontent with our landscape-gardening convinces me that we have a future before us for a good while to come. Our picture will bear a lot of working on for many years yet, and in the mean time we have room for a succession of despairs that will serve to keep us properly humble.

But that we have on the north of our house a landscape to evolve that is a true picture no one can deny who looks out upon the ever-changing meadow from the bowery veranda from which we view it with never-failing joy. Not a far-reaching view, but such a one as Englishmen like to paint, a distant hill, a few clustering cottages, a level stretch of meadow with a winding stream; some Willows near at hand. So far so good; but the foreground is the puzzle. It is a muddle at present, being a sacrifice to the utilities, and is more or less disfigured with fruit-trees and vegetables, and piles of sand that have been dumped upon the marsh. A good deal veiled it is, fortunately, by the bending boughs of Pear and Apple-trees laden with fruit, which is their plea for life, and when one is seated, the balustrade of the veranda is an efficient screen, so that one can freely enjoy the pleasing prospect.

The French talk of the *St. Martin des femmes* which comes to them after the *beauté du diable* has long gone by; and our meadow, too, has its fleeting glory of youth in early spring, with Apple-bloom flush, and delicious verdancy to match, and then, after a common-place summer of good looks, it comes to its Martinmas, and burns and glows and smiles with a richness and warmth that are the precursor of the

Hectic of the dying year.

In this mature beauty, which is far more permanent than the more exquisite spring loveliness, there is a great charm. The monotony of July greens has yielded to the deeper tones of the woodland in August. The declining sun casts longer shadows in the afternoon. The grass, along the winding stream now at its lowest, stands up high from the surface of the water, with darkly shaded edges the more apparent that its prevailing tones are russet, with bright golden lights, where the hay has not yet been cut. Here and there the broad expanse shows a hay-cart and a few moving figures, the one touch of life wanting at other seasons to the landscape. The rounded hay-cocks in the distance are lightly shaded on the side opposite the light. There are streaks of red-brown where some of the grass is in blossom, and of vivid green where masses of sedges line the low banks of the tiny winding river, in which their reflections tone the blue through soft gradations to the deepest shadow. A solitary heron floats above the marsh, beating the air with slow strokes of his broad wings. In the evening sometimes the clanging of the wild geese is heard, the first deep tone in the knell of dying summer. Now and then a white flight of gulls comes up from the harbor searching for fish, pouncing down behind the grass after some luckless perch in the water. The shadows of the distant Oaks are darkest blue, and some far-off Elms fleck the front of an orange-colored cottage and subdue it to harmony. The gray roofs and red chimneys of the distant houses and barns, half-buried in foliage, seem an essential of the picture, giving it that touch of humanness without which a landscape lacks its final charm. The veranda-rail, with its drapery of Woodbine, gives a strong accent that brings out the values of the middle distance, while the tops of two old Apple-trees, laden with fruit, make a pleasing curve in contrast to the level lines of the parti-colored marsh, elsewhere broken by the ashy green foliage of some graceful Willows across the invisible road.

So much, at least, our landscape-gardening has accomplished; the ugly line which killed our predecessor has been obliterated by our border-plantation, and, to all intents and purposes, the great stretch of grassy meadow, with its winding stream and its bounding masses of Oak and Maple woods, is our own park, for none of its owners get the good of it as we do. For us it glows with sunshine, or frowns with a passing cloud; ours all this wealth of jasper and chrysoprase and turquoise; as much ours as the silver sheen of the Willows which wave so softly gray against it, and rest the eye from the dazzling tints in which the old marsh arrays herself for the mowers. But the problem that vexes our spirits is that unshaped foreground, and how it may be made to blend more completely with the meadow into one harmonious whole. If the great Apple-tree could but change places with a certain Elm that is of no use in the landscape where it stands the matter would settle itself. Two more Apple-trees to cut down, and you have a composition.

But a Seek-no-further, which bears several barrels of early apples that are very good eating, is not easily to be sacrificed, even to the demands of a landscape, to which it is also advantageous from its height and mass, that could not be reproduced by any planted tree in our day, unless, indeed, we had the purse of Miss Catherine Wolfe to spend thousands in moving giants. If it could be had for the asking, I think I should choose a low, wide-spreading Oak rather than a stately Elm, or possibly the view might be improved if we had no tree at all, but that effect we have from an upper window which may have its balcony some day.

A whirlwind swept up the valley on the twelfth of August and very nearly settled the question for us by making a clean sweep, but, luckily, contented itself with two or three great boughs full of apples, which are hanging now by a slip of bark, in hopes that they may get sap enough through this narrow channel to ripen, but it looks doubtful.

The same storm made havoc in the garden with such tall Hollyhocks and Poppies as had carelessly been left untied, and then whisked a branch from off our great Elm, and split in two a large Swamp Maple on the other side of the street. A five-minute tornado it was, with pouring flood that swept the main street of the village and littered it with fallen trunks and limbs twisted off in its whirling flight; as brief, but more violent a gale I have seen in Maine, cutting a forest into windrows as a mower would cut grass with his scythe.

To make a landscape-garden one must live with it and study it, putting in a touch here and there, as the painter treats his

canvas, now effacing a spot, again adding an accent, blending, harmonizing, even destroying, if need be, and beginning once more. Advice you may listen to, but be not over-hasty to accept suggestion. Weigh each idea well before you admit it, look at it from all sides, for it will always have more than one. It is you who will have to live with the picture, and it is your mind that should lend the individuality that will make the scene your own. It is, after all, the personal touch that is worth while.

A fair woman, who is a summer neighbor of ours, took me the other day through interesting grounds, which her own taste and care had brought into a wild, and yet controlled beauty. Boulders draped with vines, and shrubberies of native growth, lined the long avenue that wound up a wooded and rocky hill-side to a home which overlooks Massachusetts Bay. But the finest feature of the commanding prospect was a glimpse of the rounded hills and silver-shining water of Hingham Harbor, toward which the eye was led over miles of tree-tops. Just in front was a lawn of perfect turf, golden green in the low sunlight, and a little way off, against the blue dome of sky, stood up some heavy Cedars, their black masses of foliage giving just the required force of accent to the foreground, throwing far away into the remotest distance the lovely outline of the Blue Hills of Milton.

Such a picture one cannot forget. Intelligence and taste have added to it the last refining touch. Remoteness is here, and sylvan wildness, contrasted with the gentle charm of well-swept turf, and skillfully subordinated groups of flowering shrubs and plants, that complete, but form no jarring note in the beautiful scene. To me it seemed perfection, but with the eye of the true artist who loves his work, my hostess noted a ledge here, an obtrusive Oak-top there, which, to her fastidious taste, seemed to intrude. For the true lover of nature works forever at his picture, ever sensitive to a new charm, watchful for a fresh effect, rejoicing in each change, painting with a palette of the great Mother's blending, on a canvas of her own contriving, with an impressionism that cannot falsify, and a detail that is never intrusive. In this great school one learns breadth without vagueness, intensity without violence, and softness that cannot be effeminate. The value of atmosphere, the glory of the sky, can never be out of key with the picture, and the "seeing eye," by careful study and patient waiting, can here evolve ideal beauty from material form.

Hingham, Mass. *M. C. Robbins.*

The Weeds of California.—IV.

THE *Rosaceæ* furnish no plant that could properly be classed as a weed in California, save perhaps that the *Chamæbatia foliolosa*, the procumbent "Tarweed" of the Sierra foot-hills, sometimes persists for some years after the land it covered has been taken into cultivation.

Of the *Onagraceæ*, *Œnothera ovata*, the stemless Evening (here more properly morning) Primrose, is somewhat persistent in pastures, and if not suppressed will gradually shade out the grasses with its dense rosettes of leaves. It plays the same part that the several Plantains do in grass-lawns; but its beautiful and abundant flowers plead for its toleration as do those of the Dandelion in Europe and the east. *Epilobium paniculatum* locally invades the moister fields, but is not very persistent.

Of the *Cucurbitaceæ*, two species of *Megarrhiza* (vulgo Big-root), occurring both in woods and open grounds in the Coast ranges, retain their hold on cultivated lands as well as pastures for a number of years, owing to the enormous tubers which, lying from two to four feet below the surface, can be reached only by laborious digging. Persistent cutting off of the shoots will gradually exhaust the tuber, but if allowed to grow even a short time during each season it will continue to send forth its succulent climbing runners almost indefinitely.

The *Cucurbita fœtida* (*C. perennis*, Gray), the Calabazita of the Mexicans, is common in open grounds in the southern half of the state, and retains a place in the fields with some tenacity, on account of the multitude of its gourds and the protection their hard rind affords to the seeds. It covers the ground in wheel-shaped masses eight to twelve feet across, and, of course, is a very unwelcome visitor in all cultivated grounds. But by cutting off the perennial root-crown and picking up gourds for a season or two it can be readily extirpated.

Of the large and largely represented family of the *Umbelliferæ* scarcely one can be counted as a seriously obnoxious weed. The Fennel, heretofore mentioned, is a hardy roadside weed, but is easily dealt with in cultivation. The Caraway makes no headway; the Anise and Coriander retain a place in fence-corners, but do not spread. The Celery seems to have escaped from cultivation into wet grounds, and sometimes covers them thickly, but quickly yields before culture. The Carrot is abroad in woodlands and pastures, but is not troublesome. Of the numerous native species, *Sanicula Menziesii* and *S. bipinnatifida* are apt to maintain themselves in pastures for some time, as do certain species of Peucedanum and Caucalis, as well as the large *Heracleum lanatum*. But none of these can be accounted serious pests in cultivated ground.

Of the *Rubiaceæ*, the native Galiums are quite innocent of harm; Diodia, so troublesome in the Cotton states, is occasionally seen, but makes no headway. *Rubia tinctorum*, however, spreads energetically in heavy soils, and would doubtless prove a serious pest were it to escape from cultivation.

Of the *Dipsaceæ*, as stated above, the Fuller's Teasel has become a common roadside weed in the Bay region, and runs riot in waste grounds; it could doubtless be cultivated to great advantage in this genial climate could a market be found for it. The garden Scabious, also, has escaped from the gardens, and frequently occupies the ground on dusty roadsides.

The *Composite* family furnishes some of the most obnoxious and interesting weeds, and a considerable number. Broadly speaking, there are five chiefly introduced species that give serious trouble—namely: first, and worst of all, *Centaurea Meliteasis* and *C. solstitialis*, introduced from southern Europe, and almost universally diffused under a variety of names; second, *Anthemis Cotula*, a comparatively recent arrival; third, *Silbyum Marianum;* fourth and fifth, the two Cocklebuns, *Xanthium Canadense* and *X. spinosum*. To these may be added as of less importance, although likewise widely diffused, *Senecio vulgaris*, *Sonchus oleraceus* and *Erigeron Canadense*. All of these well-known weeds may be seen at their best in the fields and pastures of California, but little changed from their eastern or European habits, but exhibiting a resistance to heat and drought that would hardly have been looked for in plants of their native climes.

The two Centaureas, the Tocalote of the Mexicans and the Napa Thistle and Prickly Tarweed of the Americans, deserve more than a passing notice as being, with the Black Mustard and the Barley Grass (*Hordeum murinum*), the most formidable weed pest for both fields and pastures, particularly in the central and northern parts of the Coast ranges. Starting in early spring, *Centaurea Melitensis* especially will mature seeds in May; these, or any others, will germinate again, under conditions of heat and dryness that will permit no other seed to move; this second generation again runs to seed rapidly, and may, in its turn, be succeeded by a third, maturing its seed in December. The wiry tap-root, penetrating deep into the soil, requires a sharp tool to cut it. The Tocalote is thus a weed that, unlike almost any other within the state, gives the farmer no summer rest where it is once well established. In pastures it is even a worse pest than in cultivated fields, as it will take possession of the ground so soon as even a casual overstocking occurs, being able to avail itself of any chance that may occur throughout the season. It quickly and completely runs out the native grasses, and it is impossible to restore the grass without previous cultivation. For, although the plant is an annual, if cut anywhere above the root-crown it soon sprouts decumbent branches that will bloom and fruit under the very tread of cattle, and if again cut the same process will be repeated the same or the following year. The slender, sharp spines of the involucral scales (quite strong and long in the true *C. Solstitialis*) render the plant doubly obnoxious to the pedestrian when dry; while in the green state the viscous tomentum of stems and leaves soil the clothes. In grain fields it sometimes covers the ground completely after harvest, seeding it thoroughly for the coming season.

The Anthemis (Mayweed, Dog-fennel) comes next to the Tocalote as the enemy of overstocked pastures. It is not yet widely diffused, and, I think, has reached the eastern borders of San Francisco Bay only within my own recollection, about ten years ago, when I first observed it on the road from Oakland Point to Berkeley, four miles away. Within two years it reached Berkeley, and then, favored by the trade-winds from the west, it quickly ascended the Coast range and now disputes precedence with the Tocalote, up to an elevation of nearly 1,700 feet. As its vegetation is somewhat earlier than that of the Centaurea, it shades out the latter during the early part of the season; but later the Tocalote takes its turn, and between the two, the hill pastures are left in a sorry plight. The May Weed does not, however, occupy waste places in this region as generally as is the case in the cotton states; its growth is low, and as there is only one generation each season, it seems that it might readily be kept in check

on cultivated ground, which, as yet, it has not invaded to any great extent.

Silbyum Marianum (the true Milk Thistle) has, in the Bay region and elsewhere, become a common roadside weed, whose masses of handsomely veined foliage surpass in beauty many a carefully nurtured plant, but present an aspect of ragged dilapidation after the (annual) plant has completed its vegetation and sends its hairy-tufted akenes flying all over the country. Curiously enough, the Silbyum was for several years mistaken for the Canada Thistle, and the legislation regarding the latter was partly enforced against it, until the mistake was brought out in a lawsuit for neglect to comply with the law. Systematic mowing at the time of heading soon disposes of the plant, but when it has once gained possession for the season it is hard to subdue, and shades out everything else.

The true Canada Thistle was at one time imported into the state, and took possession of some land near Chico, Butte county, but was promptly recognized and subdued. Professor Greene has lately received it from Humboldt county in northwestern California.

An experimental planting of the *Carduus benedictus* in the University garden revealed such dangerous qualities as a rapidly spreading weed that it was promptly extirpated.

Of the two Xanthiums already mentioned, the *X. spinosum* especially has become ubiquitous in the state, at least from Chico to San Bernardino. Roadsides and fields are equally favored by it, and no summer drought or heat seems to affect it materially. Like the black Cocklebur, it differs from the eastern form only in a lower and more spreading habit, and both are redoubtable weeds if neglected.

University of California. *E. W. Hilgard.*

Foreign Correspondence.

London Letter.

ALTHOUGH we have scarcely had a day without rain for some weeks past, this is not an unmixed evil, for all open-air growth has been benefited by the abundant moisture, and if we are only favored with a dry and sunny autumn to ripen their wood, Rhododendrons, Azaleas and other flowering shrubs will be unusually good next year. Ornamental trees and shrubs are making extraordinary growth, which brings out their leaf-beauty to perfection, and I have rarely seen variegated and golden shrubs so fine as this year, particularly those that are liable to become scorched in hot and dry summers.

Among the new variegated trees that may perhaps have an interest for your readers is the golden variegated Ash-leaved Maple, which has now found general favor. It will, no doubt, become as popular as the now too common silver form of the same tree which defaces so many otherwise pretty gardens. The variegation of the golden sort is not so staring as that of the older variety, and, therefore, can be used more freely, without producing that spottiness which white-leaved shrubs and trees do when too plentiful. Spath's variety of *Cornus alba* is here considered the best of the variegated Dogwoods, as it is vigorous in growth, and its variegation is as good in dull and moist as in bright and hot weather. Novelties among trees and shrubs are never plentiful, and this season there seems to be fewer than usual. One of the best new shrubs I have seen is *Hypericum Moserianum*, now in full flower. It is a hybrid obtained on the Continent by crossing *H. calycinum* and *H. patulum*, the result being an exactly intermediate plant. The growth, however, most resembles that of *H. calycinum*, as it is dwarf, and the stems recurve in a similar way. The leaves, too, are similar, being obovate, pale green, with reddish bark on young stems. The flowers produced, from three to five together, at the tips of the shoots are as large as those of *H. calycinum*, but instead of being narrow are broad, and overlap, as in *H. patulum*, and are of thick texture, while the feathery tuft of stamens is not so spreading as in *H. calycinum*. The color is a very bright and clear yellow, and as the plant flowers so freely a mass of it makes a fine display. It seems to be a first-rate new shrub, and it is to be hoped that the intercrossing has not rendered it less hardy than *H. calycinum*, which naturalizes itself in all parts of these islands.

Among noteworthy trees and shrubs in flower last week none was so interesting as *Stuartia Virginica*, of which there are some grand specimens in old arboreta, like those of Syon and Coolhurst. The Syon specimen is a wide-spreading small tree planted in a dampish part of the grounds, and for the last fortnight has been crowded with its large ivory-white flowers, with crimson-topped stamens in feathery tufts. It is remarkable that, while we not unfrequently see this Stuartia in old gardens, one has a difficulty to buy it in nurseries.

A beautiful Chilian shrub, *Eucryphia pinnatifolia*, is just now in flower and is of much interest, since it has proved quite hardy and because it flowers when so little bloom is seen in the shrub garden. It is a close-growing twiggy shrub, with deep green pinnate deciduous leaves, and with flowers similar in form to those of *Hypericum calycinum*, and almost equal to them in size, but pure white. This shrub flowers freely, and for a long time. It is not, I presume, hardy enough to stand your climate. In the nurseries about London and at Kew the interesting tree received a few years ago from the Amur River, *Cladrastis* (*Maackia*) *Amurensis*, is in full flower now, and seems to improve each year. The largest tree I have seen is about ten feet high, with a spreading flat head and tabulated branches, which are now studded with erect dense racemes of white blossoms, which, from their number, are conspicuous. It is quite different in aspect from *C. lutea*, and, perhaps, will not make so handsome a tree, but any tree is welcome which flowers in August.

Of small flowering shrubs, the most remarkable are two varieties of Spiræa. One is a very dark rich crimson variety of *S. callosa* called Atro-sanguinea, which is considered one of the choicest hardy shrubs for English gardens; the other, a variety of *S. Bumalda*, known as the Knap Hill variety, and which is remarkable for its rich color as the variety of *S. callosa*.

At Kew there are just now several plants of more than ordinary interest, but the chief attraction is the gigantic-flowered *Aristolochia grandiflora*, already mentioned by Mr. Watson, the largest-flowered of all the species, and only surpassed in the size of its flowers by those of the wonderful Rafflesia. The Aristolochia is by no means new, as it was cultivated at Kew fifty years ago, and was flowered there in 1848. It was, however, lost to the collection until it was obtained, two or three years ago, from Mr. Sturtevant, of New Jersey. It is a strong-growing climber, with heart-shaped leaves. The flowers and buds so far number about three dozen, but the expanded flower lasts only a day. In its various stages of growth the flower is most remarkable, and just before it expands it reminds one of a plucked goose hung up by the neck, the front of the flower corresponding with the breast of a bird. The color before opening is a pale creamy gray, strongly marked with a prominent net-work of veins. The expanded flower measures from fourteen to seventeen inches across and between four and five feet in length, for the sepals are attenuated to a tail, which is forty-two inches in length. The plant was figured and described in Garden and Forest last year. (See vol. iii., pp. 597, 598, 599.) The inside of the flower after expansion is a jet velvety black, paling in the tube to a deep vinous purple, while the rest is a heavy net-work of purple on a greenish gray ground.

We are now in the height of the Lily season, and nowhere in England can all kinds of Lilies be seen to greater perfection than at Kew, where considerable attention is given to them, though a few years ago it was thought that they would never thrive at the Royal Gardens. Especially fine is your common Turk's-cap Lily (*L. superbum*). Here it is fully eight feet high, and with pyramidal racemes numbering from thirty to forty flowers on a stem. Being grown in large masses they make a splendid show, and last for weeks in perfection. It is far finer than *L. pardalinum*, better suited to our climate, and is hardy beyond

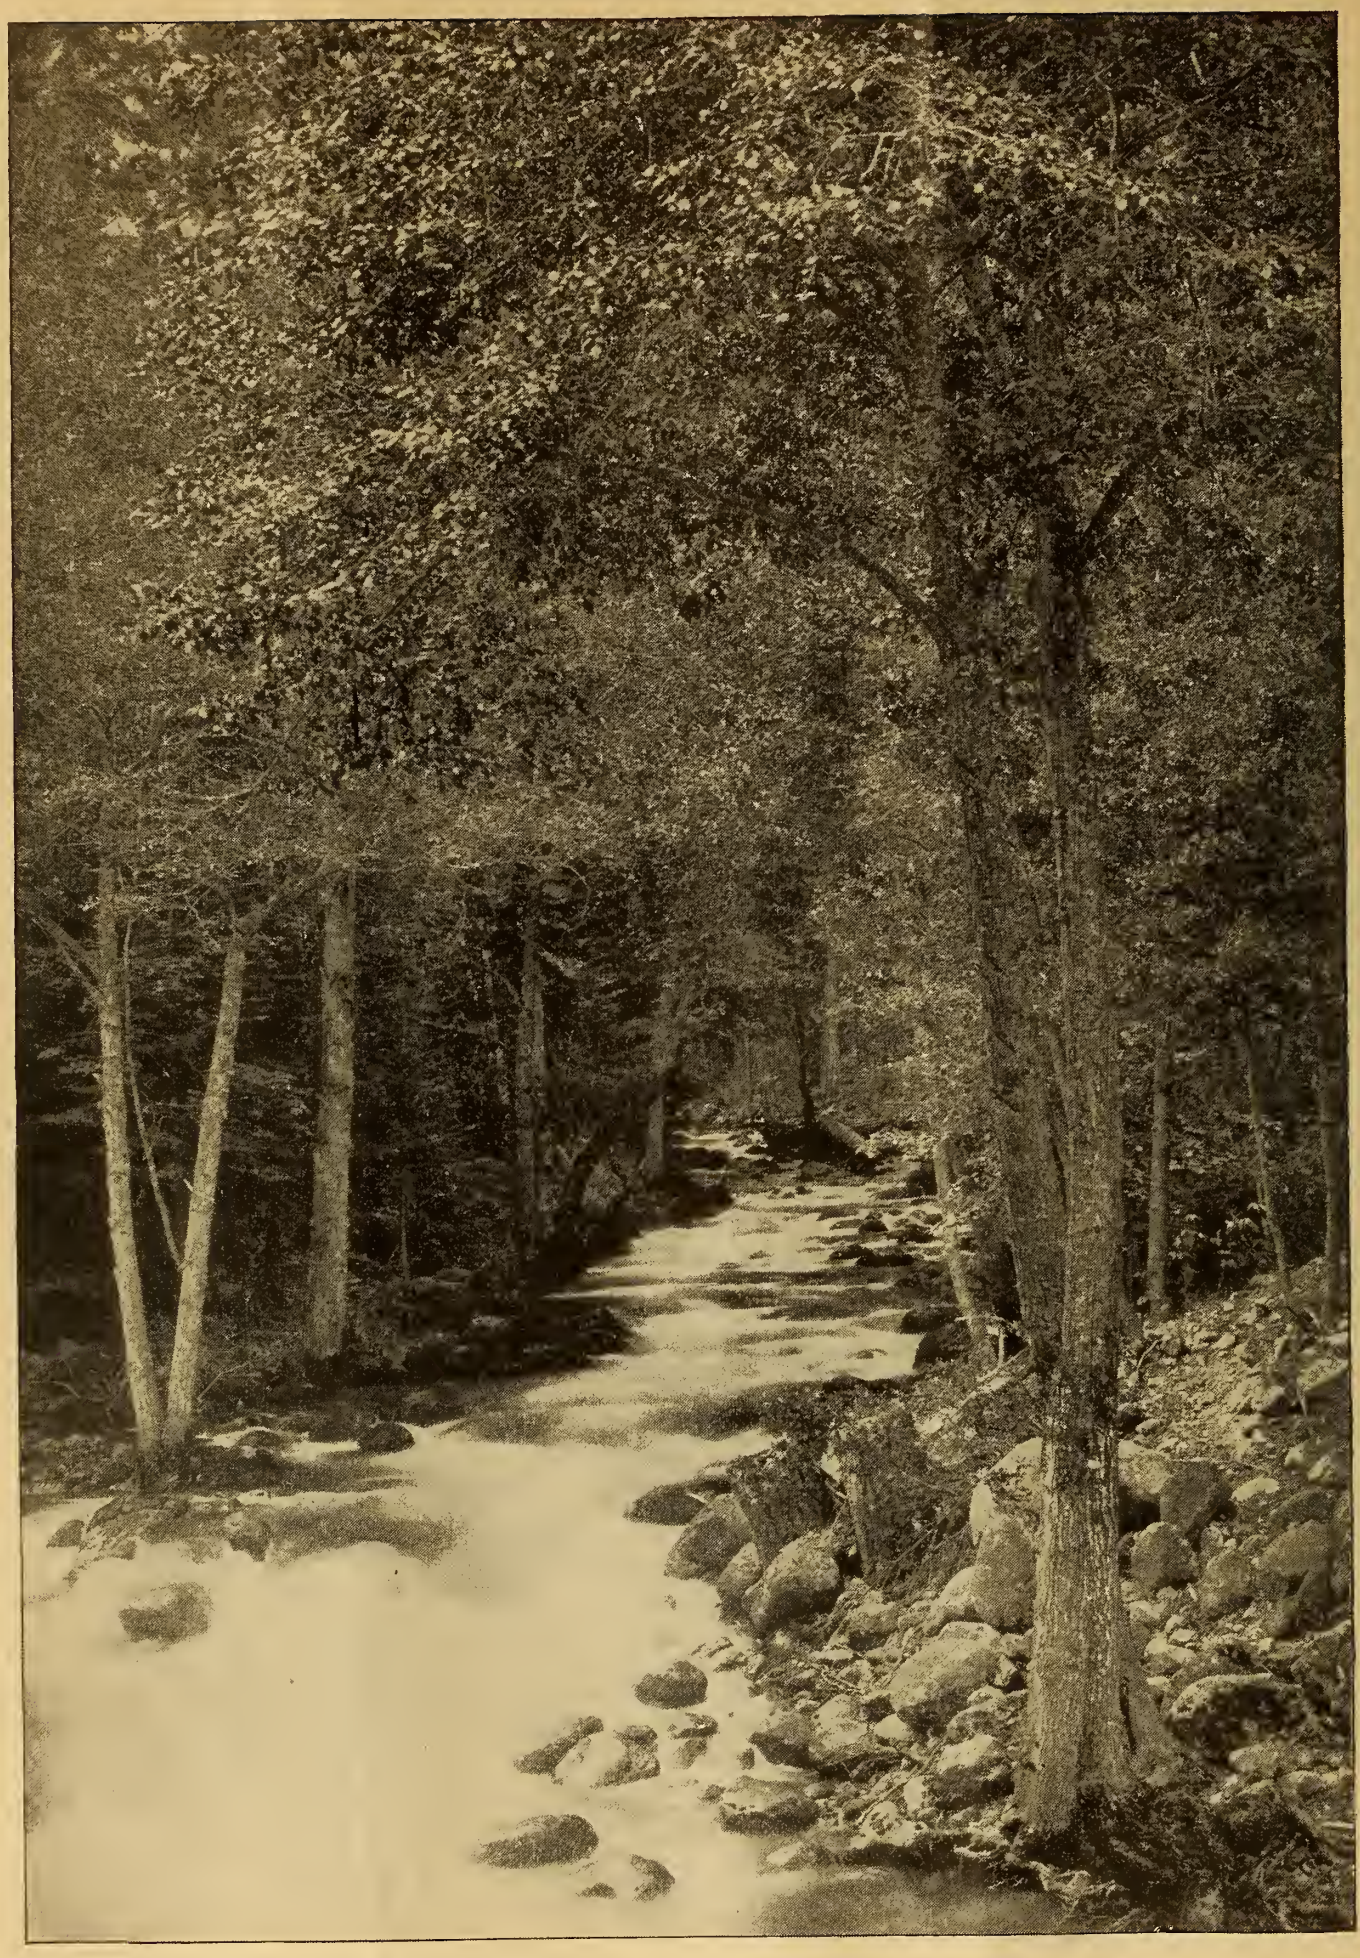

Fig. 68.—A Stream in the Yosemite Valley, bordered with Alders.—See page 422.

a doubt. Another grand Lily now in flower is *L. longiflorum Takesima*, the most dwarf of all the varieties, and better and more certain than the Bermuda Lily. It grows about eighteen inches high, and carries on the strongest stems as many as six flowers. It is also grown in peat in beds mixed with Kalmias and Heaths. It is one of the finest plants we have for the greenhouse as well as the open border. Rarer Lilies in flower are *L. Henryi*, a new species from west China, which has the habit of growth of *L. speciosum*, and with flowers of similar shape and size, but a pale orange-yellow like *L. Leichtlini*, a very choice Lily, also in bloom now. Probably *L. Henryi* will develop into a fine garden Lily, for one cannot judge of a new plant the first season. Another new Lily is *L. chloraster*, which Mr. W. Baker first regarded as a variety of *L. longiflorum*, but which he now considers as good a species as *L. Brownii*. It is not unlike this last, except that on the outside it lacks the claret-colored stainings. Inside it is a pale green; hence the name given to it. *L. Formosanum*, also a variety of *L. longiflorum*, has an interest for the Lily specialist, but in no way rivals the older and commoner varieties.

Among other bulbous plants in flower at Kew is a white variety of *Crinum Moorei*, itself one of the loveliest of greenhouse plants, but the white form of it is even more beautiful, the great open flowers being spotless white and delicately perfumed. *C. Moorei* flowers more or less continuously throughout the summer, and grows into a noble plant with massive foliage and with stems four or five feet high.

A beautiful species of Gladiolus in flower now is *G. decoratus*, as it was named a few years ago by Mr. Baker when received from south Africa. It is a slender plant with medium-sized flowers, forming a loose spike. The petals are a bright scarlet, the three lower ones being adorned with large blotches of clear chrome-yellow, making a striking contrast of color. It will, doubtless, be of value to the hybridist, who seizes upon everything to create new combinations of color.

London. *W. Goldring.*

Cultural Department.

Apples in Maine.

IT is stated that of the forty-seven varieties of apples starred by the American Pomological Society for Maine, only seventeen varieties are double-starred, "to indicate great superiority in that state.' But double-starring indicates only great commercial value; quality being indicated in the Society's lists by letters—g., v. g. and b., for "good," "very good" and "best." This does not seem to be so well understood as it should be. When we come to examine the lists of the Society, however, we at once see that comparatively few of the very good and best sorts are double-starred; while many sorts of inferor quality, such as Ben Davis and Oldenburgh, receive double stars on account of their commercial value only. As Maine is too far north to grow some varieties much valued in southern New England and the middle states, it is quite easy to see why her double-starred list is not so large as it otherwise might be.

In this connection it is important to understand that the rating of fruits on the American Society's lists is dependent wholly upon the opinions of those fruit-growers who are members of the Society, and attend and take part in its meetings. No one else has any authority to modify the starring or lettering, and it thus often happens that the larger portion of a state is quite unrepresented as to the relative values of its fruits. It is entirely safe to say that, as to the quality and commercial value of the fruits of Maine, their status represents the opinions of fruit-growers south of forty-five degrees, although quite three-fourths of the state is north of that parallel. The same fact also applies to New Hampshire and Vermont.

It is worth noting which are the double-starred Apples of Maine. They are: Early Harvest, Fameuse, Gravenstein, Hubbardston, Jewett's Red, Minister, Mother, Northern Spy, Oldenburgh, Porter, Red Astrachan, Red Canada, Rhode Island Greening, Sops of Wine, Tetofsky, Tompkins' King and Williams. Of these only five, namely, Fameuse, Oldenburgh, Red Astrachan, Sops of Wine and Tetofsky can be profitably grown north of the latitude of Bangor. The Baldwin is not on this list, although it is the most extensively grown and most profitable apple of south-eastern Maine. Its profitable area, however, is limited to parts of five or six counties only.

It is understood that the Maine Pomological Society will recommend, at the Washington meeting of the American Pomological Society, two stars for the Milding, Rolfe and Stark, and one star for Boardman, Dudley's Winter, Gloria Mundi, Golden Sweet and Munson Sweet. But, very singularly, the Wealthy, which is quite extensively planted in Maine, and is very successful over nearly the whole state, gets no mention, and the same has to be said of Yellow Transparent and Scott's Winter, which have proved successful over a large part of the state. Of Dudley's Winter (which has been lately renamed North Star) only the original seedling tree is yet in bearing; and although a promising sort (a seedling of Oldenburgh) it is hardly yet in a position to receive any rating by so conservative a society as the American Pomological.

It is quite evident that middle and northern Maine cannot have any very effective representation in the state society, and that this matter of rating is entirely in the hands of persons who, however well informed in the older pomology, are not so well instructed in the newer, albeit the latter is of very great importance to the larger part of that large and productive state. Northern Maine has nothing but its severe winter climate to prevent it from equaling western New York as an orchard region. Its deep and rich limestone soil, and its gently rolling surface, eminently fit it for orchard culture of a high type; and the recent introduction to our continent of the very distinct races of tree-fruits from eastern Europe, as well as the production at home of several of that class of apples known as the Iron-clads, opens up a great future for such localities.

It has been so often repeated, and is so widely believed, that these newer fruits are of very slight importance in American pomology, that a more than usual insistence upon, and repetition of, ascertained facts in regard to them is necessary. The efforts of Professor Budd, of the Iowa Agricultural College, in collecting and testing foreign tree-fruits of great hardiness in the extensive grounds of that institution, are, as yet, hardly estimated at their true value and importance. From my own careful observation and experience I am convinced that it is but a question of time, and not of very long time, when we shall have collected and selected from these fruits a full list of apples, pears, plums and cherries as well adapted to our colder states as the present standard varieties are to the middle states.

But we are not shut up to these. We are, by selection and the growth of seedlings, rapidly adding to the number of sufficiently hardy native varieties, at least of apples. Our wild native fruits, quite as promising as the originals of other continents, are being developed by selection and culture, so that it is fair to anticipate as successful a future for native apples, cherries and plums as we already see in our native grapes. I submit that it is a worthy and noble work, in which the workers are entitled to respect and encouragement from every well-wisher to his country.

Sweet Peas.

REV. W. T. HUTCHINS, who has made a specialty of these plants, has written an instructive essay about them for the *Tolland County* (Connecticut) *Leader*, from which we extract the following by permission:

"There is some uncertainty as to how many so-called varieties really deserve the name; but they may be divided into three classes: The first class includes those with the form of the old-fashioned Sweet Pea. There are about thirty named varieties of these, and cultivation is putting new blood into them, so that they are now conspicuous for beauty of color and size. These principally take their variety name from the color or markings of the standard, that is, the single erect petal which rises back of the wings. To this class belong the new Blanche Ferry, which is a great improvement on the old Painted Lady, and has a brilliant rose-pink standard and white wings; Scarlet Invincible, a dazzling scarlet, both in standard and wings; Invincible Carmine and Cardinal, both but slight variations from the Scarlet; Vesuvius, blue and violet, shading into white and dotted, with crimson spots; Duchess of Edinburgh, an orange-scarlet standard, margined with white; Primrose, with a suggestion of buff yellow; Orange Prince, the finest of

this class; the Black and the White, two familiar sorts, but now cultivated to a remarkable size; Salmon or Flesh color; Crown Princess of Prussia, a delicate blush; Captain Clarke, of which the newer strain deserves to be called Columbia, because it is red, white and blue; Scarlet Striped, now improved into Queen of the Isles, a magnificent flower; Adonis, a uniform pink; Boreatton, the finest of all the darker kinds, a deep velvety maroon, both standard and wings; Purple and Brown, and Blue and Purple, and both of these beautifully marked with stripes; Violet Queen and Princess Louise, shades of violet; the Queen, lighter shades of mauve and violet; Fairy Queen, white, delicately lined with crimson; Isa Eckford, a beautiful blush; Delight, suffused with crimson; Blushing Bride, an improvement on Blanche Ferry; Purple Prince and many more.

"The second class is distinguished by flowers of a newer form, and in some of the larger ones the fullness of size produces a wavy look. Among these are Apple-blossom, a beautiful rose and white; Splendor, a deep rose color, half of the stems bearing four blossoms each; Indigo King; Grand Blue; Imperial Blue or Mauve Queen; Butterfly, shaded blue and white, and sometimes blue-edged; Princess Beatrice, a fine rose-pink; Senator, chocolate and white stripes; Princess of Wales, blue and white stripes; Countess of Radnor, very choice, a soft lavender, shading into mauve; Monarch, Miss Hunt, Mrs. Gladstone, Mrs. Sankey, Princess Victoria, Queen of England and Empress of India.

"The third class includes the new hybrids, some of which are promising, and others simply show their shifting nature. By the way, there seems no reason why the production of new varieties by hybridizing cannot be accomplished as well in this country as in England. The odd little blue Pea, Lord Anson, deserves mention here. In a mixed row it has a decided value, though it is not properly a Sweet Pea, and has nothing but its bright azure color to commend it. The red and white perennial Peas, bearing their showy blossoms in clusters, are also well worth growing.

"For cultivating Sweet Peas there are six simple requisites, but they are inexorable. Of course, such general rules as rich ground, sunny exposure and thorough weeding are understood. The special requirements are: (1) early planting; (2) deep planting; (3) extra fertilizing; (4) strong bushing; (5) watering; (6) free picking, which means keeping the pods off. Planting early means as soon as the ground can be worked. Sweet Peas are very hardy, and, like the earliest garden Peas, need to make their root-growth in the cool, moist spring ground. Frosts need not be feared. Sometimes they are planted in the fall. Deep planting is very important to guard against the drought of midsummer. They should be planted five inches deep, but to cover them with five inches of cold, wet March soil almost insures failure. Hence they should be sown in a trench or furrow at the right depth, and covered but one inch at first. As they grow the earth is filled in, until when leveled they are at the right depth. They should be sown in a double row about ten inches apart, and the seeds dropped an inch and a half apart in the furrows.

"By extra fertilizing is meant the application of such stimulants as wood-ashes, bone-flour and nitrate of soda. The garden should be well manured in the fall to give the soil a good body of vegetable matter; but to get a quick growth of thrifty vines and early flowering the above-named plant-foods are excellent. Scatter the wood-ashes on in the winter; hoe in the bone-flour just before bushing; and, in May, scatter along, just outside the rows, a handful of nitrate of soda for every four feet, stirring it in, but not allowing it to come into immediate contact with the vines. They will then grow a foot a week in June, and one can look for blossoms a month ahead of the man who believes in the 'good old way.' This kind of cultivation necessitates strong and tall bushing. Get the best Birch tops, at least seven feet high, and, if two inches thick, all the better, and set them firmly in the ground with a crowbar. Bush between the double row, and train the vines to the bushes if they rebel. Where bushes cannot be obtained resort must be had to a trellis of poultry wire or a frame, with horizontal wires or strings, taking great care to secure strength and height. It is a calamity to have a thrifty row lop over or blow over in the height of the season.

"An ample supply of water is always needed, and in a dry season it must not be neglected. A rainy summer is friendly to Sweet Peas, and gives us about as good conditions as they have in the moist climate of England where they flourish. Pick the blossoms every day; sacrifice the pods if you want flowers from June till October. You cannot have blossoms and save your own seed; if you did save it from a mixed row it is very sure to be unsatisfactory."

Begonias.

Begonia metallica variegata.—*B. metallica* seems to have sported in several different places lately, as often happens with plants after being under cultivation. One of our prominent horticulturists has a theory that many plants resent high culture and artificial conditions of growth, seeking to escape them by either a disguise in the way of change of foliage, or by putting forth flowers of other colors. This, of course, credits the plant with the ability to reason in this way: "as my present dress is attractive, if it is changed perhaps my persecutor may neglect me." The theory is a pretty one, and, true or not, it is certainly of frequent occurrence, that after a plant has been cultivated for some time—it may be months or years—the whole stock, though in widely separated places, shows a tendency to sport. Roses are frequently observed to give a same or similar sport in a number of places during the same season. Chrysanthemums seldom give a noticeable sport, but as soon as one appears others of the same character are quickly reported in other places. Now, the plant of *B. metallica variegata*, which has been in my possession several months, originated near here, and the variegation seems constant. I observe that the same variety is being offered in England. The marking of my plant is white and pink, in blotches, the young foliage being mostly light. The plant seems a fair grower, though I cannot, without further experience, say that it is as vigorous as the thrifty type so well known as a fine foliage plant of rapid growth.

Cyprea and Velutina are two seedlings of *B. metallica* which do not seem to me an improvement on the type, they lacking the dark veinings which are so effective in the parent.

Souvenir de F. Gaulin is a new hybrid, said to be a cross between *B. olbia* and *B. rubra*. It has attractive, thin, satiny leaves of olive-green and large racemes of large coral flowers, and is a very fine plant and an acquisition.

Bertha McGregor is one of Mr. E. G. Hill's seedlings between the Rex and flowering sections, and is of the class of which Clementina is probably the best-known variety. The new plant has large-pointed, finely notched leaves, and is a good grower. The centre of the leaf is small, of a rich deep maroon, the body silver outlined with bronze. It is a beautiful variety in every respect. It is not surprising that so many new Begonias are offered, for they are a wonderfully sportive family, as is well known to every one who grows a number of them. Seedlings of new forms are continually springing up in the pots or on the benches of the greenhouse. Some kinds, like *B. Schmidtii* and *B. semperflorens*, may always be found in neglected corners, but usually these two come quite true.

Begonia Sunderbuchii is not a new species, but should be better known. It has smooth leaves, deeply cut in the way of *B. ricinifolia*, but smaller; these are green, with a brownish cast and with light veins, though this description gives an inadequate idea of the dainty coloring. It bears large panicles of light pink flowers in winter. It is not as massive or tropical as *B. ricinifolia*, but the effect, when in bloom, seems to me as satisfactory as that of any variety of the family. The charming flowers surmount foliage which is beautiful in coloring, but somewhat stiff and unbalanced, producing what may, for lack of a better name, be considered a Japanesque effect.

Begonia Semperflorens atropurpurea, or *B. Nelsoni*, is a French variety of the old Semperflorens, with purplish markings of the leaves. The markings have not proved constant with me, and I am inclined to doubt if they will prove so under our hot sun. A Begonia with colored foliage would be a gain for a bedding plant, and I am inclined, from indications, to think it may yet come in the tuberous section. For a good bedding Begonia it is doubtful if any surpasses old *B. Evansiana*, which is handsome in leaf and flower, and will survive the hottest sun. It needs little room or care in winter, and, in fact, the bulblets are hardy and will germinate in the spring in the borders where the old plants have grown.

Begonia Scharffiana.—The unsatisfactory opening of the petals of this variety, reported by Mr. Hatfield, is evidently owing to some fault of culture. One of my plants now in flower opens its blooms satisfactorily, though a very large plant in the winter could not be induced to spread its petals.

This Begonia is very distinct and very attractive, especially in a young stage, but it has a trick of partially dying off and resting, which vagaries will prevent its becoming a popular plant.

Elizabeth, N. J. *J. N. Gerard.*

Correspondence.

Nature's Nurseries.

To the Editor of Garden and Forest:

Sir,—In these days when, fortunately, the need for preserving our forests is proclaimed on every hand, and when even those who do not think of this need are pretty sure to find a wooded country beautiful and to rejoice in the presence of forests near their homes, it is interesting to hear the opinion of an occasional "survival" of a day when a very different state of mind was prevalent. It is interesting, because such an opinion strikes us as singular and reprehensible, and thus it is proved that "public sentiment" has changed, even if it has not yet conspicuously expressed itself in a practical way. The "survival" whom I have now in mind is a survival indeed—an old country-woman living near the shores of Buzzard's Bay who claims to have seen 107 years, and who is proved by the town records to have seen 103. To visit her one leaves the highway and follows a rough farm-track, first through a couple of fields, and then for more than half a mile through a dense wood composed in greater part of White Pines. Her cottage stands in what looks like a western "clearing," three or four acres in extent, and surrounded on all sides by the forest. One day when we were remarking on the quiet charm of the spot, she protested that it was much prettier years ago, when there were no trees in sight. "When was this?" I asked. "Well," said the ancient dame, "I took care of Johnny Stuart's mother when he was born, and he's about thirty years old. And I reck'lect that as I was coming home the last of the old woods had been cut down, and the timber lay there all nicely corded up. My! it looked lovely; no woods just as far as you could see!" And then, when we remarked that we admired the woods, she said: "Well, you haven't had too much of them. We had. We got tired of looking at them, and liked to see them go." And this, in truth, was a not unnatural state of mind in those who had to make their living out of the land, and had had small chance to cultivate feeling for beauty devoid of a utilitarian flavor.

If old Aunt Keziah's memory is not at fault, and Johnny Stuart is indeed about thirty years of age to-day, the tract to which she referred cannot have been long under cultivation. Indeed, it would seem, from the size of the trees, as though it must have been allowed at once to grow up in forest again, were it not for the character of the present wood. Neither here, nor in any of the adjacent parts of Plymouth County, so largely covered with forests of Pine, Oak, Swamp Maple and Birch, does one often see those ancient stumps from which tall, thin, sapling-like trees have sprung, which in other districts show that the land was never cleared for the plow. All our miles and miles of forest, so far as I have walked and driven through them, are devoid of stumps, and composed of trees that have evidently grown from seed. Some of them, notably those tracts exclusively covered with Pines, have evidently been planted; but in this immediate vicinity they have chiefly covered themselves, and have once been cultivated meadows and farms; and here and there, even at considerable distances from the highways, one comes in their densest shadow upon lines of ruined stone walls, upon ancient Apple-trees and the foundations of former homes. In one way the sight sometimes affects one sadly; but the forests themselves, though they contain few large trees, are extremely pretty—far more charming than those which have immediately sprung up again on land never thoroughly cleared. Lacking near standards of comparison, one soon forgets that trees grow larger than these, and notices only their varied spontaneous grouping, and, on the outskirts of the woods, their beautiful development. And those who like to study the methods of Nature may find ample and varied fields for observation. Here we can see, better than in any other district I know, how eager Nature is to grow trees whenever she gets a chance. For instance, next this cottage, which stands by the highway, is a wide meadow, where horses and cattle are pastured, covered with close grass, and quite unbroken by even the smallest sapling. The next field, divided off by merely a slender wire fence, was probably devoted to the same use, or perhaps to some crop, until ten or twelve years ago, but since then has been left untouched. And here is a mass of little trees growing as one might think trees never could grow, of many varieties, but all practically of a size, packed densely together, and pressing so closely to the slight fence that it seems as though it must soon give way, and then the pasture would be covered not by seedlings, but by regiments of young trees from this baby forest, eagerly rushing out for a little wider foothold and a little more air and sun. It is impossible, looking at the edge of such a young wood, not to fancy its trees are sentient beings, panting and stretching to relieve themselves from their crowding neighbors, and able to do so if the fence were gone.

A little further on we may come to an older piece of wood where the struggle for life has thinned the ranks of the trees, and where they have attained a considerable size, leaving space between them for an undergrowth of shrubs and vines. Again, if we follow some wood-path—the remains very likely of an old wagon-road—we shall come upon a plantation of White Pines, perhaps fifteen or twenty years old, where the lower branches are all dead but have not yet dropped off, where we see into, but cannot walk through, a ghostly-looking thick maze of brown twigs, and the shade is so dense that no undergrowth can live on the carpet of brown needles. A little further and the Pines are bigger, the lower branches have fallen, and the spot is a great solemn grove, its brown carpet sparsely dotted with a few straggling Brambles or Huckleberry-shoots. But I think the most charming places of all are those where a meadow is in process of capture by a surrounding forest, which is sending out colonies of seedlings from its borders. Here we shall have a central area of grass sometimes entirely free from trees, encircled by conical young White Pines from four to ten feet tall, and feathered to the very ground—masses of delicate light green needles, smooth and solid in outline but deliciously soft in texture. Back of these will be the taller masses of the forest growing on fields earlier abandoned, while in front of them, if we look closely, the ground will be found covered with baby trees, tiny Pines born last year or this year only. And if we come again in ten years the whole field will be covered with seedlings, and the conical soft green pyramids of to-day will be losing their lower limbs and assuming the habit of maturity. I remember one Pitch Pine, standing in the centre of a meadow surrounded with White Pines, beneath which three years ago nothing grew but grass. Now, as the encircling trees have sent out their flights of seeds, its branches shelter a thick expanse of tiny White Pines, from an inch to six inches in height. Those who try to grow Pines sometimes say it is not easy; but Nature seems to do the work without any trouble at all in this vicinity. Indeed, after living here half a dozen summers, one begins to feel that ere long we shall all be crowded into the bay by the trees; and so perhaps in time we too shall come to the state of mind expressed by old Aunt Keziah's words. Meanwhile, however, if any one wants to see how trees grow of themselves, and so to divine something of those processes which built up the "primeval forest," he can find no better place than this. Exhaustion of the soil is usually given as the reason why these districts have so largely been abandoned by the farmer, but Aunt Keziah lays all the blame on the eagerness of the young folks to journey cityward. And though we know at least the partial truth of the other explanation, we are tempted to believe her, for a soil does not seem exhausted which can produce woods so easily as this. A little further eastward, when one gets really on Cape Cod, one clearly reads poverty of soil in the disappearance of many of our most common trees and the almost universal sovereignty of the Pitch Pine. But along this eastern shore of the great bay there are more White Pines than Pitch Pines, and, in addition to the other trees I have named, shrubs and vines of many sorts grow by the way-side and along the woodland edges with marvelous luxuriance. For man's crops the soil may be as poor as you will; for Nature's most beautiful crops it seems, to the eye of the uninitiated at least, a very good soil indeed. It may be that wise men would say that, however long our woods remain undisturbed, there will never be arboreal giants in the land; but it grows very beautiful trees of a smaller size to-day.

Marion, Mass. *M. G. V. R.*

Periodical Literature.

A Ride Through the Caucasian Mountains.—II.

After leaving this forest the road descends to the river, which for want of a bridge must be forded, and then crosses a wide stretch of once cultivated country. Only a few years ago this region supported a large population, but, finding Russian rule insupportable, its inhabitants sought a new home in Turkey, too often finding instead only worse suffering and a speedy death. It will not be many decades, says Dr. Dieck, before all traces of former cultivation will be overgrown, and then there will be a fine chance for some exploring botanist to surprise the world with sensational accounts of plants which are indigenous to the region or have been introduced by natural means, for already garden-plants are beginning to dominate in the wild-growing vegetation. Hazel and fruit-trees,

various kinds of the Alutscha Plum, Walnuts, Medlars and Weeping Willows, and even such American trees as the Catalpa and the Locust (which a former apiarist brought from Suchum) occasionally appear. Wild Roses of many sorts grow rankly with *Crætegus heterophylla*, *C. melanocarpa* and *C. oxyacantha*, and a wilderness of Brambles, yielding their products only to the wild sows and bears which have marvelously multiplied in these depopulated valleys.

Soon after leaving this meadow-valley, the road, which becomes so bad that riders must dismount to advance with safety, reaches a forest of Beech-trees "whose beauty and majesty defy description." This Beech-forest has returned to the condition of a primeval wood. From time to time the path is barred by fallen trunks, so large that one can neither climb them nor see over them, and a long detour must be made to resume the journey, while other fallen giants form archways underneath which the traveler must creep. Only after the most trying efforts on the part of man and beast did Dr. Dieck's party eventually reach the top of a mountain range, and, at about 4,500 feet above the sea-level, the subalpine region characterized by *Gentiana auriculata*, *Swertia*, *Trifolium polyphyllum*, Mulgedium and *Campanula lactifolia*, but especially by the charming dark yellow *Crocus Scharojani* (*Suwaroffianus*), which was just beginning to bloom. In one place the beautiful *Rhamnus grandiflora* (*imeretina*), of European gardens, appeared in quantities, reaching a height of twelve feet—a plant which the author regards as distinct, although Herr Dippel now considers it merely a form of *R. alpina*. Lunch was eaten in a picturesque ravine (this was the second day of the journey) in the vicinity of Cherry Laurels and Rhododendrons, the wood of which was used to boil the travelers' tea. From the top of a rocky wall nodded the flowers of *Vaccinium Arctostaphylos*, which was seldom met with in this region, but was found later in Pontus in incredible quantities, bearing refreshing fruit.

After another difficult hour in the Beech-forest the wood gradually gave place to an alpine undergrowth. Instead of *Rhododendron Ponticum* appeared *R. Caucasicum*, and, instead of the Beeches, scattered specimens of *Pyrus Aucuparia* in a gray-green form, *Pyrus Aria* and *Acer Trautvetteri*, which resembles *A. Pseudo-Platanus* so closely that the two might easily be confused. In thickets of *Rhododendron flavum* (*Azalea Pontica*) there grows a form of *Salix caprea* which, in the color of its branchlets and the shape of its leaves, is so much like the Rhododendron that one must look carefully to distinguish the two, especially as here they grow to the same height. "I believe," says Dr. Dieck, "that this is a very interesting case of 'mimicry,' which I explain by the fact that animals avoid the leaves of the Azalea, while they relish those of the Willow. A natural effect of this fact is that the large Willows which most nearly resemble the Azalea more easily arrive at the production of flowers and fruit, and thus the Azalea-like form becomes more and more widespread. Between the stones of the mountain-comb and on the shady side of the occasional elevations and rock-points grow *Salix arbuscula* and *S. Silesiaca*, *Daphne glomerata* and a beautiful dwarf Rose which was still in bloom."

Almost exhausted, the travelers found rest the second night of their journey on the shore of a miserable little pond of snow-water called by the high-sounding name of Lake Lachda. The view from this plateau, at an elevation of 7,000 feet, is majestic, showing in front, over a deep valley, the snow-mountains of the main Caucasian range, on the slopes of which were seen, for the first time, dark masses of coniferous trees. But both Dr. Dieck and his guide felt unequal to the further effort required to reach this range, and, after a cold night passed on the bare ground, returned to Amtkjel by another path still more difficult than the one they had traversed—so difficult that they were in constant fear of accident and actually lost one of their beasts of burden by a misstep. They were glad, too, of the protection against thieves insured by their meeting with a former acquaintance, a chief of police. But, says Dr. Dieck, in conclusion, "the wonderfully luxuriant vegetation, and the grandiose panorama of the primeval forest which again offered themselves to our astonished eyes, helped us through the pains and troubles of this return journey."

The August issue of the Bulletin of Miscellaneous Information from the Royal Gardens at Kew contains a statement of the position of Kew with regard to the naming of Orchids. During the middle of the present century Dr. Lindley was recognized everywhere as the authority upon these plants, and all questions relating to their determination were entrusted to him. On his death the Orchid mantle fell on the shoulders of the late Dr. H. G. Reichenbach, who was more familiar with the family than any of his contemporaries, and to whom all scientific questions relating to it were referred. The defect of his method was that he did not bring the scattered work of his life into anything like one comprehensive study. He had the clue to it himself, but when failing health came in the latter years of his life he was overwhelmed with the enormous amount of material which he had accumulated, and now it is found that he often described the same species more than once under independent names. The difficulty which this state of things would have produced would, in any case, have been considerable. It has been enormously increased by the fact that after his death in 1889 he left his collections to the Imperial Hof Museum at Vienna on the condition that they should be sealed up for twenty-five years. Reichenbach was no longer available to furnish names to the cultivators of Orchids, and his herbarium was not accessible to ascertain what he had done in the past. Something had to be done, and the amateurs of Orchids naturally turned to Kew for help. Kew was not badly equipped for the task. It possessed Lindley's collections, the classical starting-point of systematic orchidology. Mr. Bentham had devoted two years at Kew to the elaboration of the family for the *Genera Plantarum*, and in doing this had sorted the material at Kew into genera, which he clearly defined. Reichenbach, too, had for years passed several weeks of every summer at Kew working on the collections there, which he enriched with valuable notes; and Hooker had worked up in the same herbarium the Indian Orchids, amounting to nearly thirteen hundred species, for the "Flora of British India." Kew, too, possesses a collection of fourteen hundred species of living Orchids out of a total of about five thousand existing species.

Our correspondent, Mr. Rolfe, has been placed in charge of the Orchid department of the herbarium, and will now publish in the Bulletin descriptions of new garden species, ten of these appearing in this issue. Kew is in a better position to serve as the last resort in Orchid nomenclature than any other botanical establishment. Certainly there is none in this country properly equipped to deal with such subjects, and American cultivators of Orchids in doubt about the names of their plants will be forced to communicate with Mr. Rolfe if they desire the most authoritative determinations. There is, however, always the risk that when an unnamed Orchid cannot be determined in the Kew herbarium that it may not really be undescribed, but may be in Reichenbach's collections and already furnished with a name. These are questions which cannot be settled for another quarter of a century. For practical purposes it has therefore been decided at Kew to assume that any such Orchid is new, and to describe it with an appropriate name. "It must be the aim of every botanist to avoid the multiplication of names and the piling up of synonyms. But the world cannot wait on posterity, and some one, a quarter of a century hence, may have the patience to disinter from Reichenbach's herbarium, if it is thought worth while, any names which have the prescription of priority."

The subject of "Country Roads and Highways" is taken up in *Lippincott's Magazine* for September by Mr. John Gilmer Speed. He well says, "It would be a waste of space to attempt to prove that our common country roads are, as a very general thing, as bad as they can be; they are so generally bad, indeed, that I have met native-born Americans, who had never traveled abroad, who could not be brought to believe that good roads were possible." And his words are equally true when he adds that common roads are "at once the means and the measure of civilization," that we have for long been paying a very heavy penalty for the neglect of our highways in a tax upon agriculture, so great that "the farmers are getting behind more and more every year, and are generally dissatisfied," and that "very few of them know what is the chief cause of their lack of prosperity, for they have never had good roads, nor did their fathers and grandfathers." Mr. Speed then recounts the measures which have been taken or proposed in various states for the amelioration of the roads, and then, to show the extreme need of legislation, describes the roads in the New Jersey township in which he has his own country home, and which is one of the very few in that state untraversed by any railroad. The roads were laid out about a hundred and fifty years ago, probably following the "hap-hazard paths and trails which ran through the woods before any clearings were made. From the township village to the county town the distance is about seven miles, and the difference in elevation about two hundred and fifty feet. There is a valley running all the way between the two places. Had the highway been located in this valley the distance between the points would have been less than it is, and there

would not have been a heavy grade on the whole route. Instead of this the highway has been placed variously over the hills, on the hill-sides and in the valley, so that whichever way one goes it is always up or down hill. All the produce not consumed in the township has, during a century and a half, been hauled over this dreadful road. The tax that this unskillfully constructed road has entailed upon the several generations that have lived in the township has, of course, been enormous. And the roads are not merely badly laid out; they are wretchedly built and maintained. Yet the people have always had at hand the best kind of material to make good roads, for the surface of the fields is covered with stones which need only a little breaking up to be just what is needed. And then there is limestone in abundance all about, and gravel too. For many years past the township has levied a tax of $1,600 each year for repair of the roads. Only about one-third of this amount is paid in money. The rest is paid in labor, and that, too, at the rate of one dollar and a half per day, when the prevailing rate of pay for much harder work is only one dollar and a quarter per day. When the farmers have finished their spring plowing and planting they go out on a kind of picnic frolic on the road. They plow up all the grass along the sides of the road and put the sods and muck from the ditches into the centre of the road, and very carefully throw all the small stones up against the fences on either side. I need not tell what the consequence of this is. When the weather is wet the roads are six inches deep with a heavy and adhesive mud; when the weather is dry, as it is apt to be in summer, the roads are fetlock deep in dust. What should go on the roads, so as to make them hard, is left lying loosely in the fields; and what, if put upon the fields, would make them rich and fruitful is put in the roads to hinder traffic." This last epigrammatic, but most veracious, sentence might well be printed as a warning and posted up in most of our village neighborhoods, for, as Mr. Speed explains, "I have described the system of my own township, because I am sure the same system prevails in many other localities." Then he adds: "In the whole township there is not a rich man, and there are not more than two or three who are moderately prosperous. Nearly every farm is mortgaged, very many up to their full value, while each recurring census shows that the population is getting smaller. And this is only thirty miles from New York, and in a section for which Nature has done the most liberal things. . . . The farmers say that their lack of prosperity is due to an absence of railroad facilities. I am sure that if they had ever had good highways, or had even spent with any kind of wisdom and judgment the money each year levied for roads on the highways as they exist, they would not have felt the want of railways as they do." Truly, in the words which Mr. Speed quotes from Professor Shaler, "if we take the misapplied expenses of our country ways, and if we count at the same time the mere social disadvantages which they bring to the people, it is probable that the sum of the road-tax is greater than that of our ordinary taxation."

Exhibitions.

The Massachusetts Horticultural Society.

COPIOUS rains and abundant heat have made the gardens of Massachusetts flourish this year, and perhaps a better show of their floral products was never made than that which filled the two halls of the Massachusetts Horticultural Society last week in Boston. The fact that only space for plants and flowers could be found, the annual exhibition of fruits and vegetables being postponed until a fortnight later for want of room, shows that the season has been a good one, and that the taste for gardening is increasing in the Bay State. There have been better rich men's flower-shows in Boston, perhaps, with more large specimens of tropical stove-plants and Orchids, but there has never been a better all-round exhibition of flowers, or one in which collections of the popular flowers of the masses have been seen in such profusion and of such high quality—a fact which may be taken, perhaps, as a hopeful sign of the broadening tendency of our horticulture.

A number of excellent collections of greenhouse plants were shown, it is true, and each contained a large number of well-selected and well-grown clean and healthy young plants, much better adapted to the purposes of decoration, for which these plants are often so well suited, than the enormous specimens often found in prize groups in American and European flower-shows. Orchids, it is true, did not appear in great profusion or in great variety, and none of the famous collections were represented; but even Orchids are not missed from such an exhibition as the people of Boston had the opportunity of witnessing last week.

Special features were large, well-selected and well-arranged collections of the flowers of hardy herbaceous plants from J. W. Manning and Temple & Beard, who now pay much attention to the cultivation of plants of this class, which are every year increasing in popularity. The same firms, and W. C. Strong, staged large collections of coniferous plants in pots in competition for the Hunnewell prizes, the first prize being awarded to Temple & Beard.

China Asters appeared in force in competition for the special prizes offered by Parker, Wood & Co. Joseph H. White took the first of these prizes, and R. T. Lombard the second, for the best collections of large flowering Asters, one hundred vases, with three flowers in each vase. Japanese Lilies were shown in profusion and of remarkable quality and in great varieties of color. The first prize for these flowers was given to T. C. Thurlow, and the second to William K. Vanderbilt, of Newport, who also received the society's prize for fifty vases of large-flowered China Asters. Prizes offered for Dahlias by J. C. Vaughan, of Chicago, brought out several good collections of fifty vases with not less than twenty varieties, the first prize being secured by W. C. Winter, who also obtained the prize for Lilliputian Dahlias. There was a good show of the new French flowering Cannas, of Nasturtiums, and of the other leading garden-flowers of the early autumn.

The collections of wild flowers of eastern Massachusetts, which are almost always an important feature of the Boston shows, were not wanting, and delighted the lovers of nature as much as the showier inhabitants of gardens.

The feature, however, which most took the popular fancy was the exhibition of aquatic plants and flowers which filled two large tanks in the upper hall, and which had been sent up from Mr. Simpkins' garden at Yarmouth, where the cultivation of these plants is a specialty and where they are more successfully grown than anywhere else in the United States. Crowds of people, filled with admiration for the strange and beautiful flowers, surrounded the tanks from morning until night, and it is doubtful if a more successful or more attractive exhibit was ever made at any flower-show. One tank contained a leaf of the *Victoria Regia* about six feet across and bearing a vase containing one of its great flowers, and the other a collection of the following Nymphæas arranged with their leaves: *N. Marliacea chromatella*, an interesting hybrid with delicate lemon-colored flowers; *N. rubra*, *N. gigantea*, *N. dentata*, *N. odorata rosea*, and the Japanese Nelumbium, with a few smaller aquatic plants.

A number of mantel-piece decorations were set up in competition for the prizes offered by the Gardeners' and Florists' Club of Boston. The first prize was awarded to Bowditch & Long, florists, and the second to Mrs. E. M. Gild, of Medford. The arrangement which was considered the best was composed of a great mass of Orchids, Ferns, Lilies, Lapagerias and Palms, which entirely covered not only the shelf above the fire-opening, but the fire-opening itself and the whole wall-area about the shelf. It appeared to us that this arrangement, as well as those of the other competitors, lacked simplicity, and showed a too evident desire to use as much material as possible, without regard to harmony either of color or form. The flowers used in the first-prize decoration represented, no doubt, a larger money-value than those employed by any of the other competitors, but it is doubtful if it could be considered to have represented as much taste in arrangement as one or two of the others. They were all, however, overdone. A fire-place is made to build a fire in; if it is not to be used for that purpose, it has no reason for existing. A vase of flowers is an appropriate decoration for a mantel-shelf, or a single spray of some graceful vine may be allowed to break its formal lines; but any decoration which covers up the entire side of a room at the spot where it is intended to build a fire appears to be excessive, and therefore to be bad art, just as the decoration which loads a dinner-table with masses of heterogeneous flowers, or which finds its expression in the grouping together of innumerable varieties of plants in gardens without reference to their fitness for association or without regard to their surroundings, is bad art.

Mr. George A. Nickerson, of Dedham, took the first prize for six greenhouse and stove plants, his collection containing some remarkably well-grown and well-colored Crotons. The second prize went to Nathaniel T. Kidder, and the third to Dr. C. G. Weld; Mr. Kidder taking the first prize for ornamental leaved plants, and for the specimen flowering plant with a well-grown and well-flowered *Ixora Dixiana*. E. W. Gilmore took the prize for six Orchids, and a silver medal was awarded to Mr. George McWilliam for a superb plant of *Alocasia San-*

deriana. Pitcher & Manda, of Short Hills, New Jersey, received the Society's silver medal for a plant of *Pteris Victoria*, and first-class certificates of merit for *Alocasia Chambieri* and *Dracæna argentea*. The same firm received a gratuity for a small collection of new and rare plants.

Notes.

The portrait published as a frontispiece to the *Popular Science Monthly* for September shows the face of Professor George Lincoln Goodale, of Harvard University, and is accompanied by a sympathetic sketch of his life and his labors in the interests of physiological botany.

In an article recently published in *Harper's Magazine*, it is stated that the New York Chamber of Commerce, one of the most intelligent and conservative bodies of practical business men in the world, regards the preservation of the Adirondack forests as "of vital commercial importance."

The memory of Dr. Joseph Priestley, the famous chemist and discoverer of oxygen, and a great-grandfather of our distinguished architect, H. H. Richardson, is perpetuated in botany by the name Priestleya, denoting a genus of some fifteen species of shrubs, natives of South Africa, and sometimes cultivated in northern greenhouses.

Other societies besides the well-known New York Flower Mission aid in the work of brightening the lives of the poor of New York during the summer. One of them is the New York Moderation Society, which distributes flowers, contributed by florists, in the most destitute and grimy regions of the Five Points and "Mulberry Bend." It is said that on the appointed days crowds of expectant children fill the sidewalks long before the welcome wagon appears. Both cut flowers and plants in pots are given away.

Spinach should be sown, according to *Meehan's Monthly*, a trifle before the forest-leaves color in autumn. It will then grow very rapidly in the temperate weather. No frost will injure the plant, but it should have a covering of straw so light that the green leaves can be seen through it. The use of this mulch is chiefly to keep the frost from lifting the plants out of the ground and to prevent the leaves from discoloring. The soil should be very strongly fertilized, for the richer it is the larger and more tender will be the leaves.

Modern botanical explorers may well envy the triumphant pleasures of those who, in early days, explored new regions, for now hardly any remain in the world which can offer anything approaching the same wealth of "novelties." How, today, can any one hope, even remotely, to compare his results with those, for instance, of Tournefort, who, after spending two years at the beginning of the last century in lands no further afield than Greece and Asia Minor, brought back representatives of 1,300 hitherto unknown species of plants?

Plants of *Hydrangea hortensis* will live out-of-doors in the vicinity of Philadelphia without any protection in the winter, and Mr. Joseph Meehan writes of a specimen in Laurel Hill Cemetery, which is one of the largest near that city. This plant is eight feet in diameter and four feet high, and recently held more than eight hundred, and probably a thousand, flower-heads fully expanded at once. The flowers on this Hydrangea, as well as on the many others in that cemetery, are of the deepest blue color, not one of them being pink or rose-color.

The Delaware peach crop has this year been unprecedentedly heavy, but it seems that growers have, nevertheless, something to complain of. It is estimated that two million baskets are needed for the crop; but as a great many basket-makers went out of the business in consequence of the disasters of the years 1889 and 1890, baskets are difficult to get, and their price has risen from three to five cents each. Factories are running at full speed with increased facilities, and growers are importing baskets from regions as distant as Michigan, yet the demand is not properly supplied.

According to a recent dispatch to the *Evening Post*, Professor J. C. Arthur has been examining the street trees in Cleveland, at the request of Mayor Ross, of that city, in order to discover, if possible, why so many of them are dying. Professor Arthur reports that the soot of coal, which closes the pores of the leaves, is one cause, and that water-tight pavements and deep sewers, which dry out the ground, is another cause. He recommends that smooth-leaved trees, like the Oaks, should be used instead of Maples and Elms. The street trees of Buffalo have also been reported in an unhealthy condition, and, for this state of things, Superintendent McMillan ascribes a similar cause, or, in his own terse language, "too much dust in the air and too little water in the soil."

In the report of the committee on nomenclature, made at the recent annual meeting of the Society of American Florists, it is stated that the existence and recognized activity of this committee has had a salutary effect upon the business of American Florists, and especially upon the catalogue trade. It is said that the catalogues of the present time are much more carefully prepared, so far as the naming of plants is concerned, than they were five years ago, and that the general tendency in them is toward plain facts, and away from sensational statements and sensational illustrations, notwithstanding a few aggravated instances to the contrary.

Among the superstitious precepts quoted by a recent writer in the *Journal of American Folk-lore* as current among the so-called "Dutch" of the Buffalo Valley in central Pennsylvania, we read: "All cereals, when planted in the waxing of the moon, will germinate more rapidly than if planted in the waning of the moon. Beans planted when the horns of the moon are up will readily pole, but if planted when the horns are down will not. Plant early potatoes when the horns of the moon are up, else they will go too deep into the ground. Plant late potatoes in the dark of the moon.. Plant onions when the horns of the moon are down. Pick apples in the dark of the moon to keep them from rotting. For abundance in anything you must plant it when the moon is in the sign of the Twins."

"Within a generation," says the *American Architect and Building News*, "the United States, from one of the most richly wooded countries in the world, has become comparatively sparsely provided with timber; yet such is the force of the habits handed down from our grandfathers, who supposed that the forests among which they dwelt were inexhaustible, that we still see our small remaining area of timberland diminishing day by day, partly under the axes of reckless lumbermen, and partly through the gigantic forest-fires, whose smoke obscures the sun over half the continent for weeks in every year; while in Germany, which at this moment pos sesses a forest-area much larger, in proportion to its population, than the United States, fire-wood is sold, in the cities, b the pound, all the forests are guarded by state officers, thory oughly educated for the purpose, the underbrush is kept cleared away, to prevent fires, the cutting of timber is restricted to a limited number of mature trees to the acre, so that the supply shall be kept constant, and no timber, except a little oak of specially beautiful grain, is sent out of the country; while the United States, out of a smaller reserve, exports timber to the value of more than five hundred thousand dollars a week."

A correspondent of the Philadelphia *Ledger*, writing recently of Alaska, says that one can scarcely imagine, from the usual forest-experience how closely the trees in the forests of that country are packed together. "I and my wife," he says, "undertook to walk four miles by an Indian trail through one of these woods to a point where we might head off our vessel. So thick was the mass of vegetation on each side of us, the path being wide enough for us to travel single file only, that we could not have seen a bear ten feet off. . . . One reason for the dense covering of the land with trees is the favorable conditions for seed-germination and the apparent scarcity of seed-eating creatures. The warm temperature given off by the Sea of Japan, which comes up south-westerly to break against Alaska shores, meets the snowy cold of the mountain-peaks, condensing the moisture so that the surface of the ground, or indeed anything else, is never absolutely dry, and every seed that falls to the earth has a chance to sprout and grow. In the old Indian village were White Spruces twenty feet high growing out of the top of totem-poles. These poles are themselves thirty or forty feet high, and seem to have been selected from the largest trees. They are stripped of their bark, and have carved on them series of likenesses of creatures, real and imaginary, representing the genealogical descent of members of the tribe. It was a curious sight to see the White Spruces, like huge Christmas-trees, growing from the flat tops of these poles. In some cases the roots of these living trees had split the poles in their descent downward to the earth, into which the roots had in some cases so thoroughly penetrated that should the poles finally rot away the trees would probably on these stilts of roots continue to grow on as trees high up in the atmosphere. Nothing but a climate continually saturated with moisture would permit of seed-sprouting and the tree continuing to grow out of the top of a pole in this manner."

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by . . . . . Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, SEPTEMBER 16, 1891.

TABLE OF CONTENTS.

Artist and Client.

"IN the magnificent city of Ephesus," wrote Vitruvius nearly nineteen centuries ago, "there was an ancient law, hard indeed, but equitable, to the effect that when an architect was entrusted with the execution of a public work, an estimate thereof being lodged in the hands of the magistrate, his property was held as security until the work was finished. If, when finished, the expense did not exceed the estimate, he was complimented with degrees and honors. So when the excess did not amount to more than one-fourth of the estimate, no punishment was inflicted. But when the excess was greater than this amount the architect was required to pay it out of his own pocket. Would that such a law existed among the Roman people, not only in respect of their public, but also of their private, buildings, for then unskillful architects would not commit their depredations with impunity, and only those who were the most skillful in the intricacies of the art would practice it. Proprietors would not be led into ruin through extravagant expenditure. Architects themselves would be constrained to closer accuracy in their calculations, and the proprietor would complete his building for the amount, or a little more than the amount, which he expected to expend. Those who can afford a given sum for any work would cheerfully add one-fourth more in the pleasing expectation of seeing it completed; but when they find themselves burdened with the addition of half, or even more than half, the expense originally contemplated, they lose heart, and are willing to sacrifice what has been already laid out."

This passage is an interesting proof that human nature has not greatly changed in nineteen centuries, and that even the wonderful legal system of Rome, like the modern American system, did not cover all possible contingencies of dispute. How far an artist is justified in "exceeding the estimates" agreed upon at the outset of his labors, is a question still as frequently discussed as it was in the time of Augustus. Clients still protest that they are robbed when made to expend more than they anticipated, and doubtless artists then claimed, as they do to-day, that they may be so hampered as to destroy the artistic value of their work if a rigorous adherence to the bargain is insisted on.

It is, of course, difficult to say upon which side the blame most often rests. There are certainly artists in this time and land who are unskillful and who "commit depredations" upon the pockets of their clients without the excuse of giving him a superior piece of work in return for its extra cost. There are others who, while their artistic conscience is highly developed, have little pecuniary conscience; they honestly desire to give their client work of the highest quality, but they fail to remember that they are likewise bound to respect his pocket, and, if needful, to show him that he cannot have the best for the price he is willing to pay. On the other hand, clients too often insist on having the best, "regardless of cost," and afterward grumble about expense; or, a price once settled upon, they alter their demands without sufficiently considering that this may mean unavoidable increase in price. The task of a designer, whether his problem be to build a house or to lay out a park or garden, is a complicated one, involving outlays not only in final construction but in preparatory study, superintendence, and the office work of subordinates, which are rarely taken into account by the client, who thinks he has only to pay for stone and brick, soil and trees, and their actual manipulation. Every change from the plan first settled upon brings a new necessity for such outlays, even if it does not make needful the undoing of work already accomplished or the adoption of a scheme intrinsically more costly. "He keeps absolutely within his estimates if you do not change your mind," we heard a client say of a well-known architect not long ago, "but he is very extravagant if you change it." The truth is, that her change of mind had meant the need for renewed study on the architect's part, as well as more expensive features in the house. "The only way to get a house for the sum you have named," replied one of her hearers, "is to go abroad as soon as the contract is signed and not come back until the house is finished." The cause of many unfortunate disputes was certainly implied in this wise advice.

While there is reason, then, for insisting that some of our artists should be more conscientious as to expenditures, many clients also ought to reform their habits. There are a few rules which should be heeded by every person about to build or about to lay out a country place, and among them are these: Take plenty of time to decide, in consultation with the artist, just what it is you want. See that he understands you clearly, leaving no question of importance open for casual deciding as the work progresses. Then think no more about it, except to watch, if you will, lest, through misunderstanding or carelessness, something not in the bond is being done. Or, if you must change your mind, ascertain what the act will cost you and decide, before it is too late, whether you will assume the additional expense or not. Do not think that "a few little alterations" will be of no consequence. Probably those which seem little to you will not be little from the artist's point of view or in a pecuniary sense. If, however, you cannot decide upon what you want, hand over your house or your grounds to a reputable artist, name the sum you are willing to spend, and let him manage as he sees best—in which case you must not interfere at a later stage. And, finally, if you refuse to follow either of these modes of procedure, but give vague directions in the beginning, or recklessly change your mind from time to time, or else interfere when you have granted the artist a free hand to do as he likes, do not grumble at the sum you may eventually have to pay.

Indeterminate orders and loose bargains never result satisfactorily as regards either product or price, and it is the client's own fault if they are made. If the orders are clear, and the bargain hard and fast, and if then you are

asked for any important increase in price, the law will surely protect you as it would in a bargain of any other sort. But it is instructive to remember that in almost every case where client and artist have recently come into our courts, it is the artist whose claims have been sustained. When dealing with an artist many men, who are honorable and fair in other business matters, seem to think they have a right to get something for nothing, or to get more for a given price than was promised them. This proves that, as yet, we do not value art as we do other commodities, nor do we realize that the work of a man's brain has a marketable worth as fully entitled to respect as that of the work of his hands. If, indeed, we estimated art as it deserves—high above any commercial product—we should even feel willing to pay more for what we get than was at first decided. No artist, be he ever so conscientious, can, at the outset, tell to a dollar what a large and complicated piece of work will cost; and if we deprive him of the right to a reasonable margin of excess, we may fatally injure his work, and so commit a crime against him and against the art he practices. Vitruvius recognized this fact; although few clients to-day would be ready for a law which bade them stand ready to "add one-fourth more" to the contract price of a piece of architectural or landscape-gardening work if the artist demanded it; in fact, a much smaller increase often discourages them.

This may prove that modern men do not estimate art as highly as the ancients did; but, although human nature has not radically changed since the days of Augustus, the pecuniary conscience of artists has at least developed somewhat. It is still a common enough occurrence to find estimates exceeded, but seldom, we apprehend, to such an extent as fifty per cent., unless the client is wholly or partially at fault. If landscape-gardeners or architects or other artists were asked to fix a legal margin for such excess, they would probably be content with a smaller amount than the twenty-five per cent. of the contract sum. Vitruvius regarded this alleged Ephesian law as hard from the architect's point of view. Modern communities would regard it as very hard from the client's standpoint. We may conclude, then, that nineteen centuries have improved the architect more than the client, and that it is especially needful now for the client to look to his own development.

Nearly two years ago Professor W. W. Bailey complained in the columns of this paper (vol. ii., p. 610) that the linemen of some telegraph companies in Providence had been climbing the street-trees, and had mutilated them with the spikes on their feet, so as to invite attack from rot-fungus. Nobody seemed to have any authority to stop outrages of this sort, although Professor Bailey was informed in a later issue (vol. iii., p. 46) that the incident which aroused his feeling offered an admirable opportunity for testing the power of the citizen against the invasion of his rights. We allude to this matter again simply to introduce the statement that the last Legislature of Pennsylvania took pains to pass a law which provides directly for the recovery of damages to trees along the public highways by telegraph, telephone or electric-light companies. In the first section of this law it is enacted that when any company shall have erected poles and lines along any highway in the state it is lawful for the owner of the land adjoining, who may claim to be damaged by the maintenance of such lines by reason of the cutting of trees, whether in the highway or in the land adjoining, to petition the court of the county in which the damage has been committed; upon which petition the court shall appoint three citizens as viewers, who, being duly sworn to the faithful performance of their duty, shall assess the damage done to the petitioner and report the same to the court, which report shall, upon its presentation, be confirmed *nisi;* and if no appeal be entered to the same within ten days it shall be confirmed absolutely and judgment entered against the company. Lovers of trees in other states, who are contemplating additional legislation for their protection, would do well to study the text of this law, which was enacted on the 2d of June, 1891.

A Garden Pool.

One of the most important points to be considered in landscape-gardening is the relation of parts to the whole. A thing beautiful in itself may be so out of proportion to its surroundings that it fails in effect, either from being so large that it overpowers its neighborhood, or so small that it is insignificant. Constructed detail is particularly difficult to manage, so that its artificiality is not apparent enough to strike a false note in the general harmony. Rocks in composition are unruly, as too many unfortunate struggles to introduce them into parks and gardens bear witness. If isolated they are apt to be discordant, if grouped they are inclined to be cluttered; witness the rockeries in which so many country dwellers take pride. A cairn of stones interspersed with pockets of loam is a melancholy sight in winter, and in summer is too apt to be meaningless and intrusive, even when imperfectly concealed by masses of incongruous plants, sprinkled by a palpably unnatural fountain, and severely exiled, by trim cutting, from the lawn, of which it should form an integral part.

Appropriateness is too rarely considered in ornaments of this kind, which seldom bear refined relation to the things about them. Rough and informal constructions are particularly out of place in a purely formal system of lawn-planting, and are only to be endured where the nature of the ground suggests them, and enhances their beauty by suggesting that they are natural. We have selected the rocky basin, an illustration of which is to be found on page 439, because it gives an idea of fitting garden decoration, where the space is limited and the surroundings wild. The picturesque pool represented is a feature of a small terraced garden, built out from the rocky side of a steep hill that descends abruptly to the sea-shore of Massachusetts Bay. This terrace is approached from the level on which the house above it is built, by a rough stone stairway, that has for a balustrade a huge granite boulder, overgrown with Ivy, and surmounted with trees. Great rocks enclose the terrace on three sides, and down the almost perpendicular face of one of them trickles the thread-like stream that falls into the pool below. The overflow wanders away in a small grassy channel, along the edge of which tiny water-plants grow, and Cardinal-flowers blossom. In the basin a pink Water-lily is blooming, dainty dweller in a fairy home, and somewhere in the shadows a gold-fish has a lurking-place. On the stone curb a blue jug, and a Japanese drinking-vessel formed of a shell, with a handle of bamboo, give the requisite touch of human needs and uses to this lonely dell.

The little green-turfed terrace is encircled with flowers that thrive in this warm nook, where the morning sun shines hotly, and where its south-western rays are tempered by the shade of great forest-trees. So steep is the hill that the shining waters of the ocean are seen through the topmost branches of tall Oaks and Pines, while others stand far below. The brown seedy spike of a Dock-plant hangs out against the lichened crag, and forms a spot of rich color amid the prevailing gray, while all about, from crevices in the rocks, and from shady recesses beneath them, spring Ferns and Grasses, with wild flowers and picturesque weeds. Some young Sassafras-trees, or rather bushes, near by, which have sprung up of their own accord, have a particularly pleasing effect with their yellow-green leaves, and down the face of the rock straggles a Blackberry-vine, as perfect in outline and graceful in sweep as if it had been drawn by the hand of a Japanese artist, each cluster of finely serrated leaves having a distinct value against the mottled stony background, which also gives a

fine relief to the groups of flowers and ferns that cluster at the base of the pool.

In such a situation nothing showy should find place, but only those things which might naturally grow around a forest-spring. The little Cresses along the brook, the tender Forget-me-nots, the fine small Grasses, the water-weeds and ruby Lobelia, that have been wisely set here to enjoy the moisture, add to the wild-wood charm of the pool with its tinkling water.

Taste has gone hand in hand with nature and produced a lovely picture, delicate in detail, fine in color and grouping, harmonious in general composition. Minute the space is, almost as a Japanese garden, but the effect is dignified and poetic. It is not mere prettiness that charms, but the true artistic feeling with which the idea has been conceived and executed. The little scene touches and captivates, while gratifying all the senses with sound and sight and color, and soft touch of ocean breezes and of waving leaves.

The plate fails to show what is another feature of the real picture, a second semicircular terrace below, with Clematis-clad wall, to which one clambers by another flight of steps hewn in the rock to find more flowers and more lovely weeds and grasses, and a second space of well-mown turf, with a fine outlook on the tossing sea. From this a rugged path leads by devious ways to the beach below, where are boats and a yacht riding at anchor, and the wide stretch of the great deep, with white sails upon the surface and whiter clouds overhead.

A Fine Road.

ALTHOUGH in years gone by Chicago allowed a railway to be run along the lake-shore in the southern part of the city, there seems no danger that the mistake will be repeated, and, indeed, eastern cities might well emulate the care Chicago is now taking to make proper use of her water-fronts. The most noteworthy of recent improvements is the "Sheridan Road," which, starting from the end of the Lake Drive at the northern outskirts of the city, extends to Fort Sheridan, on the bluffs some twenty-five miles away. A correspondent of the *American Architect and Building News* recently wrote :

When first mentioned, this road was scarcely more than an idea, while by utilizing, to a certain extent, existing roads and condemning property, the general outlines of the scheme are now practically completed. The plan is to keep much of the picturesqueness of the country road, while a few of the conveniences of a city drive will be connected with it. The ditches, which heretofore have bordered the old road in many places, will have to disappear; in fact, have partially disappeared already. Drains are laid, the ditches are filled in and then sodded over, so that while the actual drive-way will not be made any wider than it is at present in many of the old roads, ample accommodations will be given for an occasional crowd upon the turf on either side. Space is gained in this way, and the amount of area liable to become dusty is lessened. Concrete sidewalks are being laid along the way, and before many years will, very probably, be laid most of the way to Chicago. . . . Where the original country road skirts the bluff quite closely, it has been converted into the Sheridan Road, but in places where it leads away from the lake new routes are being surveyed for the proposed drive. In tracts already opened up by it in the vicinity of Chicago marked advances are noticeable in the price of real estate, as well as a considerable amount of building. This growth has been gradual and healthy, and the homes being erected along the shore of the lake are of an extremely good class. . . . There is nothing wild or rugged about this shore of the great lake, but for quiet beauty this northward stretching coast has nothing to equal it in any way in the near vicinity of Chicago, and this locality must assuredly be destined to be the site of the finest summer houses around the city. One feature of this lake, which few realize who do not live by its side, is the immense size and amount of the shipping which passes daily up and down its northern shore. . . . At the terminus of the drive is Fort Sheridan, which, for the last three years, has been slowly assuming a somewhat settled aspect, till now this brand-new United States army fort is looked upon as one of the sights worth seeing in a visit to Chicago. It is situated on bluffs seventy-five or eighty feet above the lake, and with its winding ravines has at least much natural beauty to help out whatever improvements the Government may see fit to lay out on it. To reach the long Government pier a road was necessary, and, fortunately for the picturesqueness of the place, a more accessible one could be cut through one of the beautiful ravines, where a more gradual ascent could be made than up the steep bluff. This fine drive-way leading to the pier is now one of the features of the place.

Not only scattered semi-country homes, but "model villages," are already growing up along the Sheridan Road, laid out with broad tree-planted macadamized streets and controlled with a disregard of mere private eccentricity in taste, and a demand for general neatness and harmony of effect and for common comfort to which, one might have thought a few years ago, no Americans would ever submit. But, in truth, Americans are quick to appreciate improvement in any direction, even when it somewhat limits individual impulses, and there is no happier sign for the future well-being of our communities or the future aspect of our land than such carefully ordered villages as those which, in more than one of our western towns, are taking the place of those old-fashioned outskirts which have made the term suburban residences a by-word of reproach and a symbol of uncomfortable living in so many of our older localities. Such enterprises as the Sheridan Road prove, of course, the immense material as well as æsthetic value of a fine highway, and supply examples which can be used with telling effect elsewhere.

Notes on North American Trees.—XXVII.

THE number of changes in the names of our arborescent *Leguminosæ*, made necessary by the restoration of the oldest specific names, is not large.

The Clammy Locust is generally known as *Robinia viscosa*, the name given to it by Ventenat and published in 1803 in the "Description des Plantes Nouvelles et peu Connues Cultivées dans le Jardin de J. M. Cels," but it had been described, two years earlier, in England in the *Botanical Magazine* (t. 560) as *Robinia glutinosa*. This last name, which has every claim to priority, was taken up by Koch in his "Dendrologie," but has been neglected by other authors.

The character of the buds of Robinia is not explained in any of the published accounts of these trees which I have read, except in the "Flore Forestière" of A. Malhieu, who hints, in his third edition, published in 1877, at their structure and arrangement. Sir John Lubbock, who has recently published the result of his observations on the development and uses of the stipules of a number of plants, says that "the winter-bud of *Robinia Pseudacacia* is protected by three short, brown, triangular-pointed scales" (*Jour. Linn. Soc.*, xviii., 228). In reality, there is not one but three or four superposed buds under each petiole, and they are not covered individually by scales, but are sunk in the cavity under the base of the petiole and covered collectively by a thick scale-like coat which is lined on the inner surface with thick rusty brown tomentum, and which, in early spring, splits open to allow the growth of the upper and larger of the four buds, which is the only one that develops, although, if this is injured or destroyed, it is, no doubt, replaced by the next bud below it. The parts into which this bud-like covering splits remain on the base of the branches during the season. The subpetiolar buds are often accompanied by a supplementary supra-axillary naked bud, corresponding to the supra-axillary bud in Gleditsia which develops into a spine. In Robinia this supra-axillary bud, late in the season, sometimes produces a feeble branchlet, especially on vigorous shoots, which, probably, does not survive the first winter The apparently superfluous number of buds and their careful protection enables Robinia to pass uninjured through periods of excessive winter cold, and accounts for the ability of these trees to inhabit regions many degrees

north of their native home. *R. glutinosa* and *R. hispida* grow naturally only in the southern Alleghany Mountains, at the same altitude, and nearly at the same elevation, as *Magnolia Fraseri*, but are hardy several degrees farther north than that tree.

The nature of the buds of Cladrastis, which appear to have escaped the attention of botanists, also enables this tree to flourish many degrees north of the somewhat restricted region west of the southern Alleghany Mountains, which is its home. The buds are sub-petiolar, but I do not find that it has been explained that, instead of a single bud, there are under each leaf-stalk four, superposed and closely compressed together, forming by mutual pressure a rather thick cone, each bud being covered with thin lustrous scales. The lowest one is minute and rudimentary, and probably it is only the upper one which develops into a branch. If this should be injured, then perhaps the next one takes its place. The four sub-petiolar buds of Cladrastis serve to keep it separate from the Asiatic Maackia (united by Mr. Bentham with Cladrastis), which has solitary supra-petiolar buds, besides differing in habit, in inflorescence, in its accrescent persistent bud-scales, and in some floral particulars from the American tree, as has already been pointed out by Maximowicz.

The Jamaica Dogwood, a fine tropical tree which occurs on the keys of southern Florida, was described by Linnæus in the first edition of the "Species Plantarum" as *Erythrina Piscipula*. Later he recognized it was not an Erythrina, and made a new genus, Piscidia, to receive it, changing, however, the specific name in the second edition of the "Species Plantarum" from Piscidia to Erythrina. The successors of Linnæus have written *Piscidia Erythrina*, but if the oldest specific name given to a plant by Linnæus, or by any subsequent author, is the name by which the plant is to be known, then that of the Jamaica Dogwood must be *Piscidia Piscipula*.

The synonymy of the Water Locust is confusing. It was first described by Linnæus in the first edition of the "Species Plantarum" as a variety of *Gleditsia triacanthos*. Miller, in the eighth edition of his Dictionary (1768), called it *G. inermis*, which would be the oldest name for the Water Locust had it not been already appropriated by Linnæus in the second edition of the "Species" (1763), in which there is a *G. inermis* taken up from a plant of Duhamel's which Mr. Bentham (*Trans. Linn. Soc.*, xxx., 557) was probably right in considering the spineless form of *G. triacanthos*, although Duhamel himself supposed that it might be the *Acacia Javanica* of Plukenet ("Phyt.," t. 123, f. 3). The identity of this plant was further confused by Linnæus referring to it Miller's figure ("Icon.," t. 5), which represents *Calliandra Houstoni*, a tropical American plant, which, Mr. Bentham remarks, could "only have been quoted by Linnæus at second hand or through some inadvertence." In any case, the *G. inermis* of the second edition of the "Species" cannot refer to the Water Locust, which still appeared there as a variety of *G. triacanthos*, so that Miller's name, being a synonym, is not available, and the next oldest name, that of Marshall (1785), *G. aquatica*, will have to be adopted. Fortunately, the name is the best of all those which have been given to this tree, which grows in water or in very wet places.

In the spelling of the generic name I have followed Linnæus in writing Gleditsia, although most modern authors have changed his name to Gleditschia. *C. S. Sargent.*

New or Little-known Plants.

Cereus (Pilocereus) Sargentianus.

THIS plant has eight or more stems from the same base, the sterile stems two to five feet tall, five or six angled with obtuse ribs, separated by broad, deep intervals; the woolly areolæ closely set and touching each other on the ribs, the gray spines stout, straight, one-fourth to three-fourths of an inch long, in clusters of ten or more; the flower-bearing stems ten to fifteen feet tall, erect, five or six angled, intervals usually shallow, the ribs closely set with woolly oblong areolæ, each bearing about fifty long, flexuous, grayish or white spines which almost hide the small inconspicuous flowers.

The flower is of a delicate shade between rose-pink and flesh-color, an inch long and less than an inch across; petals about twenty-four in number, thirteen scales in the ovary; anthers yellow, filaments, style and stigmata white.

The Indian name of this Old-man Cactus is *Carambuya* or *Garambulla*, and it is called by some *Hombre viejo* or *Cabeza vieja*, according to Brandegee, who found it from Comondu to San Quintin, Lower California.

I have referred this plant hitherto to *Cereus Schottii*, Engelm. (vide Garden and Forest, iii., 439), and Brandegee (*Proc. Cal. Acad.*, 2d ser., ii., 163) has referred to it by the same name.

I first found it near San Quintin, Lower California, in 1886. The fruit I have not seen, but it is said to be edible, without spines, red, and attaining a much larger size than the fruit of *C. Schottii*, as is evident in the illustration (see page 437), from a photograph taken by Messrs. Roscoe Howard and Russell Gannis.

The plant differs also in the number and characters of the spines, and will probably prove to be a distinct species. I therefore venture to name it provisionally for Professor C. S. Sargent, whose interest in the Mexican flora is well known.

San Diego, Cal. *C. R. Orcutt.*

Foreign Correspondence.

London Letter.

THE most interesting event of the week in the open-air garden is the flowering of *Lilium Parkmanni* in the Knap Hill nursery, Woking, where only it can be seen. By reputation this Lily is known to all who take an interest in Lilies, but comparatively few have seen it in bloom, as it flowers when no unusual display attracts visitors to the great Surrey nursery. As every Lily-grower knows, we are indebted to America for this magnificent Lily, considered by many the queen of the whole family, and it is a singular fact that none of our hybridists have obtained such successful results as did Mr. Parkman, though they have tried over and over again to raise a similar hybrid between *L. auratum* and *L. speciosum*, which are the parents of Parkman's Lily. Neither is it likely that this Lily will ever become common, owing to the slow way in which it increases. For thirteen years has Mr. Anthony Waterer been trying to make the most of the four bulbs he bought from the raiser at the highest figure that has ever been paid for a hardy herbaceous plant. Those who do not know what Parkman's Lily is like must imagine a very large *L. auratum* flower, a foot across from tip to tip of the petals, each banded like auratum with yellow and stained with the richest carmine-crimson and broadly edged with white. Every Lily specialist here is eagerly waiting for its distribution, and, no doubt, it will then soon find its way back to the land of its birth.

An uncommonly successful meeting was held this week by the Royal Horticultural Society at Westminster, and quite a number of novelties were placed before the committees. Gladioli from Kelway, and Dahlias from various growers, were the special features, but several other interesting plants were there, and especially Orchids. There seems to be now a continuous succession of hybrid Orchids, for at every meeting one sees new ones. The most important new hybrid shown on this occasion was from Messrs. Veitch. This was a Lælio-Cattleya named Nyssa, a cross between *Lælia* (*Cattleya*) *crispa* and *C. labiata*, var. *Warsceiczii*. The progeny is intermediate, both in growth and flower, the latter being somewhat larger than those of *L. crispa*. The sepals are a delicate mauve and spread out widely; the labellum is larger than in *L. crispa* and quite shows the dilation of that of *C. labiata*; the color is an intensely deep purple-crimson, surrounding an in-

terior blotch of golden-yellow, and with a well-defined crisp edging of white. Altogether, the flowers recall the features of the rare *C. Exoniensis*, one of the earliest hybrid Orchids of Dominy's. It is looked upon as one of Mr. Seden's chief successes in hybridizing. Another hybrid Cattleya was named *C. Behrensiana*, from Messrs. Sander, of St. Albans. It is a cross between *L. elegans* and *C.*

Fig. 69.—Cereus (Pilocereus) Sargentianus.—See page 436.

Loddigesi. The growth is similar to that of *L. elegans*, but the leaves are broader and shorter. The flower is as large as those of the latter; sepals very pale lilac; lip broad, amethyst-crimson on the lower lobe, white on the incurved upper lobes. Though not such a strikingly distinct hybrid as that from Messrs. Veitch, it was much admired. A third hybrid Orchid was *Masdevallia Measuresiana*, a pretty and interesting little plant obtained by crossing *M. Tovarensis* with *M. amabilis*. The flowers are about the size of those of the latter, and with attenuated sepals which are white striped and clouded with violet-purple, and the influence of *M. Tovarensis* is seen by the several flowers it carries on each spike. *Cypripedium apiculatum*, a cross between *C. Boxalli* and *C. barbatum*, was from Mr. Palmer, of Reading. It has the mottled foliage of *C. barbatum* and the flower of *C. Boxalli*, rendered darker by the crossing, and with spots on the lateral sepals, but the dorsal sepal is much reflexed, which detracts from the symmetry of the flower, and is considered a fault by orchidists.

A supposed hybrid named *C. leucochilum*, between *C. Godefroyæ* and *C. barbatulum*, was shown, but the evidence of the cross was not clear, and so may be passed over. Besides the hybrids there were shown *Dendrobium Phalænopsis*, var. *Statterianum*, a really splendid variety, much superior to the type, inasmuch as the spike is longer, the flower larger and more deeply and richly colored. The broad sepals are a purple-crimson, and the labellum many shades deeper. *Sobralia leucoxantha*, with the growth of *S. macrantha*, has flowers five inches across, sepals snow-white, lip broad, frilled at the margins, and of a rich golden-yellow. It is one of the loveliest of all the species and a rival to the rare *S. xantholeuca*. It came from Messrs. Seeger & Tropp. *Cattleya amanda*, also known as *C. Rothschildiana*, is a pretty Orchid at this season, supposed to be a natural hybrid, and reminds one of *C. maxima*, having sepals of a pale rose-pink, with a deeper lip with purple veins. A very uncommon looking Orchid, under the name of *Zygopetalum grandiflorum*, came from Messrs. Shuttleworth & Co. It has the habit of growth of one of the larger Maxillaria and one-flowered spikes. The flower is three inches across, pointed, broad sepals, pale green, striped with purplish brown, and a large labellum, white, lined with purple.

The Gladioli from Messrs. Kelway, numbering hundreds of spikes, made the usual magnificent display, though, owing to the cold wet season, they were not as fine as in former years. Many new seedlings were submitted to the committee, but only a few were distinguished by awards of merit, because it is so difficult to discern the difference between the new and the old kinds among the Gandavensis section, now that the climax of perfection has been reached as regards size of spike, shape and size of individual flowers, and brilliancy of coloring. A smaller collection of Lemoine's hybrids, which Messrs. Kelway have at length taken in hand, comprised some wonderfully fine sorts, and it is in this section that we must in future look for progressive improvement, for, though they are at present inferior in spike and bloom to the Gandavensis tribe, they combine such striking contrasts of colors that they will probably prove a far more valuable race of garden-plants, since they are so much hardier and may be left in the open ground here throughout the year, which, to amateurs, is a great consideration. There has been such a rapid improvement made with this race that Lemoine's original seedlings are rarely shown now, though the features of those first hybrids are plainly discernible in newer sorts that have been again crossed with the finest of the Gandavensis type. The first bright, clear yellow Gladiolus that I have seen was among Kelway's new seedlings, and others had those combinations of yellow and crimsons, pinks and scarlets, that render them so distinct from the ordinary Gladioli.

The Dahlias, like the Gladioli, were in strong force, and a great number of new, or so-called new, sorts were placed before the committee, especially novelties in the Cactus-

flowered section. Messrs. Cannell, of Swanley, seem to be leading in the race for novelty, and certainly some of their seedlings are of great beauty, and, for the most part, distinct from older kinds. They had a few new colors representing the true original Cactus Dahlia (*D. Juarezii*), not the nondescript coarse-flowered sorts that pass as Cactus-flowered Dahlias. Their new Swanley Cactus is a counterpart of the Juarez Cactus, having the same semi-quilled florets, but of a much more brilliant scarlet. Their other varieties of Cactus—Ernest Carronel, magenta-crimson; Robert Cannell, bright carmine; Oban, yellowish, flushed with plum-purple; and Eynsford Gem, purple-crimson—were among the finest of a remarkable collection of Cactus Dahlias. Other great Dahlia-growers, such as Keynes, of Salisbury, and Phippen, of Reading, had large collections of single show and pompon varieties, but they did not attract such attention as the group of new Tom Thumb single Dahlias, from Cheat, of Crowley, who has acquired the stock of these remarkable pigmy Dahlias from the raiser, Mr. Girdlestone, the well-known rosarian. This dwarf race of Dahlias grows at the tallest only eighteen inches high, and are sturdy in growth, and are very free-flowering. For massing in beds on lawns they are of especial value, as they require no supports. There is nothing extraordinary about the flowers, which are all single, but there is no knowing where this new break may lead. They are different from the dwarf double varieties that have been grown during recent years.

Some interesting Lilies from Messrs. Low were noteworthy, especially the variety of *Lilium Wallichianum* named Superbum. It has flowers in shape like *L. longiflorum*, but in this variety they were much larger. They are white, and colored on the inside with pale yellow. The plant grows some three feet high. Another fine Lily from the same exhibitor was *L. Nepalense*, also from northern India. This is a Turk's-cap Lily with large flowers of a blood-red color, with the petals broadly tipped with yellowish green. It is a striking plant, and still very rare in cultivation. Some slight forms of *L. longiflorum*, under the names of Magnificum and Giganteum, were shown, but they were not superior to the variety Takesima, which was shown grandly in a mass, and which were described last week.

Other bulbous plants were *Crinum Powelli*, the very fine hybrid between *C. Moorei* and *C. Capense*. It carries a stout flower-stem, bearing from nine to twelve flowers of a lovely rose-pink, and nearly as large as in *C. Moorei*. It has proved quite as hardy as *C. Capense*, and is, therefore, an invaluable addition to our open-air flowers. This was from Sir Trevor Lawrence, who also showed the hybrid *Cyrtanthus rosea*, interesting and beautiful, but not so fine as the old *Vallota purpurea*.

Among the trees and shrubs from Messrs. Veitch the committee selected *Cupressus Arizonica* as worthy of a certificate of merit. It reminds one of *C. macrocarpa*, but is more glaucous, and it is evidently an elegant shrub, and the fact that it has proved quite hardy at Coombe Wood, in Surrey, enhances its value. *Retinospora squarrosa sulphurea*, with slightly yellowish foliage, and *Cupressus Lawsoniana versicolor*, with ill-defined yellowish variegation, were two other novelties from the same exhibitors, who also had a fine gathering of the beautiful *Eucryphia pinnatifolia* alluded to last week. The beautiful new hybrid, *Hypericum Moserianum*, was shown in fine flower by Mr. Anthony Waterer, of Knap Hill, who thinks so highly of it that he is growing it on a large scale in his nursery since he has proved its thorough hardiness and its free-flowering character and elegant growth. Under the name of *Catalpa Himalayensis* Messrs. Veitch have in flower a variety that flowers habitually when only a few feet high. In other respects it is not different from *C. bignonioides*, so far as I can judge. The name may be wrong, but perhaps this variety is cultivated in the Arnold Arboretum. If so, it would be interesting to know what it really is.

Cultural Department.

Iris reticulata and its Allies.

About twenty-five years ago the typical form of *Iris reticulata* with violet-blue flowers was introduced into cultivation through the agency of English and Russian botanists. It is a very hardy plant, flowering in early spring, and its fresh-colored flowers, with narrow falls and standards, are very striking. The Reverend G. T. Nelson, of Aldborough, whose name is prominently associated with the improvement of hardy plants, first produced, through constant sowings and careful selection, two new forms of this Iris, named Major and Cœrulea. The first is a more robust plant than the type, stronger in all its parts, and the divisions of the flower are broader and more spreading, thus presenting a larger surface of color. The second resembles the type except that the plants are cœrulean blue. Dr. Edward Regel, not long after the introduction of *I. reticulata*, introduced the deep purple-flowered *I. reticulata Krelagi*, with rather dull-colored flowers. Forms, however, raised from seed of this and others obtained from Koordistan produced brighter-colored flowers. About the same time *I. reticulata cyanea* was introduced by Haage & Schmidt, also from the Caucasus. It has a smaller flower than the last, but the small size is more than compensated by its lovely color, the falls being dark blue, with an orange blotch, the standard pale sky-blue. These are all the forms of *I. reticulata* proper, its specific name, by the way, being derived from the netted outer coat of the bulb.

It appears, however, that the type in descending from the lofty heights of the Caucasus plain eastward to Persia and southward to Palestine has undergone material changes in the form and color of the flowers, and that from the original *I. reticulata* have been developed by gradual evolution species of greater beauty and of greater value to the horticulturists than *I. reticulata*. Boissier, the great botanist, brought home from Mount Gherizin, in Palestine, thirty years ago, some bulbs of the lovely *I. Histrio*. This is an early-flowered plant, producing in mild winters its flowers as early as January in Germany. It is distinguished from *I. reticulata* by the broader blade of the falls, with brilliant ultramarine blotches on a white ground. In later years *I. Vartana* has been introduced through the exertions of Professor Foster, of Cambridge, and of Dr. Vartan, of Nazareth. This plant produces here greenish blue flowers in November. Fifteen years ago Mrs. Danford, during a hunting trip which she made with her husband in the Sicilian Taurus, discovered the small, but brilliantly flowered, *I. Danfordiæ*, which three years ago was found again in large quantities by Sintinis in northern Koordistan. These plants have succeeded well at Baden-Baden, and, in spite of snow and ice, have flowered in February and March, or when they have been potted and kept in the greenhouse they have flowered as early as November. Later a variety of *I. Danfordiæ*, or perhaps a distinct species, *I. Bornmüleri*, was found by Bornmüler in another part of Armenia, and sent to Baden-Baden. It differs from *I. Danfordiæ* in its more robust growth, in its broader floral segments, with a green stripe on the claws, the green color being of a slightly deeper shade of yellow.

Through the kindness of American missionaries in Armenia, Professor Foster received a number of other forms of Iris, and in search of these I was fortunate enough to introduce a large quantity of *I. Bakeriana*, *I. sophenensis* and *I. histrioides*. *I. Bakeriana* has sky-blue standards, with white falls tipped and penciled with deep indigo-blue, with an indigo-colored blade marked with orange. The flower is very sweet-scented, and opens toward the end of February. The flowers of *I. sophenensis* appear in all shades of color, from almost white to mauve-purple and metallic-red. It grows well and flowers early. *I. histrioides* is, perhaps, the prettiest of all the group, appearing in the form and color of the flowers almost intermediate between *I. reticulata* and *I. Histrio*. This also flowers very early,

and the flowers present a large surface of the brightest ultramarine-blue shading, or varying in some individuals to violet, and in others to a paler shade. All these plants are very easy to cultivate, and, when better known, are sure to become general favorites. In America, where in early spring-time heavy snow may occur, it will be necessary to plant them in frames, or to make such arrangements that when they are in flower they may be protected. At Baden-Baden they are planted in borders along the bottom of walls, where they can be kept safe from the destroying influence of heavy or wet snows by leaning mats against the wall over the beds.

Baden-Baden. *Max Leichtlin.*

Fig. 70.—A Garden Pool.—See page 434.

Keeping Fruit in Winter.

A WRITER is quoted as objecting to the practice of gathering apples for keeping "as soon as the pips begin to turn brown." He says apples gathered at this stage "do not keep as well, or average of so good quality." Certainly they do not. An apple makes a noticeable portion of its growth—often as much as one-fourth—while its seeds are coloring. But, on the other hand, the keeping of late-ripening apples is greatly lengthened by gathering them as soon as the seeds are fully colored. Up to that time the fruit improves on the tree. After that it deteriorates, so far as keeping is concerned, and, with some varieties, it deteriorates rapidly, so that winter fruit becomes in a few days fall fruit.

The art of handling fruit for keeping is very imperfectly understood, both as regards principles and practice. The season of many of our fruits is capable of being much lengthened in the hands of growers and dealers who are willing to learn and make use of the principles involved. In the first place, so far as Nature's purpose is concerned, the external coverings of the true fruit—that is, the seed—exists primarily for the sake of the seed itself, and only secondarily for its envelopes, which are the parts that give it its chief value for human use. As soon as the fruit and its seeds are ripe the fleshy exterior part begins to decay, and what we call ripening or maturing are only primary stages of that process, which is to release the seed, so that it may grow into a new plant.

After the fruit is carefully gathered, the whole question of keeping resolves itself into a question of temperature, but with due attention also to moisture. Pears, apples and grapes require a low and uniform temperature, and proper protection from fungous attacks. Aside from the latter danger, which may be favored by dampness, a saturated atmosphere is not objectionable; but care must be taken not to allow cold fruit to be taken into a warm atmosphere, producing that deposit of visible moisture upon its surface which is erroneously called sweating. In such cases it is not so much the moisture itself that harms the fruit as it is the moldiness which is apt to ensue. Apples can be well preserved in very damp cellars if these points are kept in view. In fact, a cellar with a spring in it is thought by many fruit-growers to be specially favorable to the perfect keeping of apples. In Russia it is a custom to preserve apples fresh in cold water; and the late Charles Gibb, of Abbotsford, Quebec, once told me of some very fine Fameuse apples which he found on sale in April, and which, he was told, had been part of the cargo of a canal-boat that had sunk and been frozen in and had just been raised. The Fameuse can rarely be kept in air much beyond the first of February.

The temperature of a fruit-cellar is best when kept as near to the congealing temperature of the fruit as possible. It is not safe to freeze so watery a fruit as the grape; but apples and pears can be frozen without injury, if slowly thawed again in the dark. I am not quite sure of the latter condition being essential, as I have had apples that had been slowly frozen, and as slowly thawed, in a light cellar, come out of the trial apparently uninjured.

But, unquestionably, an even temperature, near to freezing, is the best. Even this, however, is of small avail toward good keeping if the fruit does not go into its cold storage in

perfect order, and at the right stage of its existence. That stage is reached, in apples and pears, as soon as the seeds are fully colored. Fruit designed for long keeping should be gathered early in the day, or in cloudy weather. A barrel of sun-heated apples, even if put at once into a cool cellar, has lost greatly in keeping quality. If fruit must be gathered in the heat of a sunny day let it be in baskets, which are to be kept under airy cover until they are well cooled before they are placed in the cellar.

For the best results gathering and assorting ought to be simultaneous; but in a large orchard, when careful hands are scarce, this is not possible, and the best alternative is a large and airy sorting shed, where the work can be deliberately done by skilled hands. I prefer round-bottomed half-bushel baskets, with drop handles, for use in gathering and assorting. It takes a good many of them in a busy time, but in the end they are economical. They are easily handled, and will not be slung around, as bushel baskets with side handles are sure to be, to the great injury of their contents. The small baskets can be put down into the barrel and emptied without bruising their contents in the least. Hand-barrows for two men are much better than wheel-barrows. A stone boat answers well on smooth, level ground.

As an evidence of the value of careful attention to all the points above referred to, I may be allowed to say that our chief winter apple in northern New England is the Wealthy. Observing all these rules, I find that I have not the least difficulty in keeping it firm, fresh and free from decay up to April, while less careful neighbors (and growers generally) decry it as merely a fall apple. By similar care the Gravenstein, grown in southern Maine, is found in the Boston market all winter in prime order.

Newport, Vt. *T. H. Hoskins.*

Dracænas.

THESE useful plants are generally easy to grow; they often have bright foliage, and all are graceful in habit. In a majority of instances they are most satisfactory when grown moderately warm, though some varieties do well in a cool house. Moderately light soil is most suitable, but it should be well enriched with some old manure, and the addition of some bone-dust will be beneficial.

They are readily multiplied by laying the canes in sand or moss, or a combination of both, in a warm house, and young plants will be produced from nearly every joint. For large specimens it is best to root the top of an old plant by making an incision in the stem, and then covering that portion with moss in order to induce root-growth. By this means a specimen may be secured with large foliage close down to the pot.

While most of the varieties and species of Dracænas require plenty of light at all times, yet it is better for many of the more tender ones to have a slight shade during the summer, else some of the foliage may be injured. During the past ten years or so there have been many fine hybrids introduced, but there are excellent varieties among the older ones, and as these are more easily procured, they will be the ones chiefly spoken of in these notes.

Prominent among these older sorts is *D. amabilis*, which has leaves nearly two feet long and from four to five inches wide, the ground color bright green and the central leaves suffused with creamy white and frequently tinted with pink. *D. Cooperii* is another fine variety, which probably originated from the well-known *D. terminalis*, as, in fact, have a large number of good varieties. The leaves of *D. Cooperii* are, however, much broader than those of *D. terminalis* and are gracefully recurved, the color being reddish bronze, while the young leaves are frequently bright red.

D. Chelsoni is remarkably handsome when well grown, the leaves being large, dark green, and marked with crimson.

D. ferrea is another fine variety that has long been known in gardens and is of rather upright habit, with leaves about one foot long and purplish red in color. This variety and *D. terminalis* are among the most satisfactory kinds, with colored foliage for vases and other out-door decorations.

D. gracilis is not often seen now, though well deserving of a place in any collection. It is of slender habit, and the stem is thickly clothed with narrow, dark green leaves, the latter being edged with a narrow border of dull crimson.

D. Dennisonii is a handsome dwarf variety, and has broad purplish leaves that are about one foot long. The leaves of this variety are closely arranged on the stem, and it makes a very compact little specimen.

D. magnifica is quite a contrast in size with the preceding, the leaves of this variety being often eight to ten inches wide and two feet long; the color being pinkish bronze with darker petioles.

Still another fine one among the large growers is *D. Mooreana*, in size somewhat similar to the preceding, but much darker in color.

D. indivisa Veitchii and *D. indivisa atropurpurea* are two decidedly ornamental forms of this popular species, and are admirable for out-door planting or for conservatory decoration. They both have the long and graceful leaves of the type, but differ therefrom in color, *D. Veitchii* having a reddish midrib, and *D. atropurpurea* has a purplish flush about the base of the leaves and a darker midrib than its companion.

D. fragrans is still reckoned among the popular decorative plants, its broad dark green leaves having a very pleasing effect, while the two variegated forms of this species are both worthy of cultivation, *D. variegata* having most of its creamy yellow color about the margin, while that of *D. Lindeni* is chiefly found in the central part of the leaves.

It may be noted, too, that *D. indivisa* also has produced variegated forms, that known as *D. Doucetii* being, perhaps, the prettiest.

D. umbraculifera is a somewhat unusual species, but makes a fine specimen, the narrow leaves being very dark green and glossy, and very closely arranged on the stem, from which they diverge in umbrella form.

This species is, however, rather difficult to increase, as it makes a stem very slowly.

Holmesburg, Pa. *W. H. Taplin.*

Notes on American Plants.

Chelone Lyoni, one of the Turtle Heads, a native of the southern states, is in flower the last of August. The plant is rather stocky, about fifteen inches high, and bears, in long succession, handsome rose-purple flowers an inch long. The numerous leaves are oblong-ovate and very dark green.

Sedum telephoides, from the same locality, is a useful plant to cover rockwork, and will live almost on air alone. It grows on dry rocks. Its height is about one foot, and the thick, fleshy leaves, as well as the stems, have a purplish tinge. The not very attractive flowers are borne in small cymes, and are of a pale flesh-color. This species, with *S. Telephium* (Common Live-for-ever), could be grown in places where few, or no other, plants of their size would live. Their foliage remains fresh the entire season, and the thick compound cymes of purple flowers of the last are certainly quite attractive.

Our North American Gentians, of which there are said to be fifty species and varieties, are for the most part worth cultivating. They do not transplant so well as most of our wild flowers, but if the soil is light and moist they generally establish themselves by the second year. They are late-flowering plants and come at the season when they are most needed.

The Soapwort Gentian (*G. saponaria*) has proven with us a good species for cultivation, and its pale blue flowers appear at nearly the same season with those of the White Gentian (*G. alba*), making a fitting companion to it. Both do well in either sun or thin shade, in a light moist soil.

G. linearis is found in swamps, and is a good species to plant in artificial bogs, in not too wet or sunny portions, but in partial shade and elevated, so as not to be wet. It likes a peaty soil. It has simple, slender, leafy stems, often over two feet high, terminating in three or more blue flowers an inch or thereabout in length.

Few of our wild flowers surpass the Fringed Gentian (*G. crinata*) in attractiveness, but, unfortunately, it is a biennial and a difficult plant to grow.

G. Amarella, var. *acuta*, is a boreal variety often only six inches high, with pale blue flowers half an inch long. We have never attempted its cultivation, but, no doubt, it should be treated as an alpine.

Charlotte, Vt. *F. H. Horsford.*

Hybridizing the Sweet Pea.

THERE are several ways of producing new varieties of Sweet Peas besides hybridizing. Special strains may be developed by selection. Old varieties may be increased in size. Occasional sports will hold good from year to year. The striped sorts have a way of ranging back and forth from delicate markings, and even pure white, to solid colors. For instance, the Senator, a noble flower in dark stripes, and of the new, large form, has, with me, this year produced a solid purple blossom, which, if it can be held, is an acquisition. Since Eckford himself leaves many hybrids without a name,

other experimenters ought to be cautious about claiming anything new.

Hybridizing must be the short and sure road to really new varieties of merit. I can only speak from a short experience, but my experiments this year seem to warrant more confidence than those of last year.

Each Sweet Pea blossom is an independent and self-fertilizing flower. The keel is a sac containing the stamens and pistil, and in healthy blossoms the latter rarely are exposed. So jealously does each blossom fertilize itself that it sheds its pollen when about half-open, and the sac at the upper end draws snugly up around the anthers, pressing them closely about the stigma. Cross-fertilization, even by bees, is almost impossible. The bumble-bee comes, but he works down at the base of the wings. No member of the Pulse family appears to be in less danger of mixing than the Sweet Pea.

But here is a neat and difficult opportunity for artificial hybridizing. My experiments in trying to cross them after the blossoms were open had no effect. This year I have worked on the buds. They must be taken before they have pollinated, and to mutilate the bud so early is rough treatment. The few pods which I have secured this year are a modest but much-prized return for the patient labor expended. My judgment now is that it is preferable to take the lowest bud on the stem, at just the right stage, and remove the others, to give all the strength to one. Delicately open the sac and cut away the stamens. Let the bud stand till it would naturally pollinate, and then cross-fertilize as you wish. Better than using a pencil-brush I have found that by tearing away the standard and wings of the blossom whose pollen you wanted, you could lay open the sac gently with a penknife, and, like an oyster on half-shell, you had the pollen in a handy vessel and could press it on to the stigma of the other. Judgment must be used as to the time to transfer the pollen. Open the bud in the early morning, and perhaps by nine or ten o'clock it is sufficiently advanced.

It may be that in this country the results will compare unfavorably with Eckford's, but further experiments are worth making. Great possibilities are in this beautiful and fragrant flower. Who will get the first real yellow Sweet Pea?

Correspondence.

Gardening on the Shores of Buzzards Bay.

To the Editor of Garden and Forest:

Sir,—It may be well to state, for the benefit of those persons who have an inaccurate idea of the situation of Buzzards Bay, or a mistaken or vague idea of the character of the country about it, that the bay is, in shape, like a horseshoe. It opens on the ocean only to the south. The butt of Cape Cod forms the north-east and east side, and lies between the bay and the Atlantic. The land hereabout is not a level waste of drifting white sand; it is, on the contrary, a rolling country, rising to considerable heights, mostly covered with wood, and full of lakes, ponds and brooks. It offers to lovers of gardening—who are but beginning to appreciate it—great advantages over those undertaking the art in most other parts of our country; and one who is familiar with it foresees that the number and beauty of its cultivated grounds, and the variety and rarity of the trees, shrubs and flowers to be found in them, will one day make it famous.

This land of promise, like England, Japan and the shores of Puget Sound, lies near a warm ocean current, which regulates the temperature and modifies the extremes of heat and cold, and no other part of our country, except the Pacific coast, has so equable a temperature and so great a rainfall; while, besides innumerable lakes, ponds and brooks, inexhaustible supplies of water may be had from underground.

It is true that much—though by no means all—of the soil is poor. Sometimes it is of sand and nothing else; but meadows, pockets of loam, and large muck-beds furnish plenty of other material. Where soil is lacking it can be made or imported, if need be, but climate and rainfall can neither be produced nor bought. Besides, sand is a much better basis than either gravel or clay, and is a most useful, often an essential, constituent; and without admixture of any other soil will convey to a plant all the artificial food that may be supplied. The loss of nutriment by leaching through sand is a theory with the weight of evidence against it.

That the neighborhood—indeed, the whole of Cape Cod and Nantucket—was once covered with noble trees, is matter of record; that it will and does now support such is matter of demonstration; for within a short drive of Wareham are hundreds of acres of tall forest, containing scores of tall trees, giving convincing proof of the capability of the soil. The Atlantic coast of Massachusetts is not fended from the cold northerly winds from seaward; but here the Cape intervenes, and the wooded shores of Buzzards Bay afford a local protection which is invaluable. Here are found, then, the best climate, the maximum of water-supply and shelter, and we have soil, or the means of making it.

The aim of good taste should doubtless be to choose, for the purpose of giving pleasure, only those trees and shrubs that grow cheerfully and thrive; and while great variety and rare specimens add much to the interest of a collection, experiments with doubtful exotics are inconsistent with that sense of rest, harmony and gladness which one would wish to produce in a natural garden. At the same time, it cannot be denied that there is a fascination in trying these experiments; nor can it be denied that English gardens, for instance, have a quality which we can never get, because we have not the plants that furnish them so richly.

Even here, on and about Buzzards Bay, I doubt if the English Laurel—which is a necessary part, singly and in masses, of every cottage-yard and every lawn in England—can be left in the ground the year round. The fantastic Chili Pine, which there breaks the sky-line so picturesquely, and emphasizes the quiet order of the garden, probably cannot, but the English Holly and the Cedar of Lebanon, on the other hand, undoubtedly can, for both have survived more than one winter and summer here; so has, indeed, the Exmouth Magnolia, the most brilliant in leaf of any of them, but it is not thrifty. About Boston even the American Holly is grown always with difficulty, and rarely with success; here it is native, and is delightful in the vigor of its green when other leaves are gone, and in its brilliant decoration of scarlet berries.

Here two most beautiful and much-neglected trees, the Tupelo and Sassafras, are in their own home. A real Tupelo cannot be had from a nursery—a nursery-bred tree has neither character nor foliage. The only way is to choose in some pasture or upland an orthodox-looking Tupelo, not over-large—one that has decidedly a look and way of its own—and then, with a long-bladed narrow post spade, to cut a circle round the tree, severing every root on the way, and to drive the spade through under the tree, dividing the down-going roots as well. Wait a year, and then in the spring move your tree. Let the new hole be dug four feet deep, even though the same soil is replaced; fertilize it liberally, for which purpose wood-ashes are excellent; and by and by you will have a tree of some interesting and beautiful shape, covered with more leaves than can be found in the same space on any tree, each leaf as rich in color and lustrous as that of an English Holly, and the whole tree in autumn a jewel of deep and brilliant color.

The Sassafras, with the liveliness given by fresh color and variety in the form and motion of the leaves, is a charming tree all summer; and, as every one knows, its leaves turn with great beauty in the autumn. It may adopt, or be made to adopt, other forms than that of a succession of parasol-like layers of leaves on a slender trunk, which is its natural habit. If cut down close, it will sprout into a bush; suckers will appear on every side until a thicket appears, rising everywhere to the middle, a natural bit of artificial work; or, again, a good-sized stem may be cut five or six feet from the ground, and the tree forced to grow so freely that the branches droop and the whole becomes a pile of charming foliage, and a mass of glowing color later.

Returning again to the advantages of the place, there are many trees and shrubs more or less useful, more or less doubtful, elsewhere in Massachusetts, which may be counted upon here. Among these are the Sweet Gum, with its star-shaped leaves that keep their color and freshness long into and often beyond October; and even then keeps many that are green as a setting for the crimson-maroon and golden-yellow of the rest. The Hollies, the ever-green sweet-scented Magnolia glauca, the Irish Yew and Juniper, the Golden Yew, the Cypress, all the Retinisporas, are thrifty here; and I am told by a most trustworthy person that there is a Live Oak of considerable size, of many years' standing and in good health, near Kingston.

Many of the ornamental evergreens which elsewhere must be stored in the pit, or, if left out, are made ragged with frost-bites and brown patches, appear here after the winter in perfect condition, with no protection except perhaps mulching; so do, of course, Rhododendrons and Mountain Laurel, which flourish greatly.

With such advantages, may one not look forward confidently to the fulfillment of a belief that this will become a region of delight to the lover of landscape-gardening?

Boston, Mass. *Wm. Minot, Jr.*

Pitch Pine from Seed.

To the Editor of Garden and Forest:

Sir,—A large field, worthless for cultivation, almost pure sand, in places a little loamy, is growing up with Bayberry, Sweet Fern and Golden-rod. Would seeds of *Pinus rigida* catch here, and if so, how should they be sown, or is there any chance of success in using other tree-seeds, and if so, what sorts—either deciduous or evergreen? Expense is very much to be considered.

Providence, R. I. *Bayberry.*

[Such land as our correspondent describes will quickly produce a crop of Pitch Pine (*Pinus rigida*); but it often possesses more plant-food than its natural plant-covering would indicate, and such land will often grow White Pines, Oaks and Chestnuts of a considerable size and value, as the plantations made in East Greenwich, Rhode Island, by Mr. Henry G. Russell demonstrate. The best way to plant Pitch Pine is to sow the seed in the spring with an ordinary seed-sower in shallow furrows four or five feet apart each way; but, as the surface of this particular piece of ground is already more or less covered with dwarf shrubs and other plants, it would be cheaper to scatter the seed broadcast over the surface and take the chance of a sufficient number germinating to cover the ground with plants. White Pines are best transplanted when ten or twelve inches high. It is a good plan to plant acorns of the White, Red and Black Oaks and Chestnuts among young Pines, to replace these in case they are destroyed by fire or other causes, or to take their place after the Pines are cut. The seeds of such deciduous trees can be quickly and cheaply planted in holes an inch or two deep, made with an ordinary walking-stick. The holes, after the seeds have been dropped in, should be covered by a pressure from the foot, which will make the soil compact over them. The seedling Oaks and Chestnuts will exist for years under the dense shade of the Pines, and will grow rapidly as soon as light and air are admitted to them.—Ed.]

Recent Publications.

The relation of electric light to vegetation is a subject of interest to horticulturists, both from a scientific and economical standpoint, and therefore we are glad to see in Bulletin No. 30, of the Cornell Experiment Station, an account of what Professor Bailey accurately calls "Preliminary Studies of the Influence of the Electric Arc Lamp upon Greenhouse Plants." The bulletin contains some forty pages, and therefore we are able to give only a condensed account of the methods employed and the conclusions reached.

A forcing-house, twenty feet by sixty, was divided into equal portions by a partition, one of which was left under ordinary conditions of sunlight during the day and darkness at night. The other had sunlight during the day, and in the first series of experiments an electric light was suspended from the peak of the house, which was run all night from dusk to daylight. The same kind of vegetables were planted in each compartment, and, as a rule, the general effect of the electric light was to hasten maturity, and this acceleration was greater as the plants were nearer to the light. This tendency was particularly marked in Endive, Spinach, Cress and Lettuce, so-called "leaf-plants." They ran to seed before edible leaves were formed, and the leaves of those near the light were small and curled. The Spinach under electric light matured good seeds, while that in the dark house was still making large edible leaves with no indication of flower-stalks. The microscope showed that there was apparently the same amount of starch in the plants of each compartment, though the starch-grains of the plants under the electric light were larger, had more distinct marking and gave a better color-test—that is, they seemed more perfectly developed than in the others. Lettuce behaved in the same way, most of the plants being killed outright for three feet on either side of the lamp soon after they came up, and the plants which survived were seriously injured, the leaves being curled and small. The plants increased in stature and vigor and size of the leaves as they were at greater distances from the lamp, and those nearest the lamp made the most of their leaves early in their growth. The plants at five weeks all ranged from a little more than one inch to a trifle over two inches high, while the average height of the plants in the dark house was two and one-quarter inches, and they were much more vigorous and had larger and darker leaves. In two varieties of Cress the plants under the electric light were in bloom although they were small and sickly, while those in the dark house were strong and vigorous, with good leaves and no blossoms. Endive gave practically the same results. It chanced that two rows of plants were parallel to each other in the lighted house, but one was shaded by an iron post only an inch and a half in diameter, while the other stood in the full rays from the arc. Two months after planting, the average weight of the plants in full light was about fifty grains, and that of the plants in the shade of the post was ninety-four grains, while the average plant in the dark house of the same age weighed 575 grains, and had larger leaves and of a better color than those grown in the other apartment. Young Radish-plants seemed strongly attracted by the electric light, and in the morning they all leaned at an angle of from sixty to forty-five degrees toward the lamp. During the day-time they all would straighten up again, but would reach out for the lamp on the succeeding night, and this was repeated until the roots began to swell and the plants became stiff. When the Radishes were large enough to market, the entire plants in the light house were lighter by nearly half than those in the other compartment, while the tubers were lighter by more than fifty per cent., and there were three times as many of these large enough for market in the dark house as there were in the light house. All these results are made very striking in the bulletin by reproductions of photographs, which show clearly the differences, while chemical analysis showed that plants under the electric light had reached a greater degree of maturity than those under normal conditions.

Altogether it was plain that the plants in the lighted house were injured, and the question was, whether this was due to the quality of the electric light or to the fact that the plants were in continuous light during the entire twenty-four hours. To settle this point some plants were covered during the day so as to receive no sunlight, although they were well ventilated, and the covers were removed so that they could receive electric light for twelve hours during the night. But under these conditions Radishes made but a sickly growth, assumed a faint green color, and died within three or four weeks. An experiment of the same character was now conducted on a larger scale when the hours of sunlight were about equal to those of electric light, and the plants were shaded, not completely, but only from the direct rays of the sun, so that they could receive diffused light. They quickly died. Lettuce, Beans, Corn and Potatoes repeated the same lesson. Plants which had already been well started behaved in the same manner, so that it seems to be established that, within the range of an ordinary forcing-house, a naked arc-light running through the night is injurious to some plants, and that it was not found profitable in any case.

The fact, however, that the light hastened maturity or seed-bearing suggested that some modification of the light might be useful under certain conditions, and, therefore, an experiment was made with a protected light running through the night; that is, a white opal globe was placed over the lamp, and, for five weeks, experiments similar to those formerly described were carried on. The effect of this modified light was much less marked than that of a naked light, the plants showed less tendency to run to seed, and were not so much affected by proximity to it. Lettuce, however, was decidedly better under the shaded electric light. This fact that the Lettuce, as well as the leaves of Radishes, grew larger under the subdued light than in ordinary conditions, indicated that there might be conditions under which artificial light could be made profitable to the gardener, and therefore an experiment was made, during the early part of the present year, with the naked light running for a portion of the night only. The house was arranged as before, but the lamp was connected with the street-lighting system, so that it never ran on moonlight nights, and only for a few hours on dark nights. Under these conditions Lettuce was greatly benefited. The plants were fit to market two weeks earlier in the lighted compartment than they were in the other. They were on the benches only forty-four days before the first heads were fit to sell, and during this time there were twenty nights in which the electric light had not been run, and during the whole time there had been but eighty-four hours of electric light, which

would cost about $3.50. It was not known how far the influence of this light would extend, but it was noteworthy that the results were as well marked in the most remote parts of the house as they were near the lamp.

These results suggest many questions which can only be answered by further trials. We need to know whether there is any particular time in the life of the Lettuce-plant when electric light has a predominating influence; whether a mild light is as good as a strong one; whether the failure of the light during moonlight nights is a drawback; to what distance the influence of the light extends; whether the same results can be obtained by hanging a lamp over the house as inside of it, so that several houses could be lighted at once; and whether any other plants can be profitably forced by electric light.

Experiments with ornamental plants showed that the influence of light upon the productiveness and color of the flowers varied with different species and different colors of the same species, and that there is usually a perceptible gain in earliness under the lamp, so that on the whole it seems possible that electric light can be used to pecuniary advantage in floriculture.

The second part of the bulletin gives an account of the experiments tried elsewhere, commencing with some made by Hervé-Mangon thirty years ago, and including those of Dr. Siemens, which have been published in the *Proceedings of the Royal Horticultural Society*, and of Dehérain's tests conducted at the Exposition d'Électricité, which were published in the *Annales Agronomiques*, vii., 551.

In conclusion, it appears, from the many conflicting and indefinite results so far obtained, that the problems to be solved vary widely under different conditions and with different plants. The points made clear are: The electric light promotes assimilation, and often hastens growth and maturity; is capable of producing natural flavors and colors in fruits; often intensifies colors of flowers, and sometimes increases the production of flowers. Since it is found that periods of darkness are not necessary to the development of plants, there is every reason to suppose that the electric light can profitably be used in growing them. It will be necessary, however, to overcome the injurious influences which this light exerts upon plants too near it and the too rapid maturing of some species—in short, a whole series of practical adjustments of conditions to individual circumstances is required. So far, we have learned more of the injurious effects of the light than of the beneficial ones, but this means simply that we are learning definite facts concerning the influence of the electric light upon vegetation, and in some cases, especially in the Lettuce tests carried on at Cornell, this has already been found a useful adjunct to a forcing establishment. Professor Bailey concludes this highly interesting and instructive bulletin as follows:

"The experiments suggest many physiological speculations upon which it is not the province of this bulletin to enter. Yet two or three of them may be mentioned. It is a common notion that plants need rest at night, but this is not true, in the sense in which animals need rest. Plants have simply adapted themselves to the conditions of alternating light and darkness, and during the day they assimilate or make their food, and during the night, when, perforce, assimilation must cease, they use the food in growth. They simply practice an individual division of labor. There is no inherent reason why plants cannot grow in full light, and, in fact, it is well known that they do grow then, although the greater part of growth is usually performed at night. If light is continuous they simply grow more or less continuously, as conditions require, as they do in the long days of the arctic regions, or as our plants did under continuous light. There is no such thing as a plant becoming worn out or tired out because of the stimulating influence of continuous light.

"It would seem, therefore, that if the electric light enables plants to assimilate during the night, and does not interfere with growth, it must produce plants of great size and marked precocity. But there are other conditions, not yet understood, which must be studied. Our Radish-plants, and many others, were earlier, but smaller, under the influence of the light. Observation and chemical examination showed that a greater degree of maturity had been attained. Perhaps they assimilated too rapidly; perhaps the functions of the plant had been completed before it had had time to make its accustomed growth. Perhaps the highly refrangible and invisible rays from the electric lamp have something to do with it. In fact, this latter presumption probably accounts for much, if not all, of the injury resulting from the use of the naked light, for the effect of the interposition of a clear pane of glass is probably to absorb or obstruct these rays of high refrangibility. Good results which follow the use of a globe or a pane of glass show, on the other hand, that the injury to plants cannot result from any gases arising from the lamp itself, as has been supposed by some observers. In our own experiments, particularly with the Brush lamp, there was no perceptible odor from the gases of combustion; and it may also be said that commercial forcing-houses, like our own, are not tight enough to hold sufficient quantities of these gases to injure plants.

"It is highly probable that there are certain times in the life of the plant when the electric light will prove to be particularly helpful. Many experiments show that injury follows its use at that critical time when the plantlet is losing its support from the seed and is beginning to shift for itself, and other experiments show that good results follow its later use. This latter point appears to be contradicted by Dehérain's results, but his experiments were not conducted under the best normal conditions.

"On the whole, I am inclined toward Siemens' view, that there is a future for electro-horticulture."

Periodical Literature.

The mid-August issue of the *Revue Horticole* describes the interesting and important discovery of a French entomologist, Monsieur Lemould, who has devised the means of destroying the larvæ of the Hanneton, the insect which in this country is known as the May-bug or Dor-bug, and which for years has done a serious injury to agriculture and horticulture in France and in this country also. Monsieur Lemould has been studying a cryptogamic plant parasite on the larvæ of the Hanneton, and has been experimenting with it at Céaucé, where he found a field so infested with the white grubs, as these larvæ are usually called here, that the sod could be lifted with the hand. About ten per cent. of the grubs was dead, their bodies being covered with a white moss-like cryptogamic growth. The dead were placed in contact with healthy grubs, and these at the end of a couple of weeks had all contracted the disease. Two months later the spread of the parasite had made enormous progress, the affected grubs amounting to from sixty to seventy per cent. of the whole number left alive in the field.

On the 25th of last July Messrs. Prillieux and Delacroix communicated to the Academy of Science the result of their experiments on the destruction of white grubs by the aid of *Botrytis tenella*, a minute cryptogam, whose spores propagate with prodigious rapidity, and which they had cultivated in the following manner: A large crockery dish was set in a cool, shady place and filled with a thin layer of moist sand. Upon the sand were placed one hundred white grubs, and these were covered with the spores of the plant reduced to powder. A covering of damp moss was then placed over the grubs, and the whole was covered with boards. In six or seven hours the grubs were infected, and were then planted in an infested field. The disease spread rapidly, and at the end of a few months destroyed all the grubs, which died by myriads.

The practical results of these experiments are assured, it appears, and this new insecticide can be purchased from certain French chemists, who are prepared to deliver tubes filled with it similar to tubes of vaccine. "We cannot foretell yet," the editors of the *Revue* remark, "what results this discovery will have for our agriculture or say that if its employment is easy, practical and cheap, it will enable our agriculturists to fight a pest which ravages whole regions, as was seen three years ago in the departments of Mayenne and of Orne, but it seems, at least, that it is capable of rendering immense services to horticulture."

The July number of *Pharmaceutische Rundschau* contains an instructive article on the alleged poisonous properties of the Wild Parsnip, that is, the common garden Parsnip, *Pastinaca sativa*, when it has run wild. It is stated in Dunglison's Medical Dictionary that this is an irritant poison, and this is a widespread popular belief. Dr. Frederick Power, however, read a paper before the Wisconsin State Medical Society last June, in which he gives the result of his investigation of several cases of what was said to be poisoning by the Wild Parsnip, which he had seen reported in the papers. In every case where fatal effects occurred it was found that the root eaten was not the Parsnip but *Cicuta maculata*, a plant which belongs to the same family, and is known under the common names of Spotted Cowbane, Musquash Root and Water Hemlock. So far as Dr. Power's investigations go, the wild Garden Parsnip is not at all poisonous when taken, either in a raw state or when cooked. Since this root of Cicuta is most frequently taken for the wild Parsnip, and since such mistakes are often attended with fatal results, the distinguishing characters of the two roots are given. *Cicuta maculata* has

an oblong thick fleshy root-stock, or a fascicle of fleshy tubers, which sends out several strong light-colored rootlets in a horizontal direction. The interior of the root is nearly white, and contains one or more cavities formed by the absorption of the tissue, and these cavities, which form one of the special and most important characteristics of the Cicuta root, may be easily seen when it is cut longitudinally through the centre. The root, when cut in this way, exudes drops of a yellow resinous juice which possesses a strongly aromatic odor closely resembling that of the Parsnip. The taste is at first sweetish, but afterward sharp and acrid. Cuts of the two roots are reproduced from Dr. Power's paper, in which their individual characters are very plainly seen.

Notes.

The first elementary work on botany published in this country bore date 1803, and was written by Professor D. S. Barton. The systematic teaching of botany in American schools seems not to have begun until some twenty years later.

Professor Goodale has commenced the publication in the *American Journal of Science* of a series of short sketches of the botanic gardens in the equatorial belt and in the south seas, which he has visited in his recent journey around the world.

At its recent meeting in Washington the Association of Agricultural Colleges and Experiment Stations passed a resolution urging the Secretary of Agriculture to do what he could to secure the passage of a law or laws for the preservation of the public forests.

Several of the large Palms in Horticultural Hall, Fairmount Park, have been fruiting freely this season. Among them are three or four specimens of *Seaforthia elegans*, and the long drooping branchlets of the flower-clusters are studded with fruits of various colors, from olive-green to dull red, according to their degree of ripeness. *Thrinax elegans* has also produced an abundant crop of seeds in the same establishment.

Flower-beds arranged geometrically are not always to be commended, but a circular bed filled with succulents seems to attract more attention than any among the large number of beds in Fairmount Park, Philadelphia, this season. The bed is between twenty-five and thirty feet in diameter, and special care has been taken in arranging the thousands of plants it contains with due regard to their individual forms and colors.

Mr. C. L. Allen says, in the *American Agriculturist*, that in cultivating the Amaryllis the most common mistakes are (1) the use of too large pots, (2) the too deep planting of the bulbs, and (3) too frequent shifting. As a rule, the bulbs should not be more than half-covered with soil, and they should not be shifted until the pots are filled with roots, and then they should be placed, while resting, in pots only one size larger than those they were occupying.

It is observed by many persons in the east that the California pears, which are so plentiful this year, are better-flavored than in former years, although they are somewhat smaller. This change is attributed to the fact that the California fruit-growers no longer keep their orchards irrigated up to the time when the fruit ripens, but shut off the water when the pears are well grown, so that they are permitted to ripen in the California sun and wind without the aid of artificial moisture.

The value of our native *Viburnum cassinoides* has often been insisted on in these columns. At this season of the year no hardy shrub, whether in flower or in fruit, equals it in beauty. The fruit is now bright pink, although in many of the clusters some of the berries are flesh-colored, and others have already assumed the dark blue of their maturity. The contrast of the colors of the different berries among themselves and with the large and lustrous leaves is beautiful. This inhabitant of our northern swamps takes kindly to cultivation, and is worthy of a place in any garden.

The common Stramonium, or Thorn-apple (*Datura Stramonium*), is, in some parts of New England, generally called "Jamestown-weed," or, by elision, "Jimson-weed." This name, says a recent writer in the *Atlantic Monthly*, sprang from the fact that the plant, which was medicinally esteemed, had been brought over by the Jamestown colonists and "spread miraculously" from the place of its first establishment. At an early date it had become so troublesome in the New Haven colony that a law was passed to enforce its destruction as "a great, stinking, poisonous weed."

Every year there is a more general appreciation of the truth that public pleasure-grounds are indispensable to every urban community where the health and happiness of its citizens are considered worthy of attention. The last legislature of Pennsylvania recognized the tendency of public sentiment in this matter by passing a law to enable the various cities of that commonwealth to acquire lands for park purposes. It authorizes all cities in Pennsylvania to purchase and hold ground for such purpose, and empowers the councils of such cities to enact ordinances for the purchase, improvement, management and control of such ground; to enforce said ordinances by proper penalties; and to make appropriations for the payment of property acquired under authority of this act.

The botanists who attended the meetings of the American Association for the Advancement of Science at Washington last month were each presented with a neat little hand-book, entitled "The Trees of Washington," which had been prepared by Geo. B. Sudworth, Botanist, and B. E. Fernow, Chief of the Forestry Division. It contains a list of all the trees in the grounds of the city, with numbers to indicate the park in which specimens are to be found. The grounds containing the greatest variety are represented by plans, with a list of the species of trees there found and the location of the individual trees indicated. The different parks and grounds of the capital contain many interesting trees which are overlooked for lack of such a guide, and this list, with the accompanying plans, will prove acceptable to many other visitors, as they did, no doubt, to the Botanical Club for whom it was prepared as a souvenir.

A letter from the Acting Chief of the Department of Horticulture of the World's Columbian Exposition informs us that the building for the horticultural department, which is to be located immediately south of the entrance to Jackson Park, in the main portion of the World's Fair Grounds, will be 1,000 feet long, with an extreme width of 286 feet. The plan embraces a central pavilion, with two end pavilions, each connected with the centre by front and rear curtains, which form two interior courts, each 270 x 88 feet. These courts are to be decorated in color and to be planted with ornamental shrubs and flowers. The central pavilion is to be covered by a dome 187 feet in diameter and 113 feet from the ground, under which it is proposed to exhibit tall Palms, Bamboos and Tree Ferns. The contracts for the building have been let, the estimated cost being $400,000. We are told that the horticultural exhibition is to excel anything heretofore attempted.

Mr. J. J. Willis, who superintends the experiments of Sir John Bennet Lawes, says that it is now admitted at Rothamsted that free nitrogen from the air is fixed in the growth of some leguminous crops under the influence of suitable microbe infection and the development of nodules on the roots of the plants. How this fixation is brought about is yet unknown. Dr. Gilbert does not believe that the plant accomplishes this through its leaves, nor that the microbes do the work in the soil so that the roots can take up the nitrogen compounds, but that the nitrogen, by the aid of the organisms, is fixed in the root-nodules, and from thence absorbed and utilized by the last. Among many interesting queries suggested by this now recognized fact, is one as to the cause of "Clover sickness." Experience has shown that clover, in many cases, cannot be grown by ordinary methods on lands where it once flourished. Is this because of the absence of the microbes which help to form the nodules and fix the nitrogen?

In a recent quarterly number of the *Journal of American Folk-lore* reference is made to a paper called "Popular Names of American Plants," which was read at a meeting of the Boston Association of the American Folk-lore Society last spring by Mrs. F. D. Bergen. This lady is desirous of completing a collection of such names, and, says the Journal, "as the interest and value of a good collection of popular plant-names is obvious, it is very desirable that persons who may be able and willing to contribute should send their material to Mrs. Bergen, Cambridge, Massachusetts," or else to the editor of the Journal itself. In connection with this notice is printed a letter from a resident of Massachusetts, in which are cited scores of popular plant-names current in various parts of New England at the time when the writer was a child, and which includes many that seem unfamiliar to-day. One of the most curious is Election Pink, applied to *Rhododendron nudiflorum*, "because in bloom at the old-time 'election' when the governor took his seat"; and another is Heart's-ease, since it was applied, not to the Pansy, but to *Polygonum Persicaria*, more commonly called Lady's-thumb. A pretty term was Baby-feet for *Polygala paucifolia*, and another for *Arisæma triphyllum*, which New England children now call Jack-in-the-pulpit, was Lady-in-a-chaise.

GARDEN AND FOREST.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, SEPTEMBER 23, 1891.

TABLE OF CONTENTS.

The Possibilities of Economic Horticulture.

"SOME of the Possibilities of Economical Botany" was the subject selected by Professor Goodale for his valedictory address as President of the Association for the Advancement of Science, and it is one of exceptional interest. An attractive field of speculation opens before us at once as we begin to inquire what plants the coming man will use for food and forage, for timber and tanning, for fibre and cordage, for perfumes and flavors and medicines. This is especially true when we are reminded that of the more than one hundred and ten thousand species of flowering plants known to exist on the globe, scarcely one per cent. are utilized to any considerable extent by man. If we include the Ferns, Mosses and Liverworts, the Algæ, Fungi and Lichens, the percentage of utilized plants will be much smaller still. The questions discussed by Professor Goodale were: How can this short list of useful plants be increased to advantage? What likelihood is there that our future food-supply will include other vegetables, fruits and cereals than those we now use? Will new fibres replace those we now spin and weave? Will new remedial agents be discovered among plants now unknown or neglected?

Omitting a consideration of the cereals we find that the plants which would be more strictly classed as horticultural have undergone remarkable transformations under cultivation. Wild Cabbage, a tall perennial weed of open growth, shows to the unscientific observer scarcely any likeness to the garden forms with which he is familiar. The largely developed leaves of some of these forms are imbricated and overlapped into a compact spherical, conical or flattened head; others, like Borecole and Kale, have branching leaves; in some, like Broccoli and Cauliflower, the flower-stems have been transformed into fleshy edible masses; in others, as in the Kohl-Rabi and Turnip-rooted Cabbage, the stem or root has been developed into a large ball, and there are others still with modifications in the ribs of the leaves or in the axils of the shoots, or in several organs together, to produce such varieties as Brussels Sprouts, the Marrow Kales and many more. The Cabbages have been cultivated since the earliest historic time, and no one knows how many years of selection have been needed to produce these striking morphological changes. But the Tomato is younger as a garden-plant. It is a native of America, but, although cultivated more than three centuries ago in Europe, it has come into general use only within the memory of men still living. It is not unreasonable, therefore, to suppose that there are many garden-plants now used only to a limited extent which merit a wider employment, and which we may hope can be developed into much wider use. Professor Goodale names some of these, and he also suggests that we may expect to obtain from Japan, for example, whose flora is closely related to our own, many other vegetables which are already used there. Dr. Curtis, of North Carolina, has suggested that we have in the unutilized Mushrooms an immense amount of available food of delicious quality, and we may add that researches now in progress at the Experiment Station of Indiana prove that many other Fungi furnish nutriment of the best quality, and that they can be largely improved by careful selection.

The improvement which has been made in oranges, pears, apples and other fruits, within historic time, suggests that there is an opportunity for much further development, and Professor Goodale adds that there is no reason why we should not have strawberries without seeds, blackberries and raspberries with only delicious pulp, and large grapes as free from seeds as the small ones which we call currants, but which are really grapes from Corinth. Coreless apples and pears, stoneless cherries and plums, must be propagated by bud division, it is true, but bananas and pine-apples have been propagated in this way for centuries. Then, many of our wild fruits are promising subjects for selection and cultivation. The common Blueberry and its allies are, no doubt, worth trying to improve, and so is the Juneberry and others. The eastern coast of Asia will, beyond question, add largely to our future fruits, and it cannot be long before the list is considerably increased. Professor Goodale went further, and discussed the probability of new timbers and cabinet woods, new vegetable fibres and tanning materials, new resins and new plants for fragrance and flowers, and spoke of the need of systematically investigating plants of promise under the most exhaustive conditions. When our botanical gardens, museums and laboratories of economic botany, as well as our experiment stations, work together, with the co-operation of all persons interested in scientific matters in the domain of commercial and industrial botany, we may reasonably hope for discoveries of immediate and growing importance.

But there are possibilities of horticulture in other directions which are well worth considering. As increasing population presses upon the world's food-supply it is a matter of interest to know to what extent the productive powers of the earth can be increased. As new fruits and vegetables are brought into use we ought to be learning how to obtain the greatest quantity from a given area within a given time, and with a given outlay of labor and expense. Even now the difference between the amount of wild fruit which an acre will naturally yield and the amount of the same fruit which an equal area, carefully prepared, will yield under cultivation is enormous. An acre of wild Cranberry-vines, fighting for life with the other vegetation in a swamp, would give but a few bushels at most, and these could only be gathered at considerable trouble; but on the leveled and sanded bogs of Cape Cod the uniformly loaded vines on a single acre have yielded a hundred and fifty barrels, and even more, of choice fruit, or a barrel of berries to every square rod. This is accomplished by thorough preparation, sleepless care, clean cul-

ture and the proper use of fertilizers. The market-gardeners about Paris are able to pay $125 a year rent for an acre of land and yet make a good living. A thousand bushels of potatoes to the acre can hardly be counted an impossible crop in this country, even with our present knowledge, and in the island of Jersey the money returns from a glass-covered garden of thirteen acres exceed those of an English farm of thirteen hundred acres.

But it is not reasonable to assume that the best crops which can be produced with our present knowledge illustrate the maximum productiveness of the soil. As we learn more of the laws which govern the growth of plants we ought to be able to supply conditions more and more favorable to the highest success. We have much to learn, for example, of the relation of light to plant-growth. Experiments at Cornell University have shown that Lettuce, by the use of an electric light, can be forced to sufficient maturity for table use in six weeks from planting, while eight weeks are required to grow plants to the same size without the light. There is little doubt that further experiments will prove that artificial light can be used to still better advantage in many cases. The French market-gardeners have already found it profitable to warm the soil by hot-water pipes, and this indicates another direction in which, especially when glazed sashes are used to cover the ground, vegetation can be hastened, and additional crops secured from the same land every year. Sub-irrigation, especially with diluted sewage, has multiplied production enormously in the neighborhood of some European and American cities, and the systematic use of this waste matter is yet in its infancy. The mines of Stassfurt and the rocks of South Carolina are already furnishing potash salts and phosphates at small expense, and new discoveries may render these elements of plant-food cheaper still. Nitrogen is yet expensive, but when some economical method is discovered of collecting it in available form from the limitless supply of that material in the air, garden-crops can be cheaply fed with all the nutriment they are able to assimilate. It has long been known that microscopic plants do an important work in the soil in preparing food which plants can take up and digest, and these organized ferments will, no doubt, in time become articles of commerce supplied by special breeding establishments.

Altogether, we may hope, without presumption, that, in the times next ensuing, our improved fruits and vegetables, as well as plants for ornament, can be grown more rapidly, more abundantly and more cheaply. Increased knowledge now enables us to hold in check plant-diseases and injurious insects, before which we were powerless a few years ago. Recent progress in the science and art of gardening justifies the belief that study and experience will in like degree increase our knowledge of the relation of light and heat and moisture, as well as of the mechanical and chemical constitution of the soil to the development of plants, and we shall devise means of controlling these conditions more perfectly and of adapting them more intelligently to horticulture as a business and as a diversion.

Monuments in Public Places.—IV.

ANOTHER important question in the out-door placing of works of sculpture is whether they shall be seen from every side, or from one or two sides only. A figure or group not specially designed for a given spot is, of course, most beautiful when, as we walk around it, each step reveals new beauties of line and mass; and great injustice is done alike to the artist and the public if such a work is set where only one aspect can be appreciated. But, on the other hand, it is unfair to artist and public if a work that looks its best from one side only (and very likely has been designed simply to be thus beheld) is stationed so that the back will be as clearly seen as the front. We can thus imagine works which would be very unfairly treated if placed along the Mall in the Central Park, as here their backs could be seen only if a forbidden walk on the grass were taken; but there are many others to which, for the same reason, a place like the Mall offers the kindest possible hospitality. In general, seated statues are eminently well fitted for such a place as this, as their backs can seldom be given any strong quality of interest.

This question of desirable points of view is even more imperative than the question of scale in prescribing that, when a definite commission is given for a monument, the artist should know in advance just where it will stand; he can then decide whether he must consider all of its aspects with equal care, or may subordinate some to concentrate his attention on the one that will be of primary importance. Such subordination, by the way, even if it amount to total sacrifice, is a perfectly lawful and laudable exercise of the artistic prerogative. There is no more reason why the back of a statue standing out-doors should be as beautiful as the front if the back will never be clearly seen, as why similar care should be bestowed upon one that is to be fixed in a niche in a wall, or upon the groups of a pediment. If, when a statue is ordered, the sculptor is not told just where it will stand, then upon its completion he, and no other, should choose its place; but, of course, in view of the possibility that no thoroughly good site may present itself, it is always best that the question of site should be a preliminary one.

Works of sculpture, or of architecture and sculpture combined, are just as appropriate to a pleasure-ground when their value is simply artistic as when they are monumental, historic in character. Indeed, as the chance that a high degree of beauty will be secured is greater in such works than in commemorative ones, it is especially desirable, for the sake of the public's pleasure and the development of its taste, that these should be the ones generally placed in our parks. When they are concerned the question of site will almost always arise after the artist has finished his work; but it should be as carefully considered as with regard to portrait statues, and likewise their pedestals should be as carefully designed. For neither class of objects is a simple, plain base always the best; and nothing less than the best should ever satisfy us in constructions of so permanent a sort.

It would be well, too, if those who give non-commemorative works of art to our parks would intelligently consider what special kinds are fitted for such service. Of course, no general rule can be laid down; but we may say that, broadly speaking, a statue or group for out-door placing is best when it has a definite out-door character itself. The Falconer in the Central Park, to which we have already referred, is, in idea, an excellent out-door figure, and so is Mr. Ward's Indian Hunter; while the group called Auld Lang Syne seems to cry out for a roof above its head, and no one would care to see under the open sky a figure, for example, of a mother rocking her baby to sleep. Questions of exact placing, moreover, are involved in the general question of appropriateness. Ward's Indian Hunter looks well standing on the edge of the road under a spreading tree; but a portrait-statue would look badly there, and very badly, indeed, perched on the rocky slope where we can see the Falconer without strong objection. In certain retired nooks, provided some other formal elements were present to sustain their own artificial character, we can fancy little groups of animals or figures of a rustic character looking well, though a commemorative bust or figure would seem sadly out of place.

For obvious reasons, it is less easy to give the right out-door look to a seated statue, even of a purely commemorative kind, than to a standing or mounted figure; but such a one might look better in portions of a park, where people sit at rest and the idea of repose is prominent, than in a city's streets. Seward, poising his pen on the corner of Madison Square, looks sadly out of place, and many travelers must have noticed in London the almost comically inappropriate air of the seated figure of George Peabody surrounded by the rush and clamor of the busy city. Sometimes the architect might well be called in to

the aid of a seated statue, to furnish not merely a fitting base, but some sort of a canopy or roof which will mitigate the impression that it ought not to be out-of-doors. It would be interesting to know just how the Greeks and Romans treated this question of seated statues; it almost seems that they must have preferred to place them under porches or colonnades rather than boldly beneath the sky; but, in any case, our climate is not the climate of Greece, and a statue sitting placidly with its lap full of snow does not produce a very fortunate effect.

Finally, the question of treating the ground around the base of a monument should be given due attention. The equestrian statue of Washington in the Public Garden at Boston is excellently placed, near the boundary of the pleasure-ground at the intersection of its main paths. But, this summer at least, it has had a curiously inappropriate look which, upon examination, was seen to result from the wide bed of tall, ornamental plants encircling its base. The profusion of these plants hid the connection of the pedestal with the soil and thus deprived it of solidity of aspect, while their freely waving leaves had no artistic relation to its rigid lines. Did it rise naked from the smoothly clipped grass it would look much better, but, best of all, if partly draped in a closely clinging vine which would not disguise its form, and, instead of separating it from the ground, would more intimately connect the two. Nothing is more beautiful than the way in which the French use Ivy to drape the pedestals of their open-air statues, and even where these stand, as we think they should not, in the centre of open lawns, the mistake is partly condoned by unifying creepers. So far as we remember, the French never surround a statue with a high growth of foliage-plants or a wide pattern-bed of flowers. The distinction between a right and a wrong method of treatment is here perfectly clear and valid: the vines unite themselves to the monument and unite it to the ground, while the pattern-beds supply a third element which has no vital relationship to either turf or stone. The good effect of vines on pedestals may be studied in a few places in this country also, as on the pedestal of the Webster in the Central Park. One would like to see them planted around the statues on the Mall as well, and, afterward, carefully restrained from undue luxuriance. For such a purpose, we need hardly say, the best possible creeper is the so-called Japanese Ivy, which looks as though nature had invented it to serve the architect's needs. The Ivy is not so certain to prove hardy in our climate, and, though the Ampelopsis loses its foliage in winter, even then its beautiful net-work of delicate branches seems to tie the stones to which it clings to the bosom of mother earth.

Formally clipped plants, growing in simple but handsome pots, would sometimes be appropriate around the base of a monument, especially if it were placed on a terrace; and in certain other cases a plantation of shrubs may be desirable, though rather as a background to the pedestal than encircling it. Such a background is positively needed by the Farragut monument on Madison Square, and was, undoubtedly, contemplated by its makers. It will look much better than it does now when, from the rear, only the figure itself is visible.

When we think of the variety in effect that might be secured to our parks by monuments carefully planned for given situations—as for niches in foundation-walls, for the crowning of balustrades and bridge-parapets, the adornment of drinking-fountains, the completion of rond-points, and the lining of formal avenues—most of what has been already done in these places seems unimaginative and monotonous. The chief trouble has been that we have thought too little of the question of site. When we order a statue we are too indifferent as to where it may go; when we buy one already made, we are too careless in its placing. Whatever thought we have thus far given has been directed to the works themselves; now we should begin to think of them in a wider way, as chances for the architect as well as the sculptor, to give more care to the matter of appropriate and helpful bases, and especially to use the utmost pains and invoke the most skillful help in their eventual placing.

Northern Plants in Pennsylvania.

THAT part of the Appalachian Mountains between the west branch of the Susquehanna and the Juniata, in Pennsylvania, would be thought rather tame and uninteresting by the lover of mountain scenery. Although erosive action has been enormous here, as in other mountain regions, the absence of any but local glacial action has left a surface but little varied. There are no lakes or ponds, and but few and small marshes, while the low mountain-ridges, running north-east by south-west, are frequently so close together as to leave only long narrow valleys, or even none at all.

But the interesting features in any region are always multiplied by search and careful examination, and if extensive surface waters are here unknown, the great springs in the limestone districts and the frequent sinks or disappearance beneath the ground of streams of considerable volume are sure to attract the attention of the traveler and excite his curiosity and interest.

Years ago I was told that somewhere in these mountains ice accumulated so abundantly, and was so well protected from waste, that it remained through the whole year. As time went on, and no such place could be found, it was put down as one of those exaggerations to which new-comers are so often treated. But one day, picking up General Brisbin's "Trees and Tree-planting," this astounding statement was found in the introduction, where the natural features of this very district were being described: "If we turned over a rock in the mountain-side we found ice beneath it even in the hottest days of August." Having turned over a great many rocks on that particular mountain-side, and never having found any ice in August, the whole matter was cast out of mind as useless rubbish, when within a very short time an interesting botanical discovery was made. *Linnæa borealis* was found in a wood which had been under close observation by botanical students for a number of years, and yet I knew of no record that the plant had been seen here before. Running over the back numbers of the *Botanical Gazette* to see if this or other northern plants had been recorded from this part of the state, an interesting note was found (vol. ii., p. 8), from Mr. J. R. Lowrie, of Huntingdon County, in which not only were such species named, but their persistence in a given instance was credited to the perpetual ice which was found among the rocks in late summer about three feet below the surface. The precise locality was named, and visits to it have shown much of botanical interest, besides confirming, in the main, what was said regarding the ice.

Spruce Creek is a small tributary of the Juniata running parallel to Tussey Mountain for several miles. About three miles above its mouth, near Colerain Forge, in Huntingdon County, it cuts close in to the mountain-side, and by wearing away the easily eroded Utica shale has exposed a nearly vertical wall of the overlying Oneida sandstone. For ages this cutting and scouring have been going on until at the base of the wall, and running into the stream itself, lies a heavy talus of broken rock from the undermined cliff. In the interstices of these rocks ice forms readily in great quantity in cold weather, and such is the protection afforded by the sweep of the mountain itself as well as by the cliff, that but little direct sunshine is received, and that only in midsummer. Until then it is only necessary to throw aside a few blocks of stone in order to reach the ice, but as the season advances it retreats further and further until late summer, when it is frequently, probably commonly, so deep that it is inaccessible except by a great deal of labor. But its presence is shown by the low temperature of the rocks and the surrounding air. Bending low in any of these ice-holes one's breath quickly becomes visible, as on a winter's day in the frosty air. No ice could be seen at the date of my last visit, August 28th, but old residents in the vicinity are quite positive that in some years ice has been taken out during the entire season, although it was necessary to dig deep for it during August and September.

While a large part of this talus is completely bare, there are portions of it which support a poor growth of the ordinary trees and shrubs of the vicinity. But near its base are found, particularly, our Mountain Ash (*Pyrus Americana*), Canoe Birch (*Betula papyracea*) and *Ribes prostratum*, none of which are common elsewhere in the neighborhood, except at occa-

sional points at greater elevation. Of humbler plants, *Heuchera pubescens* and *Linnæa borealis* are the most conspicuous, the latter, in great profusion and of great vigor, spreading widely under the adjacent Pines and Hemlocks, where it seems perfectly at home. One can scarcely imagine a more perfect example of a high northern flora localized on a few square rods, because of favorable temperature conditions.

As if to give emphasis to this little boreal colony among the rocks, there is found, scarce two hundred yards away, a narrow intervale bordering the stream, which here makes another abrupt turn. Upon this alluvial bottom grow a score or more of vigorous Papaws (*Asiminia triloba*), with trunks six, eight and ten inches in diameter. Their lustrous dark green and pendent leaves mark them at a distance as distinct from any other native tree, and suggest a grove of Horse Chestnuts. They must have been here a long time, for they seem perfectly established, fruit readily, and young trees are not uncommon. One such clump, strangely placed high and dry on the border of the dusty pike two hundred yards away, seems quite successful in its struggle for existence. Professor Porter long ago told me that the Papaw followed the Juniata, and was found at the mouth of Spruce Creek. He may have referred to these same trees. I know of no others to the north, and infer that these mark the furthest point for this species in the mountain districts.

A fine *Aristolochia Sipho*, clambering over and well-nigh smothering a Red Cedar, seemed to add to the southern character of this Papaw bottom.

A grove of stately White Pines completes the attractions of this unique spot, which is a favorite picnicking ground for the neighborhood. In the early summer such parties frequently make ice-cream on the spot, using the ice taken out of the holes in the rocks.

State College, Pa. *W. A. Buckhout.*

Notes on North American Trees.—XXVIII.

THE synonymy of the Texas Cercis, or Red Bud, is peculiar. This plant appears to have been first collected by Berlandier, in the region of the lower Rio Grande, as long ago as November, 1828, one of his specimens of that date being preserved in the Gray Herbarium. Lindheimer, many years afterward, found it at New Braunfels and sent it to Engelmann, who called it *Cercis reniformis*, but did not publish his name, or anything about the plant. Gray, in the second part of the "Plantæ Lindheimerianæ" (*Bost. Jour. Nat. Hist.*, 1850, p. 177), was the first author to describe it, making it a variety of *C. occidentalis*, "var. *floribus etiam paulo minoribus, foliis supra nitidioribus*," referring to the *C. reniformis*, Engelmann, but without taking up Engelmann's manuscript name for his variety and without giving it another. Torrey next mentioned it in 1859 in the "Botany of the Mexican Boundary Survey" as *C. occidentalis*, confounding it with the California species, and Hemsley, much later, did the same in his "Botany of the Biological Survey of Central America." Watson, in his "Bibliographical Index to North American Botany," next called the Texas Cercis *C. occidentalis*, var. *Texensis*, but in the "Botany of California," and later, in a list of plants from south-western Texas and northern Mexico, collected chiefly by Dr. Edward Palmer in 1878–80, and published in vol. xvii. of the *Proceedings of the American Academy*, called it *C. reniformis*. This name, as of Engelmann, had, moreover, appeared many years before without description in Roemer's work on Texas, in which it was, no doubt, included by Scheele, who supplied the botanical parts on the strength of specimens which Engelmann had probably sent to the Berlin Herbarium, with which he was always in active correspondence.

From this it appears that the first published specific or varietal name is Watson's *C. occidentalis*, var. *Texensis*, and the Texas plant, being considered distinct from the California species, should be called *C. Texensis*.

Mr. Sereno Watson calls my attention to the fact that the date of the publication of Ventenat's "Description des Plantes Nouvelles et peu Connues Cultivées dans le Jardin de J. M. Cels" is not 1803, as I had supposed, but 1800, which, being the date of the publication of *Robinia viscosa*, that name must take precedence of *Robinia glutinosa*.

C. S. Sargent.

Filices Mexicanæ.—I.

WE take pleasure in offering our readers an enumeration of the Ferns collected in the states of Nuevo Leon, Jalisco, San Louis Potosi and Machoacan, Mexico, during the seasons of 1888, 1889 and 1890, by C. G. Pringle, of Charlotte, Vermont, with notes and descriptions of new species and varieties by George E. Davenport, of Medford, Massachusetts.

Mr. Pringle's Fern collections are now so well known that it may be of interest to preface these notes with some extracts from his correspondence, in which he describes the regions where, for the most part, the Ferns herein enumerated grew. Writing from Chihuahua, under date of August 4th, 1888, he thus described Monterey and vicinity, where, during the early part of 1888, his collection was principally made: "Delightful are my memories of Monterey, a quiet pleasant city, with lofty precipitous mountains round about it on three sides, mountains furrowed with cañons shady with numerous grand trees, and musical each with its clear, cold brook. It is the paradise of Ferns! Common as any weed on the foot-hills which overlook the city was *Adiantum tricholepis*, so rare hereaway. On limestone ledges or bluffs, soft and crumbling, whose bases were laved by water, was *Aneimia adiantifolia*. *A. Mexicana* was very abundant on moist shaded banks of the base of the Sierra Madre. *Aspidium trifoliatum* on limestone ledges dripping with water. On moist shaded banks *Cheilanthes meifolia* (Palmer's find of 1880) was abundant; with it a Pellœa which I don't know, and an Aspidium strange to me. What I guess to be *Llavia cordifolia* was common near brooks of the mountains, and rare there a Polypodium which I never saw, and in their dark, cold nooks still another Polypodium, with annual fronds. Here, of course, *Aspidium patens* was luxuriant, and sometimes *Pteris Cretica*."

Pellæa flexuosa, *Cheilanthes leucopoda* and *Cheilanthes aspera* are some of the other Ferns mentioned by Mr. Pringle in the letter just quoted. Subsequently, on his return home to Charlotte, he sent to me the following interesting account of "The Haunts of Ferns about Gaudalajara":

"Some six miles northward from the city the great St. James River (Rio Grande de Santiago) which carries the overflow of Lake Chapala down to the Pacific, falling more than 5,000 feet in a course of 250 miles, has cut a chasm through the plains which the proud city crowns, and among various chains of low mountains which interrupt those plains and this chasm is the great barranca of Gaudalajara. You stand on the verge of the plain and see the river rushing white 1,500 feet below you. Beneath your feet are dizzy cliffs on cliffs, steep grassy slopes and still deeper descents which are a luxuriant growth of tropical shrubs. Here and there, over these steeps, springs start from the rock or rise from the soil, and streams leap down to the river. Against the face of fearful precipices they hang as a slender veil of a waterfall, or they saturate the rich soil of the thickets. All the diverse situations on the slopes of the great barranca are the favorite haunts of some Fern or other, whether it be the dry cliffs in sun or shade, the ledges of cliffs sprayed by falling water, the deep shade of thickets clustered by brook-sides, the cool and moist grassy banks, or the mossy banks and ledges in the humid forests near the river.

"Down to the river from among the hills come lesser cañons, each with its noisy brook, which sometimes pours over a precipice in its way, and diffuses over the adjacent walls a perpetual mist or spray.

"Again, just north of the city walls, a strange thing has happened. The occasional floods from the plains above have cut gullies, sometimes broad, grassy and shaded with trees; sometimes too narrow to admit the passage of your body. The walls of these are twenty to fifty feet high, perpendicular, firm sand or gravel, more or less moist. From the foot of these walls water drips, and close by a a brook flows.

"Still, again, there are conditions favorable to Ferns supplied by man. It is customary to mark the bounds of highways and fields by trenches five to ten feet deep. Along the edges of these are planted, or grow spontaneously, Cactuses and shrubs, so that shade is provided.

"At the end of my stay I crept for a long way through the vegetation filling a trench of this sort which borders the north side of the highway leading westward from the city gate; and I remember declaring to a friend, as I came out of it, that I had seen on its steep moist banks nearly all the Ferns which I had met with in all the region roundabout.

"Now you can form a definite idea of the habitat of the species of my collection from the words borne by their tickets."

The numbers herein used should correspond to those on Mr. Pringle's tickets accompanying his distribution.

ACROSTICHUM ARANEOSUM, D. C. Eaton (2590). Shaded cliffs near Guadalajara, November, 1889.

Fig. 71.—Asplenium Pringlei.—See page 448.

ACROSTICHUM SPATHULATUM, Bory (2606). Cool damp bluffs near Guadalajara, November, 1889.

ADIANTUM CONCINNUM, H. B. K. (1866). Moist shady banks near Guadalajara, November, 1888.

ADIANTUM CONVOLUTUM, Fournier (1868). With 1866.

ADIANTUM PATENS, Willd. (1869). Cool grassy slopes of the Barranca, November, 1888.

ADIANTUM TENERUM, Swartz (3360). Cool ledges, Tamasopo Cañon, San Luis Potosi, 1890.

ADIANTUM THALICTROIDES, Willd. (1867). Moist shady banks, Guadalajara, November, 1888.

ADIANTUM TRICHOLEPIS, Fée (1981). Foot-hills near Monterey, abundant; (1843) moist shady places in the Barranca, near Guadalajara, December, 1888, scarce.

ANEIMIA ADIANTIFOLIA, Swartz (1977). Moist calcareous river bluffs, Monterey, June, 1888.

ANEIMIA HIRSUTA, Swz. (1833). Moist slopes near Guadalajara, November, 1888, and with it a deeply cut form approaching Baker's var. *tenella*.

ANEIMIA MEXICANA, Klotzsch (1976). Moist ledges and banks, Sierra Madre, near Monterey, June, 1888.

ANEIMIA PHYLLITIDIS, Swz. (3361). Moist shady banks, Las Canoas, November, 1890.

ANEIMIA TOMENTOSA, Swz., var. *fulva*, Hooker and Baker (1834). Moist slopes, near Guadalajara, November, 1888.

ASPIDIUM ACROSTICHOIDES, Swz. (2604). Sierra Madre, near Monterey, August, 1889.

ASPIDIUM ATHYRIOIDES, M. & G. (*Nephrodium syphærocarpum*, Hook.), (1840). Wet banks and ledges, near Guadalajara, December, 1888. This and *A. patulum*, it seems to me, are scarcely more than forms of one protean species, *A. Mexicanum*. The differences between them all are hardly greater than those which exist between the different forms of *A. spinulosum*.

ASPIDIUM JUGLANDIFOLIUM (1982). Cool, shaded cañons, near Monterey, June, 1888; and again in Tamasopo Cañon, June, 1890.

ASPIDIUM MEXICANUM, Kunze (2605).

ASPIDIUM PATULUM, Swz. (3362). Shaded ledges, hills of Patzcuaro, November, 1890. See remarks on *A. Athyrioides*.

ASPIDIUM TRIFOLIATUM, Swz. (1983). Wet ledges and banks, Sierra Madre, near Monterey, June, 1888.

ASPLENIUM CICUTARIUM, Swz. (3365). Rich soil, mountain sides, Tamasopo Cañon, November, 1890. Specimens remarkably fine and beautiful.

ASPLENIUM ERECTUM, Bory (3413), normal form; (3412), var. *proliferum*, Hooker, both from rich forests, Tamasopo Cañon, November, 1890; and (3367) var. *sub-bipinnatum*, Hook., from rich soil, mountain sides, Tamasopo Cañon, November, 1890. The last two very proliferous.

[NOTE.—I have preferred to follow the authority of Sir William Jackson Hooker here, in using Bory's name in preference to *A. lunulatum*, Swartz, notwithstanding the eminent authority of Mettenius and Kunze, because, if, as Dr. Hooker stated in the "Species Filicum," no authentic specimen and no authentic intelligible description of Swartz's species exist, and if, as Dr. Hooker asserted, the plant itself was really unknown to Swartz, it is difficult to understand upon what justifiable grounds the adoption of Swartz's name rests.]

ASPLENIUM FRAGRANS, Swz. (3364). On rocks and trees, Tamasopo Cañon, November, 1890.

ASPLENIUM FURCATUM, Thunb. (3363). On Oaks, hills, Patzcuaro, state of Machoacan, November, 1890.

ASPLENIUM PRINGLEI, *n. sp.* (1837). Root-stocks tufted; fronds clustered, 3′ to 9′ tall, ½′ to ¾′ broad in the middle,

narrowed both ways, evergreen, pinnate, with from twenty to thirty pairs of variable oblique pinnæ; stipites short, blackish brown, naked, or with a few slight scales at base; pinnæ generally subsessile, 2" to 5" long, half as broad, deeply cut into irregular oblique obtuse lobes, unequally wedge-shaped at base, cut away most on the lower side, and sometimes almost if not wholly dimidiate, often truncate at base on the upper side with the superior basal lobe again deeply cleft into incised lobes; lower pinnæ gradually reduced, more equal-sided, ovate, slightly stalked, with cuneate or truncate bases, and cleft into three incised lobes; rachis, blackish brown, like the stipes, channeled, flexuose, curving from above the middle into semicircles; sori large, borne on the free veinlets in two to four pairs, each sorus, when mature, filling an entire lobe, and set obliquely to the costa.

Habitat: Wet cliffs, near Guadalajara, state of Jalisco, December 5th, 1888. This very lovely Fern bears some resemblance to the incised form of *A. Trichomanes*, and it is closely allied to that species. It differs from that species, however, conspicuously by the unusual size and position of the prominent sori, which are placed within and near the edges of the lobes, so that the fructification appears to be marginal, and by the remarkable curvatures of the exceedingly flexuose rachises. In some specimens there appears to be a slight membraneous edge running along the sides of the rachis and round the margins of the pinnæ, having the appearance of a faint bloom when held to the light.

The excellent portrait of this Fern, on page 449, is from a drawing by Mr. C. E. Faxon.

Foreign Correspondence.

London Letter.

THE end of the flower-season in the open-air garden is approaching, and the Dahlias almost monopolize the attention of florists, for the unusually wet and cold August has been disastrous to such flowers of the sun as Gladioli and Lilies, which are the features of English gardens in August. This week I have had a look in at some of the nurseries, and the finest flowers of the season, to my mind, are the hybrid French Cannas at Cannell's, at Swanley. No doubt, the grand productions of Crousse have already crossed the Atlantic, and your lovers of brilliantly colored flowers and noble foliage already have the older kinds under cultivation. These gorgeous plants have come upon us all of a sudden, for I know of no flowers that have been improved in such an extraordinary way in so short a time, and our French neighbors seem to have been at work upon them before we were aware of it. The French florists seem to take the initiative in the production of new races of garden-plants, which they do with few exceptions; Roses, Gladioli, Delphiniums, Ivy Pelargoniums, Montbretias, Chrysanthemums, Caladiums, of all of which we have now such a variety, are mainly due to the enterprise of the French hybridists. These Cannas are well worth a long journey to enjoy, for the brilliancy of their flowers en masse rising from their handsome foliage is different from the ordinary run of greenhouse plants. There are now a good many sorts, mostly all with French names, but those that pleased me most were the following: Paul Bert, a noble, tall-growing variety, with broad leaves stained with plum-purple and large Gladiolus-like flowers of a brilliant orange-red; Francois Morel, three feet high, flowers an intensely deep crimson; Keteleeri, dwarf flowers, orange-scarlet; Edouard André, brilliant orange-scarlet, rather tall, and certainly one of the finest; Wilhelm Pfitzer, flowers large and of the richest deep crimson, remarkably showy; Madame de Grillon, flowers yellow, with red centre; Jules Chretien, flowers large, brilliant scarlet; Comte de Choiseul, dwarf, only about one and a half feet high, and similar in color to the last; Admiral Courbet, cherry-crimson; Professor David, a very distinct sort, with flowers scarlet, blotched and margined on the petals with yellow; Legionnaire, tall purplish foliage, vivid crimson flowers; T. S. Ware, orange-scarlet. These comprise a dozen of the very finest kinds, and though from description they may seem to be similar to each other in color, they are really distinct, either in growth or shade of color. The best time to obtain a stock of Cannas is when the plants are in a dry state in autumn; they will then travel as safely as bulbs, and I am taking with me to India a large number of the best kinds. I can foresee what grand plants they will be in masses in the open, as the common *Canna indica* is one of the most effective plants there in the garden-landscape.

At Veitchs', at Chelsea, one may see another new race of hybrids which is purely of English origin. These are the hybrid Streptocarpuses, which Mr. Watson has already mentioned. It may be well to add, however, that these new Streptocarpuses are regarded here as one of the most important novelties that have been produced by skillful hybridizing. It seems but a few years ago when the species from which these hybrids have been mainly produced were obscure botanic garden-plants, and even up to within a year or so they were not generally known, and Mr. Watson had raised his first crosses at Kew long before even the nurserymen knew about them. But now that the Messrs. Veitch have taken up the thread of the work where he left off, we shall soon see these beautiful plants common in every greenhouse, for they need only to be seen to be appreciated even by those who will only look at showy plants. The species that have been worked upon were generally known in cultivation under the names of *S. Rexii*, *S. biflorus*, *S. floribundus*, *S. polyanthus* and *S. Saundersi*, but it was not until the extraordinary monophyllus species, *S. Dunni*, was introduced that any decided break was obtained. This species has a huge leaf, and produces an abundance of dull red small flowers, different in tint from any of the rest, so that there was something to work upon. Mr. Watson raised several striking crosses, among them being those named *S. Watsoni* and *S. Kewensis*, the former especially showing in its flowers the distinct reddish color of *S. Dunni*. Among the multitude of seedlings he has raised you may single out every shade, ranging from pure white to bright purple, stained with plum-purple and violet, and these are the foundation that the hybridist at Veitchs' had to work upon. Now one may see seedlings at the Chelsea nursery by the thousand, planted out in cold frames, and flowering profusely, and, naturally, some show an advance on the original Kew hybrids both in size of flower and variety and brightness of coloring. It may not be rash to predict that eventually we shall have Streptocarpus-flowers as large as those of Gloxinias, the horizontal-flowered type of which they somewhat resemble. As the Streptocarpuses are so easily grown in an ordinary frame during summer, or in a greenhouse, they are destined to become popular, and the fact that they flower so freely and so continuously for several months in the year enhances their value. I counted as many as twenty flowers on a small plant at Veitchs', and being on slender long stalks they are very suitable for cutting. Already the seed of these hybrids is enumerated in the seed catalogue of the firm, so that a pinch of seed may be obtained that would furnish enough plants for a greenhouse.

As this is the dull season for Orchids they comprise one of the features of the great Chelsea nursery, but I lingered over the other great feature at the present time, which is the Nepenthes, or Pitcher Plant house, which, at this season, after the pitchers have reached full size and color, is at its best. Among the kinds that the grower points out as being of superlative merit is the new *N. Northiana*, named after Miss North, the traveler and artist who, I believe, discovered it. It has the full-grown pitchers, over a foot long and from three inches to five inches broad, heavily spotted and striped with crimson on a pale green ground. It is extremely handsome in form also, as the broad rim of the pitcher is shaped and reflexed in a beautiful way. The other new or notable Pitchers are *N. Burkei*, *N. Curtisii superba* and *N. cincta*, which has the pitchers most beautifully marked with crimson and purple-crimson on pale green. But I consider the finest of all is *N. Mastersiana*, which has a number of red pitchers on every small plant, and has a striking effect among the others. It is

such a strong grower, and produces pitchers so freely, that it is decidedly one of the best.

Coming to Kew, one finds some remarkable plants in flower, perhaps none more interesting to the general public than the Wedding Flower of Lord Howe's Island. *Iris Robinsoniana*, which has flowered for the first time at Kew, has been illustrated in the daily papers, and has been inquired for by visitors more than any other plant during the past month. It is certainly a noble plant, producing a huge tuft of long, reflexed leaves and flower-branched spikes, five or six feet in height, on which numerous flowers expand in quick succession day after day. The blossoms resemble those of *Iris Kæmpferi*, but are smaller; they are pure white, with blotches of clear yellow at the bases of the petals. *I. Robinsoniana* has been described and figured in GARDEN AND FOREST, vol. iv., p. 355.

The "Wedding Flower" absorbs more interest at Kew than the grand climber, *Solandra grandiflora*, which is in flower close by. This, though an old plant from South America, is rarely seen in bloom. It has very large tubular, or rather funnel-shaped, flowers of a creamy white, stained with purple, inside the tube. It is a rampant climber, but may be grown and flowered in small pots, as Mr. Parker used to do, in his nursery at Tooting, in the old days.

Another climber I must mention as being a great attraction at Kew just now, and, indeed, has been throughout the summer. This is *Solanum Wendlandii* (see GARDEN AND FOREST, vol. iv., p. 258), a tropical American species, and, I consider, the finest of the cultivated species. It has huge clusters of rich, mauve-purple flowers, two inches across, which are produced abundantly and hang from the long rambling shoots in a most graceful way. It is, I believe, not in commerce yet, but when it is readily attainable it will be sought for as a choice stove climber. A more modest climber, but very pretty, is *S. Seaforthianum*, which is a less vigorous plant, and bears much smaller flowers in drooping clusters. This is also in flower in the stoves at Kew.

W. Goldring.

Kew.

The Bermuda Onion.

THE island of Bermuda, where the Onion, Potato, Tomato and other garden vegetables make their most vigorous growth from December to May, lies seven hundred miles due south-east from New York, and eight hundred miles due east from Charleston, South Carolina. The temperature from November to June ranges from fifty to seventy-five degrees, never higher, never lower, with never a greater monthly range of temperature than twenty-three degrees, or a greater daily range than fourteen degrees. It is in such a climate as this that the Onion grows with that mild and delicate flavor which gives the Bermuda product a special value on account of quality apart from the advantage it has of coming at an unusual season.

Fig. 72.—Harvesting Onions in Bermuda.

The seed (black seed) of this Onion is all grown in Teneriffe Island, and is of two kinds, one producing white bulbs, and the other red bulbs. The white variety matures from two to three weeks earlier than the red, but is not quite as sweet. No other seed seems to be worth planting in this climate. I have tried many kinds from all parts of the world—black seed, tops, buttons, potato onions, and many more, with the invariable result of a fine crop of "scullion"; they absolutely refuse to "bottom," while with the black seed Teneriffe nine out of ten will make fine bottoms.

The seed is very thickly sown in rows eight inches apart in seed-beds three feet wide, these beds being prepared with the most scrupulous care and enriched with enormous quantities of well-rotted cow or pig manure. The failure of these seed-

beds means the failure of the crop. The first sowing is usually made the last week in September—at the time when the northern farmer is getting ready for the long winter—and the sowing is kept up with seed of both varieties until the first week in November, and this gives a succession of plants for transplanting into the fields. This transplanting begins in December and continues until the middle of January.

The fields are little pockets of earth scattered here and there over the island, being deposits in the depression between the rocks at some period during the submergence of the island; they seldom contain an area of more than two acres, and the larger proportion of them contain less than half an acre. These fields are usually surrounded with Oleander-hedges to keep off the winter gales which are likely to do some harm to tender vegetation. The soil is prepared with great care by plowing or spading in stable-manure, sea-weed and every artificial fertilizer known in the market. Beds three feet wide are made by treading paths through the field, and in these beds the little plants, about as large as a goose-quill, are transplanted from the seed-beds. This is a rather slow process, but the Bermudian farmer finds it much the best method of cultivation. It is often asked by Americans, "Why not sow the seeds in the field to begin with, and thus save all this labor of transplanting?" In the first place, the Onion makes a better growth and forms a better bulb when transplanted, and not two out of a hundred plants are lost by transplanting, as they are sure to take root, and in two or three days are just as fresh as when they were taken from the seed-bed. Again, it takes from four and a half to five months for the Onion to mature for the market from the seed, and from two to two and a half months of this period, while the plants are in their tender growth, is spent in the seed-beds, where one man can weed and care for enough plants for ten acres. If these plants were in the fields, at this stage, it would take at least ten men to keep the weeds down, and therefore much labor is saved. Bermuda weeds do not succumb to the hoe and sun as in the north, but each weed must be carefully pulled by the roots and carried away to the pig-pen or else spaded deep in the walkways.

I suppose no land is free from plant-disease, and the Onion here has its diseases, though the only one causing much trouble is a fungus growth, attacking the leaf just as the bulb is forming, causing the leaves to rot and arresting the growth of the bulb.

When the Onion is ready for the market, men, women and children, mostly colored, are employed to pull, pack and cart to the steamer, packing the Onions in bushel crates made from box stuff brought in shooks from Maine. These crates, when ready for packing, cost about twelve cents each. During the crop season a steamer is loaded and departs for New York every Thursday. The balance of the year we only have fortnightly communication with New York.

The number of crates harvested from an acre varies with the year, season and amount of disease. I have known eight hundred crates to be gathered from an acre, but probably two hundred is nearer the average. The price varies with the season, usually opening in January at $2 a bushel box here, and rapidly dropping to $1.50, and then on down to $1 and to 75c. in May.

The average price paid here for the past six years is as follows: 1886, $1.35; 1887, $1; 1888, $1.65; 1889, 53c.; 1890, $1.44; 1891, $1.28.

The quantity shipped for the same period is as follows: 1886, 154,000 bushels; 1887, 197,000 bushels; 1888, 163,000 bushels; 1889, 227,000 bushels; 1890, 252,000 bushels; 1891, 261,000 bushels.

The total number of acres cultivated on the island in the winter of 1890-91 in Onions, Potatoes, Tomatoes and Beets was 2,422.

Much alarm was felt over the M'Kinley bill, as onions now pay to the United States a duty of forty cents per bushel, but, after all, the price kept up well through all the season. The Bermudians generally feel that they pay this tax, as that amount has to be paid before they can enter into competition with the American farmer. $104,400 was paid into the United States Treasury by somebody because of the importation of 261,000 bushels of Bermuda Onions into the port of New York during the winter of 1890-91. As the average price paid here was less than any year, except one, during the past six years, I am inclined to think we pay the tax.

Hamilton, Bermuda Island. *Russell Hastings.*

[The illustration of an Onion-field in Bermuda, on page 451, gives a fair idea of the general appearance of the scanty farm-land on the island and the ever-present Cedars.—Ed.]

Cultural Department.

Insecticides for Greenhouse Plants.

In the press of fall work the cleaning of plants is often postponed until some more convenient time, and this is usually regretted afterward when the stock is found permanently injured by the ravages of scale or other insects. Among Palms, for instance, some of the scale insects are the most troublesome, and if allowed to remain on the foliage or stems for any length of time the plant will be badly disfigured. A whale-oil soap solution, made by dissolving one ounce of the soap in one gallon of water, or a very weak kerosene emulsion, may be applied with a spray-pump or syringe about once a week, with good effect, though if a plant is badly infested with scale it will need more than mere spraying to clean it. In using the kerosene emulsion it is safest to make the solution rather weak, to guard against injury to the young foliage if the liquid drains down into the heart of the plant.

Some of the prepared insecticides, for instance, Fir-tree oil, may also be used in the same manner, and they are doubtless of some value, though much more expensive than the home-made remedies. Thrips are best controlled by the use of tobacco-stems for fumigating, or the infected plants can be dipped in tobacco-water, the latter plan being most convenient where many kinds of plants are grown in the same house. Red spider is seldom found among plants that are syringed properly, but when it gets a foothold in a warm house the plants should be carefully sponged at once.

The so-called "spot" on Pandanus, and on *P. utilis* especially, is caused by a minute mite or insect, and is not, as some have supposed, due to a fungus, and the most satisfactory remedy is thorough dusting with sulphur. The credit of this discovery should be given to Professor Halstead, of the New Jersey Experiment Station, who kindly examined specimens and suggested the remedy which has proved effective in practice.

The Ferns are subject to various insect pests, the most injurious of which are scale and thrips, and as these plants will not endure as much smoke as the insects will, it becomes necessary to depend on dipping the plants in weak tobacco solutions. Some of this trouble may be avoided, however, by keeping the Fern-house as cool as the welfare of the plants will permit during the winter. Many of the best-known species thrive admirably in a temperature of fifty degrees at night. Another troublesome pest to the Fern-grower are the snails, and while the old-fashioned method of spreading about the house cabbage-leaves or pieces of potatoes as traps is still a good one, yet a cleaner and more efficient plan is to sprinkle camphor among the plants. This gum is so obnoxious to the snails that a few pieces the size of a pea thrown in the crown of a large Adiantum will surely drive them out. Of course, the camphor needs renewing from time to time, as it soon evaporates, and, consequently, will cost rather more than the old vegetable remedies.

Among other insecticides that I have tested for general use are corrosive sublimate, one part in solution with 2,000 parts of water, and carbolic acid in various degrees of strength, but with little success in either case. Acetic ether is useful at times to destroy mealy-bugs in the flower-trusses of Ixoras or Stephanotis, but it should be applied with a camel's-hair brush. Sulphate of lime has been recommended for scale on Orange-trees, but my experiments with this mixture on some young Palms have not proved successful.

Holmesburg, Pa. *W. H. Taplin.*

Border Flowers in Autumn.

Erythrolæna conspicua.—This plant, the "Scarlet Mexican Thistle," as it has been styled, promises to be useful for sub-tropical bedding, for, though only a thistle, it has an imposing appearance when well grown, and when in flower arrests attention at once by the bright-colored bracts of the flowers. From a packet of seeds sown in February we obtained three plants, which were liberally treated, and one of these is now flowering. It is six feet high, with branches overshadowing a square yard of ground. The plant is distinct in habit, and, when in flower, very ornamental. It is necessary to sow the seed early in the year to get the plants to flower the same summer, as our seasons are too short, and, as it is, we shall not be able to obtain any seed this year.

Helianthus mollis.—Of the many species of hardy Sunflowers this is one deserving of front rank as a hardy garden-plant. I know of no species that flowers with such persistency, for since it began in July we have always had an abundance of bloom, and there are still many to follow until frost comes.

Part of our plants were obtained from Tennessee, where it is said to occur occasionally in a wild state, and is often cultivated in gardens even there. Other plants were received from another source, which, I believe, was said to have been originally New Mexico, and this is quite probable, as this species has a wide distribution in the southern and south-western states; consequently there were doubts in my mind as to its hardiness, and a plant was left out in a cold wet border last winter. It came through safely, so there need be no doubt about it in the future, for in the same border strong and established clumps of *H. orgyalis* were completely killed, and so was the double *H. multiflorus*, so often catalogued as being perfectly hardy, which it certainly is not here. *H. mollis* grows about five feet high in good soil. The flowers are large, bright yellow, of good substance, and can be cut with long stems for vases, and when it is offered to the public and becomes better known will surely be appreciated as one of our very best hardy Sunflowers.

Helianthus grandiplenus.—This is our first season's experience with this new form of the common double *H. multiflorus* as introduced by Hartland, of Cork. There are said to be other forms distributed under this name, so care was taken to procure the true variety direct from the introducer. The difference in the individual flowers is not very apparent except by comparison, when it is seen at once that in the variety Grandiplenus the outer row, or guard petals, are not present, as in the older variety, making it quite distinct in that respect. Our plants, also, are much taller than in the older variety. One clump has grown eight feet high and is much more spreading in habit, the flowers also can be cut with longer stems; but these three traits may all be due to liberal treatment. It is to be hoped it will prove hardier than the older variety. Judging from the plant as it is, it is a question if there is any great advance made from the old double *H. multiflorus*, of which there are several very good single forms which do not seem to have gained popularity as they deserve, for they are as beautiful as single medium-sized Sunflowers for cutting purposes.

South Lancaster, Mass. *E. O. Orpet.*

The Water Garden.

Nymphæa Mexicana, of which Mr. Pringle wrote so charmingly in Garden and Forest (vol. iii., p. 415), may be botanically the same as *N. flava*, but it proves superior to the type in its more free-flowering habit. Growers generally find *N. flava* very slow to establish and very shy to flower, but *N. Mexicana*, in its second season here, grows strongly, with many strong runners, which quickly bloom, and it has given a long succession of its deep yellow flowers, which are attractive, though small. They are much darker than those of *N. chromatella*, and, unlike this variety, the stamens and petals are of the same shade.

N. chromatella, however, is far the best yellow Nymphæa, a strong, compact grower, easily propagated from its numerous eyes, and constantly in bloom. A strong plant, with only the root-room of a small box, has been constantly in flower since early May, and still has some buds unexpanded.

Eichornia (*Pontederia*) *azurea*, the new pond-weed introduced this year by Mr. Sturtevant, proves much superior to *E. crassipes major*, it being not more interesting, perhaps, but less weedy. The stems, produced freely, are sent out laterally, and from these flowers are produced very freely. The flowers, which are clustered on a short stem, are one inch in diameter, a dark purple, with a darker eye, and in every respect more attractive than those of *E. crassipes*. Unlike the latter plant, however, which is a weedy grower, whether floating or planted in earth, *E. azurea* requires planting in shallow places.

Elizabeth, N. J. *J. N. Gerard.*

In the Vegetable Garden.

As the nights grow cool Celery is making its best growth. Pick off the rusted leaves, keep it clean and never let it thirst for water. It is too early to earth up the main crop, but it is well, once a fortnight, to draw a little soil about the plants needed for early use. Celery will whiten now much more rapidly than it does after the middle of October.

Lettuce can endure a light frost, but it is better to have cold frames ready. Lettuce had better be planted now in frames, but sashes should not be used, except as a protection against beating rains, until heavy frost comes. It is a good time to sow Lettuce, and if the ground is kept clean among the plants they will head in November, and the rest of the half-grown plants will head in the winter.

Spinach can still be sown in sheltered beds facing the south, and some of the plants will be fit to use before winter sets in. At all events, it will be in good condition for early spring use.

When the Asparagus begins to turn yellow it is well to cut the beds over before the seeds fall, for the young plants will prove troublesome weeds in the bed next year. If the tops are burned it will lessen the attacks of the beetles next spring.

Cabbage and Cauliflower which are still growing should be kept well hoed. If Cauliflowers do not make full-sized hearts before freezing weather they can be heeled thickly in cold frames, and will be fit to use by Christmas. If the larger Cabbage shows a tendency to burst open it is good practice to loosen their roots with a fork.

Lima Beans that are not matured can be kept through early frosts by laying down the poles so that they can be covered by newspapers or muslin; and Snap Beans can be saved for a little while if protected in the same way. If you have no Snap Beans this autumn make a memorandum now to plant some of the prolific sorts, like the Valentine, next year for autumn use.

Montclair, N. J. *S.*

Pelargonium Blight.—During the present season the variegated Pelargoniums, or Geraniums, as they are commonly called, so popular for bedding and borders, have been noticeably blighted, and in some instances so much so as to become positively unsightly. As a rule, the outer or lower leaves are the most susceptible, but not rarely the best of the large central leaves become attacked. This blight is due to at least two fungi, working singly or together, and either one of them is able to do serious mischief. One of these fungi is a Colletotrichum, akin to that causing the anthracnose of the Vine and many other cultivated plants. There is little doubt that this blight could be checked by spraying with some of the copper mixtures. A second fungus is an Aschochyta, which may be called a leaf-spot fungus. This is more inclined to produce a well-defined infested area near the centre of the leaf, but the two enemies may work together upon the leaf. The same remedy is recommended.

Nematodes in Zinnias.—My attention has been called a number of times recently to a trouble among the Zinnias, and particularly *Z. elegans*. The lower leaves prematurely die, and hang upon the stems as crumpled brown masses, giving the afflicted plants anything else than a handsome appearance. Above these the leaves are more or less blotched with light brown, the affected areas varying in size and color, but usually quite angular in outline. The whole aspect of the sick plants suggested the work of eel-worms, and a microscope examination revealed them at work in the leaf-pulp, and in great numbers. Plants thus infested are beyond recovery, and should be burned. Last season eel-worms were mentioned as occurring in quite a number of the cultivated plants, and particularly the Chrysanthemums, Coleus, Lantanas, Bouvardias, Violets and Roses.

Rutgers College. *Byron D. Halsted.*

Cestrum elegans.—This is generally grown as a climber, and is best seen trained over an arch, where its graceful flower-stems, sometimes nearly two feet in length, hang out in all directions, with clusters of tubular wax-like pink flowers. It would be a most excellent plant for cut flowers but for its strong potato-like odor when handled, an odor which is not surprising, for it belongs to the *Solanaceæ*. Grown as a pot-plant it is equally handsome, and useful for decorative purposes. Cuttings taken in winter, and planted out for the summer, grow to a size which makes a twelve-inch pot necessary when they are lifted in autumn. My plants are showing flower-buds now in the open ground, and will bloom in the greenhouse through November and December, when I take a few more cuttings and throw the old plants away. Although used as a climber when grown in the open air, it shows no tendency to climb in the house, and makes good bushy plants without any trouble.

Peristrophe speciosa.—This handsome winter-blooming greenhouse plant is of very easy culture, and should be common. Cuttings which have been rooted during the winter, when planted out-doors make very neat plants by autumn, and, unless large plants are needed, they are more satisfactory in every way than old plants cut down, which are generally used. To have them bushy, they need to be "topped" two or three times during the season. They can be lifted with a good ball of earth, and usually go into a seven-inch pot. Their foliage is handsome. The flowers are labiate, crimson or pink in color, and are sessile on conical heads.

Correspondence.

The Boston Public Garden.

To the Editor of Garden and Forest:

Sir,—There are some questions that I should be glad to have answered with regard to the floral decorations of the Boston Public Garden.

We who live in the neighborhood of the Modern Athens naturally go there for our ideas about gardening, as well as other things, and we feel as if the Public Garden, which, next to the State House and Faneuil Hall, is an object of legitimate pride to that city, ought to furnish for the million the best sort of example.

That its directors, whoever they may be, understand their business no one ventures to doubt, but do they not make a mistake in trying to popularize the garden by introducing objects not in the best taste?

Is it conceivable, however the pure Greek artistic sense displayed itself in gardens, that Pericles and Aspasia would ever have encountered, at the foot of Mars Hill, such a horticultural construction as that which causes the bosom of the Modern Athenian to dilate with civic pride—Item, a spread eagle with a glass eye, complicated with a design of anchors, coiled ropes, and the shield of our country, surmounted by the letters U. S. N., painfully manufactured, at enormous expense, of minute plants of the requisite colors, and resembling nothing so much as those feats in worsted-work rugs which are the glory of agricultural fairs?

Would the Attic idea of color and form have found expression in floral hearts and rounds, aces of spades, crescents and likenesses to half-eaten doughnuts, brought out in shades that swear at each other in the loudest tones? Pink and yellow, deep crimson and scarlet, orange and rose-color, sometimes all six together in one bed, seem to be a favorite combination, to the defiance of harmony and repose.

Boston delights in sending missionaries of its somewhat Philistine civilization to Japan, why does it not occur to the philanthropists of the Flowery Kingdom to send it a few in return, missionaries of taste, whose "oriental eye" should educate it to a comprehension, if not of subtleties of color, at least to reticence in its use, and teach it, once for all, that the desire to mix crimson Coleus with scarlet Geranium is a temptation of the devil to be strenuously resisted.

Might it it not be well, too, that the same apostle should direct the curves of those labyrinthine paths, so that, however sinuous their course, they may lead somewhere, and not necessarily force you to come out, like the well-known parliamentary speaker, at the same hole you went in at.

Is the confusion of effect desirable or necessary? Is there not some way by which we could be given masses of color, and yet an element of repose? It is not that one objects to formal gardening, but to the lines on which that formal gardening is laid down. Certain ideas have occurred to me which I venture to submit for your approval, asking for correction if they seem unreasonable. And what especially strikes me is the thought of the great amount of money and labor necessary to maintain the grounds in their present condition, which, perhaps, might be expended to better advantage.

The Public Garden is in itself a lovely spot, well shaded, refreshing, with agreeable variety of shrubbery and grass, around a pond of shining water, that is a comfort to the eye and a means of amusement to innumerable children. With some few and inexpensive changes and some guiding taste, it seems as if it might readily be made the thing of beauty that it ought to be, to comport with the elegance and charm of the picturesque city of which it should be a thoroughly artistic ornament.

It is now conducted on an unnecessarily costly scale. The elaborate and doubtful floral designs once banished, with the Palms and Tree Ferns, money would abound for more pleasing adornment. The paths should, in the first place, be reconstructed, so that they would lead from one point to another without maddening turns upon themselves. The restricted patches of greensward should be combined into broad stretches of almost unnbroken lawn, shaded and cool, with borders and vistas of shrubbery that should seclude, and, at the same time, seemingly increase its extent.

Geometrical flower-beds and formal gardening need not be given up, but they should be confined, as in the great pleasure-grounds of Europe, to a central parterre in the neighborhood of the leading walk across the bridge, while the rest of the garden should be kept simple and restful.

The taste that demands eagles, and anchors, and designs drawn from the poker-table should be ignored, and an effort made to educate the public to an appreciation of something better. The instinct for beauty is strong in our people; though often misdirected, it can be easily influenced in the right direction by proper example in those public places which they frequent, and from which they bring away new ideas. The harm done by setting a false standard for imitation is incalculable.

The Public Garden should, above all things, be made a unit, and an intelligent design should animate the whole, and the varying parts be made interdependent. A pleasure-ground of this description is not a botanic garden, where it is necessary to exhibit myriads of incongruous things. Harmony and grace, and beauty, and continual bloom there should be, but not violent contrasts nor inharmonious groupings. There are numerous brilliant and beautiful flowers which could be kept protected in winter at a less cost than the great tropical things, that look so out of place when the east wind is whistling about their elephantine ears, and which would really render the grounds far more gay and charming and delightful to the popular eye.

The opportunities of the pond are wholly neglected, and we see none of those interesting groups of Lotus and Water Lilies that prove so attractive in New York, both in Central Park and in Union Square. If it is objected that the boats are incompatible with the Lilies, why could not some portion of the lake be set apart for their cultivation, and still leave room for the amusement of the children? The people all love these delicate flowers, which shows that they do not demand incongruous groupings for their satisfaction.

Why not make the Public Garden a school of appropriate floral design, rather than a museum of curiosities? The best intelligence and the subtlest perception are none too good to devote to it, since it should be properly regarded as a great educator. What people see here they imitate in their cemeteries, in their gardens, on their lawns. If purple and scarlet are seen combined in the Public Garden, you will find the same enormities repeated in handsome country places, whose gardeners think they have imported a brilliant idea. Canons of elegance must be laid down; beauty must be inculcated by a positive standard; teach what is lovely and of good repute, and education conquers even bad taste. How are we to know the evil from the good but by some striking example of loveliness and harmony to which all can repair for new inspiration? Such an example it is the duty of the Public Garden to set. To know a thing is wrong is easy; to know how to set it right is another matter; and nothing can be more idle than criticism which fails to suggest a remedy. This garden is a boon we all appreciate; the plants in it are remarkably well grown and healthy; we all desire that it should be perfect in beauty, and we ask nothing better than to be shown the paths of beauty that we may walk therein. Knowledge of plants is far more common than a proper sense of their artistic distribution, and it is for these we need the canons and the guiding hand.

Our Japanese apostle might find us unwilling listeners to the preaching of his crusade; but in his land, generations of cultured taste have made the very infants adepts, while the language of their subtle art is still foreign, and hard for many of us to learn. But its restraint, its simplicity, its delicate effect, we can study and practice in our clumsier fashion, until the lessons of ages shall have trained us, too, to a larger, a more subtle sense of what is alike beautiful and befitting.

Newton, Mass. *Sidney Hyde.*

Plants for Shady Places.

To the Editor of Garden and Forest:

Sir,—Will you kindly inform me whether *Daphne Mezereum* would thrive on the north side of a house, where the sun shines about two hours in the morning and perhaps a little longer in the late afternoon?

Millbrook, N. Y. *J. J. D.*

[Few plants can flower successfully on the north side of buildings when they are shaded during the greater part of every day. For such positions plants like the Periwinkle or the Ivy, whose chief beauty consists in their evergreen foliage, usually give greater satisfaction.—Ed.]

Periodical Literature.

In an article called "Woodlands," recently published in the *Nineteenth Century*, Mr. Herbert Maxwell reviews the extent and condition of the forest of Great Britain, and discusses the report of the committee of the House Commons which was appointed to investigate this subject in 1885, and formulated its conclusions two years later. This committee declared

themselves "satisfied that the management of our woodlands might be materially improved . . . and that some considerable proportion of the timber now imported to the (annual) value of £16,000,000 might, under more skillful management, be raised at home." They pointed out that, "whereas nearly every other civilized state possesses one or more forest-schools, there exists in this country (although it boasts a Department of Woods and Forests) no organized system of forestry-instruction except in connection with the Indian service." They unanimously agreed "in recommending the establishment of a Forest Board, of which the main functions should be the establishment of forest-schools, or, at least, of a course of instruction and examination in forestry." From the conclusions of these gentlemen Mr. Maxwell dissents. Although he says they deserve gratitude for having proved "beyond the possibility of doubt that British forestry is at a lamentably low level, and that hardly any effort is being made to redeem what might be a source of public and private wealth from the state to which it has been reduced by ignorance, indolence and indifference," he protests that "it is not possible to endorse their proposal to create a new department of the government to revivify it." He believes that reform should be brought about by concerted action on the part of large land-owners, and that "the first step in the right direction will be taken . . . by summoning a meeting in London of land-owners and others interested in the matter to discuss the position and to take counsel with the managers of the English and Scottish arboricultural societies with the view of securing their co-operation in undertaking the work which the select committee has rightly described as necessary, the neglect of which is discreditable."

Mr. Maxwell's article is suggestive reading for all who are interested in the subject of forests and forestry, but it supplies, of course, little help to those who are anxious to see our own forest-problems satisfactorily disposed of. The condition of our forests is so unlike that of English woodlands, their ownership is so differently distributed, the extent of our country is so much greater than that of Great Britain, that American and English needs cannot be discussed from the same point of view.

Mr. Maxwell's article contains, however, many items that should interest any reader. We read a family likeness to ourselves in his account of the way in which, in most parts of England, the minor products of the forest are systematically wasted. In Surrey, he says, convenient little fagots "made of small brush-wood bound together with a green withe" are used, in continental fashion, for the lighting of fires; but they are unknown in the northern counties and even in London, "whose countless fires are kindled by the much less effective fagots of split-wood." Brush-wood fagots, he explains, "have this advantage over fagots of split-wood, that they kindle much more readily, bursting into a blaze at once, whereas a fire laid with the larger sticks often requires re-kindling."

As an example of the lack of knowledge possessed by English owners and land-agents, with regard to even the commonest native trees, the author cites the case of a gentleman in the south of Scotland who, desiring to make a plantation of Oaks, procured with great pains fine acorns from the south of England. Here the indigenous Oak is *Quercus robur pedunculata*, while in the north of England and in Scotland it is *Q. robur sessiliflora*, the so-called "Durmast Oak." The latter flourishes if planted in the south, but the former does not find proper conditions of growth in the north, and, consequently, though "thirty, forty and fifty years have gone by since these woods were planted, the present owner of them has to deplore that the energy and good intentions of his predecessor were not better directed."

Under the rule of the Romans, which lasted some four centuries, says Mr. Maxwell, the vast forests that had covered England were largely swept away, especially in the north, where strategic considerations long remained paramount. But as early as the twelfth century strict laws were formulated in Scotland for the preservation of what remained, and in 1513 the Scottish Parliament insistently commanded the plantation of woods and hedges in denuded districts, and ordered land-owners to compel their tenants to plant on their holdings one tree yearly for every "mark" of land. "Many traces of this legislation may be recognized to-day in the scenery of Scotland. In every district round old houses or house-sites stand aged Ash-trees, the planting of which was specially encouraged for the manufacture of pike-staves, the pike being the national weapon of Scotsmen as the yew-bow was of Englishmen"; and, we may add, ash-wood having been the favorite material for spears ever since the days of the mighty Achilles.

But denudation went on in Scotland, unchecked by further legislation, until, in the last century, her people had leisure to appreciate their necessities and to attempt to meet them. Then many new plantations of great extent were made, and "a pathetic monument of the good intentions of one great Highland chief in this respect still remains. Just before the rising in 1745 Cameron of Lochiel received a quantity of young trees for planting round Achnacarry, his principal seat; when the summons came for the clan to join the standard of Charles Edward, the plants were hurriedly healed-in, in long lines, to await the return of more peaceful times. But the men who were to have set them out 'came back to Lochaber no more'; the saplings struggled into growth in the trenches as best they could, and there they stand to this day, a double row of Beeches, their silvery stems so closely crowded that a man may hardly force his body between some of them, and under this dark canopy of foliage, the outer boughs of which trail in the swift-running Arkaig, there broods a green twilight the long summer through."

Exhibitions.

The Elizabeth Horticultural Society.

THE flower-show of the Horticultural Society of Elizabeth, New Jersey, held on September 17th and 18th, was of more than local interest. In the early spring, the society, at the suggestion of one of the officers, Mr. T. K. Pembrook, concluded to offer a packet of Aster-seeds to any child who would agree to plant them and bring the result to an exhibition to be held in September, and some five hundred packets were applied for in response to an advertisement in the local journals. This was, so far, encouraging, showing rather more widespread interest than the society had expected, but there was some doubt as to the result, the successful growing of plants from seed sometimes puzzling older persons. The plants were brought in in great numbers, something over five hundred plants in all, and, on the whole, in creditable condition, scarcely up to the florists' standard but vastly more interesting. Taking them as a lot, they indicated probably too much attention, care having degenerated to coddling. There were pathetic exhibits of poor little single weaklings, starved and colorless, on which evidently great care had been expended. The most interesting plants were in two little window-boxes, from two little girls who had no garden, but had managed to grow the greatest variety from their packets of seed, and secured the prizes in the class. Such a curious lot of dwarf, starved plants perhaps never grew in the same space, but it was a pleasure to see the winning cards on them, as they spoke of so much simple, loving, patient care.

The wild flowers collected by the children were not a very satisfactory exhibit, owing to a failure to provide that they should be named and arranged for effect. The true province of a horticultural society would seem to be not the speculation in exhibitions, but the endeavor to induce the cultivation of plants and flowers by the masses, and such experiments as that of the Elizabeth society, if repeated, are sure to result in much good. The large hall was closely filled with collections of flowers and plants from amateurs and florists. The amateur exhibit was led by a grand mass of tropical plants from H. W. and R. Pierce, which occupied a space some forty by fifteen feet, in the centre of the hall. Among these were fine Cycads, Musas, Palms, Marantas, Ferns, etc. Other amateur exhibits were Palms, Dracænas, Tuberous Begonias, etc., by H. A. Haines; garden-flowers, by T. K. Pembrook, T. C. English, and F. K. Day; Eucalyptus, *Grevillea robusta*, Coffee-plants, etc., by E. C. Woodward; specimens of Papyrus, and Aquatics, Bamboos, interesting Begonias, etc., by J. N. Gerard.

The local florists exhibited some fine decorative plants, the first prize for which was awarded to John White. For the best display of cut flowers the first prize was given to J. W. Blakeley. Other prizes went to Miss Hutchinson, J. M. Horsburgh and J. W. Bonnell for floral designs.

The Elizabeth Nursery Company exhibited rare Retinsoporas and shrubs.

One of the exhibits which attracted most attention was a complete collection of rare Nymphæas, Nelumbiums and various Aquatics from Wm. Tricker, Dongan Hills, New York. From the roseries of S. C. Nash, Clifton, New Jersey, came a mass of the fragrant and popular American Beauty Roses.

The interest in this exhibition was so great that the society is considering a Chrysanthemum show during the approaching season.

Notes.

Immense tracts of the Pine-forests which cover the sandy shore regions called the *Landes* in the vicinity of Bordeaux, in France, were recently destroyed by fire, the flames spreading so rapidly that at least ten persons—wood-cutters, hunters and charcoal-burners—are known to have perished.

Under the title "Berlin et son Exposition Horticole de 1890," Monsieur Ernest Bergmann has reprinted from the pages of the *Journal de la Société Nationale d'Horticulture de France* his account of this important exhibition, in which he took part as a member of the jury for awarding the prizes.

A new edition of Gray's "Manual of Botany" has just been issued for the special use of the working botanist. The plates are the same as those from which the larger volume was printed, but this is reduced to 12mo size, printed on thin, yet tough, paper, bound in limp leather covers, and is sold for $2.

We rarely see the Sweet Birch, *Betula lenta*, planted for ornament, but if allowed room to develop into its full proportions it is one of the most graceful of trees. In Laurel Hill Cemetery, in Philadelphia, there is a specimen which stands by itself and has formed an open spreading head of great size, and among the many noteworthy trees in that place this is universally considered one of the most beautiful.

The variety of *Solanum jasminoides*, which has been largely distributed under the name of Grandiflorum, is certainly an admirable summer climber for the garden. The racemes are much larger and more open than those of the type and often carry as many as twenty flowers; while the flowers themselves are larger, some of them being an inch and a quarter across. Its foliage is clean and healthy, and of the deepest green, and forms an admirable background to the pure white flowers which are borne in abundance.

A fountain covered by a large stone canopy, ornamented with a bronze figure of Hebe, has recently been erected in Tompkins Square in this city. The name of its giver has not been made public, but his gift passed through the hands of the New York Moderation Society. The fountain will supply ice-water to all comers free of charge, and will be administered by a keeper who will open the faucets at eight in the morning and close them at midnight. It is estimated that in this poor and densely crowded district fully 5,000 persons will daily avail themselves of the luxury thus supplied.

According to the *Popular Science Monthly*, there are in Hungary about 22,000,000 acres of forest, the Government owning some 3,500,000 acres, while the rest is divided between public corporations and individual owners. "The Government does not sell any part of its forests, but buys more each year. In some parts of the country, as in the eastern region of the Carpathians, woods are found of several thousand acres in extent, consisting for the most part of Red Beech. This is used for fire-wood, carriages, staves and agricultural implements, and in the manufacture of bent wood. There are few fires, and they seldom permanently damage the woods. There are large resinous forests in Transylvania, but they are not very accessible; and there are also some in the district of Marmaros, in the north-east of the country."

The Government report on the condition of the crops notes that the condition of the Potato crop has never been so uniformly good since the Department of Agriculture began to issue these bulletins. This shows the continued prevalence, in all parts of the country, of favorable conditions. Last year there was a decline of twelve points, during August, in the condition of this crop, which followed the drought in the central and trans-Mississippi states. This year the rainfall has been distributed, generally, in accordance with the needs of the crop, although there has been some local excess in sections of the country lying east of the Alleghanies, and deficiencies over small areas in the Ohio Valley. The crop, however, is not entirely out of danger, since the blight appeared during the closing days of August, and the weather conditions since then have been favorable to the development of this disease.

A law was passed during the last session of the California Legislature making it the duty of the County Board of Horticultural Commissioners to inspect orchards, nurseries, or other places in their jurisdiction where they shall deem it necessary, and if such places are found infested with the scale insect, the codlin moth, or other pests injurious to plants or trees, that they shall notify the owner of such a fact, and that they shall request such owner to eradicate or destroy the said pests within a time specified. Such orchards or nurseries are adjudged to be public nuisances, and when their owners shall refuse to abate the same within a specified time it shall be the duty of the County Board to destroy said insects, and the expense thereof shall be a county charge. All such sums shall be a lien on the premises from which said nuisance has been removed, and may be recovered by an action against the property, in the name of the county making such payment, and when the property is sold, enough from the proceeds shall be paid into the county treasury to satisfy the lien and costs, and the overplus, if any there be, shall be paid to the owner of the property.

No. 7 in the "Evolution Series" of pamphlets, published to give permanent form to the lectures and discussions organized by the Brooklyn Ethical Association, is written by Mr. Frederick J. Wulling, and is called "The Evolution of Botany." Its title is somewhat misleading, for it is simply a brief history of the progress of botanical research and knowledge, which closes with a rather forced attempt to prove that this history establishes the truth of the doctrine of evolution. But in itself the pamphlet is an excellent one, supplying an account of the development of the science which, for combined clearness and brevity, we do not remember to have seen equaled. The only faults we have to find with it are, that the exact character of the "natural system" of classification, now universally adopted by botanists, might have been more definitely explained, and that the list of American botanists and explorers might have been drawn up with a keener regard for their relative degrees of distinction. For instance, the value of the labors of Rafinesque, Michaux and Pursh should have been more clearly pointed out than by the including of their names in a list of some dozen persons who have "contributed papers on botany to the various scientific journals."

Mr. C. Wolley Dod contributes to a recent issue of *The Garden* an account of the Madeira Orchis (*Orchis foliosa*), which he finds succeeds well in his English garden, where it is growing even more vigorously than the allied British species, as it is easy to believe from the illustration made from a photograph, and which seems to us to be about as perfect and delightful an illustration of its kind, both in composition and in the exquisite detail with which the wood-engraving has been executed, as we remember to have seen. In speaking of this plant Mr. Dod, who is one of the most skillful cultivators of hardy plants in England, recommends that "it must be planted in a sheltered place in good, moist, open loam or peat, where the soil does not dry up in summer. The shade of trees is not bad for it, provided their roots do not drain the ground too much, but the food of trees and the food of Orchises seem so different that I have seen this plant growing very fine within the limits of the roots of Lime-trees, especially near water where the subsoil is never dry. It seems to like rich feeding, and, though manure is generally forbidden for bulbs of this kind, I find a top-dressing of leaf-mold, mixed with well-decayed stable refuse, very beneficial to growth. August, when the annual growth is completed but before the leaves have changed color, is the best time for separating the bulbs, when they have increased into a mass and want replanting. Neither this nor any other plant ought to be moved when resting. *O. foliosa* does very well in large pots, wintered in a cold frame and moved into the greenhouse to flower, as they are there protected from the very injurious spring winds. Among the variable native Orchises included under the names of *O. maculata* and *O. latifolia*, individuals may be found well worth cultivating, especially amongst those intermediate forms which are not uncommon where these two species grow together."

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

Office: Tribune Building, New York.

Conducted by . . . . . Professor C. S. Sargent.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, SEPTEMBER 30, 1891.

TABLE OF CONTENTS.

Jeffrey's Pine.

ONE of the interesting journeys that can be made through the forests of North America is from some point in Nevada, like Reno or Carson's City, at the eastern base of the Sierra Nevada, across the mountains into California. The Yosemite Valley can be reached in this way from Nevada by an easy drive of four or five days, during which the traveler will be able to examine the flora of the two sides of the range, and to study, as well as in any other part of the world, the influence of moisture upon the growth of forests. The scenery which will unfold before his eyes as he mounts the eastern slopes will well repay the fatigue and trouble of such a journey; and a more comprehensive and satisfactory idea of the Sierra Nevada and its forests will be obtained than can be acquired in the conventional, and now somewhat hackneyed, journey into the Yosemite from the California lowlands.

The hot, dry barren foot-hills which stretch along the eastern base of the mountains do not offer much that is beautiful or attractive, but when these have been crossed and the real ascent of the mountains begins, a wonderful forest of Pine-trees will be entered. The lowest limit of this forest is rather below 6,000 feet above the sea-level, and it is necessary to climb 3,000 or 4,000 feet higher to see its upper limits. To the person coming from the east for the first time this forest will appear marvelous. Its floor is bare of vegetation, except where here and there a Ceanothus has gained a foothold and spread into a low broad mass of spiny branches, or where taller shrubs occupy the abrupt sides and the bottoms of narrow cañons. The trees stand sometimes close together, and sometimes at considerable distances apart; they are often 250 or 300 feet tall, their great trunks ten or twelve feet in diameter and free of branches, except near the top of the trees. These trunks are splendid; there are not many things more impressive or more beautiful. The bark is immensely thick, and is broken by deep fissures into great cinnamon-red armor-like plates, across which the sunlight, as it flickers down through the scanty canopy above, casts long shadows. The branches are few and small in proportion to the trunks, and bear at their ends great brush-like clusters of pale blue-green foliage and immense quantities of large chestnut-brown cones, which, in early autumn, sometimes completely cover the ground under the trees.

This tree is Jeffrey's Pine, the *Pinus Jeffreyi* of botanists. It is a so-called Yellow or Pitch Pine, and, botanically, is very closely related to the California Yellow Pine (*Pinus ponderosa*). It belongs to a small group of western America Pines, to which the name of "Broken-cone Pines" has been applied, from the fact that when the cones ripen and fall their bases, with a few scales attached, remain on the branches. Jeffrey's Pine, probably, never grows to such an enormous size as the California Yellow Pine, but it is a handsomer tree, one of the noblest of all Pines as it is seen in its native forests, and one of the largest, for only two of the genus grow larger, the Sugar Pine and the Yellow Pine.

Jeffrey's Pine may be recognized by its stout, pale blue-green leaves, which are seven or eight inches long, and produced sometimes in twos and sometimes in threes on the same branch; by the pale glaucous shoots, which sometimes become orange-colored during their first winter, and which, when broken, exhale a pleasant aromatic perfume like that possessed by some plants of the Rue family. The cones, too, distinguish it from its nearest ally, the California Yellow Pine; they are elliptical, purple at first, and only become brown as they approach maturity, when they are from six to ten inches in length, and four or five inches in breadth after the stout scales, armed with slender, strongly recurved prickles, have opened. The seeds are an inch long, with long, rather narrow wings, and usually contain more cotyledons than the allied species.

Jeffrey's Pine, like most trees of wide distribution, varies considerably in habit and in general appearance in different parts of the country. The form, which may be considered a type of the species, as it was the first one known to science, is a comparatively low tree, with a trunk four or six feet in diameter covered with dark bark, and with rather pendulous branches. This is a common tree on the high mountains west of Mount Shasta in northern California, and occurs on the southern and south-eastern flanks of several of the high Sierra peaks in the northern and central parts of the state. On the eastern slopes of the Sierras, where Jeffrey's Pine is found, from northern California to the San Jacinto Mountains, Jeffrey's Pine becomes a larger tree, with red bark and larger cones. For this form Mr. Lemmon, who gives an excellent account of the California Pines in his two reports upon the Pacific coast conifers, proposes the name of Red Bark Pine; in a Pine of lower California he recognizes another form of our species, which he designates as var. peninsularis. "It forms," he tells us, "east of Todos Santos Bay, at an elevation of about 4,000 feet, an extensive forest upon loose débris of white granite, seemingly to cover the region where this rock prevails."

Economically and commercially, Jeffrey's Pine is a tree of the first importance. The wood which it produces, when it has been developed under favorable conditions, is strong and light, although rather hard and coarse-grained. It has been manufactured in immense quantities on the eastern slope of the Sierras, especially in the neighborhood of Donner's Lake and other points convenient to the line of the Central Pacific Railroad. It is this tree which has supplied the timber for the mines at Virginia City and Eureka, and at hundreds of less-important mining-camps. Three-quarters of the buildings which have been erected during the last twenty-five years in Nevada and western Utah are built of the wood of this tree. The demand has swept the mountains bare in many places, and it is still increasing. The climate in which Jeffrey's Pine has grown to its greatest size is one of excessive summer dryness. Trees in such a climate grow very slowly, and

sometimes require centuries in which to reach their full size. Few young trees are springing up on the Sierras to replace the giants as they fall under the axe of the Nevada lumberman. Fires are increasing in number and destructiveness in all this region, and it appears a foregone conclusion that as a national source of lumber-supply the forest of Jeffrey's Pine on the eastern side of the Sierras will have ceased to exist before another quarter of a century has passed.

The discovery of *Pinus Jeffreyi* was one of the results of the so-called "Oregon expedition," an association of Scotchmen who sent John Jeffrey, a Scotch gardener, to the Pacific coast in 1852 to collect seeds and plants. He found the Pine which now bears his name on Scott's Mountain, a rugged range west of Mount Shasta, and in the same region the rare *Pinus Balfouriana*, and, in different parts of California, a number of other plants, including *Pinus Murrayana* and *Pinus albicaulis*. These Pines and some other trees were described and figured by Mr. Andrew Murray, Secretary of the Oregon Association, and by Professor Balfour in a pamphlet of three pages, without a title or a title-page, but accompanied by five plates. It was printed privately and distributed among the subscribers, and is one of the rarest works which have been published on North American trees. A single copy is now known to exist in the United States.

The illustration on page 461 represents a grove of Jeffrey's Pine growing on an elevated spur of the Sierras, above the Yosemite valley. The trees are characteristic of the species as it is found at high elevations and in excessively exposed situations. They are small and stunted in comparison with the great trees which grow at lower elevations on the eastern side of the mountains, where, as we have already said, this species is seen at its best. The illustration is from a photograph made by Dr. William H. Rollins, of Boston.

Mr. P. L. Simmonds contributes to a recent issue of the *Gardeners' Chronicle* some interesting information about the so-called English walnuts, from which the following facts are gathered:

There are many varieties of these nuts, such as the oval, round, double, large and small-fruited, early and late, tender thin-shelled and hard thick-shelled. An almost huskless variety occurs in the north of China. The larger portion of the walnuts consumed in England are of foreign growth, and average in quantity about 250,000 bushels. The bulk of these come from France and Belgium, and small quantities from Germany, Holland and Italy.

Bordeaux is one of the largest exporting ports in the world, perhaps the largest for walnuts; and small quantities are now sent from Chili to Europe. The culture of the so-called English Walnut, which, by the way, is not an English tree at all, but a native of the Orient and of central and eastern Asia, from whence it was early introduced into Europe, is now diffused all over Italy, from the Alps to the valleys of Sicily. It is thought, however, that the number of cultivated Walnut-trees in Italy is diminishing as the demand for the timber is increasing, being in great demand by the cabinet-maker.

Persons with weak digestions will do well to bear in mind Mr. Simmonds' warning, that walnuts, as long as the skin can be easily removed from them, are a nutritious and healthy article of diet; but when they become dry, so that they cannot be easily peeled, they are indigestible.

Walnuts in the shell yield about one-third their weight of picked kernels, which are the crumpled cotyledons or seed-leaves. In some northern districts, particularly in Piedmont, Walnut-trees have always been held in high estimation for the production of oil, which, when newly made, has a very agreeable taste, and can be employed in cookery as well as in the preparation of varnish.

The Walnut grows abundantly in Kashmir, Nepal and other parts of India, where the fruits are largely used. It forms also an important article of consumption in Japan, quantities being eaten in a raw state. They are also much used for making a kind of confection, by cracking and removing the shell without hurting the kernel, which is afterward coated with white sugar, thus making an attractive and agreeable sweetmeat.

The Walnut also furnishes in Japan a bland oil, used for domestic purposes. In China it seems to be pressed for oil, as in some years over 12,000 tons are exported from the port of Tientsin in the year. The Walnut is extensively cultivated in the Punjab, among the Himalayas and in Afghanistan, a large annual supply being brought to the plains of India by the Kabuli and other traders from the hills. There are several well-known forms of this nut met with, the soft-shelled kind of Kashmir and Chamba being considered the best.

The Gardens of Le Nôtre.

THE determining power of fitness, appropriateness, in all periods when art has really been great, the fact that its greatness sprang from its truthful expression of material needs and social conditions, is well shown by the following passage, which we quote from Planat's "Encyclopédie de l'Architecture et de la Construction." What, asks the author, were the architectural requirements of society in the time of Louis Quatorze? "Spacious, richly decorated apartments, in which the court could stand in state while awaiting the passage of the king; in which painting and sculpture should play a secondary, decorative rôle, not the principal rôle as in Italian palaces. In an Italian gallery art was the chief occupant; here it was society; there, architecture supplied a setting for pictures and statues; here, pictures and statues adorned the architecture. French society demanded festal halls and gardens which might serve as open-air drawing-rooms, prolonging the architecture of the noble and stately palaces; gardens embellished with white allegorical statues and colonnades, with trimmed hedges enclosing rooms of living green; gardens furnished here and there with marble stairways, whereon the court could range itself in successive rows; gardens with canals and lakes dotted over with pleasure-galleys bedecked with flags, and with carefully managed perspectives opening in all directions. Under Louis Seize it became the fashion to ridicule these geometrical parterres, these trimmed Yews, these waters trained to spout in complicated patterns and figures, this entire absence of all real nature." But, the author explains, it was much more ridiculous for courtiers to disport themselves in the "dairies" of the Trianon, aping in satin and powder the tasks and amusements of peasants. The main fact is, that the destination of such gardens as those of Versailles "precluded all pretension to rusticity; that their architecture could serve only as a setting or background for the toilets of ladies in grand state and the costumes of men dressed in velvets and brocades; surely damp grass, wet ground, bushes and underbrush were out of the question in the circumstances. . . . In the city likewise, from the street which was still usually narrow and dirty and was nothing more than a way of communication, a lofty porte-cochère gave entrance to a vast court, where a great number of carriages could freely circulate; a noble flight of steps hospitably offered access to a well-lighted vestibule. Galleries with high windows opened, even in Paris, on broad regularly laid-out gardens, which imparted a seigneurial air to the edifice. Studying the old city maps one is struck by the number and extent of these gardens, and their existence explains the fact that so little attention was paid to the plan of the streets themselves."

The Weeds of California.—V.

THE entire tribe of Ragweeds (Ambrosia) is absent from the California list of weeds. The native Franseria is innocent.

Sonchus oleraceus (the Milk Thistle of Californians) and *Senecio vulgaris* thrive as well in California as anywhere in the world, and are found throughout the settled portions of the state. The Senecio will germinate in the middle of the summer's drought almost as well as the Centaureas.

Erigeron Canadense affects chiefly the irrigated lands, and there demonstrates an unexpected resistance to even very strong alkali, such as few useful plants could resist. In Fresno and Tulare counties it reaches easily the height of eight feet, and forms thickets not pleasant to penetrate. In unirrigated lands it rarely becomes troublesome, and is of small stature, but, nevertheless, maintains itself fully where once established.

Cichorium Intybus obstinately retains possession of fields where it has been cultivated, and spreads more or less, but outside of such cases can hardly be considered troublesome.

The *Matricaria discoidea* is extensively diffused in the state, and lines the roadsides all over the Bay country, emitting its pleasant fragrance in the hot sun. *Chrysanthemum Leucanthemum* has gained a foothold in a few localities in the same region, but is not troublesome, and does not seem to spread rapidly. *C. segetum* is found at a few points on the Bay borders.

Of native composites, the Tarweeds are the most objectionable; not so much because of their persistence as weeds as on account of the inconvenience caused by their viscid secretion, both to the person and clothes of the farmer and to certain products. *Madia sativa* is the most generally obnoxious, both because of its almost universal occurrence in fields and roadsides, its extremely abundant secretion and its disreputable aspect when covered with dust. An expensive bath of alcohol alone seems capable of removing the resinous slime from the injured clothes.

Several Hemizonias are hardly behind the Madia in these respects, and several add to it a strong, and sometimes disagreeable, odor; among these the *H. elegans* stands foremost, but this species is not often found in cultivated fields. The *H. luzulæfolia*, on the other hand, exhales a spicy odor of myrrh, which is wafted over the harvest-fields in July and August, and, in a measure, condones the disagreeable qualities of the plant, which really hurts the grain but little, attaining its growth after the crop is off the ground, and then seeding the latter most thoroughly when plowing cannot be done on account of the dryness of the soil. Several other species, however (*H. virgata*, *paniculata*, *Kelloggii*), are not so innocuous, as they grow up very rapidly among the grain while in milk, rendering it impossible to harvest without commingling it with the grain, and then often spoiling both straw and grain with its resinous exsudation. They often form impassable thickets along the irrigation ditches in the San Joaquin Valley.

The Wild Sunflower (*Helianthus annuus*, or *lenticularis*), occurring naturally on rich and moderately moist soils, finds greatly increased opportunities for development when the land is cultivated, and sometimes covers the ground first broken completely in defiance of crops sown. It is not, however, very persistent, and repeated mowing soon diminishes it down to an easily manageable condition. But its complete extirpation is quite difficult. *Helianthus Californicus*, occurring only in low, wet lands, is not very troublesome.

The place held in Europe and the east by the Dandelion is measurably filled in California by several large-flowered species of Troximon (popularly called Dandelions) and Hypochæris, whose feathered akenes fill the air in summer. They hardly invade the cultivated ground, but chiefly pastures and lawns. The true Dandelion (Taraxacum) was at one time introduced as a matter of sentiment by an admirer, but showed such wonderful powers of development that it was with some expense extirpated from the threatened lawns.

Of other composites that invade the fields more generally but without doing any material injury, the beautiful Layias deserve mention. They make the ground gay beneath the half-ripe grain and afterward develop more fully. The *Achyrachæna mollis*, very inconspicuous while in bloom, sometimes forms a dense mat beneath the grain, and after harvest covers the field and fills the air with its beautiful silvery winged akenes.

Matricaria occidentalis invades the grain-fields of the Bay region to some extent, but is not seriously troublesome.

The *Primulaceæ* furnish only the ubiquitous *Anagallis arvensis*, but this attains a degree of development which, from its prevalence in the moist European climates, would hardly be expected. From early spring until the beginning of winter the multitudinous seeds of this little plant germinate, from the surface of moist soil or from the depths of that which is parched and hot, and with a tenacity of life worthy of a better cause. With the two Centaureas, the Stellaria and the *Erodium Cicutarium*, it constiutes a group of weeds that make an exception to the prevalent rule that after the cessation of rains the California farmer may consider the weed-fight over for the season. In the northern part of the state its flowers have the usual dull red tint; in the southern, their color is frequently purple or almost blue.

Of the *Apocynaceæ*, *Apocynum cannabinum* invades pastures from the woodlands in the northern part of the state, but does not become troublesome south of Oregon and Washington.

Asclepias fascicularis maintains a place in cultivated fields of the black adobe character with some tenacity; *A. Fremonti* and *A. eriocarpa*, and locally *Gomphocarpus tomentosus*, maintain themselves in pastures to the occasional detriment of sheep and cattle who are tempted to vary their dry summer diet with something green, and are poisoned by eating the leaves.

Of the *Gentianeæ*, *Erythræa Muhlenbergii* keeps a place even in cultivated fields to some extent, and very commonly in pastures.

Of the numerous Gilias only *G. squarrosa* rises to the dignity of a weed, both in pastures and cultivated fields, where its spinous leaves and bracts, and, above all, the intense odor that has given it the name of Skunk-weed, render it obnoxious. Its viscous tomentum covered with dust give it a forlorn aspect, and one sees with surprise the small blue, star-like flowers amid this mass of dirt, spines and fetor.

Acelia tanacetifolia is the only weed here from the large family of *Hydrophyllaceæ*; its prickly hirsute stem and foliage render it an uncomfortable invader of the fields, and there is no compensation in its dull, yellowish white flower-coils. It does not withstand persistent cultivation.

Among the *Borragineæ*, two native Amsinckias, *A. intermedia* and *A. lycopsoides*, are truly troublesome weeds in the Coast ranges, maintaining themselves on the heavier clay soils which they naturally occupy, despite of cultivation and to the material injury of grain crops, with which in many seasons they share the ground evenly or prevalently. From the clinging quality of their hooked, hirsute tomentum the Amsinckias have received the inappropriate name of Yellow tarweed, although entirely innocent of resinous qualities. The nutlets accompany the bristly calyx on its migrations in the hair of cattle.

How We Renewed an Old Place.

XIX.—A WATER GARDEN.

IF one is unable to secure ample assistance, and is obliged to develop a place slowly, the order of planting should be trees first, shrubs second, flowers last of all.

Trees may be considered as the skeleton, the frame-work upon which the whole scheme is constructed, giving it strong substantial outlines and decisive meaning. Shrubbery plays the part of muscles and flesh, covering the unsightly bare places, rounding out the form, supplying the essential, and giving grace and symmetry to the enclosure; while flowers may be regarded as the clothing with which the completed body is finally adorned. Naturally, one cannot resist sticking in a few flowers as he goes along, but their disposition is not final, and they take up a deal of time, and are, consequently, to be relegated to a subordinate place at first, and looked forward to as the occupation reserved for those future unemployed hours when the woody plants can be left to grow and fulfill their mission.

Here, where the watering during summer, and frequent digging about and top-dressing, to retain moisture, are absolutely essential to trees and shrubs, flowers that have to be weeded and tended are much neglected, and only those hardy perennials that will take care of themselves and defy weeds, have as yet any kind of a show. But we are always dreaming of a period when the ligneous plants can be let alone and we can turn our attention seriously to the purely ornamental.

In the mean time, such wild things as come up of their own accord, on the hill and in the meadow, are full of interest, particularly in early spring and in late August, when the stock of hardy garden-flowers runs comparatively low.

At the latter period the little spot that I call my water garden is really quite a sight for such a humble affair, a mere mud-hole as it were, formed by a spring at the foot of the hill, which makes a tiny frog-pond, about ten feet or less in diameter. The frogs themselves are quite ornamental, wearing, as they do, the most gorgeous yellow and green coats, and being quite sociable and friendly, ready to sit on a chip and croak when we pay them a visit, and making music for us in the spring before the birds are fairly abroad. The old bull-frog, with a hoarse cold, is not always a comfort, for he has a way of coughing at night, like an asthmatic old gentleman, that is sometimes distressing, if you lie awake to listen, for it makes you sure his family must be anxious about him, but the piping little ones have quite a cheerful note, which blends agreeably with the chirpings of the grasshoppers.

On the marshy banks of the little pool, which cannot comfortably be reached without overshoes, some slim Willows are bravely growing, which I fear will some day make it too shady for the flowers, but at present they serve to give the spot a cosy and protected air, and the sunlight shifts through the light foliage, and falls kindly on the bright group of blossoms that make it so gay at the end of summer.

The pool is close to an old gray fence, over which the wild vines clamber, and against which the Milkwort, with its stiff stems and smooth leaves, stands up erect, its panicled pink blossom a-top; not a very choice plant, but a sturdy one, and the vivid color "carries" well against the green, and composes agreeably with the masses of Arrowheads that are at this season full of blossoms and tall-stemmed sharp leaves, like a group of Amazons with their shafts drawn to the ear.

At the edge of the pool a mass of sedges has been left unmown, and here are clumps of the creamy blossoms of the wild Foxglove, mixed with all sorts of Golden-rod and some budding Asters, while the flowers of the Grasses are themselves beautiful and various in their own quiet way, some with plumes and some with spears, as if ready to oppose the Arrowheads.

The wild Carraway and the Yarrow show white among the grass, and there is a wonderful rosy hue in the tall spikes of Dock that are blooming near by. The Forget-me-nots are still full of blue blossoms, and spread out into the water far and wide, the earliest to come and the last to go of all the simple ornaments of the water garden.

But the glory of the pool is the Cardinal Flower, of rich dark red, which lifts its bracted racemes proudly and with the dignity of a true hierarch. This shows to advantage for the first time this year, having before fallen a victim to the careless scythe, so that its blossoms, which it persisted in putting forth in spite of discouragements, were only a few inches high. But this summer no mower was allowed to come within six feet of the spot, and we are well rewarded by the glow and stateliness of this superb flower, which would be an ornament to the proudest parterre. The Water-lily bulbs that we got from a nursery in the spring have proved a failure, whether because they were planted too deep in the mud or because the bulbs were defective, it is impossible to say. It may be that the spring is too cold for them, and that they require the warmer water of a pond; but they should not be difficult to raise, for I saw a pink Water-lily blossoming this summer in a rocky pool, with nothing to grow in but the ball of rich mud in which it had been tightly packed before being gently laid in its stony bed.

A picturesque spot it was, with a stream trickling down the face of a high granite rock, that formed the background to a tiny terrace-garden, in proportion to which the miniature brook was a river, along the grassy shores of which minute water plants were growing. A flight of stone steps led down into this terrace, which was banked around with flowers, leaving in the centre a turfed semicircle large enough for an afternoon tea-table and a few seats. Tall Pines waved overhead, and the tops of Oaks and Hornbeams intervened between the garden and the sea, which gleamed whitely between their rustling leaves. On the stone curb of the spring stood a quaint blue water-jug, and a drinking-cup made of a shell and a bit of bamboo. In a corner more rough stone steps led to a lower terrace, also girt about with flowers, from which a rocky winding path led down through the forest to the beach. Ivy clambered over the rocks, and wild flowers and grasses, intermixed with Ferns, hung from the crevices. It was a bit of artistic naturalness that would have enchanted a Japanese, and was the result of a fair woman's skillful planning and fine sense of the picturesque.

But, returning to our own water garden, we find higher up the bank the Hawkweed showing its yellow stars waving on slender stems, and the Prunella displaying its stiff blue clusters, while more Asters blossom, and tufts of Golden-rod cling to the hill-side, and entice us to a climb among the Pines.

Here we find that the dry summer has made havoc. Of the thirty-five planted in April we shall barely save a dozen. This is discouraging, but we have gone bravely to work to set some more, and try whether August skies will be more propitious in the way of rain. We have also put in a few Savins, though we hear they take unkindly to transplantation.

The little Oaks and Maples have thriven, and are showing green against the already withering grass. The soil is yearly improving by letting it lie fallow, and the foot sinks into the soft cushion the uncut hay is making as a covering for the sand and gravel. If it were not for endangering the seedlings, quite a crop could be harvested. It is not soil the hill lacks so much as rain; but the long drought parches and distresses the plantation, and will do so till the trees can shade the ground and preserve its moisture.

The small Chestnut group of which I boasted in the spring has made very little progress, and hardly looks larger than it did last summer. Insects injured the early growth, and there was no later growth for lack of rain. But the trees are alive and healthy, so that we have something to be thankful for. Our one Mulberry-tree bore fruit plentifully, but failed to make much leaf-way. None of these trees were either top-dressed or watered, or they would have done better. It is impossible for us to keep everything in high condition, so that we must content ourselves with the slow progress that nature affords when unassisted. It really seems as if sunshine and water are the prime essentials, and that feeding is not half so important as drinking. With this view, it is hard to understand why it would have upset the economy of nature to have a shower every night in summer, to refresh the fields and gardens of the world. Possibly in time, when the new system of producing rain has been brought down to a fine point, there will be twice a week in villages a pyrotechnic display, accompanied with explosions, that will transform the year into a perpetual Fourth of July.

Seriously speaking, should this new enterprise prove successful, what a revolution man is to produce in nature! To trust such powers to his pigmy hand is dangerous, for the consequences of his personal gratification may be fatal to millions. Fertilize the Desert of Sahara, and you cool off the south of Europe. Alter the temperature of Spain and Italy and southern France, and what is to become of the British Isles? It may be that thus the future of the Dark Continent is to be fulfilled. Migrations southward may begin. Norway and Sweden, like Greenland, may be left principally to the inferior races, while new colonies spring up in lands now tenanted but by the wandering Bedouin or the swarthy Soudanese.

Given new conditions, results are incalculable, and if the rain, as well as the lightning, is to be harnessed to the Chariot of Man, who can tell what disaster shall await the Phaeton who dares to drive such mighty and resistless steeds? Shall he too be hurled to ruin as a punishment for his over-topping ambition; or will he prove master and lord even of the elemental forces from whence he came? What is most sure is, that before they yield themselves wholly to his bidding he must suffer the consequences of his rashness, and win his way to control only by ghastly sacrifice of human life.

Hingham, Mass. *M. C. Robbins.*

Forest-vegetation of the Upper Mississippi.—I.

THE Mississippi River and its tributaries, from Trempealeau, Wisconsin, to Dubuque, Iowa, are enclosed by bluffs varying from 200 feet to 600 feet high. At Dubuque they are much lower than at La Crosse; in the latter place they are something more than 500 feet above the level of Lake Michigan; sometimes they present steep, sandy rocks; in other places they are covered with a dense growth of trees. The region is well watered by numerous small streams emptying into the Mississippi, while it contains a number of streams of good size, as the Wisconsin, Black, La Crosse, Root and Turkey rivers. The smaller as well as the larger streams are well timbered with Oaks, Poplars, Birches, Maples, Hickories, Butternut, Walnut, Plums, Cherries, a few conifers, and, southward, the Coffee-tree and Honey Locust.

Much has been written concerning soils and the character of the vegetation. It is, indeed, a puzzling question, and I doubt whether it can truly be said that certain species strictly confine themselves to certain definite soils, yet certain trees, as well as herbaceous plants, may preponderate in certain soils. Perhaps this may be due to the physical condition of the soil rather than its chemical constitution. The Soft Maple (*Acer saccharinum*) and Black Birch (*Betula lenta*) are the predominating trees in the Mississippi, Wisconsin and Black River bottoms. They also follow up the smaller streams which flow into these rivers, but as soon as these streams are left these trees become rare. The Soft Maple and Black Birch occur most numerously where the lands are subject to overflows every year. Most of the Oaks never occur in such situations, yet the Swamp White Oak (*Quercus bicolor*) is an exception. The only place where this species occurs is in the low sandy and black bottom-lands of the Mississippi and Black rivers. The White Pine only occurs on the sandy rocks or sandy loam soil of the region, always near streams, but in the northern part of La Crosse County it is encroaching on the loamy soil. The Tamarack (*Larix larcinse*) only occurs in cold wet swamps.

The soils of the region may be classed under sandy, loamy, calcareous, alluvial and peaty. The greatest areas of sandy soil occur near the mouths of the rivers. (This is not true for the interior of the state.) These sand prairies are not, however, numerous on the west side of the river. As an illustration, at La Crosse, Wisconsin, there is a sand prairie some eight miles long, and from one-half to three miles wide. The only arboreal vegetation growing on these soils are two species of Oak, Burr Oak (*Quercus macrocarpa*), Black Oak (*Q. tinctoria*), and occasionally the Green Ash (*Fraxinus viridis*) and Black Birch (*Betula lenta*). These trees, however, only occur in close proximity to the Mississippi bottoms. Other sand prairies, similar to this one, occur at Trempealeau and Prairie du Chien, Wisconsin. As regards the herbaceous vegetation on these prairies, it might be said that it is a typical prairie flora. *Liatris cylindrica, Verbena stricta, Baptisia leucantha, Petalostemon violaceus, Œnothera rhombipetala, Bouteloua hirsuta,*

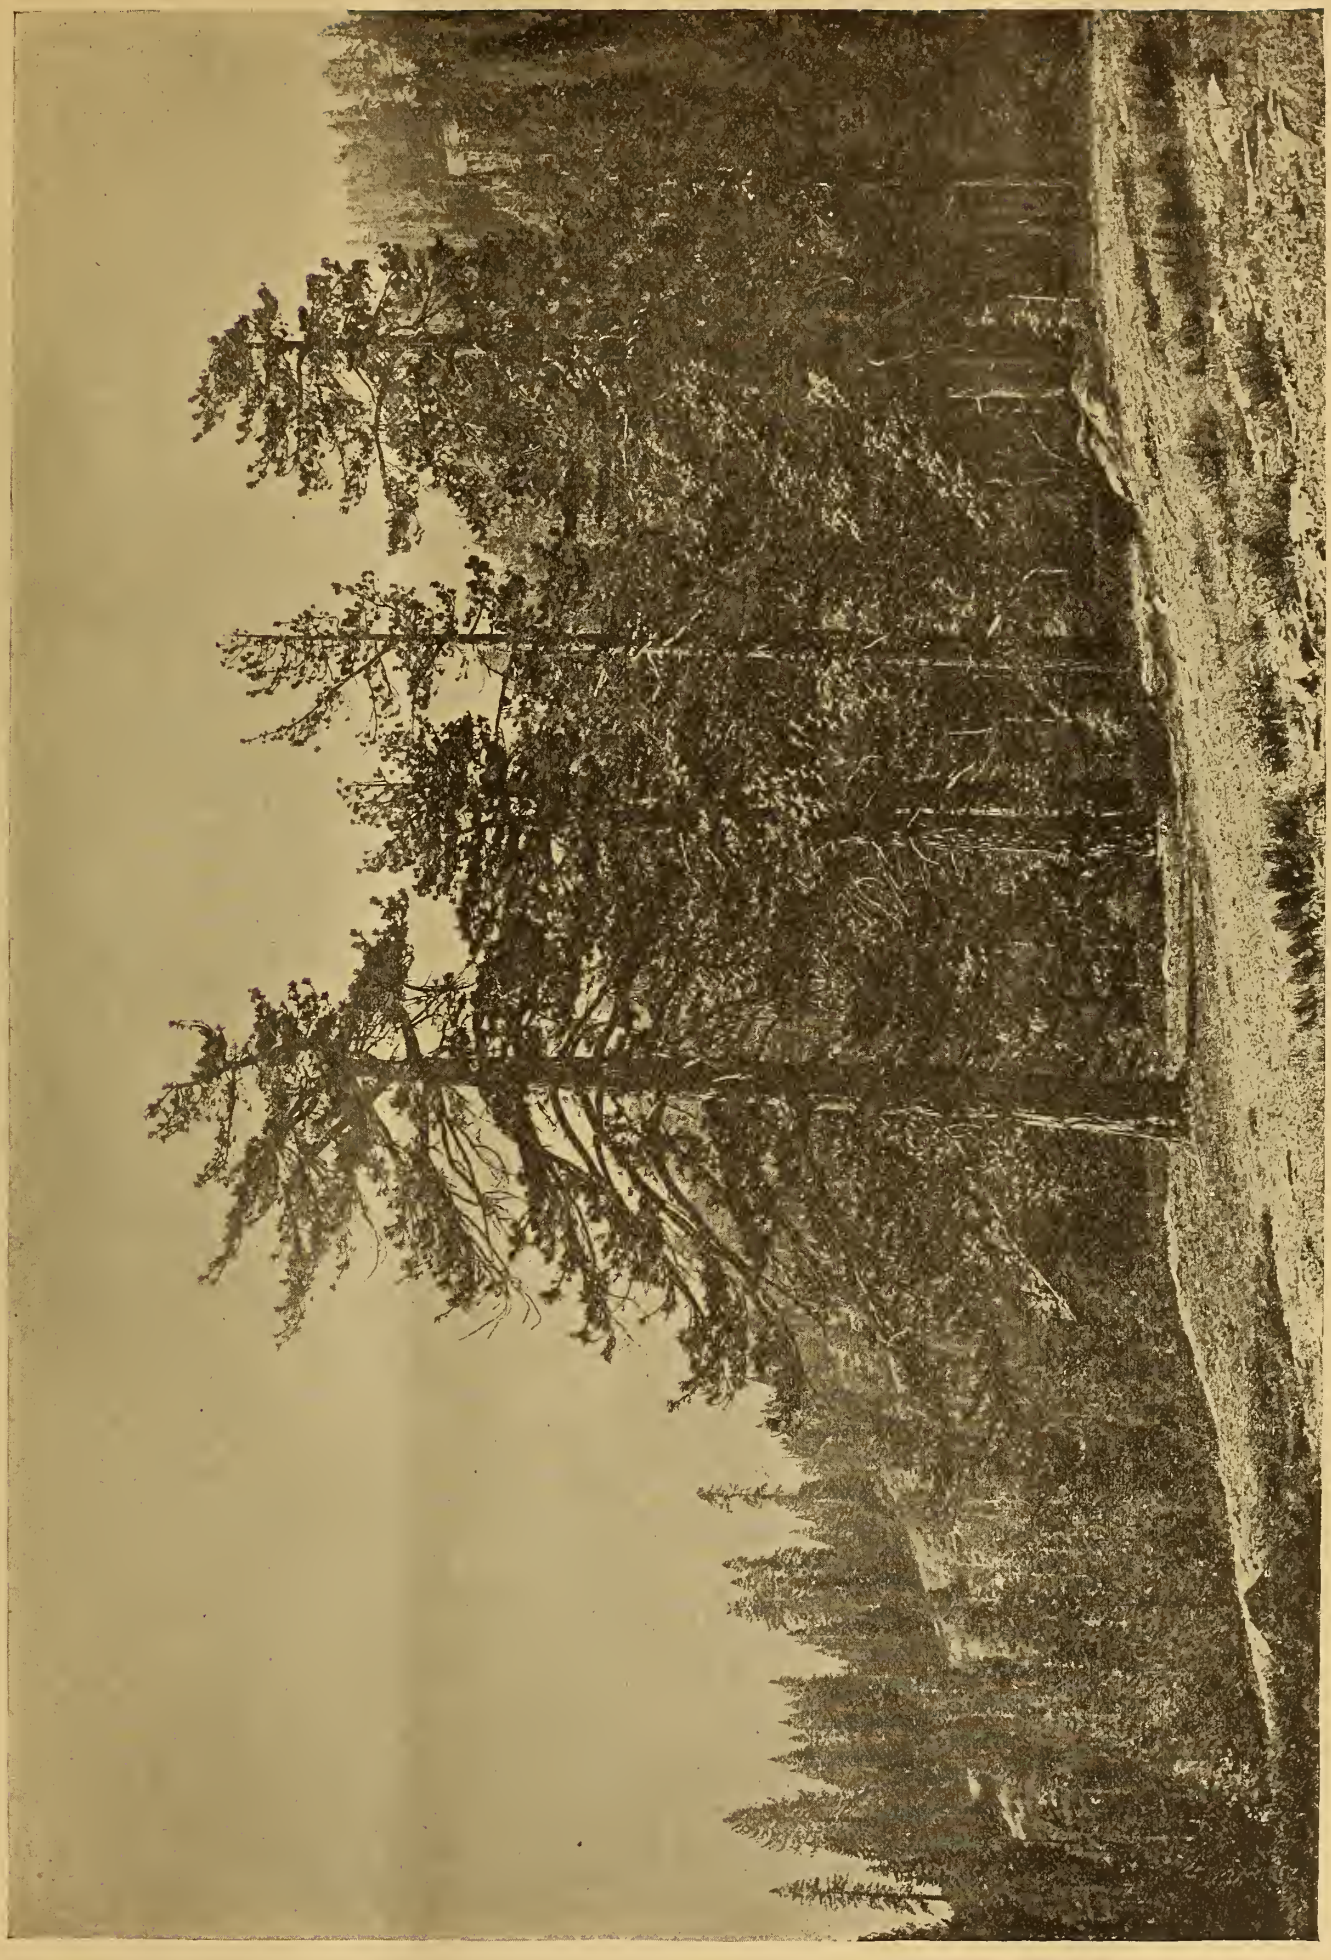

Fig. 73.—Jeffrey's Pine (*Pinus Jeffreyi*) on the Mountain above the Yosemite Valley.—See page 457

B. racemosa, etc., occur very frequently, though the Sand Bur (*Cenchrus tribuloides*) is the most characteristic plant where the soil has been plowed, or loosened by the winds.

The calcareous soils occupy the tops of the hills, and are of smaller extent, near La Crosse, Wisconsin, than Dubuque, Iowa. Birches, especially the Canoe Birch (*Betula papyrifera*), are a most marked feature of it, but this species is by no means confined to soils of this character. Two other plants only occur, so far as I have observed in this region, on the calcareous soils; they are, *Zygadenus elegans* and *Camptosorus rhizophyllus*.

Loamy soils are by far the most abundant; they occur on the slightly rolling ridges and in the valleys. The White Oak (*Quercus alba*) grows excellently in such soil. Alluvial soil does not occupy great areas, except at the mouths of some rivers. The great bottoms of the Mississippi consist mostly of a sandy soil, covered over in some places with a black, rich soil. The White Elm, Box Elder and Soft Maple are common.

The peaty soils are impassable during early spring and summer. Few trees are able to grow—only an occasional Willow or a Tamarack. The bulk of the vegetation consists of species of Carex and Scirpus. Now and then *Lilium Canadense*, *Cypripedium spectabile*, or, here and there, patches of *Drosera rotundifolia* and *Pogonia ophioglossoides*, where the soil is very peaty and wet, appear.

During the past thirty years some important changes have taken place in the growth of timber along the river. The pioneer settler found little timber on the hills, except those with a northern slope. The timber standing on the sunny sides was usually of poor quality, owing to numerous fires. Now these lands are mostly fenced, and fires are kept out, at least by the more enterprising farmers. The bleak hills are being rapidly covered with a forest-growth.

It is not an uncommon thing to observe patches of Hazel (*Corylus Americana*) beyond the outskirts of the timber; here, in course of a few years, will be found Oaks, Birches, Hickories and Poplars. The humus formed where Hazel grows is extremely rich and fertile, and I doubt whether trees could cover our treeless hills very fast without its help

Agricultural College, Ames, Iowa. *L. H. Pammel.*

Recent Plant Portraits.

The following plants are figured in the September number of the *Botanical Magazine:*

Heritiera macrophylla (t. 7192), a large timber-tree of the East Indies, which has long been known in cultivation as the Looking-glass Plant, and forms a conspicuous feature in the Palm-house at Kew with its handsome leaves, bright green above, and opaquely silvery beneath, like the silvering on the back of a mirror. It is a large evergreen tree, a native of the forests of Bengal, Silhet, etc. In India it does not, like *H. littoralis*, with which this plant appears to have been usually confounded, affect the sea-coast or tidal swamps; and it differs from the littoral species in the much larger size of more acuminate leaves, which are also longer-petioled, and in the fruit, which is nearly globose, and furnished with an abrupt flattened beak.

Tulipa Sintenesii (t. 7193); this pretty dwarf species, which belongs to the Gesneriana group and is closely related to *T. undulatifolia* and to *T. Eichleri*, was discovered by Sintenes while traveling in Turkish Armenia to collect bulbs for Max Leichtlin, by whom it has been successfully cultivated and distributed. The flower is two inches long, with nearly uniform, oblong, acute segments, which are dull pale glaucous red outside, bright scarlet inside, with a large black blotch on the claw with an obscure yellow border.

Citrus Aurantium, var. *Bergamia* (t. 7194); this is the so-called Bergamot, or Bergamotte Orange, which is believed to be of a distinct race or variety of the common Orange, although probably better distinguished by its properties than by botanical characters, which are more or less variable. The Bergamot resembles the Lemon in its large light-colored fruit, in the elongated cells of the flesh and in its acidity. The tree, however, is less spiny, the young shoots are green, the petioles are only slightly winged, and the smaller flowers are hermaphrodite, pure white, and fragrant with a peculiar subaromatic odor. "It is one of the three principal races of the Orange proper as distinguished from the Lemons and Limes, the others being the sweet Orange, which is found truly wild in hot valleys of the eastern Himalaya and the Deccan Peninsula; the Bigaradia (bitter or Seville Orange), which, like the sweet Orange, has larger convex surface-glands of the fruit, those of the Bergamot being convex or depressed. There is no record or tradition of the origin of either the Bergamot or Bigaradia, though they may probably have been differentiated in Persia, where the passion for scents being universal, that of a variety or shoot of the Orange differing so greatly in strength and quality of odor as the Bergamot does from its allies, would be sure to attract attention and lead to the propagation of the race. It has been assumed by Gallesio to be a hybrid between the sweet Orange and Lemon, but there are no definite grounds for the assumption."

We learn from Flückiger and Hanbury that the Bergamot Orange appeared in Europe toward the end of the seventeenth century, and that its essential oil was included in a list of the stores of a Giessen apothecary in 1688. The first precise notice of it is contained in *Le Parfumeur François*, printed at Lyons in 1693, where it is stated that the oil is obtained from the juice of a Lemon-tree grafted on the stem of a Bergamot Pear.

Oil or essence of Bergamot is the product for which the Bergamot Orange is cultivated. It is used in perfumery and confectionery, and is extracted by distillation or by sponging the surface of the fruit, or by means of a machine which crushes the skin and thus forces the oil from the glands. The fruit is gathered when still green, in November and December, and from two and a half to three ounces of oil are said to be obtained from a hundred fruits.

The Bergamot is principally cultivated in Calabria, and the manufacture of the oil is chiefly carried on there, and also in Sicily and on the Riviera. The name Bergamot, it appears, is derived from the Italian Bergamotta, a pear; the Bergamotte Pear itself is from the town of Bergamo.

Impatiens mirabilis (t. 7195). "It would be difficult to conceive," Sir Joseph Hooker remarks, "a wider departure from the habit of its genus than this remarkable plant presents. It is an undoubted Impatiens, but, whereas the other species of that large genus are weak, succulent annuals, or low-branched perennials, *I. mirabilis* possesses an erect naked trunk that attains, in its native country, to four feet in height and the thickness of a man's leg, crowned with a tuft of many large, long-petioled, fleshy, spreading leaves, nearly a foot long, from the axils of which spring erect racemes of golden flowers, larger by far than in most other members of the genus known to me, but singularly uncouth in form." *I. mirabilis* is a native of the Island of Langkawi, off the coast of Sumatra, where it was discovered by Mr. C. Curtis, the superintendent of Penang Botanic Garden, by whom it was sent to the nursery of James Veitch & Sons, at Chelsea, where it is in successful cultivation.

Phalænopsis Esmeralda (t. 7196), a now well-known plant in most of the large collections of Orchids, and a native of Cochin China, whence it was introduced into cultivation in 1874. *P. Esmeralda* differs from all the other known species of the genus in its erect, many-flowered racemes, and in the structure of the lip, which is not clawed, and bears no cirrhi, either at the apex or on the disk, but two narrow auricles on the prominent claw, one on each side. The plants described by Reichenbach as *P. antennifera*, *P. Regnieriana* and *P. Buissoniana* are now believed to belong to this species, although they vary a good deal in the size and in the coloring of their flowers.

Cultural Department.

Plums and Plum-trees.

THE Plum crop has been unprecedented in size and quality. The curculio was not as abundant as usual, and I believe that even those who wholly neglected to fight against this pest have had a full crop. This is certainly true of the Lombard and the Damsons. I took special precautions in the way of shaking my trees twice a day, as the plums began to form, and have had an astonishing harvest. The trees would all have broken down but for a system of tying the limbs to poles which were tied at the other end to the tree or to a fence, or rested on the ground. We used all devices to aid the trees, and succeeded in saving them.

I have seventeen varieties in bearing: Magnum Bonum, or Duane's Purple, ripening early in August and continuing to the middle of September. These, in crates, sold so as to bring about three dollars a bushel. They are excellent plums, in size, color and quality, and the texture is good for canning. Their season is late, and they are only good for the table when fully ripe. The Magnum Bonum, after beginning to ripen, if in shaded places, is likely to rot, and one rotting will infect others. Plant them in uplands and enrich the soil. My trees were loaded with superb fruit. Green Gage; this is

the richest and sweetest of plums, and when well ripened on open sunny trees is very beautiful, a ball of gold with crimson cheeks. It is unexcelled for sweetmeats and rich preserves. It melts down too easily to be a handsome fruit in cans. Washington is a handsome, large, sweet plum, oval in shape, ripening just after the Green Gage. It is moderate in flavor, a great bearer, but not a specially good plum for any purpose. It melts down as soon as it is ripe and becomes useless. On the whole it might as well be discarded. Yellow Gage, as I have it, is, in shape and size, a duplicate of Washington, but ripens ten days later. It is of moderate quality and excellent texture for canning and shipping. The color is good, and for table use it is excellent when fully ripe. Lombard, or Bleeker, is ripe with Yellow Gage, that is, from the first of September to the fifteenth. It is large and fine-looking, a reddish purple. No plum is so popular. It is sufficiently solid, and is midway between the tart and the sweet sorts. The tree multiplies rapidly by suckers, and is easily obtained and generally planted. This variety brings less in market than some others because it is so abundant. Robinson is a handsome, small, native plum, yellow-marbled red. It is of about the same value as other native plums. I do not yet find any that equal in quality the best that are of European origin. Wild Goose never bears at all with me. Abundance, a renamed Japan sort (the Botan), is a fine plum and very prolific. Coe's Golden Drop ripens in September, from the first to the twentieth. This is not a firm plum, and it is too small. A tree full will not measure a bushel. Clingstone Damson is an excellent fruit for cooking and preserving. It is round, of medium size and high flavor. It is fit to pick by September twentieth, but is better if left on the trees until October. Shropshire Damson I see no reason for preferring to the preceding, although many do prefer it. It resists the attack of curculios quite successfully and bears solid masses of fruit. The noblest plum of all for home use, and one of the best for market and all purposes, is Bavay's Green Gage. This remarkable plum is an improved Green Gage. It ripens the last of September, is exceedingly rich, and, unlike the Green Gage, is firm. It is very large, averaging with the largest Bleekers. It should become a universal family fruit. It is handsome, and the tree bears well. *Prunus Simoni* is an interesting plum that looks like an apricot and grows on a tree so upright as to suggest a Lombardy Poplar. *Prunus Pissardi*, the puple-leaved Plum, bears fruit of fine texture, the deepest purple-color and very early, ripening the middle of August, and is one of the handsomest.

For home use, I should select Magnum Bonum (or Duane), Bleeker (or Lombard), Green Gage, Simoni, Bavay and Damson. For market it is desirable to have a long season of ripening, beginning with Magnum Bonum and ending with Bavay and Damsons. The custom of sending plums to market in crates, like those used for berries, is now spreading. Packing, heating and rotting are thus avoided, and the fruit is in fine condition for retailing. The profits to the grower are one-third greater, and pay him for all extra care. The plum is a tender fruit, decaying quickly, and must be handled with care.

I have never sprayed my Plum-trees, being deterred by the experience of my friends, who have spoiled the foliage with a solution of one pound of London purple to two hundred gallons of water. This solution I have found admirable for Apple-trees. For Plums I follow the well-tested plan of jarring on sheets twice a day for three weeks. Two boys carry the sheet, which is a large spread of cotton cloth tacked to light poles on the sides, and on one end slit up to the middle, so that the tree stands in the middle of the cloth. A man butts the tree sharply with a rammer padded on the end, to avoid bruising the bark. The curculios fall, and are quickly gathered and destroyed. This is absolutely a remedy, if you begin as the petals fall and continue for between two and three weeks.

Plum-knot is never a necessary nuisance, although it will appear to some extent each year. The knot should be cut off with a sharp knife, always cutting an inch below and above each excrescence. If this were universally done the disease would soon be quite exterminated. The worms inside the soft warty swellings must not be taken as the cause of the knot, but as a coincidence. It is a fungal growth. There are trees wholly given over to the pest, and it spreads to healthy trees. Some varieties are much more subject to attack than others. Worst of all is the English Hesse Plum. This I still grow, but the battle is so constant that I retain but few trees. The cutting should be done twice a year, to be sure it is thoroughly done—once after picking the crop, and again in November, after the leaves fall.

The plum is so very hardy and so useful for canning and for preserving, that it should receive more general planting and more intelligent care. If the two enemies mentioned are attended to, the crop is assured. I have had no difficulty in marketing over fifty bushels at very remunerative prices. The chief point is nice handling and putting into market when exactly ripe, not green, and not over-ripe. Among those I have not named, McLaughlin, Pond, Bradshaw, Peters' Yellow Gage and Spaulding are all fine, as grown by my neighbors.

The Plum-tree is, at best, not long-lived, and new trees should be planted continuously. These can, in some instances, be multiplied rapidly from suckers, as is the case with Bleeker, Green Gage and Damson, if you leave these on their own roots as I have. A Plum-tree exhausts itself by bearing, or is out of health and beauty, in five years. I find that the crop is increased by growing trees quite close together, but the quality is always better on trees grown openly in sunny spots.

The Planting of Hardy Bulbs.

OUR public parks and gardens have shown us for years the possibilities of floral decoration with plants of a bulbous nature. The great majority of these are spring-flowering, and, in consequence, die down early in the summer, and need replacing with other suitable plants. I would like to offer a few remarks upon the culture of bulbs which are really desirable, and, at the same time, hardy in the eastern states.

The best soil for bulb culture is that of a sandy nature, but a stiff clay soil may be used with good success provided a liberal quantity of sharp sand or grit is mixed with it and also placed immediately under the bulbs. I was shown recently some soil taken from one of the bulb farms in Holland, and it was composed almost entirely of white sand enriched by large applications of thoroughly decomposed cow manure, the remains of which, on shaking the bottle, were easily seen on the surface of the heavier sand. It is evident from this example that there cannot be a soil too sandy to grow bulbs successfully, if it is well fertilized and sufficient moisture is assured, until June at least. If the soil is heavy, plenty of sand must be added. Naturally moist soils, with no means of draining, would offer the worst condition for bulb culture, assuming that the bulbs are to be planted, not for one season only, but permanently. I am satisfied that this can be done with the majority of bulbs, with the exception of Hyacinths; but, although these bulbs are perfectly hardy, and will flower for several years, the bloom of the first season will never be equaled.

Of strictly hardy bulbs there is no genus that will give so much real pleasure as the Narcissus, of which much has been already said in the columns of GARDEN AND FOREST. The long lists that bulb-dealers are offering to their patrons, and the number of communications received concerning Narcissus culture, indicate the growing popularity of this flower. In a list recently received from an American dealer the genus is subdivided into the different sections, as in the lists of the large European dealers who make a specialty of the Narcissus. Our experiments with Narcissus, begun last fall, were distinctly successful, as was the large bed of Asters planted between the rows this summer. We shall now give the bed a moderate top-dressing, and shall expect double the quantity of flowers next spring. There has been just one incident to mar the entire success of the plan. A zealous but unintelligent assistant, after removing the Asters from the bed, proceeded to pull up the labels he found there, which, of course, belonged to the Narcissus.

We intend to double our planting this fall. The bulbs were ordered early in July, and August delivery insisted upon, but they have not yet arrived. Directly after they reach us they will be planted in rows six to eight inches deep, and six to eight inches apart in the rows, according to the variety, the rows themselves eighteen inches apart. This allows of hoeing and keeping the beds clean until the annuals are planted between them in summer, when the weeds must be pulled by hand. Writers have differed as to the depth at which Narcissus should be planted, and have doubted the advisability of growing other plants over them in summer. It is only necessary to add that our soil is light, with a gravelly subsoil, and our success has always been certain with deep planting in soils of this nature. I do not anticipate any harm to the bulbs from the planting over them, as their roots are dormant when the other plants are growing, and, in a wild state, they always grow in pastures where they have a perennial covering of herbage above and around them. I have an idea that premature ripening of the foliage, which often occurs here during a hot and dry season, is considerably lessened by the partial shade afforded, both to the soil and foliage of Narcissus, by the summer occupants of the beds. Narcissus are equally good for massing in beds, as is done with Tulips; but for this purpose the commoner kinds should

be used, and these should be planted about six to eight inches apart each way. These need not necessarily be removed in summer, as there will be ample space between them for the insertion of Coleus, Vinca, Geranium, and other bedding plants.

South Lancaster, Mass. *E. O. Orpet.*

The Newer Phloxes.

THE garden Phloxes have lately taken a fresh start in the way of improvement. Many of the newer sorts have individual flowers which are enormous as compared with the best of the older ones, as, for example, Juliet Round and Cross of Honor. Eclaireur has a very dark carmine flower, immensely large and of a rich shade. The plant is dwarf, and the truss as fine as the flower. Bounetain is of a rich rose-color, paler at the centre, and having a ring of a brighter tint midway between the centre and circumference of the corolla. But of all my collection Liberté is most novel, and perhaps most beautiful. The clusters are large, but not the largest, while the flowers are of a deep salmon, with an intense carmine centre. Gold-leaf is notable mainly for its bright yellowish leaves. But we have little reason for indulging in abnormal colors in foliage or encouraging their propagation. Snowflake has large panicles of pure white flowers of the first quality. But of all the whites I have found none to surpass Croix du Sud. The flowers are porcelain-white, with a touch of carmine at the centre, and the plant is decidedly a dwarf. Aurore Boréale has a deep purple centre, surrounded by a shade of orange, and is very effective. General Breart has attractive flowers, which are white, touched with violet and a distinct violet centre. The Nearry has a deep rose-colored flower of the finest form and texture, while the centre is a rich carmine. Richard Wallace is better known. It is a fine flower, white, with rosy eye. Paul Bert, a bluish lilac, with violet centre, is a grand flower. Panama is a noble white, and of the best possible form. Diplomate is a soft rosy carmine, and very satisfactory. Deliverance approaches as near to scarlet at the centre as can be found in any Phlox, while the body of the flower is lilac. Regulus is a dwarf plant, giving fine panicles of salmon, with dark centre of violet shade.

The Phlox is one of our most reliable flowering plants, and is capable, evidently, of still further improvement. Its propagation and cultivation are so very easy as to make it the universal home flower. Its chief drawback is a tendency to multiply shoots and flowers at the expense of size and quality. The plants should be divided every second year. My plan has been to transplant them to a new bed, cutting them away until the root is reduced to a capacity of about three stalks. In the old bed I allow a few roots to send up shoots, which blossom much later. In this way my Phlox season is prolonged until November. Root cuttings make fine plants.

The Phlox requires soil that is strong, but not too highly manured. It must also be mulched thoroughly during the dry season, or the flowers will be unsatisfactory. No other plant on our lawns is so easily affected by drought or by dry weather. I mulch with fine cut grass, or with well-rotted manure, which is mainly sawdust run through the stables for bedding. Next to my Roses, Lilies and Gladioli I place the Phloxes. It is not a good flower for culling, as it has a habit, in vases of water, of dropping very quickly. It is, however, beautiful, fragrant, refined and very floriferous.

Protecting Plants in Mild Climates.

PASSING along one of the streets of Raleigh recently I was attracted by a massive bush, almost a tree, of *Erythrina crista galli*, loaded with great spikes of its gorgeous flowers. It was standing in a smoothly shaven lawn, and looked like one of the oldest inhabitants. As I have kept up my old habit here of lifting Erythrinas and keeping them in a cellar, I was curious to know if this great plant was lifted. On inquiry of the owner I was assured that it had occupied its present place for many years. "We saw it off a foot or more above the ground each fall, after frost has cut the top, and make a mound of saw-dust over it, and it has greatly increased in beauty since we quit lifting it years ago." I am inclined to think that a mound of earth, sodded over, would be an improvement on the saw-dust, and shall try it this winter.

This mounding with earth is a very effective protection for half-hardy plants, particularly if a cover is put over the earth-mound to keep it dry. Amateur gardeners in mild climates frequently lose half-hardy plants that they could save with a very little effort. The Lantana and *Aloysia citriodora* can both be wintered over here by the same treatment our friend gives his Erythrina. A Lantana, trained to a single stem, and pot-grown for a year until the stem gets somewhat woody, will do better for treatment than a young plant set out in spring. Cannas are commonly wintered here where they grow by cutting down the tops and laying them over the bed, but they ought to be lifted each alternate spring, and reset as growth begins, otherwise the rhizomes get so tangled up that growth is impeded. *Canna flaccida* gets to be quite a weed without any protection, and its rhizomes creep under the fences and invade neighboring grounds. It is hard to make our people understand that these tuberous roots ought to be lifted, divided and reset in spring. The fact that they live over without attention in great masses and grow vigorously is accepted as evidence of hardiness, but the scarcity of flower-spikes on these masses shows plainly that the cold has destroyed the flower-germs already formed in autumn. The earthen mound might insure the safety of the flowers, but there is no doubt that the lifting and curing of the bulbs, as practiced at the north and by commercial growers here, is the best plan, even for this section.

For plants with evergreen leaves, like the *Gardenia florida* and the Camellia, we find that the best protection is one that will allow a circulation of air, and at the same time give shade from the early morning sun. Therefore, we stick branches of Pine and Cedar thickly around them, but do not tie them up at all. In the flat, low country of eastern North Carolina these need no protection at all. This same protection with evergreen boughs will always insure the safety of the Fig here. The past two winters have been so mild that there is danger our growers will have so much confidence in the safety of their Figs as to neglect even this protection, and a sudden cold snap may injure the plants, or, at least, destroy the early crop. The cover of evergreen boughs can do no harm even in a mild winter, and will always insure a crop. When the southern people learn the full value of a light protection here our gardens will take on new beauty and productiveness.

Raleigh, N. C. *W. F. Massey.*

Centranthus ruber.—Red Valerian is one of the hardy plants the seeds of which are a regular stock article of the seedsmen, and are offered with much praise and with no qualification. The descriptions are correct, as far as they go, for the plants are neat, strong-growing trailers, covered in the spring with large rosettes of pink flowers. They are not such flowers as one would care to gather for bouquets, but for a wild place, trailing over stones, the plants would be desirable were it not for the unmistakable polecat-like odor emitted by the stems. The smell of this plant is so curious and interesting that I have continued to grow it, though I should scarcely recommend it for general culture, in the endeavor to locate the source of the scent, which seems to hover over the plant instead of being strongly localized in its parts. There seems not only an opening for a chart of colors, but for a scale of scents in describing flowers, since the favorite description of "fragrant" and "very fragrant" fails to convey a lucid idea to the intending grower. No one, for instance, in describing perennial Phlox thinks it necessary to mention the fragrance as that of burnt sugar, which is homely, but exactly describes the odor. Many plants, such as night-blooming Ipomœas and Nicotiana, are found to have the fragrance of the common Datura, a fact which somehow escapes the notice of the trade-writer. However, we are a nation of advertisers, and are accustomed to making the most of our own wares, so that if our friends, the commercial growers, characterize a flower which looks like Canton-flannel as "ostrich-plumes," the proper attitude is not one of irritation, but amused attention.

Nicotiana affinis does not seem to me to be an improvement on *N. acutifolia*, which for some years came regularly in my garden from self-sown seeds. *N. affinis* has larger flowers, and fragrance which is rather Datura-like, but it only expands its flowers late in the afternoon, and during the rest of the day the plants are unattractive. *N. acutifolia* only closes its flowers as they fade, and in this respect is a superior plant in the border. They are such easily grown and effective annuals that they are both desirable where space can be spared, the large leaves requiring considerable room in which to develop properly in true character.

Elizabeth, N. J. *G.*

Cereus triangularis, now in bloom in the Palm-house, was introduced in 1690 from Mexico. The specimen must have been in the garden for a great many years, as shown by its dimension and appearance. It covers the entire roof of the north end of the Palm-house, and I should say it will

weigh from 400 to 500 pounds. This enormous plant had no less than fifty flowers open in one night, and for several nights there were from twenty to thirty flowers open. Unfortunately for visitors the flowers of this and several other of the largest and handsomest Cacti do not open before dusk, and they close again soon after sunrise the next morning.

The flowers, when fully unfolded, measured thirteen inches across the sepals and six inches across the cup formed by the white petals. Lining the inside of the flower are numerous long hair-like stamens, which are bright yellow in color. The fleshy cylindrical style reaches just over the top of the cup formed by the petals, and is divided at its apex into a number of spreading filaments about an inch long. It is impossible to give a description of these flowers that would convey anything like a full idea of their beauty.

The cultivation of the large night-blooming Cacti is not difficult, and I would recommend them for covering bare rafters and walls in large conservatories. In addition to *C. triangularis* there are *C. Macdonaldiæ*, one of the best of the night-blooming species; *C. grandiflorus*, *C. Lemaire*, *C. nycticaulis* and *C. Napoleonis*. All these grow freely, and produce large and handsome flowers which open at night.

Botanic Garden, Cambridge, Mass. *R. Cameron.*

Symplocos cratægoides.—This Japanese shrub, which has found a place in a few American gardens in late years, under the name of *Symplocos paniculata*, is surprisingly beautiful just now. Its branches are loaded with fruit of a bright ultramarine blue, quite different in color from the fruit of any other hardy tree or shrub. The merits of this plant have already been set forth more than once in these columns, but it is unusual to find a hardy shrub, perfectly easy to cultivate, of good habit and productive of handsome flowers and beautiful fruit, and it is always a pleasure to recommend it. Those who have gardens cannot go amiss in adding this to their collections, however choice they may be, or however small the space they can devote to the cultivation of hardy shrubs. Mr. Thomas Hogg has placed us, in America, under deep obligation for several useful and beautiful plants which he was able to send home from Japan at a time when Japanese plants, with a few exceptions, were almost unknown in America and Europe. Among them none has greater value, or possesses more conspicuous and individual beauty than the subject of this note.

Boston, Mass. *S.*

Correspondence.

The Beaver and the Flow of Streams.

To the Editor of Garden and Forest:

Sir,—The most practical methods of retarding the flow of water in the smaller streams, to prevent destructive floods and maintain constant water-supply, is now a pressing question, and a question well worthy of study. Dams on rivers and on their larger tributaries—except at the outlet of lakes—are not to be thought of seriously, for the elements of expense and danger are too great for any extended practical use. The work that has been done in Europe, such as the building of retaining walls, to prevent erosion on the convex side of bends, and the construction of dams, forming basins to hold back the water and catch boulders, gravel and sand, may prove the best devices in a steep, hilly country, with valuable property immediately threatened below; but no two cases will be found precisely alike, and the individual judgment in dealing with such questions will always have ample opportunity for the exercise of practical invention.

Any attempt to give details that will apply to each case will be idle, for such work should always be in charge of men who can invent new plans for the needs of each case. A few suggestions may, however, be in order as indicating the importance of turning to use the forces of nature, when, as so often is the case, these forces, wisely guided, may be utilized to do the work.

A beautiful illustration of such management is found in the fascine dams for retarding water and débris in the rivulets at the remoter sources of streams in Europe. These dams are made by digging a shallow trench across the water-course and bedding in this trench immense bundles of live willow-rods. These bundles are then banked on the upper side, and at once the Willows begin to grow, and a living dam is formed of material that is both effective and self-perpetuating.

To one who has traveled in the primitive woods of North America, these fascine dams at once suggest the work of the beaver, whose dams of willow-fagots and mud, up to four and even five feet high, and sometimes over half a mile long, have formed or increased lakelets, from which the water has filtered in a manner best adapted to the preservation of constant water-flow.

These dams, abandoned by the destruction of the beaver, are now nearly all cut through, and to a great degree rendered of no value in retarding water, yet they remain as historical indices of the past condition of our primitive forests, and no small factor to be considered in accounting for the increased inconstancy of streams which follows settlement in a wooded country. The restoration of this valuable fur-bearing model of industry to its former domain is suggested as a project deserving serious consideration. Such a restoration might be quite effective in retarding water-flow, preventing erosion and soil moisture, and maintaining water-ways, city and mill-supply, at a minimum expense; and this expense the production of valuable furs would aid materially in defraying.

Washington, D. C. *H. B. A.*

Pomology.

Meeting of the American Pomological Society.—I.

THE American Pomological Society held its twenty-third biennial session at Washington on the invitation of the Secretary of Agriculture. As a rule, the society accepts the hospitality of some local organization, but in this instance the gathering was welcomed by the Honorable Edwin Willets, the Assistant Secretary of Agriculture, in the Lecture Hall of the National Museum. During the sessions papers were read by several of the experts connected with the department, and all the material of the department in the way of fruit models, etc., were placed at the service of the society.

The fruit exhibit, which the older members say has not been so good of recent years as it was twenty-five years ago, was very creditable in every way. The state of Virginia, through her Commissioner of Agriculture, showed one hundred and sixty-three varieties of Apples, which represented all the fruit regions of the state, from tide-water to the mountains, and many of them, notably the Albemarle Pippins, were exceptionally good. From Mississippi, Tennessee, New Jersey and many other states there were promising seedlings, and Messrs. Ellwanger and Barry had a very large display of Pears. Of the minor exhibits there was a striking collection of Citrus fruits from Florida shown by the Rev. Lyman Phelps, with some admirable Pines from the same state by Mr. H. S. Williams. President Berckmans exhibited an interesting collection of Japanese Persimmons of all sizes, shapes and colors, and Mr. H. M. Engle, of Pennsylvania, some of the remarkable Chestnuts which he is growing.

A good deal of time was spent on the revision of the catalogue, which is really one of the most important functions of the society, but very plainly it is a difficult matter for a few members in the hurry of such an occasion to pass any such deliberate judgment as they deserve on the merits of fruits and their adaptation to different regions. Mr. Berckmans' suggestion in his address, that this work should be practically done by local societies, under the supervision of the national one, commended itself to all of the members. We give below a few of the more important paragraphs from this address, which was a general survey of the field and a careful record of pomological progress since the meeting of the society in Florida two years ago. The officers chosen for the next two years are Prosper J. Berckmans, of Augusta, Georgia, President; C. L. Watrous, of Des Moines, Iowa, First Vice-President; G. B. Brackett, Denmark, Iowa, Secretary; Benjamin G. Smith, Cambridge, Massachusetts, Treasurer.

THE PRESIDENT'S ADDRESS.

In speaking of the work of auxiliary societies, Mr. Berckmans said:

These local organizations could hold meetings every month, or even oftener if need be, especially during the fruit season, and at these meetings the merits and demerits of fruits could be ascertained, annual reports made to the state society, to which these local societies should be auxiliaries. In this way the

chairmen of state fruit committees could collect more reliable reports than can be obtained where state and district societies do not exist. Our state reports are in some instances deficient in reliable and practical information. To persons unacquainted with the scope of our state reports and their influence in bringing the most desirable class of citizens to their borders, let me say, that one of the main considerations a prospective settler takes in view is the adaptability to successful fruit-growing of any section where he intends to make his residence. The state which gives the most comprehensive and reliable report as to its advantages in these productions will receive the most intelligent, energetic and desirable addition to its population; and that community most exclusively devoting itself to fruit-growing and horticultural pursuits is found to advance more rapidly in everything tending to elevate, refine and enrich its citizens.

In urging the necessity of scientific pomology, Mr. Berckmans argued as follows:

While this society has never deviated from its original object, which is the advancement of the science of pomology, yet the wonderful strides made in the production of fruits make it imperative to give commercial fruit-growing all due attention, inasmuch as the magnitude of that source of production is, in a measure, the result of the scientific work of this society. When we compare the wonderful array of the various fruits with which our markets are now supplied with those of a generation past, well may we feel amazed at the variety and abundance as well as improved quality of our market products. A few years ago many fruits were offered in such limited quantities that the names of special varieties were almost wholly ignored. Strawberries were all strawberries; the Isabella was the only name used to specify a variety of Grapes that could be found, and among Pears the Sugar Top was synonymous to the Bartlett, and every Orange, good, bad or indifferent, was sold as a Florida Orange. Now, on the contrary, the market reports issued by every commission man who values his interests name the varieties of all classes of fruits, and quotations are made according to their value. Purchasers have become gradually educated to the knowledge of the best varieties, and thus inferior sorts are driven out of the market. With these facts in view, commercial fruit-growers are interested in improving our popular varieties of fruits by the most careful methods of cultivation, picking, sorting and packing, and they can increase their pecuniary returns by promoting the advance of scientific pomology.

THE HYBRIDIZATION OF PLANTS.

Professor Charles E. Bessey began a paper on this subject by saying that in the lowest forms of vegetable life the process of reproduction is exceedingly simple—that is, one plant divides itself into two; each new plant divides again, and so on indefinitely. But when conditions are not so favorable, reproduction takes place in a general way as follows: Two of these free-swimming aquatic plants come together and merge their substance into one another—that is, fertilization consists simply of two entire plants, or parts of plants, which fuse into one, and lose their previous identity. This means the simple union of two individuals for the sake of strength and production. The united plant is able to live and resist adverse influences, which otherwise would have destroyed the single plants. The two plants after union become one round body, and this covers itself with a protecting shell, and since the larger the mass is, the smaller, proportionally, is the exposed surface, the united plant needs less covering than the two did before the union, thereby saving both material and force. Thus the union of the two into one mass has saved the life of the individual and has perpetuated the species. This is essentially what takes place in all plants where there is anything like fertilization. The law is, that fertilization is the union of two masses of living matter.

In the fertilization of flowering plants we have the same coming together of individual masses, and as a consequence of the union of the male and female cells, there begins a growth in the young seed which results in the formation of the embryo which is to be found in every seed.

This fertilization—that is, the joining of the substance of the pollen-cell with that of the seed-cell—does not differ in any essential respect from that which takes place in the simplest plant.

The old distinction between crossing and hybridization is one which has nothing like as much importance as at first sight it would seem to have. If varieties differ from species only in degree, then crossing of varieties differs from hybridization of species also only in degree. Furthermore, it is well known that no two animals are ever exactly alike. No two plants are ever exactly alike, even where they belong to the same variety; and therefore when the pollen is taken from the flowers of one plant and carried to those of another there is a slight crossing of kinds. It is not as great as when the pollen is taken from a flower of one variety to that of another, nor by any means as great as when it is taken from the flowers of one species to those of another, but all these differ only in degree.

Whenever crossing takes place the offspring will partake of the character of both parents. This follows as a necessity from the nature of the act. We have seen that in any fertilization there is a union of two plants, or two parts of plants, and in crossing the male organ belongs to one variety or species, while the female organ belongs to another. When these two organs are joined the result is a union of the character of the two varieties or species. In this way the offspring must partake of the nature and characteristics of its parents. It is impossible for it to be otherwise. Now, it has been noticed in the breeding of animals, and to a certain extent in the breeding of plants, that the two parents do not always exert the same influence upon the offspring. In the case of many natural crosses which take place between the wild species of plants, noticeably in the Verbenas, the Oaks, the Willows and others, we have been able to detect this difference with such certainty that it is not at all a difficult thing to tell whether, in the case of any particular cross, the pollen comes from this or that species.

In nature, crossing is accomplished largely through the agency of insects, but when we bring this matter within the domain of horticulture we cannot afford to depend upon such precarious aid. The time is coming when the grower of fruits will as carefully select the parents for his crosses as the grower of fine animals now does. The grower of plants, however, has one advantage over the grower of animals. He need not pen up his plants, he need not grow them in different greenhouses or in different fields. As the pollen of our fruit-trees is always yellowish, there is no difficulty in handling it upon the black point of a hair-pencil. The pencil should be slightly moistened, so that the pollen will adhere to it, and then, when loaded with pollen from one flower, it can be gently brushed over the ends of the pistils of the next one. In order to be sure that the stamens of the flower to which the pollen is brought do not themselves drop pollen to the pistils, it is well to remove them at once by clipping them out by means of a delicate pair of scissors.

This operation is not difficult. It simply requires care in watching for the exact time of the maturity of the flower, and then a very little skill will enable one to place the pollen. The maturity of the flower may be told in the following way. The stamens are matured when they are dropping the pollen. This can be seen by any one at a glance. The pistils are matured when the top stigma has a moist appearance. This moisture is what makes the pollen adhere, so that any attempt at crossing before the maturity of the pistil would be ineffectual.

There can be no question that horticulture will be greatly benefited when horticulturists begin to breed varieties scientifically. It is a well-known fact that the seeds of apples, taken from any particular tree, will produce all sorts of variations. Now, the secret of this is, that the flowers which produce these seeds had been crossed with pollen taken by insects, perhaps, from a dozen different kinds of trees. Furthermore, all our Apple-trees are now of mixed blood, and we know very well what that means, especially in the animal kingdom. Now, careful experiments should be made by members of this society. Suppose that you select two Apple-trees which are not far from one another, and which, for convenience, are not very large. It will be best to select trees of marked varieties. If they are trees which have characters about them which would indicate that they were likely to reproduce their kind and their characters, it would be better still. Now, when these trees are just about ready to flower, cover each one with mosquito netting which has been carefully sewed together, so as not to leave any opening to admit insects. When the stamens on the one tree are just bursting open so as to shed their pollen, take a soft camel's-hair brush, wet it slightly, and carry some of the pollen from certain flowers on the first tree to certain flowers on the second tree. Then carry pollen from the second tree to certain flowers on the first tree. If you remove the stamens from the fertilized flowers it will add much to the certainty of the results. Mark the flowers which you have experimented upon; keep the trees covered with the mosquito-netting until the flowers wither, and then remove it. Carefully note the growth of the apple during the season. Notice whether the flesh of the apple has been changed in any way, and when the fruits are finally

cut up save the seeds for planting. When these seeds have grown, cions should be taken from the young seedlings and placed upon old trees, so as to bring them into bearing at the earliest possible period. It will be very interesting to compare the results of such crossing. If the parent tree possessed marked characters, we should expect to find these reproduced in a modified way in the offsprings.

Similar crosses may be effected between varieties of vines, and it is still easier to secure early returns from the experiments. Cherries, Plums, and even the ordinary small garden-fruits may be experimented upon in the same way. If the members of this society were to plan a series of experiments, each man confining himself to a single one, within the next ten years we should without doubt have some surprising results.

It is by the application of exactly these principles that the breeders of animals have been able to reach the results with which we are so well acquainted. It still seems to us in horticulture rather a theoretical thing when we talk of crossing and breeding in order to produce new and desirable species, but that which has proved of such great value in the animal kingdom will in like manner prove of value in the vegetable kingdom.

The horticulturist of the future, and of the near future, too, will be a breeder of plants, and he will be able, by judicious crossing, by intelligent working for a particular form, to control the results of his breeding.

SUCCESS WITH SMALL FRUITS.

Mr. J. H. Hale delivered an address on this subject. As a first requisite he named a thorough preparation of the soil. Such a recommendation seemed hardly necessary, but in a great majority of cases fruit-growers fail for lack of attention to this fundamental matter. Of course, in the virgin soil of the prairies different treatment is needed from that required in thin and worn lands in the eastern states, but there is the same necessity of deep preparation and thorough drainage, although there is less necessity for fertilizing, which is the second requirement wherever the soil is not absolutely rich. For small fruits, potash and phosphoric acid are the plant-foods principally needed in Connecticut. Wood-ashes is the most effective form in which potash can be used, but in the south, where it can be obtained, the ashes from cotton-hulls is better still. Two hundred bushels of ashes to the acre is not too much, and to this a ton and a half of finely ground bone may be added to supply the phosphoric acid. Ground bone had proved the best form in which phosphates could be applied, but South Carolina rock and other forms of phosphate should be tried. As a rule, but little nitrogen is needed, since the tendency of this is to make a growth of foliage. Of course, in certain instances it is valuable, as, for example, while the Cuthbert and Golden Queen Raspberries will flourish under treatment of potash and phosphates only, the Marlborough, in the same field, would be improved by the addition of a trifle of nitrogen, because it is a feeble grower, and needs strengthening. (In other districts nitrogenous manures have proved essential to the highest success with small fruits.)

It is a great mistake to grow the plants too thickly. It generally happens that from two to three times as many Raspberries, for example, are planted to the acre as can be grown to advantage. They should not be set closer than six feet apart each way, and seven, or even eight feet apart, are better for strong growers like the Cuthbert. Then the berries will be big, bright and firm. Hedge-row culture and matted-row culture is wrong, and the hill system is right almost always. Berries grown in this way will be superior in size, texture and quality, and will yield more quarts to the acre, and, besides, the cultivation will cost less when it is done thoroughly.

Irrigation should be provided for Strawberries, where it is at all possible. The grower cannot afford to take all preliminary care for thorough preparation and painstaking cultivation up to the time the plants bloom, and even up to the time the green berries appear, and then lose all on account of the failure of rain for a few weeks. At such a time the control of a supplemental water-supply is invaluable.

After the crop is grown the marketing demands much thought and study. Fruit-growers often work too hard and think too little. It pays to study fruits as they come into the market and to mark the different styles in which they are offered. Fruit which is nicely topped, but does not run uniformly throughout the package, may sell well for a time, but in the long run that grower is always sure of a market who has his best fruit at the bottom, and who is willing to stamp his name and post-office address on each package, so that the people who buy his fruit will know whom to address when they want more of just the same sort. As an instance of success Mr. Hale cited the case of a man who was careful to select and grade every basket of his strawberries, and in the bottom of each basket he placed a card bearing his name, the name of his farm, with the date and the hour of the day in which the fruit was picked added in stencil, and after all this, in big type, was the legend, "This fruit will cost five cents more a basket than the market price."

The eye of a buyer must first be pleased, and the value of an attractive style of placing fruit on the market cannot be overstated. A strawberry grower in western Massachusetts found that it paid to put a rosebud on the top of each basket in the crate, for these decorated packages would sell when no other ones were wanted. The most certain way of securing a market for fruit is to establish a reputation. A grower must make his name have a positive value. He must persist in careful selection and uniform packing until buyers know that his berries are certainly of the first quality and can always be relied on. A name which stands for all that is best in the possibilities of fruit-culture will always sell the fruit upon which it is found.

After all, the home is the best market for American fruit-growers. The average American family uses too little fruit. Farmers, and even orchardists, rarely have enough small fruit. They say it does not pay to raise berries and they can buy all they want. Really they buy a few now and then instead of having an abundant supply every day. Half a bushel of fruit the year through can be profitably disposed of by the average family every day. Every one with half an acre of ground to devote to the purpose can have enough small fruit for home use. This does not mean a few berries in a corner of a garden, but a full line of the standard varieties of all kinds of small fruits planted in long rows, so that they can be cultivated by horse-power, yielding an assured abundance for the table, for canning, etc. Last year a Connecticut farmer kept account of the fruit which he supplied to his family from half an acre of ground. He watched the markets and charged his family with the price of all they consumed, and it amounted to $365, or more than $700 per acre. This was the actual money value of what the consumed fruit would have cost, but the account makes no mention of the pleasure and zest which the product brought to the table in that household, nor of the beauty of the garden, which was an ever-changing picture for the enjoyment of its owner and his family, nor of the advantages from the healthful out-door habits it encouraged, nor of the delights of tasting new fruits, or the hundred other subtle ways in which a garden ministers to mental and physical health.

NEW AND PROMISING SMALL FRUITS.

The paper of Mr. J. T. Lovett on this subject covered all kinds of small fruits, but we only have space for the following:

But little of interest is to be found among new varieties of the Currant. Fay's Prolific is a success with me, and I hear none but good reports of it from any quarter. North Star gives promise of being a valuable variety, especially for the market-grower. Black Champion is an improvement upon the old Black Naples; the berries are larger and produced in greater abundance. I am told it is of better quality, but to me all the black currants are repulsive, in odor and flavor. The Crandall has some merit for culinary purposes. It is of strong growth, exempt from the attacks of insects and disease and very prolific; but the fruit is too harsh and austere to be acceptable as a dessert-fruit. The berries are exceedingly large, almost equaling in size the Delaware grape, and are decidedly attractive. The claim that a good jelly can be made from it is founded on fact, as I can bear witness.

The Industry Gooseberry has not proved as successful with me as it has in many other places. In Monroe County, New York, and upon the Hudson River, it is giving the greatest satisfaction. I also saw it fruiting in perfection in Atlantic County, New Jersey, the past season. Although the best of the foreign varieties I have yet tasted, it loses its leaves prematurely and fails to ripen its fruit.

The dwarf Juneberries have given considerable satisfaction at the east. The chief complaint has been that the plants do not yield heavily enough, and that the berries and foliage are attacked by a fungus. The variety known as Success is an improvement upon the type in point of size of fruit, quality and productiveness, and has suffered less from the attacks of fungus than the common dwarf variety. It has suffered also to a slight extent. I find the Juneberry much better for canning, pies, etc., than as a dessert-fruit. In its natural state it lacks flavor, but when cooked it is quite acceptable.

Eleagnus longipes is an interesting fruit. Did it ripen in late autumn instead of July its value would be greatly enhanced.

The bush is of low spreading habit, densely clothed with foliage, and it comes into bearing as quickly as a Red Currant. Its yield is simply wonderful, the berries being literally crowded upon the under side of the branches. The fruit is borne upon slender stems about an inch and a half long, of cinnabar color, with numerous small light gray dots, and about three-quarters of an inch long by half an inch in diameter. It is tender and juicy, with one large, long, shapely pointed seed in each berry, but so acid as to render it unfit for use as a dessert-fruit, but useful for tarts—in fact, for all the purposes for which the Cranberry is used.

Notes.

The latest reports indicate that the raisin-crop of California, which has been estimated as high as 2,000,000 boxes, will fall considerably short of that figure.

It is reported that the presence of troops in the Yosemite this year has kept the sheep and shepherds away from the Reservation, and, as a result, there have been but two or three small forest-fires. Such fires are usually numerous in August and September.

It is probably an unusual thing for *Ficus elastica*, the so-called Rubber-tree, grown as a pot-plant, to produce fruit. The fact is worthy of notice, therefore, that a plant in the garden of the Honorable M. P. Kennard, in Brookline, Massachusetts, which has stood out-of-doors all summer, is now covered with its miniature figs. The same plant has produced fruit in previous years.

It is recorded of the isolated Andaman Islands, which have been scientifically observed since 1858, that, between that year and 1866, fifteen intentionally introduced plants and sixty-one "weeds of cultivation" were added to the six hundred species of indigenous origin; and that by 1890 twenty-three additional plants had been wittingly introduced and fifty-six additional ones had established themselves, while four of the foreigners noted in 1866 had disappeared.

Last week the Board of Health in this city seized some grapes because the stems were discolored by one of the copper mixtures used as a preventive of Black Rot. Of course, this caused something like a panic in the market, and the grape-growers on the Hudson, who were already receiving low prices, have suffered severely. We shall be disappointed if investigation does not show that the alarm was groundless. The Bordeaux mixture is certainly harmless when taken in such minute quantities as adhere to the skins of grapes which have been sprayed.

One of the most striking proofs of the advantage which may result to science from the earnest efforts of even "amateur," or partially instructed investigators, is supplied by the history of Leeuwenhoek. At the time of the invention of the microscope, in the seventeenth century, he was book-keeper and cashier in a clothing house at Amsterdam. Fascinated by the attractions of the new instrument, he devoted himself to its manufacture and use, and, despite the deficiencies of his education, made many important discoveries in plant anatomy, as well as in that of human beings, and was the first to point out that difference in the structure of stems upon which the first great division of flowering plants into monocotyledonous and dicoteyledonous is based.

In a book on the "Useful Plants of Australia," written by Mr. Maiden, we read that, with the exception of such as produce timber, these plants are not of extraordinary value. Almost all Australia's medicinal plants come from the northern regions, where species from the Malayan Islands and from the south of India mingle with those that are strictly indigenous. The Eucalyptus, with its 130 species, are the most valuable trees, supplying certain food-products as well as oil and timber. Next in value seem to be the Acacias, the leaves of which furnish fodder, while the bark is extensively used in tanning. The trees are being so rapidly destroyed for these two purposes that efforts are now being made for their systematic planting. Few Australian trees supply good fibres.

At the exhibition in connection with the meeting of the Pomological Society in Washington last week the superior brightness in color of northern fruits was very clearly shown. The apples from Wisconsin could be distinguished from those of the middle states as far as they could be seen, and it would hardly be a figure of speech to say that they fairly illuminated the part of the hall where they were placed. It is fair to say, however, that the season in Wisconsin has been exceptionally unfavorable to the growth of fungi, and this may partly account for the entire absence of all specks and discolorations on the fruit. But, after every allowance is made, the fact remains that apples of such perfect smoothness, clearness of color and delicacy of marking are rarely seen in our eastern orchards. It was remarked by more than one of the visitors that they never before realized how beautiful a perfect apple can be.

Hardy shrubs which are in full bloom during the first week of October are not common in our northern garden. The Sea-shore Groundsel-tree (*Baccharis halimifolia*) is just now in full bloom, and, although not very often cultivated except by the curious, is well worth a place in the shrubbery. It is a tall resinous, or glutinous, shrub, growing sometimes to the height of ten or twelve feet, with dark yellow-green, abundant foliage, and small heads of yellow or white flowers. Baccharis is a genus of *Compositæ*, and its individual flowers are minute and are gathered together in small heads without the conspicuous ray-flowers which make the inflorescence of Asters, Sunflowers and so many other plants of this family conspicuous. The heads are not large, and, individually, not very showy; but they are produced in such great profusion in leafy panicles at the end of the branches, that the plants make a good show at this season of the year. This is especially the case with the fertile one, for in Baccharis the male and female flowers are borne on distinct plants. The tufts of long pure white hairs give to the females an entirely different appearance from that of the yellow-flowered males. Plants of Baccharis grown in good garden-soil will be a surprise to many people who have only seen it in its native sea-beaches, and once seen under good condition its cultivation, no doubt, will become more general.

"We do not realize," says the *American Architect and Building News*, "how imperatively necessary a supply of wood is, or how little we have left to satisfy our increasing needs. The forest-producing area of the United States has long ago been settled as thickly as it is likely to be, and the tendency of population is now strongly toward the treeless, though fertile lands of Kansas, Texas, Nebraska, Colorado and Montana. The people who settle in those states must have houses, and must have timber to build them with, and the railroads which serve them must have perennial supplies of ties. For all these needs wood must be had, even if it is brought from the ends of the earth. We have known building timber to be sent from Boston to Zanzibar, and from New York to Buenos Ayres, and we may rest assured that when our stock is exhausted we shall have to buy more, and shall have to pay the people who have it whatever price they choose to ask for it. So far, the steps which have been taken by the public authority to check the annihilation of the forest-wealth of the country have been hardly more than the feeblest demonstrations of a consciousness of the evil against which they were directed. Something was done to encourage tree-planting by settlers, under the so-called Timber-Culture laws, which provided that a settler who cultivated trees on one-sixteenth of his homestead claim should receive his patent in three years instead of five; but this is a mere trifle, and the unwillingness of Congress to do anything of serious practical significance is curiously shown by the law adopted at the last session, in which it was declared that it is 'important to reserve all public lands bearing forests, or covered with timber or undergrowth, on which the timber is not absolutely required for the legitimate use and necessities of the residents of the state or territory in which the lands are situated.' It need hardly be pointed out that 'the legitimate use and necessities of the residents' in the neighborhood of Government timber-lands have generally required them to plunder and denude the lands to their hearts' content, and will be likely to continue to do so until some much more forcible language than this is used in the public statutes, and officers are assigned to see that the statutes are complied with; and even then, in our opinion, little will be accomplished toward restoring the balance between the production and consumption of timber until private plantations, as well as natural forests, are brought under official supervision."

Catalogues Received.

Currie Bros., Milwaukee, Wis.; Flowering Bulbs, Plants, etc.—Frederick W. Kelsey, 145 Broadway, New York, N. Y.; Choice Trees, Shrubs and Hardy Plants.—Samuel C. Moon, Morrisville, Bucks Co., Pa.; Circular of Exochorda grandiflora.—Schlegel & Fottler, 26 South Market Street, Boston, Mass.; Bulbs for Autumn Planting.—Dr. H. Schroeder, Bloomington, Ill.; Fruit-trees, Grape Vines, Small Fruits, Roses, etc.—Thomas S. Ware, Tottenham, London, England; Select Collection of Bulbs and Perennials for Autumn Planting. Complete Collections of Narcissus, Lilies and Irises. Autumn Catalogue of Carnations, Pæonies, Phloxes, Primroses, etc.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by . . . . . Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, OCTOBER 7, 1891.

TABLE OF CONTENTS.

Government Timber Tests.

IT is an admitted truth that there is too little precise knowledge, even among those who are considered experts, of the technical and physical properties of the more prominent woods that are used as timber in the United States. The country has been so far blest with such an abundant supply of excellent material that every one has been able to secure a kind of wood suited to his needs, so that there has been little practical necessity for studying the nicer distinctions between the various species. Again, wood of the same species varies very largely in its qualities as it is grown under different conditions, and it varies, too, in different parts of the same tree. But the study of these differences can only be made at great expense and by persons of special training, and it is not a matter of wonder, therefore, that our knowledge is no greater. It would hardly be credited, however, by the public that large dealers in lumber, and even inspectors, architects and builders, do not even know, in many cases, what kind of timber they sell or use. A large dealer in a western city, in writing to the Forestry Division of the Department of Agriculture, stated that he was selling Long-leaved Pine which came from Arkansas, but since *Pinus palustris* does not grow there he is probably buying and selling *Pinus mitis* for the true Long-leaved Pine. Not long ago a prominent dealer in Chicago, where millions of feet of southern pine are handled every year, wrote to know how timber of the Long-leaved Pine could be distinguished from that of the Short-leaved Pine, showing that such prominent timbers as these are not well known, even to those who handle them. It is a fact that, owing to the increased demand for Norway pine, certain dealers in the west met the emergency by branding some southern pine as Norway, and the sales went on as before. The ordinary macroscopic resemblance between the woods of some of the different species of Oak is so great that the three of them are indiscriminately sold as White Oak.

Now, it is plain that any help which will enable persons to identify the various woods by an examination of their structure would be of great value to all those interested in the use or the sale of timber, and this is hoped for as one of the results of the investigations instituted by the Forestry Division within this year, since the studies of Mr. Roth, of the University of Michigan, who has in charge the physical and microscopic work, are expected to furnish the means of distinguishing the wood of one species from another even when their resemblance in superficial characters is close. As a result of this there ought to be fewer mistakes and misunderstandings, not to speak of deceptions and frauds which can be practiced in general, while the vital distinctions between the woods of different species are not recognized. This work will be still more valuable in connection with a check-list of the arborescent flora of the country which is now in preparation by the Forestry Division, and which will aim not only to give all the synonyms, both common and botanical, of each species, but the geographical distribution of the common names, because nurserymen, lumber-dealers and others who use these woods are naturally misled by the indiscriminate use of the same name for different timbers in different localities. Mr. Fernow calls attention to the fact that buyers of southern pine in the north are quite uncertain how to order and how to distinguish the three kinds that reach the market here, since the same name is applied to each in various regions; and since the botanists have undertaken to revise the scientific nomenclature it is still more desirable to publish the new names, so as to establish a basis of intelligent communication.

Attention has been directed to this subject by a circular recently sent out by the Forestry Division in relation to the Government timber tests now going on, and which, as is stated with justifiable pride, are the first to be made in so complete a way in this particular direction. In order to make these investigations of the highest utility the material for study must be collected by a careful observer who has the judgment to note accurately the conditions under which the samples have grown and sufficient intelligence and training to make certain determinations on the spot. Dr. Charles Mohr, of Mobile, has been doing this work in the south, and a no more trustworthy agent could have been selected. He chooses trees of each species from a number of localities with different soil and climatic conditions, and from each site five trees are cut up into logs and disks, each division being carefully marked to show its proper position in the tree. Disks of a few young trees, as well as of wood from the limbs, are collected for biological study, so that from fifty to seventy disk pieces and ten to fifteen logs are collected for each species, and a full account of the conditions of soil, climate, aspect, measurements and determinable history of the tree and the forest-growth about it is added to the collection from each site. This is the material from which Mr. Roth makes his studies of the physical properties of the tree. He notes its specific weight, the amount of water and the rate of its loss by drying in relation to shrinkage, the structural differences between the pieces, especially as to the distribution of spring and summer wood, strong and weak cells, etc., and the rate of growth and other biological facts which may help to show any relation between the physical appearance of the tree, its conditions of growth and its mechanical properties. Finally, the logs are shipped to St. Louis, where Professor J. B. Johnson will test one-half of the logs while they are green and the other half after a thorough seasoning, in order to judge of the strength of the wood under various kinds of strain and pressure. Besides the beam tests, fifty others will be made of each tree, or about two hundred and fifty tests for each species and situation.

A few problems upon which this work ought to throw more light are stated by Mr. Fernow, as follows: What influence has seasoning of different degrees upon the quality of wood? How do age, rapidity of growth, time of felling

and after-treatment change quality in different timbers? In what relation does structure stand to quality? How far is weight a criterion of strength? What difference is there in wood of the different parts of a tree? How far do climatic and soil changes influence quality? In addition to the study of these and other problems which will suggest themselves as the work advances, it is proposed to test the influence of continued use upon the strength of timbers by experimenting, for example, with timbers which have seen service in bridges for a given length of time.

We are glad to observe that the American Association for the Advancement of Science has appointed an advisory board to assist in securing improved methods for this work, and co-operation is invited from all other scientific men and institutions, so that this will be made a truly national work. We have been permitted to examine a schedule under which various data are placed on record, and it is very ingenious and comprehensive; and, altogether, we agree with Mr. Fernow that this is the most promising work in which the Division of Forestry has yet been engaged. It is plainly a work worthy of the Government, and, from its magnitude and cost, it could hardly be undertaken by private enterprise. Many of the problems to be investigated have already been made the subject of careful study in the Tenth Census, but we cannot have too many tests to corroborate or check each other. If, therefore, the work of the Government is to be carried on with thoroughness at all stages, it has begun none too early, for some of our most valuable woods are growing scarce, and we ought to know what other kinds are best suited to particular uses, for, as the circular referred to states, the knowledge gained by these tests will enable us not only to apply our timbers to the uses to which they are best adapted, but will help us to supply conditions which will produce these required qualities, and thus direct both the consumer of the present and the forest-grower of the future.

Some years ago something like a panic seized a few city boards of health who had just learned that preparations of arsenic had been used upon potatoes to protect the crop from insects, and there was much discussion about condemning all potatoes as dangerous, unless it could be proved, in each case, that no poison had been applied to them. It was long before this that the insects made their memorable march from the Rocky Mountains to the Atlantic and farmers had been using arsenical preparations for several seasons with no evil consequences. But the city people had not heard of this, and when the matter was brought to their notice the newspapers at once sounded the alarm and the boards of health aroused themselves to sudden activity. There was a fall in the price of potatoes, which caused much loss at that time, but the arsenites are still used, and we hear no more of poison potatoes.

Four years ago we described the method of spraying Grape-vines with the copper mixtures as a preventive of certain fungous diseases which were desolating our vineyards. Without some protection against the Black Rot, the cultivation of the Vine in many parts of the country would be impossible. The use of the so-called Bordeaux mixture has become almost universal, and no one has ever been injured by it. It seems strange, therefore, that the discovery of some copper stains on the stems of a few grape-clusters should have created so much excitement as it did ten days ago. If any growers have been foolish enough to spray their vines after this treatment was useless, or with a mixture of more than the regulation strength, this mistake could have been rectified without so much noise and circumstance. The startling head-lines in the newspapers naturally terrified timid buyers, and the grape market was literally paralyzed.

Scientific men in city health boards should keep themselves a little better informed as to the diseases of plants and the remedies generally used to hold them in check.

Sacred Trees of the World.

The Palm, the Oak and the Ash are the three trees which since times immemorial were held to be sacred trees. The first among them, which figures on the oldest monuments and pictures of the Egyptians and Assyrians, is the Date-palm (*Phœnix dactylifera*), which was the symbol of the world and of creation, and the fruit of which filled the faithful with divine strength and prepared them for the pleasures of immortality. "Honor," said Mohammed, "thy paternal aunt, the Date-palm, for in Paradise it was created out of the same dust of the ground." Another Mohammedan tradition of a later period says that when Adam left Paradise he was allowed to take with him three things—a Myrtle, because it was the most lovely and the most scented flower of the earth; a Wheat-ear, because it had most nourishment, and a date, because it is the most glorious fruit of the earth. This date from Paradise was, in some marvelous way, brought to the Hejaz; from it have come all the Date-palms in the world, and Allah destined it to be the food to all the true believers, who shall conquer every country where the Date-palm grows. The Jews and the Arabs, again, looked upon the same tree as a mystical allegory of human beings, for, like them, it dies when its head (the summit) is cut off, and when a limb (branch) is once cut off it does not grow again. Those who know, can understand the mysterious language of the branches on days when there is no wind, when whispers of present and future events are communicated by the tree. Abraham of old, so the rabbis say, understood the language of the Palm. The Oak was always considered a "holy" tree by our own ancestors, and, above all, by the nations of the north of Europe. When Winifred of Devonshire (680-754 A. D.) went forth on his wanderings through Germany to preach the Gospel, one of his first actions was to cut down the giant Oak in Saxony which was dedicated to Thor and worshiped by the people from far and near. But when he had nearly felled the Oak, and while the people were cursing and threatening the saint, a supernatural storm swept over it, seized the summit, broke every branch, and dashed it, "quasi superni motus solatio," with a tremendous crash to the ground. The heathens acknowledged the marvel, and many of them were converted there and then. But the saint built a chapel of the wood of this very Oak and dedicated it to St. Peter.

The sacred Oaks, it must be admitted, do not seem to have always done their duty. Thus, for instance, a famous Oak in Ireland was dedicated to the Irish Saint Columban, one of the peculiarities of the tree being that whoever carried a piece of its wood in his mouth would never be hanged. After a time, however, the holy Oak of Kenmare was destroyed in a storm. Nobody dared gather the wood except a gardener, who tanned some shoe leather with the bark; but when he wore the shoes made of this leather for the first time he became a leper and was never cured. In the Abbey of Vetrou, in Brittany, stood an old Oak-tree which had grown out of the staff of St. Martin, the first abbot of the monastery, and in the shade of which the princes of Brittany prayed whenever they went into the abbey. Nobody dared to pick even a leaf from this tree, and not even the birds dared to peck at it. Not so the Norman pirates, two of whom climbed the tree of St. Martin to cut wood for their bows. Both of them fell down and broke their necks. The Celts and Germans and Scandinavians, again, worshiped the Mountain Ash, and it is especially in the religious myths of the latter that the "Askr Yggdrasil" plays a prominent part. To them it was the holiest among trees, the "world tree" which, eternally young and dewy, represented heaven, earth and hell. According to the Edda, the Ash Yggdrasil was an evergreen tree. A specimen of it (says Adam of Bremen) grew at Upsala in front of the great temple, and another in Dithmarschen, carefully guarded by a railing, for it was, in a mystical way, connected with the fate of the country.—*Deutsche Rundschau.*

How We Renewed an Old Place.

XX.—UTILITY VERSUS BEAUTY.

On any moderate-sized place, with only a man or two to do the necessary work, there is a constant conflict between what is of present importance and what serves for future adornment.

This is one reason why we like to have as many things done in the autumn as can safely be accomplished at that time, because of all seasons of the year the spring is the one when everything comes at once, and your factotum is more than ever distracted by the various calls upon his time and attention.

I used to wonder why farmers were always behindhand with their work, and, while apparently idle part of their time, were driven to death for about two-thirds of the year; but I have discovered that the weather is responsible for a good deal, first by being cold, and perhaps wet in the spring, so that the ground cannot be tilled until late, and then suddenly sending everything ahead by a few unseasonable days of heat and sunshine. Then there is a skurry for the hitherto impracticable digging of the vegetable-garden, a headlong rush to get the seeds in; the grass, which always interferes at unseasonable moments, demands the lawn-mower, and will not wait a minute. The shrubs that you have been waiting to move until the weather should be mild enough to permit your superintending the operation (one can cope with a piercing east wind for this purpose, but not with a north-west snow-storm), shake off their icicles, and all at once begin to leaf out; in a day or two it will be too late. If there is a tree that you have intended to plant at this season the complications are increased, for setting a tree properly is a work of time, and delay here is dangerous.

The perennials need overhauling and replanting in the flower-garden; the weeds are rushing ahead and choking everything; you want your man to attend to them when he has to be putting in Peas and Potatoes for your future sustenance.

The whole spring is one breathless moment, through which you are rushed helter-skelter, leaving half your needs unattended to; and while you are still endeavoring to catch up with the work, all of a sudden our headlong summer bounces into haying-time, and the hapless beautifier is worse off than ever.

Of what account are trees and shrubs and flowers, or even the ever-clamoring lawn itself, when the fields are to be shorn, and possible thunder-storms lurk low along the horizon? This is the weeds' moment, and they avail themselves of it promptly. Up comes the Chickweed among the Peas and Corn; the flower-garden fairly bristles with Plaintains and Mallows, and the paths are slippery with Purslane. On the lawn the Dandelions begin to intrude, and go to seed when they are only an inch high, lying down deceitfully under the lawn-mower, and poking up their white plumes the minute it has passed, in the most imperturbable manner.

It is of no use to summon any one. "That grass must be cut to-day," or "the hay must be turned, or forked over, or got in, or whatever"—there is no appeal, harvest-claims take precedence, and the weeds nod their heads at each other, and say "Come along!" and life is to them a beautiful holiday.

By the time the last load of hay has been safely stowed away these same weeds have to be coped with, for they have become a forest, and that still further postpones the time when the æsthetic side of your place can really have any consideration given to it. At last, when you do get round to it, it is too late to do anything, and one can only sit down and make plans for another season, which will again be buried out of sight in the rush which is sure of a periodical return.

For this reason August is a month which I delight in, for then there is a moment's breathing-space before the fruit-harvest and the terrible "second crop" are again upon the carpet. It is a good time for grading and sodding before the autumn rains. With care and a ball of earth, some of the hardy shrubs can be moved; if it has been a dry summer, now is the chance to put in some evergreens and to remodel your beds of dwarfs. But no sooner do we get fairly to work, and the general effect begins to improve and ideas to take shape, than the marsh, which usually claims the whole late fall and the months of March and April, puts in an appeal for drainage, and, presto! the men who were engaged in ornamental work are whisked away, and you can only see the tops of their heads above the edge of a pile of dirt, as they burrow their way along an unsightly ditch.

Then come the pears and apples. Your own fruit is a fine thing to have in theory, beautiful to look forward to, something to be proud of, but it is a tremendous burden when it comes. The gathering is an important labor, but taking care of it when it is gathered is infinitely worse. The pears, especially, must be watched daily, turned and selected, and the refuse rejected, till their owner would be happier if he never saw a Bartlett or a Jargonelle again. The early apples, welcome and useful as they are, demand the closest attention, and it is not until the last Russet is gathered and barreled and stowed away in the cellar for winter use, that the amateur farmer can have an easy mind.

Perhaps it would be wiser to choose between ornamental and useful management of a place to begin with, and content yourself with either a farm or a garden, as the case might be; but in this event, though one would probably have better results to show, he would miss much of the fun of the more helter-skelter methods of landscape-practice, as well as the profits of orderly market-gardening, which can never be very successful in the hands of amateurs. There is, however, a sense of profit in your own garden as an accessory, whatever statistics show, which is not to be foregone; and, as to the pleasure of getting trees and shrubs in their proper places, who that has read these papers can doubt that they are a source of amusement and instruction alike, even to the most unpractical of their protectors?

The problems of the old place will continue to develop and add puzzle to puzzle in our uninstructed minds; we may pay dear for our whistle, but we shall have the whistle anyhow. After a few more years of experiment and failure, or success, as the wheel turns, we shall probably come to the conclusion to let the grass and shrubs grow as they will under the trees, and let the rest go, which will, I am disposed to think, be wholly to the advantage of the looker-on. But while some vestige of vigor is left to us we shall think the puzzle part more interesting than the solution, and so struggle happily on, setting for ourselves ingenious examples, to be painfully worked out perhaps to a wrong result. Interest in the place will be less when we can no longer tinker at it to advantage, but to that excitement will possibly succeed the calm enjoyment of those who sit under the tree they have planted, and partake of the fruits of their own vine.

As we look up to-day to the trees, upon whose tops we could look down three years ago, we begin to realize the profit of our labors, and to feel that we may even live to take pride in them. The birds which sing in their branches, and build their nests among the twigs, thank us sweetly for the shelter thus provided, though their harmonious chatter adds to the precariousness of a morning nap. The shrubs expand healthily, the flowers we have planted flaunt gayly, the vines are climbing to the roof-tree. The spot not long ago so desolate and unpromising is now sheltered and verdant. The dull red walls of the house have taken on a mantle of green, as it begins to nestle into the shadow of the up-reaching branches that will, ere long, overtop its chimneys. The raw freshness has largely disappeared, the new place is melting into the old, and in a few years more people will have forgotten, as they so soon do, the former conditions, and will cease to realize the importance of the changes made.

The beauty of stately expanses, of deep solitudes, of extensive lawns, and broad park-like spaces, we can never attain, but travelers on the village highway will look kindly through the overarching trees and say, "A pleasant home is there, and a fair outlook on a quiet scene."

Already the Willows of the boundary stretch up to hide us from the rear. The Pines are showing dark once more against the hill sun-browned by the September sun. Yellow leaves are shining on the Elms and Birches, and the shrill wind streaks the green grass with bright-hued foliage torn from the Maple-boughs. The gay-colored blossoms of autumn flowers gleam from the shrubberies, and the low-declining sun casts long shadows across the turf. Soon will a nipping frost bestrew the lawn with wrecks of summer glory; the birds are gathering for their southern flight; the year is past its prime. A few short weeks of hectic color, and then—the end, the sleep, the long dull silence of winter, the sheets of snow, the chains of ice that bind the earth until her re-awakening.

How swift the silent succession of the months! September seems to tread upon the train of June, it is so quickly here, so quickly gone. The Golden-rod is the first plume of the year's hearse, yet when its earliest yellow feathers wave we burn under the hot breath of summer, but ere they lose all their gold the hand of death is on the grass, and the brown leaves have fallen.

A cold rain patters on the gravel walk, and the branches of the trees are dripping as they hang unstirred. The sky is gloomy and leaden—one vast gray cloud sullenly enwraps the heavens. There is no hope, no outlook; all is sad and drear—rain overhead, a wet earth under foot. Summer has gone; the chill of autumn is here. But hark! what is the murmur? It is the north-west wind blowing his distant horn, and in a twinkling the leaden skies are broken with windows of light. The gray scud whisks up toward the zenith, the wet trees shake off their burden and wave joyfully in the keen breeze. October comes! What though his tramp is over the dead leaves, he comes like a warrior from battle, fresh and strong, inspiriting and brave. "Be not cast down!" he cries, "by the death of fair summer. Bold winter succeeds to the throne. He is a king worth having, and his reign shall restore your vigor, men of the north! and help to make you what you

are! Behind him, hidden by his furry mantle, lurks the spring, and then once more the dead summer shall be reborn, and the world shall be again all blossom and music!"

So, with this bracing note, October passes on, and, cheered by Hope and softened by memory, we leave the old place to sleep awhile, and turn to our winter fire and the companionship of men and books, in lieu of birds and trees and flowers which have gladdened us for half a year.

Hingham, Mass. *M. C. Robbins.*

THE END.

Forest-vegetation of the Upper Mississippi.—II.

THE best Oak growing along the Upper Mississippi is the White Oak (*Quercus alba*). It is not uncommon to find trees with trunks eight to twelve feet in circumference. This species once covered a considerable portion of the ridges, especially on clay soil. The shaded slope on which the snow long remains in the spring is also a favorable situation for it. Young growth of White Oak is rapidly covering situations of this character, which formerly contained no timber. Flattened expansions of the stem are found just underneath the surface of the ground. From these arise a number of trunks. It is not improbable that, before the country was settled, late fires in spring kept the forest-growth down, but after the cessation of fires a vigorous growth started. The timber of the White Oak is uniformly straighter and easier to cut than the Scarlet Oak (*Q. coccinea*) or Black Oak (*Q. tinctoria*). These Oaks grow in more exposed localities, where the soil is drier and vegetation starts earlier in the spring, and for this reason fires usually damaged them more than any of the others. The old timber is usually gnarled and hard to split. The young growth is, however, straight and easy to work where fires are kept out. The soils on which they occur vary considerably. They do well on sandy gravelly soil, as well as on clay and black soil, and even make considerable growth on poor sandy soil. *Q. coccinea* is the more common species, although the forms are puzzling. The Red Oak (*Q. rubra*, L.) is the finest of the Oaks in this region so far as beauty is concerned. The trees are tall and straight, and sometimes yield five cords of wood. It is not an uncommon thing for them to yield three cords. The wood is easily worked, and this is owing largely to the locality and soil where the species usually grows. The large trees were less affected by the early forest-fires than were the Black Oaks. The Red Oak occurs principally on shaded hill-slopes, where the snow long remains on the ground, also on clay ridges and black bottom-lands. Young trees of *Q. rubra* are the most easily recognizable of the Black Oaks when growing in such localities. Smooth bark and straight trunk, with few lateral branches, distinguish them at once from specimens of *Q. tinctoria* and *Q. coccinea*.

One of the most variable Oaks, at least so far as general appearances go, is the Bur Oak (*Q. macrocarpa*). On the sandy soils it is diminutive in size, producing numerous lateral branches. Here it is a spreading tree. On the poor sandy soil between the Black and La Crosse rivers it is the most common Oak. On clay and rocky soil it occurs mainly in small groups. Some thirty miles east of La Crosse, in the Kickapoo Valley, Bur Oak is a most valuable forest-tree. The trunk is straight, with but few large lateral branches. In its habit it is wholly unlike the form growing on sandy or rocky soil. Many trees are ten feet in circumference. It does not grow in isolated groups, but acres are covered almost entirely with this species. It also occurs in the rich alluvial bottoms of various streams. The Swamp White Oak (*Q. bicolor*) occurs only in the bottoms of the Black and Mississippi rivers. A large number of small trees occur near North Bend, Wisconsin. I have observed a few more just below La Crosse. It becomes more common southward; and a considerable number were observed near Turkey River Junction, Iowa. No large trees have been seen, though Mr. J. S. Harris informs me that he noticed some near La Crescent, Minnesota, many years ago. The only other Oak I have seen is *Q. Muhlenbergii*. It occurred in considerable numbers on the south slope of a limestone bluff just west of North McGregor, Iowa.

The most conspicuous Maple is the Soft Maple (*Acer saccharinum*). It occurs everywhere along the Mississippi, Black and Wisconsin rivers and their tributaries. It forms more than one-half of the forest-vegetation of the Mississippi River, but becomes less common as the sources of the smaller streams are reached. It grows where the lands are usually subject to overflow, and the soil is sandy or alluvial. The Red Maple (*Acer rubrum*, L.) is not a common species. It occurs in the interior of the country, away from the Mississippi, on sandy black loam. Although the Sugar Maple occurs in the rich rocky soil along the Mississippi River it is most common in the interior of Wisconsin, away from the river. On the low ridges drained by the Kickapoo River it is one of the most common of forest-trees. The Ash-leaved Maple (*Acer Negundo*) occurs in groups in the richer soils of ravines and bottom-lands. It is seldom found in the bottom proper of the Mississippi River. The tree requires a good soil for its development.

Two species of hickory have only been observed, Shell Bark (*Hickoria tomentosa*) and the Pignut Hickory (*H. porcina*). Both species attain to considerable size. The habits of the trees are quite different. *H. tomentosa* grows on clay soil, usually in groups. *H. porcina* grows on various soils, such as rocky, sandy, and along creek-bottoms. Shaded and moist localities are favorable to its growth, which is much more rapid than that of *H. tomentosa*. The Butternut (*Juglans cinerea*) is much more common than the Black Walnut (*J. nigra*), although both are found on the rocky banks of the Mississippi, and the Butternut is abundant in sandy and gravelly soil along the Kickapoo River, while Black Walnut was not observed in this region. The latter tree is confined quite closely to the immediate tributaries of the Mississippi. Along the Badaxe River and smaller streams about La Crosse it is quite common, but as the sources of the stream are reached it gradually diminishes in numbers. It needs a much richer soil than the Butternut.

Agricultural College, Ames, Iowa. *L. H. Pammel.*

Notes on North American Trees.—XXIX.

MR. A. S. HITCHCOCK, of the Missouri Botanic Garden, sends me the following criticism upon the notes on Piscidia, published in Garden and Forest for September 16th (iv., 435):

"You give to the Jamaica Dogwood the name of *Piscidia Piscipula*. In working up the literature for my West Indian collections I reach a somewhat different conclusion, and should like to consult you about it. It seemed to me that the genus Ichthyomethia, Patrick Browne ("Nat. Hist. Jam.," p. 296, 1756), antedates, and should replace the Piscidia of Linnæus ("Syst. Nat.," ed. 10, p. 1155, 1759), and that the name for this tree should be *Ichthyomethia Piscipula*. So far as I can see, there is no doubt about the identity of the plant. Browne describes it well, and Linnæus quotes Browne's Ichthyomethia under his Piscidia, only he misspelled it. If Browne's genera are to be taken up at all, should not this one stand?"

Mr. Hitchcock's criticism is a sound one. I knew of Browne's Ichthyomethia, but had carelessly overlooked the fact that two editions of his work had been published. The second edition, the only one I have seen, was published in 1789, that is several years subsequently to Linnæus' tenth edition of the "Systema Natura," although there is nothing on the title-page to show that it is not the first edition. Browne's genera have been taken up in many cases by modern authors, and there seems no reason why the name of the West Indian Dogwood should not be *Ichthyomethia Piscipula*, Hitchcock.

C. S. Sargent.

New or Little-known Plants.

Aster Shortii.

OUR North American flora is rich in Asters, Golden-rods, Sunflowers, and many other of the tubular-flowered genera or Composite which produce beautiful and showy flowers. These make this country bright during the autumn months, and give a charm and beauty to our autumn landscape which is peculiarly American, and which the inhabitants of less-favored regions look upon with delight and admiration. Among these plants are many well suited to adorn the garden, and it is always a matter of surprise that more attention has not been given in this country to cultivating them. It is true that they are, in a certain sense, familiar outside the limits of the garden. Many of them, however, are not widely distributed, so that a New England Aster, for example, might be as unfamiliar to an inhabitant of the south or of the far west as it would be to a Japanese or to an Englishman.

Fig. 74.—Aster Shortii.—See page 472.

A collection of all our Asters, or even of a dozen or two of the best, would make an important and most interesting addition to any garden, and its value would be all the greater because many of these plants flower after the first frosts have cut down more tender plants.

Several of the American Asters have already been figured in these columns, and on page 473 of the present issue is reproduced a drawing made by Mr. Faxon of *Aster Shortii*, which, although by no means a new plant, does not appear to have been figured before.

A. Shortii is a native of cliffs and river-banks from Ohio to Illinois and of the states south of the Ohio River, and is one of the handsomest of all our species. The stems are spreading, two to four feet high, and produce great racemose panicles of large bright blue flowers and ample lanceolate elongated leaves.

Like the other species, *A. Shortii* is easy to cultivate; it can be readily transplanted from the woods, and will thrive and spread in good garden-soil. Asters, like many strong-growing perennial plants, give greater satisfaction if the roots are lifted once in every two or three years, divided and reset. In this way a large stock of plants can be obtained in a few years, and the surplus not needed for the flower-borders can be planted by the margins of wood-walks and in other rough places where all such plants flourish and appear to the greatest advantage.

Foreign Correspondence.

London Letter.

Cattleya labiata vera.—An Orchid sale of quite exceptional interest took place on September 18th in the Cheapside auction-rooms. Messrs. Sander & Co. had advertised no less than 500 lots of "the supposed long-exterminated old autumn-flowering typical *Cattleya labiata*, . . from Swainson's hunting-grounds, . . . who actually used its stems in packing his lichens for transport" (vide sale catalogue). The plants are "guaranteed true." A large number of Orchid experts and others interested in these plants assembled at the sale, and from the fact that the plants realized over £1,000 we may conclude that experts were disposed to accept them as genuine. Every Orchid fancier knows the value, interest and beauty of the autumn-flowering *C. labiata* which Lindley described in 1818, founding the genus Cattleya upon it. According to Veitch's "Manual," *C. labiata* was found by Swainson in the Organ Mountains, situate about sixty miles north of Rio, "but where it is believed to have been exterminated many years ago. Although diligently sought for by collectors it has never been rediscovered." Mr. Linden, however, claimed to have rediscovered it in his *C. Warocqueana*, and there are some authorities who declare that some of the forms of this plant do not differ from the old *C. labiata*. And now come Mr. Sander's plants, which are guaranteed to be the true thing. The source of these plants, as well as of Monsieur Linden's *C. Warocqueana*, is a trade secret, but it has been hinted that Rio is nowhere near it. Certainly Mr. Sander's plants have all the characters of the true *C. labiata*, so far as pseudo-bulbs, leaves and sheaths show, but no definite decision can be come to until the plants flower. At present we can only say that there is no reason for doubting the genuineness of the plants, and every Orchid grower will hope that they will prove to be what Mr. Sander properly calls "*C. labiata autumnalis vera*, the queen of Cattleyas." According to information sent by the collector of Mr. Sander's plants they vary in the color of their flowers: "Plenty of whites are among them, and all shades of rose and red." The few plants known to exist of the old *C. labiata* are supposed to have been obtained by division from one or two original pieces, which will account for the absence of any difference in the leaves or flowers of those known in English gardens. But among Mr. Sander's imported plants I noted some with short thick, others with long thin, pseudo-bulbs; some with purplish, others with bright green, leaves, as well as differences in the length and width of the leaf-blades. But they were all alike in having the double sheath or spathe, the valves in which are of the same length. This character is said to be peculiar to *C. labiata vera*.

Arachnanthe Clarkei.—This appears to be by far the easiest to grow and flower of the species of Arachnanthe in cultivation. The genus is made up of the plants previously known as *Esmeralda* or *Vanda Cathcartii*, *V. Lowii* and one or two others not at present known to be in cultivation. The most remarkable of all is, of course, *A. Lowii*, whose gigantic size and long drooping inflorescence, bearing two forms of flowers, make it quite exceptional, even among garden Orchids. But it requires a good deal of space, and even when well treated it does not flower annually. The same remark applies to *A. Cathcartii*, whereas *A. Clarkei* flowers when only a foot high, and, so far as my experience with it goes, it never misses a year. It has the habit and leaves of *Renanthera coccinea*, and produces its racemes laterally. Each flower is three inches in diameter, the sepals and petals spreading, oblong, falcate, fleshy and colored chestnut, with yellow bars. The lip is three-lobed and yellowish white, with red streaks. There is a plant of it now in bloom at Kew with five flowers on the raceme, whereas published descriptions limit the number to two or three. The species was discovered in the Himalayas by Mr. C. B. Clarke, F. R. S., and introduced into cultivation in 1885 by Messrs. H. Low & Co. Mr. R. Pantling, an Indian botanist, who has seen this plant growing in the Himalayas, wrote of it in the *Gardeners' Chronicle*, in 1888, as follows: "It occurs on a thickly wooded crest or ridge, at an altitude of about 6,000 feet, where sun and wind have free play amidst its surroundings, drenched with cool rain and driving mists during the wet season, exposed to a fair amount of sunshine during the remainder of the year and visited by a sprinkling of snow at the commencement of the new year. At this altitude the temperature, during the hottest month of the year, never exceeds seventy-five degrees, Fahrenheit, in the shade, while in the two coldest winter months the thermometer ranges from about thirty degrees to forty-five degrees. As a consequence *A. Clarkei* assumes a much more stunted appearance, and never at any time approaches the straggling length of *A. Cathcartii*. The flowers open in October and last about six weeks."

At Kew the plants are grown in a warm house along with Vandas, Ærides, etc., their position being close to the roof-glass and directly over a water-tank, where the air is always moving, as the tank opens into a cool house as well. They are planted in pots, in crocks and sphagnum, and kept very moist all the year round. *A. Cathcartii* is represented by a plant at Kew about twelve feet high. It is planted against the back wall of the Aroid-house, its fleshy roots clinging to the wall in the same manner as Hoya-roots do.

Stenoglottis longifolia.—This is an easily grown and free-flowering terrestrial Orchid, which was introduced at Kew from Natal three years ago, and has since flowered yearly in the cool Orchid-house. The genus comprises only two species, namely, *S. fimbriata*, a small plant, chiefly remarkable for the conspicuous black eye-like blotches on the leaves; and this new one, of which a figure was published in the July part of the *Botanical Magazine* for this year. It has numerous herbaceous ensiform wavy leaves six inches long, and a central scape a foot or one and a half feet long, the lower half bearing bract-like leaves, and the upper a dense spike of rosy purple flowers with ovate sepals and petals and a lip with a fimbriated apex. After flowering the leaves all wither, and the plant remains dormant until spring, when it pushes up new growths from its fleshy root-stock. It requires plenty of water at all times.

Habenaria militaris.—This is now flowering in the tropical Orchid-house at Kew, and it is so exceptionally bright in color that, despite its dimunitive size, it is quite a great attraction. It was first described by Reichenbach in 1886,

from plants introduced by Monsieur Regnier, of Fontenoy sous Bois, from Cochin China, but it has remained a rare plant. Sir Trevor Laurence possesses about fifty plants of it, and these, when in flower, produce an effect as brilliant as a bed of scarlet Verbenas. The whole plant when in flower does not exceed six inches in height, the erect stem bearing from six to ten fleshy, strap-shaped bright green leaves and a cluster of numerous flowers, which Reichenbach aptly described as resembling in form the flowers of a well-developed *Orchis purpurea*. The lip is the conspicuous feature of the flower, as it is flat, trifid, nearly an inch across, and colored rich scarlet; "no English soldier can boast a jacket of a brighter scarlet than this." As with all Habenarias, this species loses its leaves and goes to rest in winter, pushing up new growth in early spring. It requires a tropical temperature and plenty of moisture all the year round, and for compost a mixture of peat, sphagnum and good leaf-mold. Thrips are specially partial to it, and soon destroy the leaves; to keep them in check it is a good plan to wash the leaves with soap and water about once a fortnight.

Habenaria carnea.—This is a new introduction from Singapore which has just flowered at Kew, and which, from the size and prettiness of its flowers, is likely to become a favorite with those who take an interest in small Orchids. It is not unlike *H. militaris* in habit, but the leaves are shorter and form a rosette at the base of the stem, which rises to a height of about six inches and bears about six flowers which have a clavate spur three inches long, a spreading, flat, incised labellum, one and a half by one inch, and ovate sepals and petals. The color of the whole flower is the most delicate flesh-pink, which fades to almost white with age. The flowers last three weeks. The cultural requirements of this species appear to be exactly the same as those of *H. militaris*.

Kew. *W. Watson.*

Cultural Department.

Early Grapes in the North.

Along our northern border, and across the Canadian boundary as far as the upper St. Lawrence River, the earliest Grapes can be grown with considerable success. The Catholic clergy of Montreal have long cultivated early kinds of European Grapes within their enclosures in and about the city, and have even used them for making wine; but my occasional visits have shown me that it is with the greatest difficulty, and only by the free use of sulphur and other chemical applications, that these foreign Vines can be kept sufficiently free from disease to produce crops of mature fruit. The wealthy people of Montreal have very fine graperies, and at the exhibitions of the Montreal Horticultural Society, which I have many times attended in the capacity of a judge of horticultural and pomological exhibits, the display of house-grown grapes has not been inferior even to those seen at the fruit-shows of the Massachusetts Horticultural Society.

There is a narrow strip of country in Canada, between the northern end of Lake Champlain and the St. Lawrence, where the Concord Grape is successfully grown and ripened. There are even a few commercial vineyards on a moderate scale in that vicinity, but by far the greater portion of the native grapes sold in Montreal are either from the United States or from the south-western part of the province of Ontario, which is an excellent Grape region.

In Vermont the whole shore of Lake Champlain, together with the several islands in the lake which constitute the county of Grand Isle, produces good grapes. It was here that the now fairly well-known Vergennes Grape originated. This grape is fully as late as Concord, yet it is esteemed not only for its very good quality, but also as one of the best keepers. But beyond these low-lying water-side regions, on both sides of the international boundary, the climatic conditions change. A late spring and early fall frosts materially shorten the growing season; and although the vines grown among the hills are much more healthy than elsewhere, it is useless to plant any but the earliest varieties, and these only in warm sheltered spots open to the south and protected from cold winds. Along the shores of Lake Memphremagog, the surface of which is upward of 700 feet higher than Lake Champlain, only forty miles away, there are many nooks well suited to Grape-culture, although very few of them are yet so occupied. In such spots even the Concord often perfects its fruit, but only where the water keeps off the September and early October frosts. I have been experimenting with Grapes in this region for twenty-five years, and have been successful with several varieties, though I have never been encouraged to plant them on a commercial scale in competition with more favored localities.

Soon after I began, the late Dr. Grant, of Iona Island, in the Hudson River, introduced his Eumelan Grape, and my first plantings were chiefly with this, the Delaware, the Israella, the Hartford and the Salem. Since then I have added the Tolman, the Brighton, Moore's Early, and recently the Green Mountain and Diamond, but from the Diamond I have not yet received fruit, though the vines have made a good growth. Perhaps a few notes on these varieties may interest readers who are cultivating grapes under similar conditions.

Hartford is the oldest and best-known of these early grapes. It is hardly in advance of the wild type, and the feeble attachment of the berry to its stem as it ripens robs it of what little value it might otherwise have. Eumelan is a very strong grower, making an immense quantity of wood and requiring a great deal of summer pruning. It is early and fairly good, but the clusters are imperfect. Israella is of about the same season as Eumelan; it is a more moderate grower, with good clusters of fruit that holds well to the stem. In quality it is quite good, but I have not found it as productive as it was supposed to be. Delaware is all that one could ask for in a grape of its class, but its thin foliage makes it the easy victim of the thrips, which is the only enemy that attacks my Grape-vines, and for which I find no perfect remedy. The insects make this small grape smaller, and, by injury done, the foliage retards ripening. Still we get a lot of Delawares nearly every year.

Salem is, with me, one of the earliest and surest to ripen. It is unlike other grapes, in being quite eatable before it is fully ripe; and it is also a long keeper, improving in quality to the end. If it had a good cluster, it would be the king of American grapes. I want to protest vigorously against the common practice of selling the Agawam grape under the name of Salem. Quite often I have been taken in by dealers in the city, for the two are strikingly alike in the basket, but with no other resemblance. Tolman is simply a wild grape, very early, good for making a jelly to go with meats, but for every other use valueless. I could grow them by the car-load more cheaply than currants, but I do not. Moore's Early is as detective in its clusters as Salem, but I hear that it does better with long training and age. It is what the street-dealers in Boston call it, an Early Concord. Brighton is a grape of peculiar habit; it is early in a hot season, but in a cool one it does not even begin to color—that is, it requires a higher average temperature than it gets in the mountains to be an early grape.

Green Mountain has fruited finely for me for the first time, this year. I saw it when shown for the first time at the meeting of the American Pomological Society, in Boston, four years ago, and was much struck with it. I must set it down as being as early as Tolman and as good as Delaware, with a much larger berry and cluster. For home use I put it at the head for the cold north, but I fear it will not be a success as a market grape, except, perhaps, for a near market, because of its tender skin and weak attachment to the stem. Otherwise it is as near perfection as I expect to see in so early a grape.

Planting Hardy Bulbs.

When it is desired to mass Narcissus for color effect, as in flower-beds, it is obviously necessary to plant those kinds together that will be in flower about the same time. The flowering season lasts over a much more extended season in Europe than in America, owing to the more gradual approach of the spring season. With us Narcissus-flowers can be counted on in two weeks after the frost leaves the soil, and the different varieties may be had in abundance for about a month if the yellow kinds are used. The white varieties of the Poeticus section extend the season two weeks longer. One who wishes to plant yellow kinds can select a few of the most reliable kinds, like Princeps, which is cheap, early and good. *N. obvallaris*, the Tenby Daffodil, one of the best for any purpose, with *N. rugilobus*, *N. incomparabilis* and its variety Stella, which has white perianth and yellow crown, and *N. spurius*, the Trumpet Major of catalogues, are well-tried and reliable varieties, and we were much pleased with Ard Righ (Irish King) last season, although it is hardly cheap enough

yet to enable us to use it in quantity. All these flower early, and are suitable for naturalizing.

Of the Poeticus varieties, of which there are now many, a very interesting bed might be planted, the first of which to flower would be the variety Angustifolius, which, with us, is two weeks earlier than any other. Next comes Ornatus, followed by Poetarum, a variety with a rich orange-scarlet eye, a very desirable and cheap kind and distinct from all others. The typical *N. poeticus* is followed by Majalis and Recurvus, which flower in May and last, here, until after Decoration Day, when they are often invaluable to florists. The Poet's Narcissus are elegant when naturalized in grass or under trees. They never deteriorate under these conditions, and I have never yet found any reason to complain of flower-buds failing to develop, although I have often heard this lament from others. When planting for naturalization it is best to do so by taking out a good breadth of soil, about six inches deep, and placing the bulbs on the ground. The soil should then be filled in, and, when leveled, a little grass-seed should be sown over it and all will be well.

While the above-named kinds are all easily procured, even by those of moderate means, there are varieties which are much more expensive, and many of them are very beautiful. Among these are the hybrid varieties raised in gardens, such as Horsfield's, which have never yet been equaled, and for which we are indebted to a Lancashire weaver, John Horsfield, whose name will be perpetuated for many a year by this striking flower, with its creamy white perianth and its rich yellow trumpet. *N. Horsfieldii* will never be cheap, although it is a kind which every one wants and ought to have. Grandee, or Grandis, belongs also to the Bicolor section and is a noble flower, as is also Empress and a kind known as Maws Bicolor. We were much pleased with *N. bicolor præcox* last season; it was the earliest plant of the Bicolor section to bloom, and was quite two weeks earlier than Horsfieldii. It was in the vanguard with *N. pallidus præcox* and Ard Righ.

Of the Trumpet Daffodils, Golden Spur is among the earliest and a very fine flower, and with the true Maximus, Henry Irving, Princeps, Countess of Annesley and Obvallaris should be planted by all, if only one bulb of each variety. The latest of the Trumpet section is Abscissus, or Muticus, and desirable on this account, while Emperor is well described as a magnificent flower, and it has proved perfectly hardy with us and is increasing threefold. There is this satisfaction in growing Daffodils, that where one plants a bulb at least two, and often three, may be found the following year. There never was a more profitable bulb grown by dealers than Sir Watkin, which is surprisingly prolific, but many are disappointed on first seeing it flower; indeed, there are many better ones.

Of the Swansneck section of drooping flowered Narcissus, some are very elegant, and most of them are nearly white. Among the best are Leda, William Goldring, Pallidus Præcox, Cernuus Pulcher, and *N. moschatus*, a lovely white variety. All the above varieties are found hardy here, and can, no doubt, be grown almost anywhere in the United States. We have planted forty-two kinds this fall, and hope to be able to report later as to their behavior here. There is no end to varieties, but if one only chooses the most distinct of each section to commence with, the others can be added as time goes on and the love for them increases, as it surely will.

Wintering Aquatic Plants.

THE exceptionally warm weather prevailing in September has this season extended the usual flowering period of the Nymphæas, and at the end of the month the tender varieties are still opening. The change of weather, which may be expected any day, will, however, quickly destroy the beauty of the water garden, and arrangements must be made to winter over the stock in safety. There is little difficulty with the hardy Nymphæas, which can be left where they are if planted so deeply that the rhizomes will not freeze; or the tank may be emptied of water and filled with a good depth of dry forest-leaves. If these are covered with boards to keep out wet, they will furnish sufficient protection to hardy Nymphæas and Nelumbiums. Where the rhizomes are planted out in boxes these may be lifted and stored in a cool cellar just free from frost, the only precaution necessary being that they do not become entirely dry or be subjected to too high a temperature. These deciduous species need an absolute resting period, and excitement of warmth at that time seems to be fatal. It is said that the hardy Nymphæas will not survive in the tropics, owing to the impossibility of giving them the needed rest.

The tender species, not being deciduous, may, in the shape of tubers, be wintered successfully in damp moss in a moderate temperature, but strong plants, such as occupy the water at this season, are difficult to keep unless one has a warm tank. If exposed to a low temperature at any time they suffer a serious check, from which they seem unable to recover. In a tank with the temperature at sixty degrees, and not going below fifty degrees, Fahrenheit, they will winter safely and will make no headway. If no tank is otherwise available, a temporary one may be made on a greenhouse-bench, which will suffice to keep them in health. It is well to house the tender species before they suffer a serious check, and they are seldom safe outside in this latitude after the 20th of September.

Elizabeth, N. J. *J. N. Gerard.*

Primula floribunda.—I first saw this pretty little Indian Primrose in England at the Birmingham botanic gardens in 1883. I was struck with its neatness as a pot-plant, but not until last year had I succeeded in growing good specimens of it. I find, however, that few of my gardening acquaintances are willing to accept my estimate of its value. In the growing stage it has long, soft, rugose, hairy, strap-shaped leaves, resembling the common Primrose, and recurving in the same way. The flowers are a soft canary-yellow, produced in great abundance, in successive verticals, during January and February, and lasting fully two months in good condition in a cool greenhouse. My employer considers it a first-rate window-plant, especially on account of its color, which is rare among pot-plants at that season of the year. It is easily raised from seed, and, although biennial in character, if the flower-stems be cut away just after blooming, it will produce suckers which make just as good plants as seedlings, and with less trouble. It succeeds best in a heavy loam, in partial shade, and the more water it receives the better it appears to grow; from this I imagine it to be a swamp-plant in its native country.

Primula denticulata, and some of its varieties are exceedingly handsome and make excellent pot-plants, although they are not so well adapted for greenhouse culture. They are hardy in this latitude, and bloom out-of-doors in early spring. As greenhouse plants for conservatory decoration they do not come in well until the end of February or March. It is not advisable to force them—better to keep them in a cool greenhouse and let them come along slowly. When forced, like many other hardy plants, they have a soft look, easily fade, and are generally unsatisfactory. This spring I planted a batch of seedlings along with my English Primroses, but evidently they do not stand the sun so well, and, therefore, many died. I have, however, a nice stock of smaller plants left which I intend to winter over in a cold frame and plant in spring in a shady place. Several varieties have been named, as, for example, Cashmiriana, Alba, Nivalis and, possibly, others, but in a batch of seedlings it is easy to find any and all of them represented, as this plant varies as much from seed as the common Chinese Primrose. It will grow well in a good rich loam and bloom the second year from seed.

Early Chrysanthemums.—Much complaint has been made of the difficulty of growing good specimens of the Madame Desgranges (white) and its sport, C. Vermig (yellow). As with most other Chrysanthemums, the difficulty is to retain good healthy foliage. Last year I had a fair specimen of the white variety, but it was not so satisfactory as this year. I started in the spring with two plants, one of each variety, and to get additional stock had to take late cuttings from them. These are now in nine-inch pots, and far neater and better-looking specimens than the original plants. It would appear from this that Madame Desgranges had better be propagated late. My plants have been grown continuously under glass, along with several others, some of which have not been so satisfactory as I expected. These were mostly good varieties, which had done poorly for several seasons, and I had hoped that in the greenhouse they would do better. Some have done so, but others have been thrown out as failures. Can some one tell me what to do about a lively green bug that is spoiling the buds of my leaders? They wilt, and eventually go blind.

Cyclamen Persicum.—Gardening has always been a specialized art, and is becoming more so. The private gardener is expected to succeed with everything, but this is impossible. He finds some plants with which he can do well without trying, and others which are constant failures, no matter what his efforts. I had never succeeded well with Cyclamens until this year. What I have hitherto done has been to sow seed in spring and grow along my plants in small pots, ripen them off and bloom them the succeeding year. This year I sowed in December, and have kept my plants growing ever since. They are now larger and handsomer plants than any of my two-year-old

plants ever made. Every other year I have prepared a frame in a partly shaded position out-doors, and watched them very carefully. This year, for lack of time and convenience at the right time, they were left, just after final potting, on the north bench of a greenhouse, and seeing they commenced at once to grow nicely I left them there, and they are doing admirably. My gardening acquaintances say the plants would have done better in a frame. I reply, "Nothing succeeds like success."

Wellesley, Mass. *T. D. Hatfield.*

Hollyhock Diseases.—The Hollyhock has suffered for the past few seasons from at least three fungal diseases. There is the leaf-spot fungus, *Cercospora althæina*, Sacc., that is widespread and very destructive, particularly to the foliage in early summer, causing it to become covered with dead specks, from the size of a pin's head to that of a pea, and frequently entirely defoliating the stems about the time the blossoms should appear. The Hollyhock rust, *Puccinia malvacearum*, Mont., while comparatively new to this country, is spreading rapidly throughout the whole United States. This develops upon leaves, petioles and stems, causing all parts to sicken and die. Still more recently found is the leaf-blight, *Colletotrichum malvarum* (B. and C.), South, but it is making its presence felt in the propagating bed, where it ruins foliage and stems, and is preventing many growers from raising the Hollyhock. Last of all, and the form about which this note is particularly written, is a second form of leaf-spot, *Phyllosticta althæina*, Sacc., entirely different from the first one mentioned, in general appearance as well as in microscopic structure. The only place in American publications where the species is mentioned is in the *Journal of Micology*, where, under *Septoria Fairmani*, E. and E.—which, by the way, is the fifth and last injurious fungus of the Hollyhock found in this country—Mr. Ellis states that on the same leaves was a Phyllosticta which agrees well with *Phyllosticta althæina*, Sacc. This species occurs in northern Italy and France, and it would be interesting to know how this pest found its way across the sea, provided it is not a native here upon some one or more of our wild Mallows or Mallow-like plants. This leaf-spot is quickly recognized by the naked eye by the large brown patches, an inch or more in diameter, upon the leaves, the centres of which are usually broken away, thus presenting large ragged holes and a dilapidated appearance.

Rutgers College. *Byron D. Halsted.*

Recent Publications.

THE latest bulletin issued by the Horticultural Department of the Census Bureau relates to seed-farms, and has been prepared by Mr. J. H. Hale. Seed-production, as a business, has been carried on in this country for more than a century, although before the year 1800 there were but two seed-farms in America, one established in Philadelphia in 1784, and the other at Enfield, New Hampshire, in 1795. In 1820 there were but three such farms, and in 1830 there were but six, and of the 596 that were reported during the census year, containing a total of 169,851 acres, more than one-half had been started since 1870. These 596 farms are devoted exclusively to seed-production, but besides them there are many test-gardens and farms, which are conducted by extensive dealers in seeds, where new and old varieties are grown side by side for purposes of comparison. In such farms, too, are tested all the seeds handled by the dealers who import their supplies or contract with farmers in favored sections of this country to grow such varieties of seed as are adapted to their particular locality. Besides this, there are many farmers who grow one or more varieties of seeds every year in connection with other farming operations, so that their product has not passed into record. This means that the total amount of garden-seeds produced in the United States is much greater than is shown in this bulletin as the productions of the seed-farms proper. One dealer, for example, reports that he supplies farmers annually with 1,000 bushels of peas and 2,000 bushels of beans for planting, and then buys back all the seeds that can be grown from this stock, or about 10,000 bushels each of peas and beans. This is only one of many contracts, so that it is plain that the garden-seed business on this basis has become an important feature in the agriculture of the country. It should be remembered, also, that most of the seed of grains, cotton, tobacco and staple crops of this sort, which are used upon the farm, is either of home or neighborhood production, where it can be readily exchanged for other products. In nearly every other county, however, there are one or more farmers who, by careful selection of seed stocks and better methods of cultivation, secure greater returns than their neighbors, and are able to dispose of part of their productions for seed purposes at advanced rates. Of course, these men are not classed as seed-farmers, and it would be hardly possible to estimate what proportion of their crops are sold for seed, and yet Mr. Hale assumes that one-third of all the small grains, corn, potatoes, tobacco and cotton seed planted in the country is produced in this way. Besides, there is annually sold for seed more than a million bushels of selected grains of standard varieties, very little of which is produced on the regular seed-farms, and the same is true of Grass-seeds, which are produced in enormous quantity in many of the states.

Nearly one-half of the seed-farms are in the north Atlantic division and they average 185 acres each, while in the north central division there are 157 farms, with an average of 555 acres each. The seed-farms of Massachusetts and Connecticut average 142 acres each, while those of Iowa and Nebraska average nearly 700 acres in extent, and several of these farms embrace nearly 3,000 acres each. Some of the details of the tables are interesting, as, for example, those giving the yield per acre of the different varieties of seeds. In several states beet-seed is produced at the rate of 1,000 pounds and even more to the acre, and in Nebraska it is reported that Asparagus will yield 800 pounds to the acre. Cauliflower is reported as yielding less than 100 pounds. Lettuce averages less than 200 pounds. Onions range from 200 to 600 pounds. Rhubarb from forty to fifty pounds. The prices per pound at wholesale are averages from the reports sent in by the majority of the seed-growers in each state, and as most of the crop is delivered to contractors or dealers who supply the wholesale trade these prices are below the market rates, even in commercial centres, and yet there are striking variations in different localities. It is singular that the price of seeds in Massachusetts is much in excess of that paid to seed-farmers in other states, and averages at least twice as much as the prices in any of the states which border upon it. One reason assigned for this is, that one of the largest growers in that state is a dealer, and disposes of most of his stock directly to planters, and thus secures a somewhat higher price; and a second reason is, that many of the most successful gardeners of that state are afraid to risk their success on seeds of unknown origin and are, therefore, willing to pay higher prices to the neighboring seed-farmers who grow their choice seeds from selected stock.

It is stated that there is a feeling of depression among seed-growers. They made exceptionally large profits in the business up to the year 1883, and under the stimulus of these prices more seed-farms were established than have been able to find a profitable market since that date. The general feeling now is that there must be an advance of prices, or else methods of production must be improved, so that a greater yield can be secured at less cost of labor.

Pomology.

Meeting of the American Pomological Society.—II.

IN continuing the report of the meeting of the Pomological Society in Washington it ought to be said that the intermingling of discussions and essays on widely different phases of Pomology helped to sustain an interest in the sessions which did not flag until the final adjournment. Perhaps more time was devoted to the scientific aspects of Pomology than to what may be termed its practical and commercial aspects, but every day the programme had something to stimulate thought and arouse the attention not only of the men whose activities find exercise in the nursery or orchard, but also of the trained investigators in colleges and the experiment stations, who are studying more profound problems. The most entertaining discussion followed an address by Mr. Meehan on the "Influence of Heredity and Environment in the Origination of New Fruits." Mr. Meehan spoke without notes for half an hour very forcibly to prove the baselessness of the notion that any change in varieties could be produced by their surroundings, and he fortified his arguments with a wealth of illustrations drawn from human history as well as from plants and animals under domestication. Dr. Riley attacked the position of Mr. Meehan with great vigor, and Professor Bailey added that he was unwilling to allow it to be placed on record that the American Pomological Society held heterodox opinions on so capital a point, and cited numerous examples of variation in plants which he at-

tributed to their environment. Mr. Meehan replied with great good humor that his critics evidently did not understand what was meant by the term environment; and then Mr. Fernow added that if there was doubt as to the meaning of the term environment, there was also ambiguity in the use of the term variation, which might be structural or functional, and it was necessary to know whether we were talking about morphological variation or biological variation. The discussion became enveloped in a haze of uncertainty, as it appeared that none of the gentlemen were quite sure what the others were talking about, and it finally closed in a thick fog. It was very instructive and interesting, however, to the laymen.

Mr. J. M. Samuels, the Chief of the Horticultural Division of the Columbian Exposition, was an interested attendant on the meetings, and in the name of Director-General Davis he invited the society to hold their session of 1893 in Chicago. He also assured the society that the Director-General would appoint any man whom they should name as the head of the Division of Pomology.

We add below extracts from a few more of the important papers offered :

RECENT PROGRESS IN THE TREATMENT OF THE DISEASES OF POMACEOUS FRUITS.

Professor B. T. Galloway, of the Department of Agriculture, read a paper on this subject, which was substantially as follows :

The treatment of plant diseases is a subject of such recent origin that comparatively few are aware of the progress made in this line of work during the past few years. At the Boston meeting of this society, held only four years ago, it is doubtful if any one could have told how Pear-scab, Apple-scab, Cherry-leaf blight, or any of the numerous other diseases of pomaceous fruits, could be cheaply and effectually prevented. Nevertheless, the losses occasioned in this country by some of the maladies of pomaceous fruits have been enormous. Take, for example, the apple crop. At the very lowest estimate the damage to this one fruit in 1890 by scab alone exceeded six million dollars. The damage done to Pears, in both nursery and orchard, by leaf-blight, scab and cracking is probably as great as that of the Apple. Add to this the damage to Cherries, Plums, Peaches and similar fruits by such diseases as mildew, leaf-blight, rot and yellows, and the sum amounts to no less than fifty million of dollars annually. How to prevent this damage is a problem which has long confronted the fruit-grower, yet it was not until the year 1886 that the national Government, through its Department of Agriculture, established a branch for the investigation of plant diseases. This division, for so it is designated, has been constantly at work since its organization, endeavoring to throw light on the prevention of plant maladies.

The usual method of work is first to make a careful study of the diseases in the field and laboratory, and to follow this with practical field experiments, first on a small scale, and later more extensively if the results justify it. In accordance with a plan of this kind the work on Pear-leaf blight was commenced nearly three years ago, and is still being carried on. First it was necessary to study the life-history of the Fungus causing the disease, as it was only with a full and complete knowledge on this point that an intelligent effort in the way of treatment could be undertaken. As a result of the laboratory and field work along this line it was found that to successfully prevent the disease it would be necessary to protect the young unfolding leaves from infection by the spores or reproductive bodies of the Fungus which had passed the previous winter in the fallen foliage. As a mere statement this problem may not seem like a difficult one. The fact is, however, that a great many difficulties have been encountered, and while some have been overcome, others remain to be mastered.

The time of the first application, when the leaves are about half-grown, being settled, the next questions to solve were (1) the kind of preparation to use in order to cheaply and effectually protect and not injure the foliage; (2) the number of applications necessary, and (3) the cheapest and most practical means of making the applications. Without going into details it may be said that in treating nursery stock the best results have been obtained from six or seven applications of the Bordeaux mixture, applied with a Knapsack pump and improved Vermorel Spraying nozzle. The Bordeaux mixture is so well known that a description of its preparation is unnecessary, the standard preparation containing six pounds of copper and four pounds of lime to twenty-two gallons of water. While the best effects from this mixture have been obtained when Knapsack pumps were used, it does not always pay to use such machines for work on a large scale. Where one has 30,000, or even 50,000, stocks, two Knapsack pumps can do the work. For more than this, however, it is best to use horse-power machines. We have recently devised two machines of this kind: the first, a cart machine, holding twenty-five gallons, made to pump automatically, drawn by one horse and requiring two men and a boy to operate it. Four rows are sprayed at a time, so that it is not difficult to spray 100,000 or 150,000 Pear-seedlings a day with it. With a Knapsack pump 20,000 to 25,000 seedlings of this kind is a good day's work.

The second form of horse-power machine is simply a barrel mounted upon wheels or runners and provided with a force-pump which is worked by hand. With a horse, two men and a boy, four rows can also be sprayed at one time with this apparatus. The work cannot, however, be done as rapidly as with the automatic pump, although, owing to better control of the machine, it can be done more thoroughly. The cost of the automatic machine will range from forty dollars to fifty dollars, while the last-described apparatus complete can be fitted up at home for fifteen dollars. This includes wheels or runners, pump, suction and discharge hose, four nozzles and gearing for attaching the horse. A special feature of the machine we have devised is the pump, which is a modification of the one we use on our Knapsack Sprayer. Most of the force-pumps capable of supplying four nozzles are expensive, ranging in price from eight dollars to twenty dollars. The one under consideration can be made for two dollars and a half, and it is as durable and effective as any of the more expensive pumps. By attaching the pump to the automatic machine already mentioned the price of the same may be materially decreased. In fact, we are now perfecting an automatic apparatus that will spray four rows at a time, and which, we think, can be made for twenty-five dollars. The plan is to devise a machine so simple that the various parts may be obtained from most any reliable implement dealer and put together at home. All the machines mentioned can be used for various purposes, such as spraying Potato and Tomato-vines, Grapes, nursery stock and orchard trees.

Laying aside the question of machinery, let us turn again to the treatment of nursery stock and briefly summarize our present knowledge of this subject. We may say (1) that leaf-blight of the Pear, Plum, Cherry and Quince are best controlled by Bordeaux mixture, applied first when the leaves are one-third grown, and thereafter at intervals of twelve or fifteen days, until six or seven sprayings in all have been made; (2) that the ammoniacal solution of copper carbonate, applied the same as the Bordeaux mixture, is most successful in combating powdery mildew of the Apple. In the orchard, however, the ammoniacal solution has, for various reasons, been more satisfactory for Pear-leaf blight and scab than the Bordeaux mixture. It is also found that three or four early sprayings give as good results as six or seven made at intervals during the growing season. This statement may not hold good in the nursery where, as yet, no experiments have been made to test the matter.

The first extended experiments in treating Apple-scab were made in 1889 by Professor Goff, of Wisconsin, and Professor Taft, of Michigan, under the direction of the Division of Vegetable Pathology. It was then demonstrated that scab could be cheaply prevented by at least two of the copper preparations, namely, ammoniacal solution and modified Eau Celeste. The cost of the treatment averaged about twenty-five cents per tree, while the increase of perfect fruit on the treated trees over the untreated ranged from twenty-five to seventy-five per cent. In 1890 we continued the experiment, endeavoring to obtain information on a number of other points, chief of which was the value of early as compared with late treatments, the number of treatments necessary to obtain the best results, and the comparative efficacy of three fungicides, two containing copper and one devoid of this chemical. An attempt was also made to cheapen the treatment without decreasing their efficacy. It was found that early treatments, particularly those made just as the flowers were opening, were better than late ones. Three early sprayings—one when the flowers were just opening, one when the fruit was the size of peas, and one two or three weeks later—proved as effective as five, six or even seven sprayings made at intervals during the summer. The best fungicide was one originating with us last year, and sent out under the name of Mixture No. 5. It consists of equal parts of ammoniated copper sulphate and ammonium carbonate. It was used at the rate of from eight to twelve ounces

to twenty-five gallons of water. The special advantages of the mixture are (1) cheapness; (2) ease of preparation and application, and (3) that it can be put up in dry form in small or large packages, making it easy and convenient to handle by the practical man in the field and the store-keeper who may wish to place it on the market. The chief objection to it is that it sometimes burns the foliage. While this drawback may in time be overcome, it is necessary that we know of it, in order that due care may be observed in using the solution. Work on the treatment of this disease is being carried on this year by us in the chief Apple-growing sections of the country. As yet it is too early to speak definitely of results, but enough is known to warrant us in saying that many new points will be brought out. The conclusion of the matter is, that, with even moderate care, Apple-scab can be largely prevented in the most badly affected regions at an expense ranging from ten to twenty cents per tree.

FRUIT DISTRICTS GEOLOGICALLY AND CLIMATICALLY CONSIDERED.

Professor E. S. Goff read a carefully prepared paper on this subject. After giving many illustrations of the fact that certain regions, often of very limited area, are specially adapted to certain fruits, the author gave a brief general description of the irregular zones in which tropical and more hardy fruits are found at their best, and continued as follows:

It is a fact of importance to horticulture that, other things being equal, the further north a fruit district is located, the more profitable is the culture of the fruits to which it is adapted. Competition from the same latitude is not only restricted, but the cost of transported fruits is great. In more delicate fruits, as the raspberry, blackberry and strawberry, the lateness of maturing in northern fruit districts shuts out southern competition. In the case of some other fruits, as the apple, the longer days of the more northern clime develops a brilliancy of color that is not found in regions further south. In Wisconsin, successful apple culture is limited to a comparatively few districts, and these are mostly of small extent, yet the profits realized from the few successful orchards surpass those from the finest orchards of western New York. These facts give an added interest to these northern fruit-regions, and invite a study of the causes which serve to locate and circumscribe them.

Within a few years the eastern shores of Lake Michigan, particularly in the portion south of Grand Haven, have become famous for peaches. On the western shore of the same lake the Peach rarely yields fruit, while a few miles further to the westward only the more hardy varieties of the Apple can be successfully fruited. On the east shore of the lake, however, Apples, and even Peaches, are said to succeed as far north as Mackinaw, which is a degree north of the northern boundary of New York and Vermont. The causes for these differences of climate in a similar latitude, according to Professor Winchell, "must be attributed to the fact that the prevailing winds which bring frost or severe cold are westerly, reaching the easterly, or Michigan, shore only after having traversed nearly or quite one hundred miles of deep open water, to which, during the warm season, they will have surrendered a very considerable increment of heat, to be retained until it shall be wrestled for and re-absorbed by the colder gales of late autumn and winter, thus quenching their excess of cold by the transfer to them of a portion of the surplus heat of the warm season. . . . It is also a fact that a current sets northward along the easterly shore of Lake Michigan, doubtless occasioned by the increased influence of prevalent south-westerly winds upon the waters nearest that shore; and there is a reverse current along the westerly shore, thus causing a slow but constant transfer of the warm waters of the south toward the northern extremity of the lake, and vice versa, much in the same manner as the tepid waters of the Gulf of Mexico are transmitted by the Gulf Stream to soften the climate of north-western Europe."

In like manner the southern and eastern shores of Lake Erie and the eastern shore of Lake Champlain present a somewhat softened climate as compared with localities more remote from water, making the former district well adapted to the culture of native Grapes, and the latter to that of hardy Apples. Even the smaller lakes of central New York, aided, doubtless, by the larger Lake Ontario to the north, are surrounded by fruit-districts in which varieties of the Grape and Peach succeed that cannot be grown in northern Pennsylvania. Especially is this true of Keuka Lake, on the banks of which frosts hold off until the middle of October, and the Catawba grape ripens to perfection in the average season. The influence of physical features in modifying climate is strikingly shown in California. Here the combined influence of the great Pacific Ocean, with its Japan current washing the coast with waters tempered by a tropical sun, and the mountain barriers to the eastward, deflecting the northerly winds, actually cause the isothermal lines, which normally run east and west, to extend north and south. Indeed, in some cases, fruits ripen earlier in the northern than in the southern parts of the state.

At certain altitudes in the mountain districts of California and elsewhere occur belts of greater or less extent that are singularly free from spring and autumn frosts. These locations have been called "thermal belts," and are peculiarly adapted to fruit-culture. Their altitude secures free circulation of air and immunity from violent summer heats, which make them less subject to many fungous diseases than the valleys beneath, while their almost complete freedom from frost gives them a prolonged growing season. In seasons when premature warm weather in spring is followed by severe frosts, these thermal belts are sometimes conspicuous along the mountain-sides from the lively green of their newly formed foliage, while both above and below the premature growth has been blasted by frost. The presence of these belts has been explained by the merging of the ascending current of warm air from the valleys beneath, with the more rarefied atmosphere of the mountains. The warm currents ascend until they reach strata of equal rarefication with themselves, where they cease and merge themselves into the existing atmosphere.

It would seem that the great mountain regions of our western states and territories must abound in these thermal belts, and though comparatively few of them have as yet been developed for fruit-culture, it is not impossible that the golden fruits and rich vintages of this vast mountain system may yet rival in value the outputs of their quartz mills and placers.

Certain fruits are especially susceptible to certain features of environment. The Cranberry, it is said, cannot endure a soil that contains any considerable admixture of clay or lime. The European wine Grape (*Vitis vinifera*) is very susceptible to extremes of atmospheric humidity; the fruit-buds of the Peach are very susceptible to the cold of winter. The area of successful culture for such fruits is greatly restricted as compared with what it might be but for these special weaknesses.

I may add, in conclusion, that the subject of plant adaptation should receive much more study than has yet been devoted to it. It would seem that a thorough study of plant environment in our distinctive fruit regions should enable us to establish a formula by which the adaptability of any given locality for any particular fruit might be determined without resorting to the costly method of experiment. What expense and disappointment might have been saved could it have been determined beforehand that the European Grape could not succeed in the eastern United States! De Candolle, who has given much study to the geography of plants, was unable to explain their failure from any data that he could procure. Could he have had access to more complete meteorological facts, it is probable that he might have assigned the true cause. This, indeed, is the crying need. I have made some attempt at these studies, but have been disappointed at the meagreness of the available data. It is true that the reports of the signal service have very great value, but before the science of plant adaptation can be fully developed we must have series of observations reaching through years, not only of temperature, humidity, precipitation, cloudiness and wind, but of the intensity of sunshine, of soil temperatures and moistures, of the prevalence of fogs and dews; and we must have these observations not simply from one or two localities in a state, but from every locality that has a specially interesting economic flora. Those who are patiently making laborious observations at our signal service and experiment stations, and who often wonder if their patient labor will ever be appreciated, should take new courage. It is from data of this kind that a new science is to be developed that will prove of vast importance to a future generation.

FRUIT NOTES FROM CANADA.

Mr. L. Woolverton, of Grimsby, Ontario, reported some experience with different fruits in Canada, from which we make the following extracts:

Some standard Apples which were once counted as most valuable from a commercial point of view are now condemned entirely by many of our leading growers. One of these is the Baldwin, which, for the past few years, has been almost barren. The Early Harvest and Fall Pippin, which were considered our principal summer and fall varieties, are now no longer of value, owing to the apple-scab. Even the Northern Spy and Greening have of late been badly affected with this pest. We feel exceedingly grateful to the Department of Agriculture of the United States for the remedies

which have been proposed for this and other fungi, and we are prepared to test them fully and report to you the results. During this last season I have sprayed faithfully with carbonate of copper, as recommended by your department, but there has been scarcely an appearance of the apple-scab in our orchard, whether sprayed or unsprayed, and, consequently, we are unable, as yet, to judge of its effectiveness.

Concerning Russian apples, we are scarcely willing to condemn them wholesale, for we are finding among them some which we think will be suitable to the cold north; for instance, the Golden White, which has been tested in the province of Quebec, is exceedingly promising. Among native varieties, we think highly of the Wealthy, which has been tested faithfully in the county of Renfrew, and some of the members of our association looked upon it as the very best variety that has ever been tried in that section. Samples were sent to me last fall from there, and also some from farther south, but those grown at the north were far superior, both in size and color. Of Canadian seedling-apples of promise the Princess Louise and the La Rue are worthy of notice. Renaud's Seedling is a winter apple which appears to be very promising. It is a chance seedling, found growing on the farm of Mrs. Renaud, at Grenville, forty-five and a half degrees north latitude; should it prove equal to its promise in size, beauty, productiveness and hardiness, it will be a great boon to that section of country.

Notes.

Several of the Ginkgo-trees in Central Park are bearing fruit this year, and one of the trees in the avenue which leads up to the Department of Agriculture in Washington is literally loaded with fruit which, hanging at the end of the long stems, adds much to the beauty of the tree.

In New England, about 1635, Woods says: "The ground affords very good Kitchen Gardens, for Turnips, Parsnips, Carrots, Radishes, and Pumpions, Muskmillions, Isquontersquashes, Cowcombers, Onyons, and whatsoever growes well in England, growes as well there, many things being better and larger."

At the late meeting of the Pomological Society in Washington, in speaking of Currants, Mr. John Saul stated that he had yet to find the equal of the true Red Dutch, which is not only the most productive variety he knows, but makes the richest jam and jelly. He, however, accepted the suggestion made by Mr. T. T. Lyon that the true White Dutch Currant was quite as good.

A good late-flowering shrub for latitudes south of New York is *Clerodendron trichotomum*, which is still blooming well in Philadelphia and Washington. It will live as far north as Massachusetts, but is usually injured by the winter, so that it does not flower freely. In sheltered places it will do well about New York. It becomes a large spreading shrub when well grown, and the branching cymes of white flowers in red calyces, held well above the foliage, make an interesting picture at this season.

A schedule of prizes for the Chrysanthemum show which is to be held under the auspices of the New York Florists' Club at Madison Square Garden, in this city, from November 2d to the 8th inclusive, has been published. Six thousand five hundred dollars are offered in premiums, besides prizes for Orchids, Roses, Carnations and miscellaneous plants. Special attractions are advertised for each day of the exhibition. The Garden offers 30,000 square feet of floor surface, and the display ought to be one of exceptional interest.

An interesting feature of the *Transactions of the Indiana Horticultural Society* for last year, which has just come to hand, is a catalogue of the birds found in that state. This catalogue is illustrated with cuts from Coues' "Key to North American Birds," and it will enable the young people of Indiana to identify any of the species which come under their notice, and no doubt will encourage among them the delightful study of ornithology. The last session of the Legislature of Indiana passed an act to protect birds, their nests and their eggs. The indiscriminate slaughter of our wild birds has much to do with the increase of injurious insects, and farmers and gardeners in all parts of the country are interested in protecting these true friends of man.

Schubertia grandiflora is proving itself very useful as a summer climber. A plant two or three inches high set out last May should now be twenty feet high. We recently saw a plant trained to a fence only six feet high, and it has now spread out so as to cover fifty square feet, and its score of trusses of glittering white flowers against the dark green of the foliage makes a striking picture. The flowers, when open, are more than two inches across. They are of a thick waxen texture, and are as glossy as if they had been varnished. The individual flowers remain open a long time, and very often all of the flowers on a truss, some five or more, are open at once. It is said that the plant will survive the winters in southern California. If this is true, a well-established plant there would be very effective.

It is well known that the foreign varieties of Gooseberry are rarely cultivated with any success in this country, although there are skilled growers here and there, like Mr. Benjamin G. Smith, of Cambridge, Massachusetts, who succeed with this fruit. The great difficulty has been that the plants mildew badly. Many preparations have been used to combat this disease, but, perhaps, the most promising is the one which has been applied at the New York Experiment Station, in Geneva, successfully for the past three years. The fungicide used there is potassium sulphide, or liver of sulphur, half an ounce of which is used to one gallon of water. The sulphide dissolves readily in hot water, and as it costs only fifteen or twenty cents a pound, and a gallon of the mixture is sufficient to spray ten or twelve large bushes, it will be seen that the expense is trifling. If the spraying is done with a syringe the amount will need to be increased. At Geneva, this year, the foreign varieties have been kept entirely free from mildew, and the plants were loaded with clean bright fruit, each plant yielding over ten pounds of berries. The practice at the station is to commence spraying as soon as the young leaves begin to unfold, and to continue at intervals of from eighteen to twenty days, except in case of heavy rains, when it would be necessary to spray the plants more frequently.

For three years past the chemists of the Kansas Experiment Station have been endeavoring to improve Sorghum as a sugar-plant, by seed-selection. Their plan has been to select the seed from stalks which show an exceptionally high sugar content, although other good points, such as size of stalk, amount of glucose and yield of juice, have not been neglected. The variety known as the Orange and Amber Cross gave 12.7 per cent. of cane sugar in 1888; 14.8 per cent. in 1889; 14.6 per cent. in 1890, and 16.5 per cent. in 1891. The best stalks in these years contained 14.2, 17.5, 16 and 18.2 per cent., respectively. These figures indicate gradual advancement, and so does the sugar from seed of three stalks planted separately. The product from the seed of last year's richest stalk is the richest this year. As Professor Failyer suggests, it would be rash to do more than point to the indications of these results. Other causes than seed-selection may have helped in securing them. The apparent improvement may prove to be apparent only, and another season may see the quality revert to its former stage. The improvement of four per cent. in three years is probably too great to be permanent. But if Sorghum can be grown with a juice containing an average of even fifteen per cent. of crystallizable sugar of an average purity of eighty, the profits of sugar factories are assured. At all events, it is worth while to continue the experiment of seed-selection for some years at least.

It is stated in *Science* that, sixteen years ago, Professor Rein, the well-known authority on Japanese art and industry, planted in the Botanical Garden at Frankfort some specimens of the Lacquer-tree (*Rhus vernicefera*), from which the Japanese obtain the juice employed in the production of their famous lacquer-work. According to the *Times*, there are now at Frankfort thirty-four healthy specimens of the Lacquer-tree, thirty feet high and two feet in girth a yard from the ground; and the young trees, which have sprung from the original tree's seed, are in a flourishing condition. It seems to be proved, therefore, that the Lacquer-tree is capable of being cultivated in Europe, and it only remains to be seen whether the juice is affected by the changed conditions. The *Times* says that, to ascertain this, Professor Rein has tapped the Frankfort trees, and has sent some of the juice to Japan, where it will be used by Japanese artists in lacquer-work, who will report on its fitness for lacquering. In the mean time, some of the most eminent German chemists are analyzing samples of the juice taken from the trees at Frankfort, and samples of the juice sent from Japan; and should their reports and the reports from Japan be favorable, it is probable that the tree will be largely planted in public parks and other places in Germany. In course of time a skilled worker in lacquer would be brought over from Japan to teach a selected number of workmen the art of lacquering wood, and in this way it is hoped that a new art and craft may be introduced into Europe. Professor Rein has been conferring with the authorities at Kew as to the results of his experiment.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

Office: Tribune Building, New York.

Conducted by . . . . . Professor C. S. Sargent.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, OCTOBER 14, 1891.

TABLE OF CONTENTS.

Report of the New York Forest Commission.

THE fifth annual report of the Forest Commission of the State of New York contains much interesting information, and is full of encouragement for the future in the indication it gives of increased intelligence and a greater interest in the forests of the state than prevailed in this community at the time when the present Commission came into existence. When it is remembered how feebly the public pulse beat ten years ago for the safety of the North Woods, and how great the opposition from the inhabitants of the northern counties was to every serious attempt made for their care and protection, the present feeling of the community must be a source of gratification to the men, very few in number then, who believed that there was no better piece of work to be done than to save this wild region for the benefit for all time of the people of New York. Something certainly has been accomplished; not very much, perhaps, when one remembers the great gashes which have been made in the wilderness during these last years, but a step forward has been taken, and the fact that the Commission is able to report that, through the rules and regulations it has made and enforced, fires, always the greatest menace to the forests of this country, where climatic conditions and forest-composition specially favor their spread, have decreased to a very marked degree. Even more encouraging than the diminution of fires in the Adirondack woods is the smaller number of willful trespassers on the state lands. People are learning at last to respect the forest as property which cannot be entered and despoiled with impunity, and the purchasers of forest-supplies in New York have gradually outgrown that peculiar moral attitude which enabled them to acquire, without any great strain on their consciences, lumber, bark or cord-wood of very uncertain origin. That the Commission, backed by increased public intelligence on the forest-question, has been able to accomplish what it has done already with only a very moderate outlay of money, is certainly hopeful, and seems to indicate that while we are still very far from attaining to the system and perfect methods under which European forest-property is usually managed we are as a people in a better mental condition than we were ten years ago to submit to the restrictions which forest-control must always impose on all inhabitants of forest-regions.

The most important part of the Commissioners' report relates to the proposed Adirondack Park, the possibilities of which they have been studying, their conclusions on the subject, here reproduced, having already been presented to the Assembly in a special report. The proposal of the Commission, stated simply, is that a forest-park shall be created in northern New York to consist of some 2,200,000 acres, to be surrounded by a line not yet actually determined on, but so drawn as to enclose the principal sanitariums and the wildest and most picturesque parts of the region. A portion of the proposed park the state owns already, generally in small and often in widely separated parcels; and a very considerable portion belongs to hunting and fishing clubs, which of late years have been buying up large tracts of the wilderness. Other parts belong to hotels and sanitariums, and the remainder, and probably the largest part, to individuals or firms, who hold the land for the value of timber growing on it. The community is fully alive to the necessity of the state's securing such a park or reservation or public forest, to use what is perhaps the most appropriate name for it, and the public is now so generally in accord with the views of the Commission as to the necessity of such a reservation that it is needless to discuss, at this time at least, the merits of the measure. But the Commission finds itself when the question of methods is reached in serious difficulties. It feels that if it recommends that the state exercise its right of eminent domain and take possession of all the land within the boundaries of the proposed park, the plan would create so much opposition from interested parties that the whole scheme would be defeated; on the other hand, the state is unable to purchase the land at anything like a fair price, as much of it is held by persons who do not want to sell at all, or by men who have bought their holdings in the hope of selling it, at some time or other, to the state at a greatly increased price. The land now held by the state has been principally acquired at tax-sales, but all Adirondack lands have now become so valuable that the time has certainly passed when the state will be able to add to its holdings in this manner.

The Commission has hit upon a compromise measure by which it is hoped that the forest-reservation can be secured through arrangements made with the individual owners, under which these will agree to manage their land in such a way that the community will obtain substantially the same advantages that it would if the title to all the lands rested in the state itself. The plan seems to us to be a bad one. A great state forest, such as is needed to accomplish what is expected of the Adirondack forest, cannot be established on a really stable and permanent basis until the state itself holds the fee to every foot of land within its boundaries. What security can private owners give that they will preserve the natural conditions of the forest beyond the time when it would be for their individual interest to destroy these conditions? What is to prevent the sporting clubs from selling their land by and by to men who will buy it simply for what they can make out of it? What restrictions can be put by the state on the cutting of timber from land belonging to individuals which can be enforced for all time? Can railroads be excluded from land belonging to individuals if it is for their interest to have them built that their timber can be sent to market? The whole question is not a very different one, except in its magnitude, from that presented in the establishment of a city park. What, for example, would have been the probable consequences if some of the owners of the land which is occupied by the Central Park, in this city, had been allowed to retain the fee to their land? What sort of a park would it

have been if men, without reference to the needs or the good of the public, had been able to build a hotel or a trotting-track or a block of stores in the midst of it?

No; there is but one way to proceed if the state of New York needs a great forest-park to preserve the flow of its rivers and to afford its people for all time the opportunity to enjoy the beauties and advantages which a communion with nature always brings to the human race, and that is to take the land. It is not easy to imagine a case where the right of eminent domain could be more wisely enforced, or where the individual suffering would be smaller in comparison with the benefits bestowed upon the public at large by the taking. Bricks cannot be made without straw. A public forest in this state, covering 2,000,000 acres, and 3,000,000 would be much better, would involve a large immediate outlay, perhaps twenty millions of dollars, probably more rather than less. It might have been had ten years ago for half the money; in ten years from now it will cost twice as much, and the necessity of the reservation will be incomparably greater. But even a larger sum than twenty millions of dollars will be well invested in securing such a reservation which can be made to pay at once a fair return for the investment. A large part of the land, once the fee is secured, can be leased to the clubs and to the lumbermen on long leases, with proper restrictions as to the cutting of timber. The hotel sites and the sanitariums can be leased to the original owners if they care to continue in the business. These rentals and the sale of timber—for any sensible management of the woods means the cutting of all ripe trees under some well-considered system—the fishing and hunting rights and other sources of income would, almost from the very beginning, pay the interest on the cost of the investment, and in the future, as forest-property becomes more valuable, the operation should show a handsome profit.

Money expended on a state reservation which the state does not control is money thrown away, for it will not accomplish any good results, but the money spent in acquiring a fee to the land is money well spent, as it will bring health and prosperity to the whole state. There will be serious opposition to such a scheme on the part of many interested men, but the people in the end would favor it; and there can be no doubt that in time the measure can be successfully carried out if it is advocated intelligently and persistently.

New England Parks.

THE LYNN WOODS.

THE distinctive character of this stately park of sixteen hundred broad acres is well indicated by its name. Here are no smooth lawn expanses, no manufactured terraces, no artfully artless shrubberies, no mall, no playgrounds of skillful fashioning, but, in their stead, gigantic boulders, deep ravines, and rocky summits, and everywhere the unending forest, where one can dream of Sherwood and the merry outlaw Robin Hood. One is half-tempted to wind a bugle in these wilds to see if the men in Lincoln green might not come dashing through the bracken at the call, and behind the boles of the great trees one fancies he may catch a glimpse of Little John, or the burly figure of Friar Tuck.

From the founding of the settlement in 1629 these woods of Lynn were held as commons by its farmers, but only of late years, thanks to the public spirit of some of her citizens, has the property been legally acquired by the town, to be held perpetually as a pleasure-ground for its people.

When the plucky race that dared to settle Massachusetts first took possession of this part of the country, they found a strip of level fertile land, lying near the sea, which received the wash of a line of wooded stony hills, a part of the picturesque low range that extends along the shore, from Cape Ann to the well-defined summits of the Blue Hills of Milton. Here were good arable fields, and they accordingly selected it for their homesteads, reserving the heights behind as a common pasture for their animals.

These commons the farmers divided by long walls, built by their combined labor, and they still retain their ancient names. The Cow-pasture was the part nearest the town, that the milky mothers of the herd might easily be reached for domestic purposes. The more remote and hilly section was the Horse-pasture, where the mares and colts, and horses not in use, could pick up an inexpensive living; and a third division, across the swamp which drained the hills, bears to this day the title of Ox-pasture.

This whole region, now, all but the last, included in the park, is thickly wooded with good-sized trees, mostly Oaks, Maples and Walnuts, interspersed with some Pines and Hemlocks of great size. Black Birches and Ash-trees are also found, and here and there some Beeches. The wide marshes that separated Ox-pasture from the others have been transformed into a chain of lakes, two miles in extent, along and across which the parkways wind, while the water, now limpid and sweet, serves to supply the growing city.

The margins of these roads by the water-side, unnecessarily stripped by the engineers of the water-works of all their trees and shrubs on one side, are struggling to renew their growth, and if the Park Commissioners will put in a few Willows here and there for quick effect, bountiful nature will in a few years repair the ravages of man, and restore the lovely green screen between the road and the water, which is very essential to the beauty of the drive. Picturesque glens border this parkway, on the uncut side, with a charming undergrowth of shrubs and ferns, and fine tall trees climbing the stony heights.

Under the guidance of an enthusiastic lover of the forest, who has done much for the park, we wandered through the woods along a cart-path, outlined in soft green ferns close set as turf, until in the heart of the woods we came upon a curious reminiscence of the old settlers, the wolf-pits—two grave-like excavations, lined with stone like a well, some six feet in length by three feet wide, and originally more than nine feet deep. These holes, covered carefully with brush and sprinkled with bait, attracted the unwary wolf, who could be easily destroyed by the trapper. Tradition tells of one of the forefathers coming upon an unexpected find when he drew his traps of a morning, for there, in one corner of the deep pit, sat a cowering squaw, glared at by a terrified wolf at the opposite end, each too alarmed to approach the other.

Within the park itself are curious formations of stone; great rocks with caverns beneath them, one of which is known as Dungeon Rock. The name implies a tradition, but none has survived to fit it with a legend. The nearest approach to one is the story of the spiritualists, who here held their meetings and performed uncanny rights, excavating the rocks under the direction of their familiars, and producing strange relics which were supposed to be found beneath them. Here they built odd circular dwellings of stone, miniature towers, that will, when overgrown with Ivy, prove effective as ruins. One of their leading prophets is buried here, at the foot of the rocks, in a grave surrounded with a pointed battlement of stones, and on the leaf-strewn earth within lay some fresh flowers, showing the recent visit of some disciple to this lonely spot.

Another picturesque feature of the woods is the ravines hung with ferns and bushes, one of which is over two hundred feet in depth; but what pleased me best of all were the four rocky hill-tops rising so high above the trees that the view over the surrounding country is unobstructed. From one of these the beholder receives an extraordinary impression of the extent of the woods which surround him.

This park is the largest in the country except Fairmount Park, Philadelphia, but even the knowledge of its numerous acres does not prepare one for the effect of unbroken forest he receives when he climbs this summit and looks off upon the landscape bounded by the sea and the far-distant mountains of New Hampshire. Ten miles away the glittering dome of Boston catches the eye above its misty group of spires and chimneys, and on the other side Marblehead Light can be viewed, out on its rocky point in the north, Chicorua and Monadnock raise their giant heads above the low-lying clouds, and hill upon hill bounds the horizon, but Lynn has disappeared. Trackless woods seem to encircle the spot. No houses or spires are visible near at hand. What seem to be miles of trees lie below in varying shades of green, over soft undulations which tell of alternations of hill and dale, ravine and boulder, but all that speaks of the busy town somewhere near by has melted into the wilderness. Between Mount Gilead and Shawmut are seen only the tree-tops and the gray line of water where the coast curves.

Such a sight, lacking the dome and spires, may have met the eye of the early settler when he first climbed his way through the forest to this bald hill-top. A far-away sympathy with that lonely pioneer seizes you as you gaze. How desolate, how unconquerable must have seemed that waste of woodland, even to his dauntless spirit, strong to combat with virgin

nature. To-day, again, one feels the power of the encroaching forest; of the littleness of man against the eternal forces. Let him pause an instant and he is swept from the face of the earth; his proudest home a ruin, over which the wild vine clambers; his once stirring town a prey to the readvancing wilderness. Such sights, I am told, are to be seen in the far west, where the embryo town, deserted, relapses into desolation. A strange fear came upon me as I looked. We who preserve forests do we not cherish a foe in this great blessing? The lonely terror of the great woods came upon me, and in thought I saw this busy region once more a waste; all this bustling, nervous life stilled; our civilization an overgrown wreck; an Oak-forest where the State-house stands; a group of Pines on Marblehead Neck.

Climbing another of these hills I was reassured. There sat Lynn upon the shore as large as life, with the chimneys of its manufactories belching smoke, its railroads teeming with traffic, its harbor white with sails. Other towns came into view from other elevations—Peabody and Salem, only three miles distant from the park's eastern gate; distant Danvers among its Elms, and Wakefield, Malden, Everett and Chelsea, all within easy driving distance, on the west, while electric cars, packed with people, were bringing throngs for rest and solace to the wild solitudes of the great woods.

Then came to me a new sense of pride in our people, who in the midst of their struggle for a living, with all their greed of gain thick upon them, find time to think of their children and to plan an everlasting pleasure for the future citizens. This friendliness of spirit is more fine even than the forest which it cherishes, and one honors the men who conceive this idea and labor to confer this boon upon their neighborhood.

The moving spirit in acquiring this park for Lynn was Mr. C. M. Tracy, whose zeal and example induced many citizens to join in purchasing the land which was a nucleus for future acquisitions. Later, like all great enterprises, it outgrew its founders, and the town itself had to come in with its right of eminent domain, and add more and more to the reservation. Lovers of nature and the people, like Mr. P. A. Chase, have bought other forest-lands to protect it and ultimately increase the noble dimensions of the park, and so the good work goes on.

A fine grove of noble Hemlocks was rescued from the very axe of the headsman by Mr. Chase, and forms one of the most beautiful ornaments of the park, the trees being of great size, with a stony brook flowing between the hills on which they grow. Cardinal-flowers bloom, and great Ferns wave beside this murmuring stream, and the sunlight sifts in among the branches, and makes of it an enchanted grove, from which there is an outlook upon one of the four ponds that add so much to the charm of this region of rock and woodland.

I have not spoken of the beauty of the drives, which, following the lines of the old cart-paths, wind in graceful curves all through the forest, nor of the wild paths that lead by short cuts to Dungeon Rock and to the look-outs from the hill-tops, as well as to interesting vistas and places of interest. It was a pleasant sight to see car-loads of people hurrying to the woods for change of scene, and to hear the echo of glad children's voices and to see the look of enjoyment in the tired faces of pale mothers who had escaped hither from the town.

The scheme of the park includes places of recreation for young and old. The drained marsh in winter will be excellent for skating. There are to be ball-grounds and tennis-courts, and conveniencies for picnics, rough tables and seats being already provided for the last in an appropriate place. It is the People's Palace, where they can take continual delight, and to which not only the inhabitants of Lynn can resort, but those of seven neighboring towns, none of which are more than three miles from its various entrance-gates. This great domain is the magnificent gift of a generous people to the Commonwealth, and well may the citizens of Lynn take pride in so princely a possession.

Our "great, avaricious, sensual America," that Emerson talks of, has a warm heart beating in her young breast, and a generous hand to give. Never is the cry of the needy unheard by her, and to her children she gives royally and wisely.

This noble public spirit in our people, this large-hearted, open-handed bestowing, is a splendid sign for the future. If these things are done in the green tree, what shall be done in the dry? If now, in the hot impatience of hungry youth, our citizens still plan for the future of their neighborhoods, how much the more, as the country matures, will these gifts increase, as, fired by the great examples of their ancestors, the future sons of the Republic lay the foundations of long-enduring benefactions, none, however, to be more precious to the people than the great and beautiful woods of Lynn.

Hingham, Mass. *M. C. Robbins.*

Filices Mexicanæ.—II.

WE now continue the enumeration of the Ferns collected during the seasons of 1888, 1889 and 1890, by Mr. C. G. Pringle, of Charlotte, Vermont, in the states of Nuevo Leon, Jalisco, San Louis Potosí and Machoacan, Mexico. We are indebted to Mr. George E. Davenport, of Medford, Massachusetts, for the list, together with notes and descriptions of new species and varieties. The numbers used correspond with those on Mr. Pringle's tickets which accompany his distribution.

Asplenium pumilum, Swz. (2583). Shaded damp banks of Barranca, September, 1889; also 2028, same locality, December, 1888. This is undoubtedly true *pumilum*, and very distinct from Pringle's 1444 of his 1887 collection, which was referred to this species with some hesitation in "Fern Notes," X., in *Bulletin of the Torrey Botanical Club*, vol. xv., p. 226, and which will now have to be otherwise disposed of. Professor Eaton suggests that it may be a very dwarf form of *A. Mexicanum*, Mart. & Gal., now *A. fragrans*, or a possible hybrid between that species and *A. pumilum*. But whether those species grew in the same locality, or near by, where it was collected, or not, I do not know, as my own specimens of all three Ferns were collected in different localities far apart. It is, however, unlike any form of *A. fragrans* that I have seen, and, as it is left in so unsatisfactory a condition of determination, I venture, as a possible solution, to give to it the provisional name of *A. dubiosum*, in recognition of its present uncertain character, and submit the following brief diagnosis:

Asplenium dubiosum (1444). Collection of 1887, *n. sp.* Stipites tufted, 1′ to 2′ long, brown, naked; laminæ 1′ to 2′ long, ¾′ to 1¼′ broad at base, varying from oblong-lanceolate to deltoid-ovate or triangular, pinnately divided into from two to four pairs of wedge-shaped ovate or obliquely ovate pinnæ, lower ones the largest; upper portion sinuately pinnatifid, with obliquely obovate or cuneate dentate divisions, to the apex; lowermost pinnæ deeply cleft into one or two pairs of obliquely obovate or wedge-shaped toothed divisions at the base, and sharply dentate to the apices; texture coriaceous; main rachis green, channeled along the face and extending downward on to the stipes; sori oblique, becoming confluent when mature.

Habitat: Ledges, Arroyo, Aucho, Sierra Madre, state of Chihuahua, October 15th, 1887. Resembles *A. pumilum* in the shape of its fronds, but with the evergreen texture of *A. montanum*, and more sharply toothed divisions.

Asplenium Shepherdi, Spreng. (2025). Under wet cliffs near Guadalajara, December, 1888. A form which appears to me to be var. *inequilaterum*, Baker.

Asplenium Trichomanes, L., var. *repens*, Davenport (1838). Moist banks near Guadalajara, November, 1888.

Botrychium Virginianum, Swartz (3408). Wooded hills of Patzcuaro, October, 1890.

Blechnum occidentale, L. (1870). Springy banks near Guadalajara, November, 1888.

Cheilanthes Cooperæ, D. C. Eaton (1863). Shady mossy ledges or rocky banks, in damp places, chiefly in the Barranca and its branch cañons, November, 1888.

Cheilanthes gracillima, D. C. Eaton (2037). Dry ledges of Sierra Madre. Altitude 8,500 feet, October, 1888.

Cheilanthes lendigera, Swartz (3368). Dry ledges, hills of Patzcuaro, November, 1890. Specimens large and beautiful.

Cheilanthes meifolia, D. C. Eaton (1987). Northern slope of the Sierra Madre, near Monterey, abundant on cool, shady, often rocky, steep banks of gulches and ravines, June, 1888.

Cheilanthes microphylla, Swartz (1988). With broadly deltoid or triangular-ovate fronds, from limestone gulches and shady banks of mountains east of Monterey; and (1989) with tall and narrow fronds from partially shaded banks of dry gulches in cool, shady cañons, foot-hills of the Monterey, Sierra Madre, June, 1888; also 2024, from near Guadalajara, December, 1888, a very pubescent form, with broadly oblong fronds. The three forms are distinct enough in appearance for different species, but I can find no good characters by which to separate them even as varieties.

Cheilanthes Palmeri, D. C. Eaton (2584). Shaded ledges, near Guadalajara, September, 1889.

Cheilanthes tomentosa, Link (2603). Near Guadalajara, 1889, a rather lax form, with but slight pubescence.

Cheilanthes viscosa, Link (1842). Moist banks, near Guadalajara, November, 1888, large and fine.

Dicksonia rubiginosa, Kaulf (3407). Rich ravines, Tamasopo Cañon, June, 1890.

Gymnogramme pedata, Kaulf (1861). Damp shady banks, near Guadalajara, November, 1888; common in the Barranca and trenches.

Gymnogramme pilosa, Mart. & Gall. (2589). Wet rocks, near Guadalajara, November, 1889.

Gymnogramme tartarea, Desr. (1862). About the wet bases of sand-walls in gullies near brooks and springs, 1888.

Hemionitis elegans, *n. sp.* (2585). Root-stock, short, stout, ascending, crowns clothed with coarse pale brown scales; fronds 6′ to 16′ tall; stipites 3′ to 7½′ long, dark chestnut brown, polished, deciduously scaly at the base, naked above; laminæ 5′ to 9′ long, 4′ to 10′ broad, broadly deltoid-ovate, sinuously lobed at the base and palmately cleft into from 3, in the smaller, sterile, to 5, in the larger, fertile fronds, long acuminate divisions, the lower pair spreading and somewhat auricled at the base; texture, herbaceous; color, dark green; fructification confined to and following the course of the beautifully reticulated venation over the entire under-surface. Whole plant smooth.

Habitat: Shaded banks and ledges of the Barranca, near Guadalajara, September 24th, 1889. A very striking and handsome Fern, which takes its place at once as the most imposing member of a small genus which is confined almost exclusively to the tropics. It bears some resemblance to the next, but is from two to three times as large, and Mr. Pringle is to be congratulated on having made so fine a discovery. The figure opposite is from a drawing by Mr. C. E. Faxon.

Hemionitis palmata (3410). Tropical forests, Tamasopo, June, 1890.

New or Little-known Plants.

Habenaria carnea.

Some account of this recent introduction from Singapore was given in our London letter last week, where it was stated that the plant had just flowered at Kew. The illustration on page 487 is from a photograph of this plant. In habit the plant resembles *Habenaria militaris*, but instead of being a bright scarlet like an English soldier's jacket, the flower is a delicate flesh-pink, which fades later on to almost white. The stem rises to a height of six inches and bears some half a dozen flowers which have a spreading lip, a spur often three inches long, and ovate petals and sepals. The leaves are deciduous, and after they fall the plant rests in winter and pushes into growth again in spring. A compost of peat, sphagnum and leaf-mould seems to suit the plant, and it needs abundant heat and moisture. The flowers last nearly a month, and the plant will commend itself to all who are interested in the smaller terrestrial Orchids.

New Orchids.

Physosiphon Guatemalensis, Rolfe, is a small species which appeared with *Odontoglossum grande* in the Glasnevin Botanic Garden, where it flowered in June, 1890, and again during the present year. It is nearly allied to *P. Loddigesii*, Lindl., and has similar deep yellow flowers, but is smaller in all its parts, especially in the much shorter tube of the sepals.—*Kew Bulletin*, 1891, p. 197.

Bulbophyllum denticulatum, Rolfe, is a small species from Sierra Leone which was sent to Kew last May by Mr. James O'Brien, of Harrow. The flowers are about three lines long, and are borne on a somewhat drooping spike. The sepals are pale purple-brown, the petals white, with strong purple mid-nerve and very narrow purple denticulate margin, and the lip orange. The name is given in allusion to the denticulate petals.—*Kew Bulletin*, 1891, p. 197.

Bulbophyllum nigripetalum, Rolfe, is a distinct and remarkable species, with the petals and lip of a uniform purple-black, in allusion to which the name is given. It was introduced from West Africa by Messrs. F. Sander & Co., of St. Albans, and grown by Mr. James O'Brien, with whom it has flowered on two or three occasions. In habit it somewhat resembles the preceding, but has longer racemes, the scapes and ovaries are glaucous green, and the sepals pale yellowish white, with light maroon lines.—*Kew Bulletin*, 1891, p. 197.

Megaclinium Clarkei, Rolfe, is a native of west Africa which flowered in the collection of Major Trevor Clarke, of Daventry, during May of the present year. It is allied to *M. oxypterum*, Lindl., but differs in various details. The flattened rachis, which is the most remarkable feature of the genus, is four lines broad, light green down the centre, with purple-brown spots, almost wholly purple-brown near the margins, and the flowers somewhat similar in color.—*Kew Bulletin*, 1891, p. 198.

Megaclinium leucorachis, Rolfe, is a remarkable species, with the rachis nearly white, quite unlike any other, and, therefore, named in allusion to this character. The flowers are deep yellow. It flowered in the collection of Sir Trevor Lawrence, of Burford Lodge, Dorking, in May, 1890, and, like other species, is probably a native of some part of Africa.—*Kew Bulletin*, 1891, p. 198.

An Orchid Nursery.

The steadily growing popularity of the large and beautiful Orchid family is one of the features of modern horticulture, and no one who has not actually seen with his own eyes can realize the vast resources of some of the trade establishments devoted to their cultivation. One of the finest of these is that of Messrs. F. Sander & Co., of St. Albans, England, situated within easy distance of the metropolis, yet outside the range of those fogs which have proved so disastrous to the flowers of many fine collections during recent years. Here may be seen between three and four acres of glass devoted almost exclusively to Orchids, for the heating of which four miles of hot-water pipes are required. The houses, which range from 240 to 300 feet long, and are divided into suitable compartments, run at right angles from a long corridor of nearly equal length. They are constructed with special reference to the successful cultivation of Orchids; every point which promises to be of service being carefully considered and carried out substantially but economically, so that they serve as models for those who wish to cultivate these plants successfully. That the various changes introduced have been improvements is evident from the robust health of the plants; dark green leaves and plump, hard pseudo-bulbs being everywhere visible, and giving promise of abundance of flowers at the proper season. Mr. Sander and his manager, Mr. Godseff, seem to have proved by long experience that the most refractory subjects are amenable to cultivation when properly treated; and they lose no opportunity of ascertaining under what conditions the plants grow in a wild state. Many reputedly difficult subjects have been overcome by such intelligent treatment, among which may be specially mentioned *Phajus tuberculosus* and *Vanda Hookeriana*, the stock of each being in excellent condition.

Cool Orchids are here a special feature, and Odontoglossums may be seen in thousands. Between 2,000 and 3,000 plants of *O. grande* are now in the nursery, and a far greater number of *O. crispum*, while other desirable kinds are represented in quantities which make one wonder where they can all possibly go. Last May I here saw 5,000 plants of *Miltonia vexillaria*, and most of them in full flower, and the sight is one not easily to be forgotten. The graceful pendulous racemes of a thousand plants of *Odontoglossum citrosmum* hung from the roof of the long corridor in masses, and served to recall the glowing description given by Roezl, who met with it during his travels in Mexico. "Great was my surprise," he writes, "to see the trees clothed with a profusion of Orchids, which proved to be *O. citrosmum*, whose pendulous spikes, a yard long, were adorned with innumerable white and lilac flowers, which perfumed the air with their delightful fragrance. The stoutest branches of the Oaks were literally loaded, and it was a pleasure to see the profusion of flowers produced by these plants, a single spike bearing upward of thirty expanded flowers. During several days' march we noticed that all the Oak-trees were clothed in this way by this same Orchid, which flowers the more freely when it is exposed to the direct rays of the sun."

A somewhat novel feature in this establishment is that many of the New Granadan Odontoglossums are planted out in prepared beds of fibrous peat, and they evidently like it, for each new pseudo-bulb is much stronger than the preceding one, and on some of the plants being pulled up they presented quite a mass of healthy roots. In this way small pieces are grown into vigorous plants, and many of them are producing strong flower-spikes. Most of the best species and varieties are grown in quantity, at least 75,000 plants being in stock.

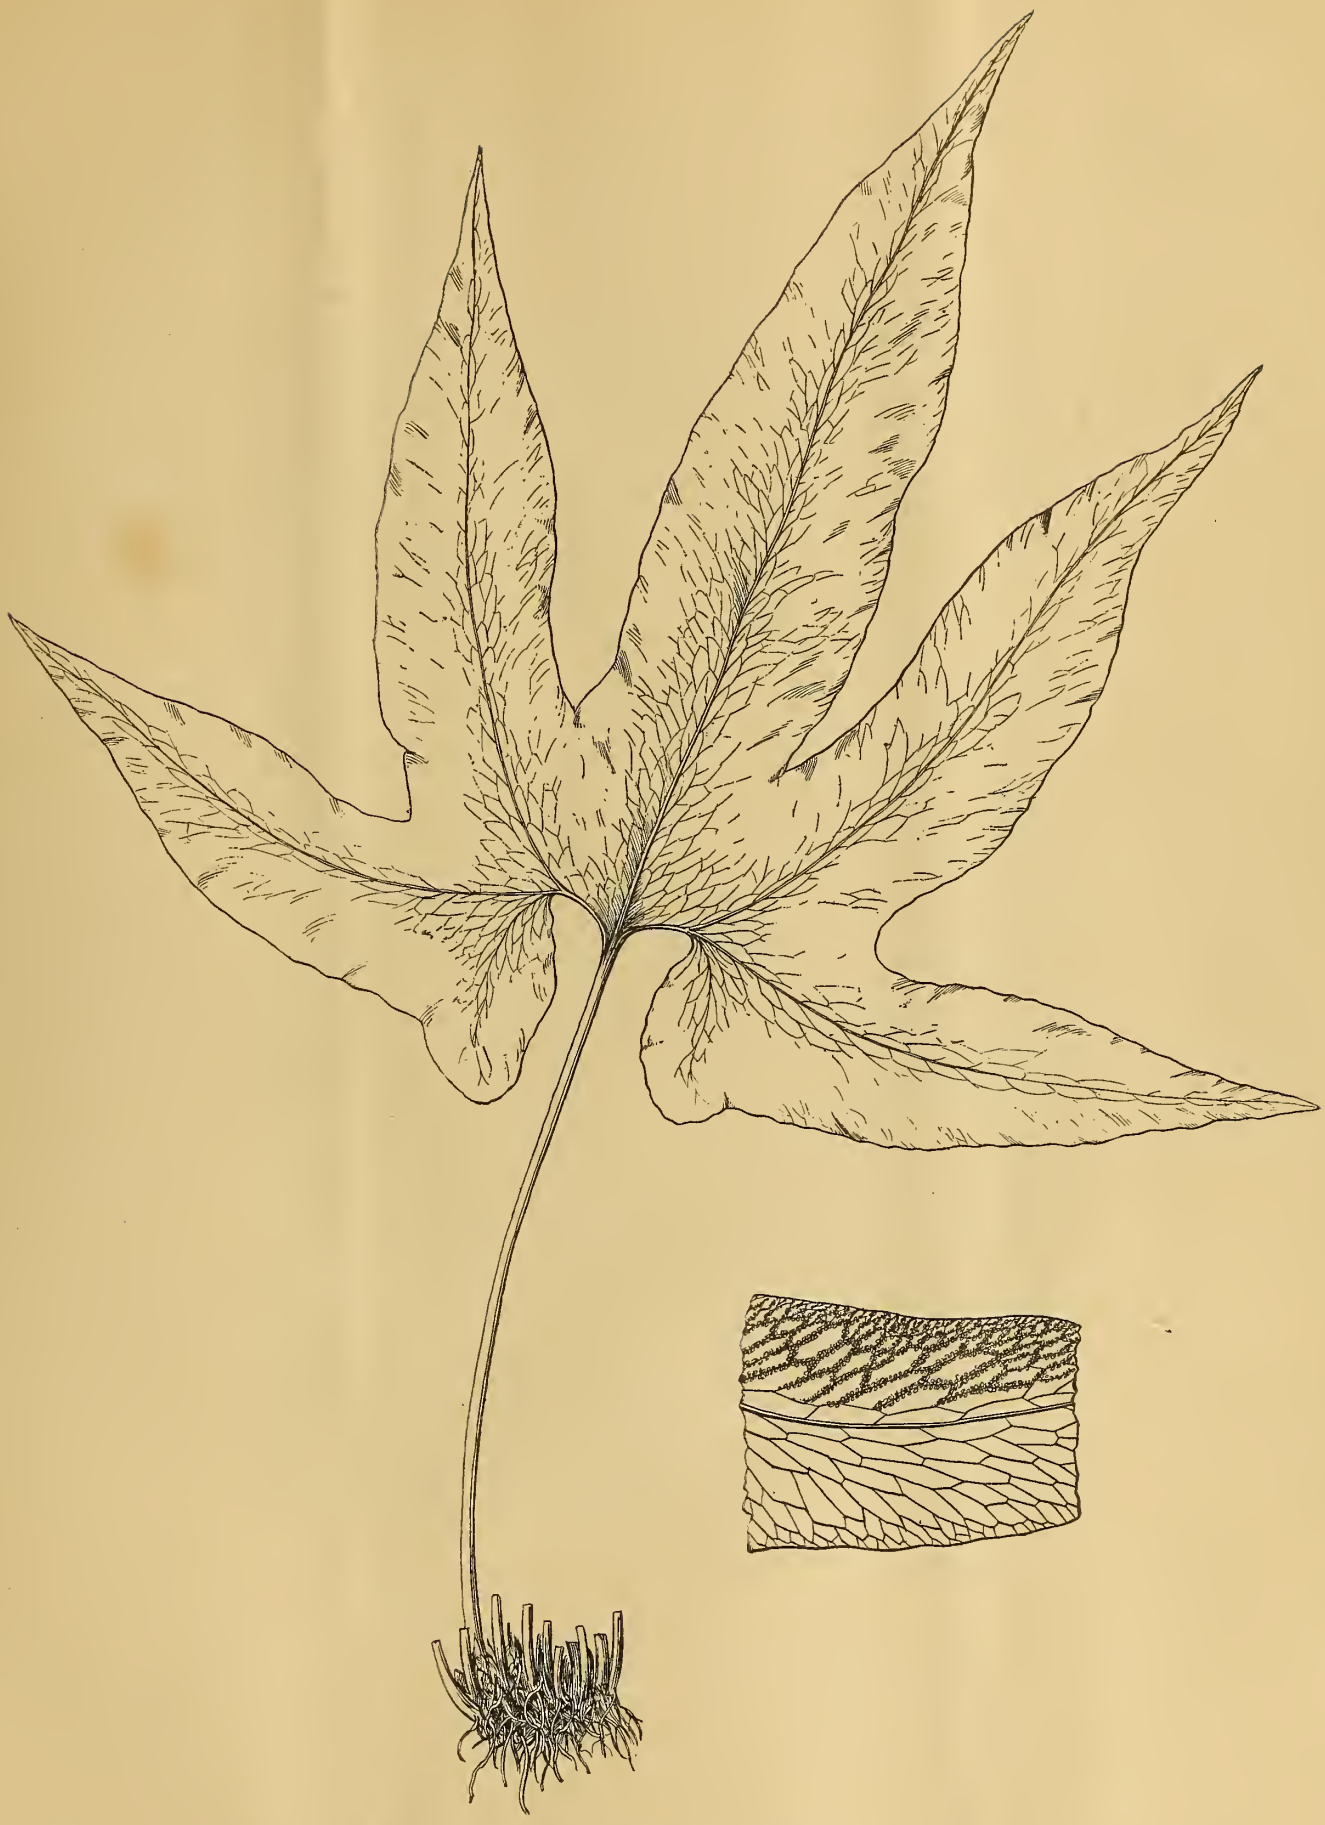

Fig. 75.—Hemionitis elegans.—See page 484.

The number of Cattleyas and Lælias in stock is estimated at over 50,000. Cypripediums, Dendrobiums, Vandas, Cœlogynes, Lycastes, Phalænopses, Angræcums, Masdevallias and other popular garden genera are also grown in immense quantities.

At all seasons of the year there is much of interest to be seen here, and a visit during the comparatively dull season of August proved no exception to the rule. Many species and hybrids of Cypripedium were in bloom, including the chaste little *C. niveum*, *C. tonsum*, *C. Parishii*, *C. Curtisii*, also *C.* × *picturatum*, *C.* × *Javanico-superbiens*, *C.* × *Hornianum*, *C.* × *Io*, *C.* × *vexillarium* and many others, some of them in quantity; also *C.* × *Maynardi* and *C.* × *Pollettianum*, two very fine ones raised in the establishment, which have recently received awards at the hands of the Royal Horticultural Society, and which, together with the equally beautiful *C.* × *Castleanum*, are to be figured in an early number of the *Reichenbachia*.

A large batch of *Cattleya Gaskelliana* was finely in bloom, including the chaste variety Albens; also *Cattleya Eldorado*, *C. Dowiana*, *C. velutina*, *C. porphyroglossa*, *C. Schofieldiana*, *Lælia crispa*, *L. monophylla*, *L. elegans* and *L. Schilleriana*, some of them in varieties of great beauty.

A healthy batch of *Vanda Hookeriana*, well known as a difficult subject to cultivate, was observed, some of the plants being in flower. A very interesting sight in one of the houses was a group of the remarkable Swan Orchid (*Cycnoches chlorochilon*), many of the plants being in flower, and among them two females, in which the column is very much shorter and stouter than in the males. It appears that while the latter have been known for so many years, the former have not been observed before the present season.

Several distinct varieties of the beautiful *Odontoglossum Harryanum* were in bloom, but among many of the better-known forms was a plant of the rare natural hybrid, *O.* × *Horsmanni*, a specially interesting subject, whose parents are believed to be *O. Pescatorei* and *O. luteopurpureum*.

Until quite recently the seedling Orchids and some others have been located in a smaller nursery some distance away, but during the present summer new houses have been erected, so as to have the collection all together. Part of the plants had been duly installed at the time of my visit, and in some respects this proved to be the most interesting part of the establishment. Here are hundreds of seedlings of various kinds, some of them from the choicest crosses, from which many novelties may be expected in the future. Some of the crosses pointed out were between distinct genera, and their flowering is awaited with considerable interest. A large stock of patience, however, is required in this work, for it is by no means an unusual circumstance for a seedling Orchid not to reach the flowering stage until it is from five to ten years old, though some arrive earlier at maturity.

Mr. Sander has introduced to cultivation many very valuable Orchids, among which may be mentioned *Maxillaria Sanderiana*, *Odontoglossum Sanderianum*, *Phalænopsis Sanderiana* and *Vanda Sanderiana*, and he has lately re-introduced the genuine autumn-flowering *Cattleya labiata*, so long supposed to be exterminated.

Cultural Department.

Cabbage and Cauliflower Plants.

PLANTS of Cabbage and Cauliflower intended to be wintered over in frames, from seed sown in September or October, ought to be gotten into their winter quarters by the 1st of November, so as to get fixed and at home before severe weather sets in. The plants should be set quite thickly. We usually put about 800 plants under a three by six-foot sash. The plants should be set, where frosts are severe, so as to cover the entire stem in the soil, or they may be split and made worthless by freezing. After placing them in the frames keep the glass off as much as possible, to harden them. The object is not to make them grow much in the frame, but to keep them in a semi-dormant state, so do not clap on the sash as soon as light freezing occurs. If gradually inured to the air, a temperature during the winter of twenty-five degrees under the glass will not hurt them, but if started into a tender growth by being kept too close they will be injured by the slightest freezing. Cauliflowers are rather more tender than Cabbages, and need closer attention in severe weather.

From Baltimore southward the practice is to set Cabbage-plants in the open ground instead of frames. Ridges running east and west are made with a plow in well-prepared and highly manured land, and the plants are set thickly upon the south side of the base of the ridge, so as to allow for some loss by winter-killing and running to seed, which sometimes happens when the seed is sown too early and too much growth is made before cold weather. The ridges are worked down and the plants cultivated by horse-power in spring. The practice of sowing Cabbage and Cauliflower-seed in fall for wintering over in frames at the north is not now so extensive as formerly, because it has been found that plants from seed sown in hot-beds or greenhouses in February and hardened off in cold frames are better, and but little later, than those wintered over. Even in this latitude, Cabbage-seed sown January 1st in greenhouses and hardened off in cold frames, so as to be set out by the middle of February, will give nearly as early and a much more certain crop than the fall-sown seed.

But for Cauliflower frame-culture here is far the best. For this we set the plants in a three by six-foot sash, for they are to head there, and fill in between them with Lettuce for heading, and later on sow Onion-seed for transplanting. The Cauliflower-plants are kept in a moderately growing state through the winter, and are gradually inured to the air by exposure on all occasions when there is no hard frost, which will here be nearly always in daylight, and by the last of February they are stripped entirely of the sashes, which are transferred to other frames to protect the early Tomato-plants. Plants of a good strain, such as the Snowball or Erfurt, will head very uniformly in March and early in April. The chief danger is in getting them stunted or checked, which causes them to "button" or form little worthless heads in February. The Lettuce will usually be cut out by Christmas, and the Onions transplanted in February.

Raleigh, N. C. *W. F. Massey.*

Roses.

THE extremely hot weather which prevailed during a large part of September has doubtless injured many Roses now in preparation for winter flowering, for the growth made during that period will mostly be thin and weak, and therefore more liable to attacks of disease. The sudden change, too, from very warm to chilly nights and more seasonable weather will be very likely to produce mildew unless strict attention is paid to ventilation and heating, and it is at such a time as this that sulphate of lime proves useful as a mildew remedy. There is not enough heat in the pipes to generate fumes from sulphur sprinkled on them, and dusting the plants all over with sulphur makes them unsightly. Syringing the plants with sulphate of lime in solution, however, leaves but a slight deposit on the foliage and soon stops the spread of the fungus. A good formula for the preparation of this mixture is the following: Slake five pounds of lime in six gallons of water, add five pounds of flour of sulphur, and then reduce the whole by boiling to two gallons. This should be allowed to settle, after which the clear liquid may be bottled off, and thus kept ready for use, in the proportion of one thumb-potful of the liquid to two gallons of water, to be applied with a syringe as the necessity arises. This preparation has a somewhat unpleasant odor, but this remains for a short time only, and as the treatment is more effective when applied late in the afternoon or evening this disadvantage is but slight.

Green-flies will also appear from time to time, and as the Roses will not yet be in flower, unless an early crop is desired, fumigation will be found the cleanest method of disposing of this pest. Later in the season fumigating should be dispensed with, for the blooms of most Roses are easily injured by this process, being either crippled in the bud or having their color bleached out. Among those specially susceptible to injury are Catherine Mermet and The Bride. To overcome this difficulty the evaporation of tobacco-water in vapor-pans placed on the heating-pipes has been tried with excellent results, since the vapor so produced is deadly to the green-fly, and does little, if any, damage to the flowers.

Neat tying and staking adds much to the appearance of a Rose-house. The neatest method undoubtedly is that of stretching wires from end to end of the beds, in line with the plants, to which the plants are tied as their growth demands. This plan does away with stakes, and allows full play for light, air and water among the foliage.

The subject of fertilizers is one that is not easily settled, for much depends on the kind of soil with which the beds have been filled. Where the compost is of a clayey nature it is not well to give a heavy dressing of stable-manure, for in this way the soil may become sodden, while a more concentrated manure may give a much better result. Hen-manure, sheep-manure, bone-dust, wood-ashes and many of the standard manufactured fertilizers are valuable, but their use should be guided by experience, for no hard-and-fast rules can be laid down for the application of special manures.

Some fire-heat will now be required, at least when the thermometer shows much below fifty degrees at night, but the sun being still strong at midday, some care is required in order to prevent the house from becoming too hot at that time, and it is during such weather as may be expected now that some of the advantages of steam-heating become manifest, because this heat can be so readily shut off from the pipes.

Pot-grown Hybrids for early flowering will soon be in condition for starting, since the hot, dry weather of the past month has rather favored the early ripening of the new growth, but it should always be borne in mind that the ripening process may be overdone, for if the wood is allowed to shrivel for want of water there will be little prospect of a satisfactory crop of flowers.

Holmesburg, Pa. *W. H. Taplin.*

Fig. 76.—Habenaria carnea.—See page 484.

Hardy Bulbs.

IF not already in the ground, the bulbs of Tulips and Hyacinths, in the colder states, should be planted as soon as possible, or by the end of October at the latest. Tulips, as seen in our public gardens and parks, are gorgeous while they last, and are eminently suited to such places, and they are often planted largely in private places, and this is the reason that other bulbs have been so long in the background. Tulips are often planted for one season's display only and then thrown away, but it is a very easy matter to plant them somewhat deeper when they can remain in the beds permanently. The bulbs will increase and the quantity of flowers will increase annually if a good top-dressing be given to the bed in the fall, as recommended for the Narcissus. In light soils a depth of six inches is ample for Tulips, but an inch less is better if the soil be of a retentive nature. If it is desired to plant the bulbs in geometrical or other designs the soil must be entirely removed from the beds to the necessary depth, leaving the centre of the bed higher than the margin, just as the surface will be when the bulbs are covered, otherwise the centre bulbs would be covered deeper than the others and they would not flower together. Care must be taken not to tread the soil too hard while planting, or a free root-action will be hindered.

If it is necessary to enrich the soil in the beds it is best done by adding the fertilizers after the bulbs are just covered with soil and before the top-covering of soil is laid on. Most bulbs are very impatient of being brought into direct contact with manure. I always like to place it over them, that the roots may have the nutriment washed down to them by the rains. If there is the least germ present of what is known as the Lily disease, or basal rot, in Narcissus, it seems to me highly important that decaying animal or vegetable matter should not be allowed to come in contact with the bulbs. In cold heavy soil a good sprinkling of sharp grit, or sand, should be placed underneath the bulbs, and the young roots will start out with more vigor and spread rapidly. Bulbs of any description, indeed, cannot be grown in a soil that contains excessive moisture in winter or summer; under-draining is in such a case imperative. Care must be taken that all the manure used is thoroughly decomposed, for in such material as half-decayed stable-manure field-mice are apt to find a happy hunting-

ground, and they are exceedingly fond of Tulips and other choice bulbs.

All these directions apply equally well to Hyacinths also, with the exception that Hyacinths, though they flower for two or three years, are never so good as they are the first season, and cannot be relied upon for permanent planting as Tulips and Narcissus can. It is scarcely necessary here to name varieties, as these are always well described and classed as to season, height and color in all bulb-catalogues, and it would be but a repetition here, but I would like to suggest a trial of the species of Tulips, even if only a few of each be planted. They are quite distinct; many are both curious and beautiful, most of them flower late, and all are worth growing. I refer to such species as *Tulipa Gesneriana*, *T. Greigii*, *T. Turkestanica*, *T. Oculis-solis*, *T. cornuta*, *T. lutea*; *T. Clusiana*, *T. Florentina*, and a few others. *T. Greigii*, the "Queen of Tulips," is especially beautiful in flower and foliage. The Parrott Tulips, though they are unfitted for in-door culture, are very much admired and useful for cutting. These succeed well in the open ground when the soil is not too rich.

South Lancaster, Mass. *E. O. Orpet.*

Planting Hardy Bulbs.

IT is an error to defer the planting of hardy spring-flowering bulbs until the earth has become lowered in temperature by the wet and cold of the late autumn months. There are cases where the planting of some bulbs cannot be done much before November. Flower-beds on the grass, for instance, often cannot be disturbed before the middle of October, and when Hyacinths, Tulips, and similar things are made use of to embellish them during the spring months, the bulbs can, of course, only be put in the ground when the summer occupants are cleared off. Even at this time, however, there is still some warmth in the ground, much more than a month later, when the soil generally comes down to such a low temperature that bulbs planted then will frequently remain until early spring before making roots. This, I think, must exercise a deteriorating influence on the blooming powers of any bulbous plant that flowers in spring. It is not at all natural for Narcissi, Hyacinths, etc., to pass the winter in a rootless condition, and when they do so they are at the mercy of an inclement winter. Being so hardy, they will not show the effects of cold and wet in such a marked manner as Lilies, for instance, but I am convinced that if a portion of the bulbs are planted at any time during the next six weeks, and the remainder at the beginning of the winter, there will be a sufficiently marked difference in the earliness and quality of the bloom to fully prove the importance of early planting. There is no time so good as the month of September for getting the bulbs in the ground, and I think that this is more especially true of Narcissi; the majority of these begin their season's work in that month, as may be ascertained by taking up a bulb or two.

Some bulbous flowers, such as Crocuses and Tulips, do not apparently suffer by being kept out of the ground during the early autumn months, but I am convinced that Narcissi, more especially those that belong to the Daffodil group, deteriorate more or less if kept out of the soil until winter arrives. Those kinds that love plenty of moisture at the roots when growing appear to feel a lengthened absence from the earth most acutely, and if not planted by the end of October good flowers cannot be reckoned upon. It is the same in pot-culture. Many persons make a point of potting their bulbs at intervals of a fortnight, so as to insure successional bloom, but this is bad practice and unnecessary as regards the result aimed at. It is better to pot them all early, and regulate their blooming season by other means, which can, of course, be easily done, and thus have the advantage of thoroughly well-rooted plants.

Opinions vary as to the depth at which the bulbs should be set in the ground, and no absolute rule can be made in this matter, not even for any one particular kind of bulb. Soils vary infinitely, and when I see the recommendation that Hyacinths should be planted three inches deep, I know that the writer is thinking of those close heavy lands into which warmth penetrates but slowly, and from which superabundant moisture passes away with difficulty. In porous soils Hyacinths may be planted from four to six inches deep, and will be more likely to do well than when set nearer the surface, as they are not likely to suffer so much if the weather is hot and dry at blooming-time. In my light soil I have planted bulbs that had bloomed in pots quite eight inches deep, and they come up and bloom very well every year. Tulips should not be planted quite so deep, but the stronger-habited Daffodils, such as Horsfieldi, Emperor, the common Lent Lily, etc., have always appeared to me to grow much stronger when planted about six inches deep. Where the Lent Lily grows naturally it is seldom found nearer the surface than this. I once had the curiosity in a copse where thousands of this Daffodil were in bloom to see if I could find any bulbs near the surface. With the exception of the very small ones, I failed to find any at a less depth than six inches, which would seem to indicate that in the case of this Daffodil at least there is a tendency on the part of the bulbs to work downward as they get older. I do not see how it can be otherwise, as the seeds, of course, germinate quite near the surface.

It is as difficult to determine the depth at which all the Narcissi should be set in the ground as to decide what kind of soil and position best suits each particular kind. I am convinced that the more delicate kinds dislike to be deeply buried in the ground. It is courting certain failure to plant such kinds as Cernuus, Moschatus, Mary Anderson, Leda and others in heavy land at the same depth as the gross-growing Sir Watkin or Emperor, and even in light soils I find they do better when not more than three inches of earth covers the bulbs. In their case success or failure may entirely depend on the influence that the sun's rays exercise on the bulbs both when in growth and during the resting period. The Lent Lily, the old double Daffodil, the Tenby, and a few others will thrive in positions where the bulbs are screened from the sun when at rest, but under such conditions kinds of a less robust nature will die out. A certain amount of the ripening process that is indispensable for many bulbous flowers would appear in their case to be necessary. In retentive soils they cannot feel the influence of the sun's heat to an appreciable extent, unless the bulbs are set within two or three inches of the surface. I have had no experience of basal rot in Daffodils, and with some kinds and in certain soils it may not be possible to absolutely guarantee every bulb from its attacks, but it is reasonable to suppose that an immature condition of the bulbs will favor its development, and more especially if they are encased in a mass of sodden soil during the winter months. In an interesting note on this subject in a recent issue of *The Garden*, a correspondent observes, "I have no doubt that the failure of these bulbs is to be attributed to the want of sun and undue moisture," and I would, therefore, recommend a trial of shallow planting in the case of kinds that are liable to this disease. —*J. C. B., in The Garden, London.*

The Hardy Plant Garden.

AT every season there are hardy plants which are pre-eminent, and in the late fall no other, at least among the tall-growing kinds, are as attractive and useful as the Japanese Anemones, furnishing as they do an abundance of handsome flowers just before the glory of the Chrysanthemums begins. Other flowers there are, of course, in various stages of perfection. The hardy Gaillardias, as for months past, are still in profuse bloom, their large flowers showy but somewhat coarse. A few perennial Asters still linger, *Anthemis tinctoria* displays a profusion of its yellow stars, *Campanula lactiflora* and *C. rotundifolia* are still covered with flowers; *Plumbago Larpentæ* will only cease to unfold its pure blue flowers when frozen; *Achillea rosea* and *A. ptarmica*, Tricyrtis, a few Phloxes and Epilobiums give stray bits of color, with no signs of suffering as yet from autumnal winds. But among them all the Japanese Anemones stand in queenly grace, though not at their best this year, owing to the dry season, for they require a somewhat moist location.

If one had the room a very pleasing effect could be made with a bed of Japanese Anemones, with, perhaps, the blue flowering Autumn Monkshood (*Aconitum autumnale*) as a foil, bordered with broad masses of Autumn Colchicums and Crocuses. With fair weather such a bed would prove bright and attractive in the "melancholy days" of the year. Ah! that weather—a subject never worn to the grower of hardy plants, which disarranges our best-laid plans and handicaps us in every cultural struggle. When the Government's rain-makers return to observation perhaps they may have so mastered the elements that we may have climates turned on to suit, and in those happy days advice as to cultural details may be of some value. At present out-of-door gardening is a hit-or-miss affair at best, and one does what experience teaches is the best average practice, with sometimes queer results. For several years my Chrysanthemums were nearly drowned out, as they were planted on the level, and this led me to plant them in raised beds. Since adapting this practice we have not had enough rain during the growing season to keep them in good health. If I have advised any one heretofore to grow

Chrysanthemums in raised beds I hereby withdraw that counsel.

This year we have had two very dry periods in this section, the present one and one in the spring, just at the time when we were trying to establish small plants. A pretty bad failure at this critical period with some Mossy Saxifrages leads me to note a device which I noticed too late to try, but which would probably be a happy expedient in a dry season with plants which require a fair supply of moisture. It consists in placing near the plant a water-tight pot, to be filled with water. Loose strands of cotton lead the water by capillary attraction in a gentle flow to the plant and keep up the moisture necessary to its growth in a dry season. This is commended on grounds of expediency rather than of æsthetic principles. But there are occasions in the hardy garden when ideas of beauty must give way to those of utility. Here is the question of labels, for instance, which at this season are apt to be especially prominent. Not every hardy garden is necessarily a "collection of labels with plants behind them," but where many varieties of plants are grown and carefully marked the garden is apt to take on the appearance of a miniature cemetery, and quite unavoidably. There are labels and labels, and which is the best one is yet an unsolved problem; the fact being that there is no one best for every purpose. The worst is probably the wooden one of the dealers, cheaply made of a soft sappy wood, which will scarcely last through the season. Probably the best label for new plants, or those one wishes to keep in prominence, is a cedar label, made of sufficient length to hold well in the ground during a thaw. If it is painted, so much the better. The name should be written firmly with a soft pencil, and will be legible for several years if well done. Where plants are more familiar, or one seldom has to refer to the name, a thin copper tag, fastened to a brass wire a foot long, is an inconspicuous and useful label. The wire is easily thrust into the earth and holds the tag securely near the ground, where it is readily found when wanted. With a smooth point one can write on the tag placed on a yielding substance, and the writing cannot be effaced. Tags without the wires may be bought or may be easily and cheaply made by any one, the sheet copper being sold by hardware dealers.

There are people who love flowers and garden without labels, but without any disrespect to a deserving portion of the community, I make bold to say that among these are a great number who know a number of things that are not true. The label habit tends to accuracy, and in the end it will add to the interest of any garden.

Correspondence.

A Fairy Candelabrum.

To the Editor of Garden and Forest:

Sir,—This is the season when it is interesting to study the various means adopted by nature for disseminating seed. One need not be a botanist to notice the difference in form and the delicate beauty of many of these waifs of the wind, usually unheeded and unnoticed because of their very profusion.

Especially charming and attractive, as its seeds mature and flit away, is the Fireweed, *Erechtites hieracifolia*. A little while since it was a rank and coarse herb, with flowers of dull white, that we passed without bestowing on it a second thought. Now, the flowers having withered and vanished, we are attracted by the tall plant, untouched by frost, that raises on finely grooved stems countless exquisitely shaped green urns, with delicate-hued tops, soft as the downiest velvet.

Let us take home a branch to watch at our leisure its further development. We put it in a glass of water, set it in a sunny spot and place a glass globe over it, for, as the pappus expands, just as the lights of a candelabrum are kindled one by one, the slightest current of air would send the fleecy seeds fluttering in every direction, and the beauty and symmetry of the dainty white spheres would soon be destroyed.

We notice first a slit down one side of the green involucre; presently it grows wider, and one after another of the fairy-like company confined within presses out of the narrow aperture to get a glimpse of the world. One green scale after another is forced out and back, till they are all wholly concealed and lost to view in the perfect downy sphere of snowy white that stands where the green urn stood an hour ago. Another urn, and another, changes in the same way before our eyes in the next hour, and our candelabrum begins to put on a festive appearance. The illumination goes on regularly and symmetrically too, the first globe of glistening white appearing at the summit, then others at regular intervals around and below, each being the terminal head of a side branch.

If called away for an hour or two we find on returning a marvelous change, more than half, perhaps, of the candelabrum being lighted up. It may be a day or two before the smaller and least-developed heads will fully mature. Meanwhile those that opened first will begin to fall. With fairy-like grace each fleecy tuft slowly settles to its place, as if half-inclined to soar aloft instead of being drawn downward by the tiny brown kernel with which it is weighted. How lightly they lie heaped one above another, and how rapidly does the heap get higher and higher! How fastidiously do the later comers roll slowly along over the feathery mound, till they find just the right spot in which to rest! This miniature snow-storm within doors is lovely and fascinating beyond description, and sometimes it will go on slowly and unceasingly for several days or a week. Sometimes, on the other hand, the heads will develop more rapidly, and the seeds will all have fallen by the second or third day.

The globe to keep the flying pappus within bounds is not absolutely necessary. If the vase be placed on a tray in a retired nook, where no current of air can come, most of the pappus will fall on the tray.

When the last white pappus has fallen down, and we tire of the beauty of the airy heap that lies high-piled and motionless, we can open the window and lift the globe, and the gossamer stars at the first breath of wind will float away, glittering in the sunshine.

Gloucester, Mass. *Sarah G. Duley.*

Recent Publications.

THE ordinary varieties of the garden Cucumber, particularly the White Spine, are sometimes grown in this country for winter use, but the so-called English varieties, which are altogether superior for forcing, are practically unknown, except to a few persons who grow them for the large cities. We are, therefore, gratified to find a late bulletin of the Cornell Experiment Station devoted to the forcing of the English Cucumber, which represents the highest type of this vegetable, and which is so distinct in appearance from our own kinds that novices often fail to recognize some of its forms as Cucumbers. Sion House is the variety which Professor Bailey grows most largely. It is of medium size, being from a foot to fourteen inches long at maturity and smooth and regular. Another favorite variety is Telegraph, which is slender and handsome, ordinarily reaching a length of eighteen or twenty inches. Kenyon is another slender variety of somewhat medium length. Edinburgh is a spiny and somewhat furrowed variety, and, therefore, not attractive, although it reaches a length of two feet. Lorne is the best of the large sorts, perfect specimens of the fruit sometimes measuring nearly three feet. Some of the very longest ones are too large for convenient table use and are sometimes inferior in quality to those a foot in length, although, when grown rapidly, the largest specimens are often excellent. The flavor of English Cucumbers differs somewhat from our own field sorts, and their texture is less brittle. They retain their green color longer than the field varieties, and are ordinarily picked before they attain their full growth, although they remain edible for some time after they have reached maturity.

In cultivation, the general requirements in regard to light, temperature and moisture are the same as that for forcing Tomatoes and Beans. They need a light warm house and facilities for brisk bottom-heat. At night a temperature of from sixty to sixty-five degrees is preferable, and seventy degrees to seventy-five degrees during the day, although the temperature will sometimes run up to eighty-five or ninety degrees when in the full sun and with open ventilators. Cucumbers are vigorous feeders and need an abundant water-supply to keep them from flagging, and in bright weather the air should be kept moist by wetting down the walks, to encourage growth and discourage the red spider. In preparing the beds, which are eight inches deep, an inch of clinkers and potsherds are placed on the boards, then three or four inches of partially decayed sods from an old pasture, the remainder being rich garden-soil, to which one-quarter of its bulk in well-rotted manure has been added. It is imperative that the soil be rich, because the productiveness of the Cucumber is almost entirely a question of food. If, however, the soil is somewhat sticky some sand should be added to increase its porosity.

The plants are started in three-inch pots filled one-third full of earth, and when a pair of true leaves is formed

above the rim the pot is filled, which gives more root-space and saves transplanting. When these pots are filled with roots the plants are set in the beds, and then follows the critical time in Cucumber-forcing. The young plants are subject to attacks of aphis and fungi, and any failure in bottom-heat will check them. Few vegetables require such careful attention until they are well established. The aphis must be kept off, or the plants will be ruined in a few days. If the plant is once stunted it will make a short bunchy growth at the top and the leaves will be small and yellow, and it may remain stationary for weeks, and even if it finally resumes growth it rarely becomes a profitable plant. To ensure a good stand three or four times as many plants as are needed should be started with the most vigorous ones set out a foot or a foot and a half apart. When they are established the weaker ones are destroyed, leaving the remaining individuals from two and a half to three feet apart. So long as the growing portions of the plant are vigorous, and the leaves are not mildewed, the plant may be considered in good condition, although the lower leaves fall off, giving it a scraggy appearance.

When there is room above the benches the plants are trained upon a perpendicular trellis of annealed wire, but on low benches they are trained along the roof. The vines are tied upon the wires with raffia or soft cord; two or three strong main branches are trained out and only enough side shoots are allowed to grow to cover the trellis, the remaining ones being pinched out as soon as they appear. The plants should not be overcrowded with young growth, and some of the large leaves may be taken off in the dark days of midwinter if the foliage is dense. The branches are all headed in as soon as they reach the top of the trellis or encroach upon the space allowed for neighboring plants. The two chief causes of failure are, insufficient bottom-heat and impatience for quicker results. Earliness is not a characteristic of the English Cucumber; from eighty to a hundred days elapse after the sowing of seed before the fruit is fit for the table, and from a month to six weeks is needed for the fruit to attain salable size after the flower has set. The plants continue to bear from three to four months under the best treatment, and each plant ought to yield at least eight good fruits. If they are pinched in, after the English custom, and allowed to bear but two or three fruits, the season can be extended, but it is probably more profitable to secure returns more quickly. The heavy fruits should not be allowed to pull the vines from their support, and those which do not hang free should be held up in slings, for if allowed to lie on the soil they do not color evenly.

Cucumbers are monœcious—that is, the sexes are in separate flowers on the same plant. The staminate flowers are the more numerous, and they begin to appear earlier, so that a sufficient supply of pollen is assured. Out-of-doors the pollen is carried to the pistillate flowers by insects, but these are absent from the greenhouse, and if the flowers are fertilized the pollen must be carried by hand. There is a question, however, whether pollination is advisable in the house, for it is certain that the English Cucumber will grow to perfection without the aid of pollen and without seeds. Many gardeners suppose that pollen causes the fruit to grow large and lumpy at the blossom end, where alone the seed forms, and they, therefore, aim to produce seedless Cucumbers in order to procure straighter and more shapely fruits. Professor Bailey is not able to make definite statements on these questions, although he has experimented on them for two winters. In his experience it has paid to pollinate by hand if early fruits are desired. The early flowers nearly always fail to set freely with no pollen. The method of pollination is to pick a staminate flower, strip off the corolla and insert the column of anthers into the pistillate flowers. Fruits which have set without pollination are uniformly seedless throughout, the walls of the ovules remaining loose and empty. To prevent misshapen fruits English gardeners often grow them in glass tubes, but the swollen end is not always caused by seed-bearing, and pollination on one side does not destroy the symmetry of the fruit as it does in tomatoes, for example. There appears to be a peculiarity in individual plants in this respect, and upon some individuals, where the fruits were liable to enlargement at the end, it was found that the fruits would grow to uniform thickness if they were hung up in slings.

English forcing Cucumbers cannot be grown in the fields successfully, but their smoothness and regularity, with length and vigor of vine, are good qualities, and therefore attempts were made at Cornell to cross the Sion House with the Medium Green in hopes of producing a superior sort for out-door use. The results have been interesting from a scientific point of view, but the desired variety has not yet been procured. Fruits of promise have been obtained, but they have not produced good seeds. Some of the mongrel fruits developed a tendency of the cell-walls to decay; the seeds did not mature and the pulp-tissue about them solidified. Near the apex of the fruit the placentæ tended to break away from the pod, and in the cavities decay set in, extending to the base of the fruit. All the fruits on one of the plants behaved in this manner, and in no case was the decay visible on the exterior until it extended well down the fruit. In most instances the mongrel vines resembled Medium Green, the staminate parent, more than Sion House. The fruits were generally intermediate through almost every gradation. Some of the vines bore beautiful fruits, twice as long as the Medium Green, nearly cylindrical and almost spineless, and good things are hoped from this cross.

The spotted mite, which feeds upon the under surface of the leaves, is the most serious enemy to Cucumbers under glass. It can be kept in check by using half a pint of Hughes' Fir-tree oil to two gallons of water and applied in spray. A large black aphis has been a serious pest, but this can also be destroyed with the Fir-tree oil. The powdery mildew will ruin the plants if it once gains a foothold, but this can be held in check by flowers of sulphur placed in a basin and set on an oil-stove in the greenhouse. The house is tightly closed and enough sulphur is evaporated to fill the house with strong fumes for half an hour, care being taken that the sulphur does not burn.

To the student in plant-variation these forcing Cucumbers possess great interest. They are quite distinct from all others, and yet they are known to have come in recent times from the shorter and spiny field sorts. The earliest mention made of the long-forcing Cucumber is in the *Transactions of the London Horticultural Society* in 1822, where it is stated that Patrick Flanagan, gardener to Sir Thomas Hare, sent two specimens of cucumbers to the Horticultural Society, one of which was seventeen inches in length and weighed twenty-six ounces. Mr. Flanagan states that he has frequently grown these cucumbers nearly two feet long, and yet in high perfection for the table. Seeds were given to the society, and were distributed under the name of Flanagan's Cucumber. The surprise which these fruits occasioned among a body of gardeners indicates that they were novelties. The oldest variety which is now grown appears to be Sion House, which was known sixty years ago. From this comparatively recent beginning the English Cucumbers have diverged from their parentage and differ from the common varieties in being very long and slender, cylindrical and not furrowed, spineless, or nearly so, at maturity, remaining green until ripe, and producing seeds sparingly. The flowers are very large and vigorous, the tendrils thick, the leaves broad in proportion to their length, and the full-grown ones have a tendency to make shallower sinuses than the field kind. The most remarkable peculiarity, however, is their habit of producing seedless fruits, which has already been spoken of.

Periodical Literature.

Mr. T. S. Brandegee contributes to the July issue of *Zoë*, which has only just reached us, an interesting paper on "The Vegetation of Burns," that is, the ground over which forest-fires have run. The open forests of Colorado and Montana are composed of *Pinus ponderosa*, mixed here and there with the Douglas Fir, and are often injured by fires which run through them and which burn the grass, the underbrush, and all fallen dead limbs and trunks, but without doing much injury to the trees themselves, except the young ones which are only protected with thin bark. The Douglas Fir, the Yellow Pine and a few other trees, Mr. Brandegee tells us, stand without injury a fire hot enough to blacken their trunks, while the Hemlocks and Spruces are killed by a very slight fire about the base of their stems. The inability of these last to withstand heat arises from the fact that their bark is much thinner than that of the Douglas Fir, the Yellow Pine or the Sequoia. The trees, in all of these interior forests killed by fire, become dry, and afford abundant material for more serious fires in succeeding years, and these subsequent fires being once started usually destroy everything that escapes the first burn.

The Redwood-trees of the forests of the California coast, when they are killed or burned to the ground, send up many new shoots from their roots, which soon surround the old stems with a luxuriant growth, from the midst of which the parent stem in time disappears, leaving only the circular groves characteristic of the Redwood. The forests of Douglas Fir in the coast region of Oregon and Washington destroyed by fire are in time replaced by

countless seedlings, which grow very rapidly, but in the interior the dry climate, the browsing of cattle and sheep, and the sensitiveness of the young trees to fire generally prevent the restoration of original forest-growth. In the high mountainous regions of these forests there is much Hemlock or Spruce and small trees of Douglas Fir, which are easily killed by the fires, which readily mount the steep slopes. This mountainous region, except where the soil deprived of the protection afforded by vegetation may have been washed away by rains, is more commonly covered with a new tree-growth than regions of a lesser altitude, although the new growth is not always at first the same as that of the original forest. Fire is very apt to destroy in the mountain regions the seeds of conifers, for seedlings do not appear immediately on the site of a coniferous forest, although trees of the original species gradually appear growing under the shade and protection of bushes, Aspens and other plants which first cover the burnt ground. That fire is the principal cause of this change of forest-composition is shown by the fact that when the original trees are cut and fires are excluded, young trees of the same species appear at once.

Mr. Brandegee notices that many of the trees which grow in these regions where fires prevail, and doubtless have always prevailed to a greater or to a less extent, have the power of reproducing themselves by root-suckers strongly developed. The Redwood is a conspicuous instance. The Nutmeg Hickory (*Torreya Californica*), another conifer, does the same thing, and so do the Manzanitas, the Huckleberries and the Madroña. The California Oaks, the Chinquapin (*Castanopsis chrysophylla*), the Hazel, and *Heteromelis arbutifolia*, a beautiful California tree of the Rose family, all renew themselves in the same manner, and almost all woody plants seem to reappear from their blackened roots.

The soil loosened by fire and enriched by the ashes of the destroyed forests provides excellent seed-beds for the germination of the seeds of many annual and perennial plants, and these California burns often offer the very best botanizing ground in the state; and several otherwise rather local plants are now appearing in such situations in much greater numbers and growing much more luxuriously than they have ever been known to before. Mr. Brandegee notices, as has already been done before in San Diego County, that the California Poppy (*Papaver Californicum*), such a very rare plant that it was never discovered until a few years ago on the Santa Inez Mountains, near Santa Barbara, is now growing abundantly on burns in two or three localities near San Francisco. *Calandrinia Breweri*, a rare plant from the southern part of the state, has made its appearance on Balinas Ridge and on the sides of the new trails of Mount Tamalpais this year, apparently for the first time, "magnificent plants appearing and spreading over the ground, forming mats three feet in diameter." *Silene multinervia*, a plant especially abundant on Santa Cruz Island and in a few places in the southern part of the state, has also appeared this year upon the Balinas burn on the southern slopes of Mount Tamalpais. It is not difficult, therefore, to imagine how great an influence this periodical burning of vast areas must have upon the composition and spread of the flora of the region, and such observations as these which Mr. Brandegee here records will some time or other be of very considerable historical value as bearing upon the distribution of California plants.

Pomology.

Meeting of the American Pomological Society.—III.

WE conclude our report of the meeting of the American Pomological Society with a few more extracts, necessarily brief, from the addresses delivered. Many interesting papers we must pass, for the present, without mention, and we may add that there were several important essays prepared for the meeting which were not read for want of time. Perhaps they could have been heard if the addresses which were delivered had been properly condensed, or if only such portions of them as were interesting to the audience and likely to be discussed had been read. It was suggested that hereafter some preliminary examination of essays should be made by the secretary and only such received as had substantial and permanent value.

The Wilder medals for displays of fruits were awarded as follows: to the Virginia State Board of Agriculture, represented by Henry L. Lyman, for 451 plates of different varieties; to P. J. Berckmans, of Augusta, for eight varieties of Japanese Persimmons, one plate of *Limonium trifoliatum*, two plates of Kieffer Pears; to Rev. Lyman Phelps, of Sanford, Florida, for Limes, Japanese Persimmons and a collection of Citrus hybrids and crosses; to Ellwanger & Barry for 112 varieties of Pears. The bronze medals were awarded as follows: to Charles H. Hedges, Charlotteville, Virginia, for Grapes; Luther Burbank, Santa Rosa, California, for seedling Quinces; J. T. Harris, of La Crescent, Minnesota, for Apples; Wisconsin Horticultural Society for Apples; The Jewell Nursery Company, of Lake City, Minnesota, for Seedling Apples; P. S. Dinsmore, of Riverside, California, for Apples; J. W. Porter, of Piedmont, Virginia, for Apples; and J. L. Babcock, of Virginia, for Apples.

SOME LOCAL PROBLEMS IN POMOLOGY.

Mr. Charles W. Garfield, of Grand Rapids, Michigan, delivered an address on this subject, in which he attempted to show that success in fruit-growing could only be accomplished by a careful study of the particular conditions of given localities, and that a large proportion of the failures in this business was due to the selections of varieties which were valuable elsewhere, but not suited to the particular spot in which they were planted, and to methods of cultivation which, although they might be the best practice in other parts of the country, were not adapted to local conditions. He concluded his address as follows:

I would not depreciate the value of our national gatherings in the interest of pomology, but the man who goes a long way from home to get advice as to what varieties to plant or how to manage them, is liable to be misled. His local conditions are the ones to be studied, and hence the great importance of carefully conducted experiments in our own neighborhood. All honor to the men who are willing to be pointed at as theorists, experimenters, book-farmers, etc., whose trials are but a few of them crowned with success, but whose failures are a perpetual help to their neighbors. General habits of thrift and scientific method are of the widest application, but the dealing with an individual's environment, so as to make the best possible use of his opportunities, is a problem which each one must largely work out for himself. He can only learn of his nearest neighbors, and he is greatly blest if these neighbors are broad-minded, careful people, given more to patient investigation than the elaboration of theories.

We think a great many things, in relation to fruit-growing, and often think aloud too quickly. We know very little, and even this grows less when we attempt to give it wide application. I have listened so often to discussions in which the relation of experience has taken a prominent part, and have noted so many false inferences that have brought disaster to those who attempted to utilize them, that possibly I may magnify the importance of varying local conditions, as affecting experience and counsel.

Of course, a successful fruit-grower must be well grounded in general principles in order to most quickly lay hold of his local conditions and manipulate them in his interests; but, after all, it is of the highest importance that people in a neighborhood, and all having similar conditions, should familiarly compare observations and experience, so there will be brought out a body of local doctrine—a consensus of opinion which can be known and utilized. It is uphill work trying to induce people to have more confidence in the counsel of their neighbors than in that of strangers, and often, when asked for advice by one far away, when I have referred the interrogation to the man's own neighbors, I have knocked a foundation-stone from under my fame. Still, I insist that the most serious problems we have to solve in growing fruit are those which are peculiar to our own localities, and these we must solve for ourselves. At all events, we cannot safely rely upon the counsel of strangers for their solution.

The Rev. Lyman Phelps, of Sanford, Florida, delivered an address to show that cross-fertilization affects immediately the quality and commercial value of citrus fruits. Mr. Phelps exhibited a great many oranges which were abnormal in form and in which the character of the skin and color of the pulp had been changed, and these variations were attributed to the fact that the blossoms had been fertilized by pollen from trees which bore fruit differing in size and form and texture. Mr. Lyman was so thoroughly convinced of the immediate influence of pollen that he declared that he had lost $1,500 in a single year from fruit which had been rendered defective by foreign pollen.

Dr. Erwin F. Smith, of the Department of Agriculture, delivered an address on the "Chemistry of the Peach Yellows,"

in which he explained the method of study he had practiced for four years in the investigation of the peach yellows. The rather disheartening conclusions were reached that the cause of the disease yet remains a mystery, that it is transmissible, that so far no remedy has been found for it, and the axe and fire is the only treatment that promises any relief from its ravages. Nevertheless, Dr. Smith's address was most instructive as an example of genuine scientific investigation, in which nothing is taken for granted, and every point is subjected to the crucial test of experiment, and it may be added that even the negative results obtained are of great value since they narrow down to definite limits the field in which further researches are to be made.

Mr. H. S. Williams, of Rockledge, Florida, a well-known grower of Oranges on the Indian River, read an essay to show how thoroughly adapted the mountain region of western North Carolina is to general fruit-culture. A few years ago he passed some time near the village of Bavard, in Transylvania County, which is between 2,500 and 3,000 feet above sea-level. He noticed that the Apple-trees which had been planted there, although very old, were still bearing well. Unpruned Peach-trees, some of them twenty-six inches in diameter, bore abundantly on the younger wood, and indicated that this region was exceptionally favorable for the growth of this fruit. A small vineyard on the French Broad River, with ground covered with weeds and vines never trimmed, showed a remarkable display of fruit. He therefore set out a small orchard with Peach and Apple-trees of choice varieties, and a few hundred Grape-vines, and passing through the property on his way to the meeting, he found the vines full of fruit and promising well. The Peaches were exceptionally fine, and some of the seedling Apples which he exhibited, and which had grown on the old trees after having been trimmed and cared for, were remarkably beautiful. Mr. Williams concluded that these mountain valleys of western Virginia would be found equal to any other part of the country for fruit-growing.

Notes.

Several leading growers of flowering plants in Europe have already offered to send large collections to the Columbian Fair, and Mr. Thorpe expects to have an extraordinary collection of Orchids ready for the opening of the Exposition.

The publishers of *Popular Gardening* announce that that periodical is hereafter to be merged into the *American Garden*. Mr. Long, of the first-named paper, will remain in Buffalo and continue to edit the new magazine, whose name is not announced, and the business will be conducted by the Rural Publishing Company, of this city.

An experienced grape-grower recently stated that when vines are forced into luxuriant growth the pruning should not be as close as when only moderate growth is made. In the latter case the best bearing buds are nearest the base of the cane, while in canes that have grown more vigorously the strongest buds are further away, and therefore are lost when the vine is pruned closely.

It is reported by Consul M'Lain, of Nassau, New Providence, that a machine has recently been invented by an American which will separate automatically the Sisal hemp fibre from the leaves, with ease, at the rate of 180 pounds of fibre in a day. This will remove one of the great obstacles to the profitable cultivation of the Agave, which yields this fibre in Texas, Florida, and perhaps in other portions of the United States.

Professor Georgeson calls attention to the fact that in Japan there are numerous dwarf varieties of Pines, Firs, Cypresses, Arbor-vitæs and other conifers, which are very distinct, and which differ much in habit of growth, the length of their leaves and their general appearance. The ordinary species are well known here, but these varieties are not well known, and no doubt many of them would prove a substantial addition to our garden trees and shrubs.

Mr. Meehan, in the monthly which bears his name, repeats his opinion that the disease known as Peach Yellows is caused by the attack of a Mushroom (*Agaricus melleus*) on the roots of the tree. Dr. Erwin Smith seems to have demonstrated that the disease can be transmitted by inoculation of the limbs of a healthy tree with the sap of a diseased one. It would be interesting to know how any vegetative portion of the fungus is conveyed in inoculation of this kind.

Mr. Robert Craig writes to the *American Florist* that he regards Marie Guillot as the best out-door Rose, and almost unrivaled as a pot-plant, and he also considers Papa Gontier as an excellent bedding Rose and the best red Tea Rose for out-door planting. Mr. Craig, in the same paper, states that young Palms when planted on benches from thumb-pots grow as fast again as when kept steadily in pots. When they are large enough to be placed in five-inch pots they do not suffer in the least from lifting.

Mr. Joseph A. Burton, of Mitchell, Indiana, considers mulching better treatment for his orchard than plowing, which is, after all, little more than mulching with surface soil. Under bearing trees it is difficult to plow, and roots are, to a certain extent, mangled; besides this, orchards on hill-sides after they are plowed are liable to be furrowed into deep gullies by heavy rains. Any waste material will do for a mulch, whether it is straw, sawdust, shavings, weeds, briers or rotten wood. Mr. Burton sows his ground to Clover and mows it, allowing it to remain on the ground as mulch, and when it rots it furnishes a valuable fertilizer.

The death is announced, in his sixty-second year, of Jean Baptiste Joseph van Vloxem, one of the most accomplished dendrologists in Europe, whose beautiful gardens and park, where he had formed an extensive arboretum and where many large specimens of American trees were to be seen, were one of the most interesting spots to visit in the neighborhood of Brussels. Monsieur Van Vloxem traveled extensively some years ago in this country, as well as in Japan, in some parts of Columbia and in the Caucasus. It was by him that the now well-known *Tacsonia Vloxemi* was introduced from South America, and it was to him also that we owe the introduction of the beautiful Caucasian Maple which bears his name.

A writer in the *Gardeners' Magazine*, London, speaks of the facility which the Douglas Spruce manifests for accommodating itself to various soils in Great Britain. Some of the best specimens of the tree are found in rich loam or alluvium and in sheltered situations. At Eastnor Castle it drives its roots down through the fissures of the rocks, which are just below the surface soil, and flourishes well on the moisture there found for its support. It grows with great vigor among the slate rocks of North Wales, even up to the very summits of the hills, and seems well adapted to elevated situations where even Spruce will not grow. In favored situations its growth is very rapid in Great Britain, and trees planted only thirty years have in that time reached a height of seventy feet, with a proportionate bulk of stem.

Mr. Albert Benz, in a late circular, divides Garden Pansies into six classes, according to the manner in which they are colored. The first class comprises self-colored flowers—that is, those which have an even shade spread over the whole surface of each of the petals. They may be white, yellow, bronze, mohogany, brown, purple, lavender, violet and nearly all intermediate shades. They can be depended on more largely than the other varieties to come true from seed. Shaded Pansies constitute the second class, in which the flowers have the darkest shade of a given color at the upper end of the upper petals gradually graded down to a lighter shade toward the bottom end of the lower petal. Others of this class are darkest in the centre and shade gradually into a lighter tint toward the edge of all the petals. The Three-spotted or Face Pansies include the flowers which show a distinct mask, or face, in their centre—that is, a dark spot on each side of the side petals, and a broad and larger one on the lower petal. This includes most of the English Pansies and the new French Trimardeau, a remarkable sort for the size of its flowers, which are, however, somewhat deficient in substance and richness of color. The Odier or Five-spotted, Pansies have a white, yellow, blue, crimson, or brown color and a large dark spot on each one of the five petals. To be perfect, these spots, starting from the centre of the flower, should cover two-thirds or three-fourths of its surface, and be of equal dimensions on each petal with a well-defined outline. Cassier and Bougnot have succeeded in improving this class materially in size of flowers and growth of foliage. Edged or Border Pansies have flowers with a narrow, but distinct, edging around the outside of each petal of a color which contrasts well with the ground-color of the flower. The color of the border is generally white or gold when on blue, purple or bronze flowers, and blue or pinkish on white and yellow flowers. The sixth and last class, called Fancy Pansies, have the marble-striped and flaked flowers, which are distinguished by great oddity and beauty in their coloring and marking.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by . . . . . Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, OCTOBER 21, 1891.

TABLE OF CONTENTS.

Forest Reservations.

WE have more than once called attention to the closing section of the act to repeal the timber culture laws which was approved on the 3d of March last. This section authorizes a distinct departure from the traditional policy of the Government with relation to the public forests by empowering the President, from time to time, to set apart reservations of timber lands in any state or territory wherever such public lands may be situated, and "to declare by proclamation the establishment of such reservations and the limits thereof." This power of the President has already been exercised to enlarge the boundaries of the Yellowstone and Yosemite reservations to the gratification of the great body of the people of the United States. There are many other portions of the national domain where the exercise of the executive power is quite as desirable. It is not to be presumed that the President will wield this new authority with which he is clothed without great caution, and, therefore, it is altogether fitting that citizens who are well informed and interested in these matters should recommend to him tracts of forest whose preservation seems to them essential to the welfare of the people.

We are glad to note, therefore, that a memorial has been presented to the President by the Honorable Edwin Willits, N. H. Egleston and Edward A. Bowers, representing the American Forestry Association, and by a committee of the American Association for the Advancement of Science, consisting of Professors E. W. Hilgard, C. E. Bessey, William Saunders, T. C. Mendenhall and B. E. Fernow. The memorial names five tracts for public reservation, each of which is described at some length, with the specification of its boundaries and the streams which take rise in them, together with the reasons offered for setting them apart and the names of those who have been active in urging the step. The memorialists wisely suggest, that, before definite action is taken, a more detailed examination should be made by the proper agencies in order to ascertain more fully what are the actual conditions, the best practicable boundaries, the arguments for and the objections to reserving these tracts, as well as those in other locations. They also state that such reservations cannot accomplish the object for which they are made without the inauguration of some strong and efficient administration which is capable of supplying local timber requirements, and at the same time of preventing depredations by lawless persons and desolation by fire, and the President, therefore, is requested not only to exercise his new right of reservation, but also his entire power under existing laws to protect this property and to urge whatever additional legislation may seem to him necessary for this end.

The first tract spoken of is that known as the Flat Head and Marias River Reservation. Its establishment was originally proposed in bills introduced by Senator Edmunds during the sessions of the Forty-eighth and Forty-ninth Congresses, which were passed by the Senate, in both cases, without dissent. This is a tract of some 7,000 square miles, covering both slopes of the Continental Divide in Montana, about the head-waters of the Flathead River, a stream which unites with the Missoula to form Clarke's Fork of the Columbia, and also including the head-waters of the Marias, the Teton and Sun rivers, which are affluents of the Missouri. This is an alpine tract of rugged peaks and deep gorges, where snows and glaciers are perpetual, and avalanches not infrequent. South of the middle fork of the Flathead River the western slope is covered with Fir, Spruce, Cedar, Pine and Larch, and north of this the mountains have been nearly stripped by fire. Innumerable streams, fed by the perpetual snows of the high ranges, furnish the bulk of the water-supply for the Flathead River, while the rivers on the eastern slope are of inestimable value for irrigation purposes before they reach the Missouri. All the land is now unsurveyed. If this forest-tract is obliterated by speculators and mill-men, who are now attacking it, no money can measure the disastrous results to our agriculture and commerce. If it is preserved, as proposed by the bill of Senator Edmunds, under the management of the Government the forests might be made a source of permanent income, and they would exert, for all time to come, a beneficient influence on two great rivers, and upon immense areas which only need irrigation to reward the labors of the husbandman.

The next tract is the Tulare Reservation, which covers also some 7,000 square miles along the western slope of the Sierra Nevada, enclosing the entire eastern watershed of the San Joaquin River and of the streams which flow into Tulare Lake. Petition for this reservation has been made by the California Academy of Science and by a convention of the citizens of Merced, Fresno, Tulare and Kern Counties. This is a mountainous tract, ranging from 2,000 to 12,000 feet high, with beautiful valleys and plateaus, and embracing a dozen groves of the famous Big Trees, besides the Pines, Firs and Spruces of the region. The memorialists ask for the establishment of this reservation so that those great natural wonders, the Sequoia groves, may be preserved, and because it is necessary to the maintenance of the water-supply in the valley, which is dependent largely upon irrigation for successful agriculture. Timber speculators are already recklessly cutting away the timber, and the sheep of herders are destroying the undergrowths, while frequent fires are carrying destruction over the forest-floor and obliterating vegetation of all kinds. The preservation of this forest seems to be necessary to this region, which has now been made fertile by irrigation, and which, in this way alone, can be kept from reverting once more to desert conditions.

The Surveyor-General of New Mexico and many of its citizens have advocated the Pecos River Reservation, about 575 square miles in extent, on the main Rocky Mountain Divide, and covering the Las Vegas and Santa Fé ranges. These two ranges enclose the basins of the Pecos

River with cañons, steep slopes and high peaks, one of which, Tuchas Peak, attains an altitude of 13,000 feet. The tract is not adapted to agricultural use, since its cañons are often filled with snow to a depth of fifty feet, which lies on the ground far into spring, precluding timely tillage. Although of little value for settlement, the reservation, if protected, would be a lasting source of benefit to a large region by furnishing a continued supply of wood and water, while if left to lawless invasion and unregulated appropriation the results would be correspondingly disastrous.

The Pike's Peak Reservation is asked for by the citizens of Colorado, by the Senators and Representatives of that state, and by its Forest Commission. It is situated in El Paso County, and embraces Pike's Peak, with its slopes, including an area of 357 square miles. Ranging from 7,000 to 14,000 feet in altitude, and furrowed by deep gorges, it is unfit for agricultural use, the few small parks adapted to grazing having been already taken, and it contains no valuable land to be withheld from settlement. Thirty thousand people now depend on this forest-area for their supply of timber and fuel, and here originate many streams which furnish water indispensable for hundreds of thousands of acres of land besides the water-supply of many thriving towns and communities in a country where water needs to be husbanded. These supplies are now threatened with extinction by loggers, who are cutting the timber illegally and wastefully, and a railroad which has recently been extended to the summit of the peak will insure its more rapid destruction. Besides this, Pike's Peak has rare attractions in its scenery, more than ten thousand tourists having visited it during the past year, and it should be preserved in its present wooded condition as one of the healthful and pleasurable places of resort in the great west.

We have already spoken of the Minnesota Reservation which is proposed at the extreme northern part of that state extending from the international boundary, including the head-waters of the Mississippi, and comprising some six millions of acres. The region is generally covered with forests of larger or smaller growth, but there are many lakes and marshes, and little of it is suited for agriculture. This fact makes its preservation advisable for productive forestry, as much of it is useless except for wood crops. Its preservation is also necessary to maintain a supply of water for the sources of the Mississippi and minor streams, and to preserve for adjacent farm-lands conditions of atmospheric humidity and protection against the cold winds of the north.

There need be little fear that too many forest-reservations will be set apart under this new law. The most we can hope is, that the woods, which now stand as a protecting cover to the highlands where a few of the tributaries of our great rivers have their source, may escape those attacks of man and beast which have already swept away the forests which were once doing the same beneficent service to many other streams. We are convinced that the question of forest-preservation is not surpassed in importance or urgency by any which has been or is likely to be brought in the near future to the notice of Congress. But the prospect of adequate legislation seems almost hopelessly remote. We trust, therefore, that the President may see his way clear to give favorable consideration to the letter and spirit of this memorial.

It is somewhat surprising and a very interesting fact that at Barnard College (the Woman's Department of Columbia College in this city) more students are enrolled in the botanical classes than in any others. The recently issued report of the institution shows that it numbers nineteen botany specials as against seven freshmen, twelve sophomores and seven chemistry specials.

When the college opened in the autumn of 1889 it possessed a well-equipped botanical laboratory, given by the Torrey Botanical Club. Two hundred dollars have since been given by Mr. C. Neustadt for the purposes of this laboratory, and it is under the competent direction of Dr. Emily L. Gregory, who is a graduate of Cornell University and holds her doctor's degree from the University of Zurich. "This laboratory," says the report, "opens to women special facilities, not found elsewhere in this country, for the study of the physiology and anatomy of plants through a systematic course, leading to the successive degrees given for similar work in other branches of science. The course includes two years of undergraduate work and two years of graduate work. There are now studying in this department nineteen students, three of whom are doing graduate work and will later enter upon the work of original research." That these young women are serious and well-prepared students is shown by the fact that, to be admitted to the departments of botany and chemistry, candidates must pass the regular entrance examination of the college, unless it is otherwise ordered in special cases, and that "a student taking the degree of Ph. D. in botany is supposed to have gone over the entire known ground of the science, to know what questions are yet to be solved and to have some practical knowledge of the methods of solving them, so she may be ready to make original investigations. The minor studies are taken," the report continues, "in order to insure a knowledge on collateral or cognate branches sufficient to enable her to grapple with the problems of the major subject," and these cognate studies include chemistry, zoölogy, physics and mathematics, while the candidate for a degree "is supposed to have a solid foundation of university studies already laid."

As regards the value of a thorough study of botany to young women the report quotes Dr. Gregory as saying: "Aside from its value in a purely intellectual way, it has a practical value in furnishing occupation, with remunerative salaries, to an increasing number of persons. One of these fields is that of pharmacy. Adulterations are constantly made in the use of drugs, and we are just learning the importance of a methodical study of the inner structure of plants. This also applies to the students of medicine, but more particularly to the pharmacist. A much wider field for trained botanists is found in our agricultural stations. In the Agricultural Department in Washington one of my former students is now doing work in mycology, and her position commands a good salary. The call for this work is the increasing devastation made by parasitical plants on our grains and food-plants. Before anything can be done to prevent failures in crops from rust, smut, blight and mildews, the nature and habits of the parasite plant must be known. Such investigations are made and the results published in journals, and the scientific advancement of the country may be marked by the number and worth of such publications. In every state these experimental stations have been started. The work of the botanist is such that a woman is specially fitted for it."

Great Hill: A New American Country-seat.—I.

The interesting letter which you recently published under the title "Gardening on the Shores of Buzzard's Bay," tempts me to write you a description of a country place in this same region which is remarkable because "gardening," in the usual acceptation of the term, has played no part in creating its beauty. It is, I am sure, one of the most attractive country-seats in New England, partly because of its size and its unusually fine situation, but largely because it has been developed out of wildness with so singular a degree of taste and so keen a feeling for the character which Nature had indicated. No one has been more in sympathy than I with the counsels so often given in Garden and Forest relative to the necessity of employing a landscape-gardener when a piece of wild nature is to be adapted to human habitation and given an artistic aspect. But there is no rule without its exceptions, and the place in question, belonging to Mr. Albert W. Nickerson, of Dedham, shows that while most men must be educated to the possession of taste, some are born with it, and are justified in dispensing with professional assistance. No hand but the owner's has touched Great Hill, and the result

is a domain whose beauty is as uncommon as it is striking, as natural as it is artistic.

If you look at a map of Buzzard's Bay you will see at its inner end, lying west of the arm into which the Wareham River flows, a promontory which is divided into two points by the deep indentation of Wing's Cove, the easterly one called Great Hill and the westerly, and longer, one called Sippican Neck. A few years ago Mr. Nickerson purchased a small hotel which stood near the extremity of Great Hill, so named, by the way, because, although the plateau it forms is only 127 feet above the sea, it is the highest ground in this neighborhood. To the land attached to this building Mr. Nickerson has gradually added until his property now covers some 1,500 acres, includes the whole of Great Hill, extends along the western shore of Wing's Cove, and, owing to the presence of the cove, boasts of some six miles of water-front. It is only a few weeks since I wrote for GARDEN AND FOREST a description of the way in which the land in this region has covered itself with forests, to the obliteration of the farms by which it once was occupied. Most of Mr. Nickerson's property, when it came into his hands, was a dense forest-growth, extending down to the water's edge, although here and there were open tracts still under cultivation. There was only one makeshift approach from the high-road to the house. Everything was to be done if a rough woodland was to be transformed into an agreeable summer residence. Fortunately, however, the man who had built the house had chosen exactly the best site, not on the actual point of the promontory, but on a broader projection toward the south-east, so that the view embraces the main expanse of Buzzard's Bay, and, as well, the long arm which runs up toward Wareham. And here he had set the house on exactly the right spot, just far enough away from the sea to leave wide foregrounds to east and south between house and water, and at the top of the slopes which thence run down to the narrow beaches. The house was left, outside, just as it stood, and now is manifestly out of keeping with its surroundings. But it is easier, one remembers, to rebuild a house than to recast an unfortunately treated landscape; and this landscape has been so well treated that, should an architect ever be called upon to rebuild, he will be very unintelligent if he fails to produce a wholly charming result.

The main approach to Great Hill is now from an entrance lying toward the north-west, on the road from Marion, and not far from the head of Wing's Cove, which, however, is hidden from view by the thick masses of the forest. Hence a finely constructed road, more than a mile and a quarter in length, leads to the house, gradually rising as it goes with perpetually varying curves, whose sinuosities, however, are never exaggerated, so that it seems to take the most natural way along the gentle ascent and between the closely pressing trees. The chief care bestowed upon the borders of the road was in the way of preservation; but along the edge of the macadam a border of turf, three or four inches wide, was laid. When I saw the road soon after its completion, five years ago, the artificial character of this little edging was apparent, but by the next summer it had become amalgamated with the natural growth of grass, wild flowers and shrubs. For a long distance after leaving the gate we drive in sun-streaked shadow beneath good-sized trees, chiefly White Pines, with occasionally a Pitch Pine, a Holly, a Swamp Maple, a Gray Birch, or a Cedar. In some places the undergrowth is low, giving a far view between the tree-trunks, but in others it forms masses of shrubbery from six to ten feet high, where Blueberries, Viburnums and Clethras, Wild Roses, Vines and young Sassafras-trees and Maples sweep the ground with their branches, while the finest feature of all is supplied by great full clumps of the shining evergreen Inkberry. Here and there these shrubberies fall back, leaving little grassy glades or vistas, with perhaps a big boulder or two, and sprinkled, now with red Lilies, and again with orange-colored Butterfly-weed or tall sprays of Golden-rod, Aster and Wild Sunflower. No one is allowed to break the shrubs or pick the flowers along the drives at Great Hill, wild though they are, and no one who sees their constant yet perpetually changing beauty thinks of wishing that a gardener had been allowed to "improve" them by any of his manipulations or additions. At one spot an unusually large White Pine accentuates a curve of the road; at another it is completely bridged, high overhead, by a slender drooping Birch, and at another a great old Cedar stands, almost dead but shrouded thick with hanging grief-moss—a figure of mortality which throws into strong relief the vigor of the life about it.

In one place the faintest glimmer of the waters of Wing's Cove may be caught through the trees. But the owner has had the right idea as regards the character of this drive, and has resisted many mistaken appeals to "open vistas" for the revelation of the sea. "This is a forest-road," he says; "you will see plenty of water when we get to it."

As one reaches higher ground, perhaps a third of a mile from the house, the soil becomes poorer, and bears chiefly smallish Oaks and Pitch Pines almost free from high undergrowth. Here on one side lies a large paddock for the horses and donkeys, and then at the end of a short straight stretch of rising road we come, facing eastward, suddenly out upon a very large, almost circular and sloping lawn with a wide stretch of blue water beyond it, and beyond this the low wooded line of the Wareham shore. Half-skirting the lawn to the right we are brought to the house; and from there, following the road as it passes between the lawn and another slope descending to the sea, it takes us out of the place again along a "sea-drive" about a mile in length.

It seems almost a pity that we had not approached the house by this second drive; for, although it is beautiful driving in either direction, it is, of course, most beautiful when our faces, not our backs, are turned to the south and the open bay. It runs close to the irregular margin of the water on one side, now skirting little white beaches and now border-like masses of low shrubs and clambering vines, from which rise occasional tall Pines or Cedars, while the forest on the landward side opens at intervals into broad grassy stretches, probably the remains of formerly cultivated fields. One of these wide pastures, almost square in shape, is especially beautiful, thickly surrounded by trees, but itself wholly unbroken save by a group of tall, graceful Birches that stands close to the roadway. Occasional pools of water also diversify this drive, as richly clothed along their edges as, I think, only the pools of this particular region ever are. Nothing but the road itself betrays the touch of art except one of these pools which, to protect the road, had to be kept within bounds by a stone curbing. Certain observers, struck by its unlikeness to its surroundings, ask why it was made of a regular oval shape and edged with symmetrically cut stone. But the owner replies that one can't make a curbed basin look really natural, and when a thing must look artificial it ought simply and plainly to confess its character. The result confirms his view, for one realizes that some necessity prescribed this treatment of the spring-hole, and, lying so close to the road, it does not strike an inharmonious note.

Marion, Mass. *M. G. Van Rensselaer.*

Seedling Almonds in California.

THE Almond groves are now one of the most charming features of many of the foot-hill districts of central California, and, when in bloom, are as fragrant and beautiful as the orange groves of the southern counties. Indeed, there is no more attractive time than the flowering time of the Almond for a visitor to go to the great centres of the fruit-industry. The Almond, it is true, comes first, and is followed in rapid succession by the Cherry, Peach and other fruit-trees. But the Almond is peculiarly fresh and lovely in its season; its petals fairly cover the grass, and are blown far across the highways in blush-tinted drifts.

One must get out of the fog belt to find the successful Almond-orchards. Niles, Livermore, Santa Clara, Los Gatos, Gilroy, to the east and south of San Francisco Bay; Sonoma, Santa Rosa, Suisun, to the north and north-east. The tree will grow almost anywhere, but it will not bear except in mild and sheltered situations. A few years ago ill-advised Almond-planting brought about a reaction, and numbers of orchards on poor soil, or too much exposed to sea-fogs and winds, were cut down for fire-wood. In the real Almond districts, however, no tree is more sure to pay well, one year with another.

California growers have originated many new and very desirable varieties of the Almond; with no other fruit or nut have the older varieties been so completely abandoned in new plantations. The Languedoc varieties, introduced into California as early as 1853, and later French importations, are now superseded by seedlings of local origin, some of them well worthy of trial by the great nurserymen of France, Spain, and Italy. Larger and better nuts, heavier crops and a greater degree of hardiness are the advantages of the California seedlings. Some of them yield nuts which bring, in the market, two or three cents a pound more than the standard imported varieties.

The leading grower of new kinds, A. T. Hatch, of Solano County, once exhibited 192 varieties of promise, four of which are now recognized as commercial sorts, and are being planted by tens of thousands all over the state. Professor E. J. Wickson, in his *California Fruits* (1889), mentions sixteen California

seedlings that are now standard varieties, and several more have come into prominence since.

It is interesting to note that, although California is now producing a great number of valuable new varieties of all the standard fruits, the Almond alone has so far improved that the older kinds are practically given up, and now can only be found in a few gardens. The same tendency is to be seen in the Peach, Apple, Pear, Apricot and Walnut, but in the case of these fruits many of the old standards still retain places in the front rank. Horticultural history must record the fact that California first originated an entirely new line of market varieties in the Almond.

The variety that I have chosen to illustrate (see page 499) is one of Lewellyn's seedlings, originating some years ago in Napa County, and considered by some growers the best bearing Almond known to orchardists. It is hardly in the general market yet, but all who have seen the orchard speak well of the variety, and it is being planted extensively. The branch from which the photograph was taken was smaller and somewhat less heavily loaded than many on the tree, and several almonds were broken from it before it reached the hands of the photographer. But it is a fair illustration of the vigor and fruitfulness of the whole race of California seedlings. It was cut from a five-year-old tree planted on a warm gravelly loam in Livermore Valley, and grown without the aid of irrigation. There was a fair crop in 1889, when the trees were four years from the bud; a large crop in 1890, the season when the photograph was taken, and a still larger crop is now ripening. Like the best of the California seedlings, it bears regularly every year.

Niles, Cal. *Charles Howard Shinn.*

A Clematis Borer (Acalthoë caudata).

A DESCRIPTION of this moth was first given by the late Dr. T. W. Harris, author of "Insects Injurious to Vegetation in Massachusetts." The original account of the moth, which he named *Ægeria caudata*, was given in *The American Journal of Science* (vol. xxxvi., 1839).

Without naming it, he refers to the insect in his volume on injurious insects, and again, in a letter to the late Dr. Le Baron, he speaks of taking a male specimen at Jackson, in the White Mountains of New Hampshire ("Correspondence," page 262). Dr. Harris has recorded that he found the eggs on Clematis, but no further account of the earlier stages is given nor of the injuries caused; and, although other authors have since written accounts of the Ægerians and have quoted Harris, nothing has been added to the facts given by him.

In the spring of 1890 it became necessary to move an old specimen plant of the Virgin's Bower (*Clematis Virginiana*) in the shrub collection of the Arboretum, and then it was found that the whole mass of roots at the crown and the bases of the stems had been bored and hollowed out by lepidopterous larvæ, a few of which were secured alive. These were kept, and on July 25th a female moth emerged, which proved these borers to be of the same species described by Harris. An examination of many other plants of the Virgin's Bower in the Arboretum and vicinity showed that almost every plant was more or less infested, a fact which fully accounted for a very apparent lack of vigor in this usually rampant-growing species. The borers attack the larger roots near the surface, infest the crown, and often enter into the larger stems, especially where these trail on the ground.

In June, larvæ of various sizes, from one-third to fully grown, may be found in the infested plants. The fully grown borer is about two-thirds of an inch in length and of a dull white color. The legs are brownish. On each side of the body there is a row of very minute brown dots placed singly on each segment, and a magnifying-glass shows several rows of solitary hairs along the body. The head is brown, and the top of the segment behind it is of a very light brown color, with two darker-colored club-shaped or spindle-shaped spots, the larger ends of which almost touch each other at the back of the segment, while the points are directed downward toward the sides of the head.

In the latter part of June or in July the fully grown larva makes a slight cocoon of silk, mixed with small particles of the wood or other material, and changes to a brown chrysalis, which is provided with a number of minute spines. These spines are largest on the last segments, and by their aid the chrysalis is enabled to force its way to the open air when the moth is about to emerge. Apparently the moths begin to emerge in the last days of July, and the eggs are deposited on Clematis soon afterward.

The male is remarkable for possessing a curious tail-like appendage, nearly, if not quite, as long as the abdomen. The general color of the insect is brown. In the male the fore wings are transparent from the base to the middle; hind wings transparent, but with a brownish fringe and subcostal spot. Antennæ, palpi, collar and tarsi tawny yellow; hind legs yellow, end of tibiæ and first tarsal-joints fringed with tawny yellow and black hairs. Tail slender, cylindrical, nearly as long as the body, tawny yellow, with a little black tuft on each side at base.

The female moth has the fore wings entirely black (opaque). The hind legs are black, with a rusty spot in the middle of the tibiæ, and fringed with black; and the caudal tuft is short, and such as is ordinarily seen in moths of this class. The female is larger than the male, and its wings expand from one to one and a quarter inches.

Besides Clematis, Dr. Harris gave our common wild Black Currant (*Ribes floridum*) as another food-plant, the larvæ living within the stems. Other writers have quoted this statement, but a careful examination of Currant-bushes growing among infested Clematis in the Arboretum failed to show any evidence of attack by the Clematis borer.

It has not been definitely ascertained how long a period is necessary for the larva to attain full growth, and no experiments have been made toward curing or preventing the attacks. Such treatment as is given in the case of the well-known Peach-tree borer would probably answer for this.

As yet no other species of Clematis except our Virgin's Bower has been found attacked at the Arboretum.

The accompanying figures are from drawings by Mr. C. E. Faxon.

Arnold Arboretum. *J. G. Jack.*

New or Little-known Plants.

New Orchids.

Pholidota repens, Rolfe, is a small species, with light flesh-colored flowers, sent to Kew by Mr. James O'Brien, in June, 1890, and again during the present year. It is a native of some of the hills of India. It is allied to *P. Griffithii*, Hook. f., of which it may be an unusually procumbent variety with differently colored flowers.—*Kew Bulletin*, 1891, p. 199.

Epidendrum Mooreanum, Rolfe, is a very pretty species belonging to the section *Encyclium*, and allied to *E. stellatum*, Lindl. The flowers are very fragrant, the sepals and petals light green, and the lip deep purple with light green margin. It is said to be a native of Costa Rica, and exists in several collections, having been sent to Kew for determination by Mr. F. W. Moore, of Glasnevin, Mr. W. Bull, Messrs. Hugh Low & Co., and Sir Trevor Lawrence. —*Kew Bulletin*, 1891, p. 199.

Polystachya bulbophylloides, Rolfe, is a minute and very anomalous species, with the habit precisely of Bulbophyllum. It is a native of west Africa, and was sent to Kew by Mr. J. O'Brien in July of the present year. The small diphyllous pseudo-bulbs are borne at intervals on slender creeping rhizomes. The flowers are white, except two orange spots on the lip and a purple margin to the column. The petals are reduced to a pair of minute fleshy tubercles, another anomalous character.—*Kew Bulletin*, 1891, p. 199.

Renanthera Ims-chootiana, Rolfe, is a handsome species allied to *R. coccinea*, Lour., and *R. Storiei*, Rchb. f., but with flowers in simple racemes and various structural differences. It was sent to Kew by M. A. Vanimschoot, of Ghent, Belgium, during July of the present year, with the information that it was received with *Ærides Godefroyæ*, Rchb. f., from Messrs. F. Sander & Co., of St. Albans, and is believed to be a native of the same country. The flowers are chiefly of a reddish vermilion shade.—*Kew Bulletin*, 1891, p. 200.

Pelexia olivacea, Rolfe, is a native of the Andes, sent to Kew by Messrs. Charlesworth, Shuttleworth & Co., of Heaton, Bradford, in April, 1890, where it flowered about a year later. It is one of those plants formerly referred to Neottia, though erroneously. The leaves are dull olive-green, with a broad, irregular, silvery band on either side of the midrib; the scape, ovary and sepals are also olive-green; the petals and lip white, with some yellow on the

mouth of the tube, formed by the union of the column with the stalk of the lip.—*Kew Bulletin*, 1891, p. 200.

Lælia grandis, var. tenebrosa, Hort.—This is a very distinct and handsome variety of *Lælia grandis*, which originally appeared with H. Tate, Esq., of Allerton Beeches, near Liverpool, in May, 1889, and appears to have been first introduced by Monsieur Travassos from a new district in Brazil. It has since flowered in several other collections. The segments are flatter than in the original form, less undulate, and of a decided copper-bronze tint, while the lip is purple, somewhat darker in the throat, and with a white margin. —*Gardeners' Chronicle*, August 1st, p. 126; *Lindenia*, t. 290.

Odontoglossum Hennisii, Rolfe.—A very elegant little Odontoglossum, sent to Messrs. Charlesworth, Shuttleworth & Co., of Heaton, Bradford, from Ecuador or Peru by their collector, Mr. W. Hennis, after whom it is named. In size and color it resembles *O. odoratum*, Lindl., but its real affinity is with *O. crinatum*, Rchb. f., which has a very similar lip. This organ is three-lobed, white marked with reddish brown, the side lobes rounded, the front one longer and acuminate, and the disk consisting of numerous hair-like filaments. The sepals and petals are yellow, barred with brown.—*Gardeners' Chronicle*, August 8th, p. 158.

London Letter.

We have had more bright sunshine in England during September than in any month this year, which, so far, has been decidedly bad for horticulture. But sunshine came at last, and it has done a great deal of good. The garden now is beautiful with yellow Sunflowers of all kinds, purple Asters, tall fragrant Lilies and many-colored Dahlias. In some few places the pretty Crocuses proper, with their mimics, the Colchicums, make the lawns, rock-garden and lake-side gay with purple color. Even the Pelargoniums are bright with flowers, and the Roses were never better. September and October bring many rich color-effects both of flower, leaf and fruit in a well-made garden. I have often wondered that the really beautiful autumn-flowering species of Crocus have not yet been properly "discovered" and taken in hand by horticulturists generally. At Kew there are beds set apart for them, not much space certainly—in fact, only just sufficient for the plants to show what they could do if they were used for the production of effect in autumn as the spring-flowering species are used now. They may be had in small quantities from the bulb-growers, and propagated just as easily as the common garden kinds. Colchicums are quite as useful as the best of Crocuses. In England one may see meadows spread over with the rich purple of the native species, *C. autumnale*, the Meadow Saffron. It is also a favorite garden-plant with a few who can appreciate the beauty of our native plants when cultivated in the garden. The English Crocus (*C. nudiflorus*) is also abundant in fields and meadows, and is often mistaken for the Meadow Saffron from its flowering at the same time and growing in similar situations, as well as from the resemblance between the flowers of the two.

Among exotic species of both genera there are many that deserve a large place in every garden. Of Colchicums there are *C. speciosum*, from the Caucasus, with flowers as large as a wine-glass; *C. Parkinsoni*, with purple flowers conspicuously reticulated with a paler color, and *C. variegatum*, of the same peculiar character. But the king of these checkered flowered kinds is a new one—new to cultivation, that is, and named by Mr. Baker *C. Sibthorpii*. It was first described by Sibthorp in "Flora Græca" under the name of *C. latifolium*, but this name had previously been used for another species, hence the present name. For its introduction into gardens we have to thank Herr Max Leichtlin, who obtained it two years or so ago from Salonica. With his usual generosity he sent a few bulbs of it to Kew, where it is now beautifully in flower. In their handsome form, large size and lasting qualities the flowers resemble *C. speciosum*, but they are of the richest rosy mauve and prettily checkered like *C. variegatum*. I should say that in the whole range of hardy autumn-flowering bulbous plants we have nothing better than this Colchicum.

A list of all the hardy bulbous plants in flower here now would be longer than one would expect. Besides those above named there are the Belladonnas, some with their large blush-tinted trumpets in full blow, others only just pushing their purple noses through the soil. When they are all up there will be hundreds of them and all on a narrow border under a greenhouse wall, which is clothed with hardy Fuchsias, while the border is edged with the white Zephyr Flower (*Zephyranthes candida*). This is proving a better edge-plant than Box even; at any rate, it is growing amazingly well in a position which appears to have been too hot and dry for Box. The deep shining green of the short, graceful, rush-like foliage and the numerous white star-shaped flowers produce an effect of value in the garden. This effect, too, is permanent throughout the summer, and in winter the leaves remain green and fresh, frost having no effect upon them. The tall scapes of the white-flowered Watsonia, which Mr. O'Brien introduced from the Cape two or three years ago, are a new and pleasing feature among bulbs, for the scapes are four feet high, branched near the top and crowded with the whitest of white trumpets, which measure two inches across the mouth. Another charming Watsonia is a white-flowered *W. densiflora*. This species differs altogether from Mr. O'Brien's plant (*W. iridifolia*) in having an erect, unbranched scape, clothed near the top with brown scales, giving the flower-head an appearance exactly like a ripe

wheat-ear. Then the white flowers burst through the brown scales altogether, making the most delightful of white flower-wands. This is a new introduction from Natal and is now flowering for the first time in a bulb-border at Kew. *Tritonia rosea* and *T. crocata* are still in bloom, as also are the bright orange and crimson-flowered hybrid Tritonias raised by M. Lemoine. At Kew these plants are grown in very large round beds in conspicuous places on the lawns. Each bed is filled with one variety, and when the thousands of spikes are all in flower the effect is of the richest.

Lilies have not finished yet. Two very large beds of *L. lancifolium* (*speciosum*) are now at their best, better even than pot-grown specimens. A few years ago no one would have ventured to grow this species for open-air effect and left the bulbs to take care of themselves after they were planted. *L. auratum* is as grand as ever. The new *L. Henryi* is not yet over, but keeps step with its near affinity, *L. lancifolium*. The rich crimson spikes of the Schizostylis have begun to unfold and will continue until severe frost cuts them down. In the greenhouses the huge trumpets of *L. Wallichianum*, *L. Neilgherrense* and the richly colored *L. Nepalense* are now at their best. The two last-named are not very easy to manage in England, but *L. Wallichianum* is apparently as good-natured under artificial treatment as *L. Harrisii*. A new addition to Himalayan Liliums has been discovered by Mr. Boxall, Messrs. Low & Co.'s collector, and has been named in compliment to him by Mr. Baker. It is like *L. Nepalense* in habit and appearance and may be called a pale, uniform, yellow-flowered form of that species. Bulbous plants are the worst of all when they do not get what they want, but no plants are more interesting or more delightful to look at than they are when at their best.

Dahlias.—These are general favorites in England now, and at all the exhibitions in autumn they form a very conspicuous feature. The Cactus section is, perhaps, the most popular, although the single flowered kinds are thought by many to be the prettiest and most useful. Messrs. Cannell, Phippen, Paul, Ware, Turner, in fact, all the nurserymen who grow herbaceous plants for sale, have contributed many new kinds within the last year or two. In form there is nothing different from the Show, Pompons, Cactus and single flowered kinds, but in shades of color great progress has been made. Brown and black are scarcely flower-colors, but in Mr. Cannell's new varieties of the single flowered these colors are represented in various shades. Single Dahlias are easily raised from seeds, so easily, indeed, that in countries where they are not destroyed by frost they have run wild. I am told by Dr. King, of Calcutta, that in the Himalayas the river-banks are in many places clothed with Single Dahlias which have escaped from cultivation and established themselves over miles of country by means of seeds. At this rate it is possible that the Dahlia may become a scourge in the subtropical regions of the east. At a meeting of the National Chrysanthemum Society at the Royal Aquarium there were no less than one hundred new kinds of Dahlia submitted to the committee for certificates. Of these the following obtained awards: Show—George Gordon, John Rawlings, Indian Chief, Arthur Rawlings, Scarlet Queen. Cactus—St. Catherine, Beauty of Arundel, Baron Schrœder, Duke of Clarence, Rayon d'Or, Mrs. Keith. Fancy and Pompon—Touchstone, Lilian. Single—Miss Glasscock, Evelyn, Little Snow White. The Royal Horticultural Society certificated the following: Cactus—Sir Roger, E. Cannell, Mrs. Thornton. Pompon—Mars, Lorna Doone, Little Sarah, Mrs. Besant, Nellie Nachray. Show—Ada Rehan, Mrs. Ocock, Mrs. Humphries.

Begonias.—The tuberous-rooted kinds, now properly known as bedding Begonias, have reached as high a place in horticulture as the scarlet Pelargoniums. Every garden here of any pretensions employs these Begonias extensively in summer-bedding. In the conservatory the most select of named sorts are a conspicuous feature. Some are remarkable for size of bloom, flowers almost large enough to overlap a man's hand being among them; others are as large and double as Hollyhocks; others, again, are of some special shade of color. As pot-plants we have nothing better, because nothing is more easily cultivated or produces a better effect when in flower. And this is quite true of the tuberous Begonias as bedding plants. The excessive wet of the summer, now almost ended here, has not disagreed with these Begonias. In the parks, at Kew, in large private gardens near London, they have been and are still a chief attraction. The great demand for them is indicated by the acres of them grown by those nurserymen who make Begonias a specialty. Messrs. J. Laing & Sons appear to have millions of them in their large Begonia-fields. Mr. T. Ware has almost as many. So, too, has Mr. Cannell. In the fields the plants are as large and healthy and the flowers as perfect as in the carefully cultivated flower-bed. Ask these nurserymen if they can find a market for so many plants, and the answer is to the effect that they haven't half enough. In England the taste for summer-bedding is in the direction of simple masses of one color, and the many-hued beds, like Joseph's coat, will soon be things of the past. Of course, the king of summer-bedders, the Scarlet Geranium, will always be of first-rate value where color is wanted. These tuberous Begonias will also be exceptionally useful for the same purpose. They require a little management at the beginning, but their wants are simple and soon mastered.

Gathering Storing Fruit.—Mr. Joseph Cheal, an eminent fruit nurseryman in Sussex, and one of the organizers of the British Fruit-growers Association, read a paper upon this subject at a conference of fruit-growers held in Edinburgh a few days ago. Mr. Cheal's knowledge and experience are such as enable him to speak with authority upon such important matters as the care of fruit after it is ready for gathering. He recommends the use of ladders that will stand alone, hand-picking, and baskets instead of sacks. Many apples, he says, should be gathered a few days before they are ripe, and at once placed in boxes or sieves to travel. For the bulk of fruit it is best to allow them to remain on the trees until they are ripe, as when gathered too early they shrink, the rind shrivels and the fruit looks leathery. All fruit should be sorted and graded if intended for market. No two kinds should ever be placed in the same basket. Small baskets of neatly packed fruits of high quality will fetch a much higher price than if placed roughly in the ordinary basket. A novel fruit-store recommended by Mr. Cheal is "a cave in a chalk-bank or sand-hill, which makes a capital apple-store when fitted with wooden shelves." Ventilation, an equable temperature, and the exclusion of frost, are essentials in a good store-room for fruit. A simple store, which answers well, according to Mr. Cheal, is made by throwing up two banks of soil and placing a thickly thatched roof across them. Pears require a warm dry store-room, differing from apples in this respect. The cool and somewhat moist atmosphere required by apples takes all the flavor out of pears. For pears hot-water pipes may be used with advantage, but not for apples.

Copper Salts and Vegetation.

THE solutions of copper are efficient fungicides. The various micro-organisms—mildews, blights and rots—infesting plants of a higher order are killed by contact of these solutions, and germination of their spores is prevented. It is believed that these uses of copper will be of untold value to agriculture. No doubt of this, provided the copper is destructive only to these lower plants, the fungi, and that it is not harmful to the vitality of our cultivated plants.

But these copper salts, sprayed on vegetation, are finally deposited on and in the soil beneath, and they may there be inimical to the germination of our planted seeds and to the prosperity of plants which spring from them. These are grave possibilities, made seriously plausible by experiences had in my recent practice. When under the direction of the United

States Department of Agriculture I began experiments with the copper compounds, I naturally did not confine the treatment to the Vine exclusively. With the view of preventing Corn ergot (*Ustilago Maydis*) I soaked for four hours a portion of my seed-corn in the Bordeaux mixture, and then planted it in a plat in the field by the side of other plats seeded with corn not thus treated, and in comparison with a plat planted with corn-seed soaked for eight hours in a solution of copperas (sulphate of iron). On the plat treated with Bordeaux mixture, the seed generally failed to germinate; on the other plats, the seed grew in usual health.

The next year I made the experiment of spraying sundry plats of Peachblow Potatoes, to prevent blight and rot. This was successful, as reported in one of the department bulletins. The sprayed plats gave a good crop; the unsprayed plats were all the victims of the fungus (*Phytopthora infestans*), dead

Fig. 78.—A Seedling California Almond.—See page 495.

and dried up six weeks before the others, and giving practically no crop. This potato-patch was subsequently planted again to Peachblows. When the tubers sprouted I saw that growth on the plat which had not been sprayed was earlier and more vigorous than on the plats which were sprayed the previous season.

The next year this patch was again planted to Peachblows. On three rows I sprayed the tubers, after they were dropped along the furrow, with Bordeaux mixture, expending about the same quantity of the liquid as would be used in one spraying of a row of Grape-vines. These sprayed tubers generally failed to sprout. Nothing from them was visible above ground for two weeks after those in the other plats were up, and at last more than half of the sprayed tubers never sprouted, rotting in the ground.

In the spring of 1891 I again planted this Potato-patch to Peachblows. On the plat where the tubers had formerly been sprayed along the furrow, but not thus sprayed this year, fully seventy-five per cent. of the Potatoes failed to grow, and those which finally did come up showed a weak and spindling growth, and yielded very few potatoes. The other plats did fairly well, excepting that the plat which has never been subjected to the copper-spraying showed the best growth of plants. These, however, succumbed to the blight, as I have continuously left this plat untreated. The Potato-plant may be completely protected from this rot fungus by persistent spraying with the Bordeaux mixture, but there is ground for fears that present benefits may be followed by a future injury, and that soils once largely contaminated by the copper salts may be thus rendered bad for the growth of plants.

I shall renew this Potato experiment another season, but I fear that similar results will be manifest. It will be a serious matter if we find that in our zeal to save the health of our plants by these copper applications we risk the permanent ruin of our soil.

When planting my hot-bed with Sweet Potatoes, this spring, I sprayed the tubers, when laid in one section of the bed, liberally with the Bordeaux mixture. None of the tubers thus sprayed sprouted; all rotted. I removed these spoiled tubers, and, without changing the soil in this section of the bed, replanted it with sound and growing tubers, the sprouts on which were half an inch long. Many of these tubers did not send a sprout above ground, but they perished as did the ones formerly planted. I did not obtain any good plants from this sprayed section of the hot-bed.
