PAPYROXYLINE FOR EMULSION WORK.

A fortnight ago we gave a preliminary account of some experiments in the manufacture of papyroxyline, undertaken with a view of obtaining a product specially adapted to emulsion work, and we have now to explain how far our object has been attained. As we had fully anticipated, from the general character of paper pyroxyline, but more especially from the very different conditions under which it is manufactured, its application to emulsion work presents some notable peculiarities which we have never encountered when using ordinary pyroxyline. We speak now of samples made under what we may term abnormal conditions, or with the conditions varied so as to produce special results; for it is possible to prepare a product which shall in no respect differ from that manufactured from raw cotton.

Thus, we have found that, though the general characteristic of papyroxyline is an almost total freedom from structure, it is possible by very slightly varying the conditions to produce a directly opposite result, and that the chemical or photographic properties of the product so obtained are eminently suited to the purpose we have in view, if only the modification in physical character of the film be not too great to render it unfit for use. The sample obtained from the formula described as No. 3 in our previous article is a case in point. Dissolved in similar proportions, and the collodion compared with that obtained from the other formulæ, the difference is striking; for No. 3 gives a solution having the appearance of containing but half as much cotton as either of the others. A tolerable quantity of sediment remains with No. 3, which is not the case with the others; but this would be insufficient to account for the difference in thickness. Nos. 1 and 2 flow smoothly, giving a film of some thickness and strength, and drying perfectly transparent and free from structure. No. 3 gives a thinner and more even-looking film previous to setting; but as it sets a sort of "chill" spreads evenly over the plate, commencing at the upper edge, and resembling the semi-opaque appearance of a plate coated with spirit varnish without heat, but more uniform in texture. When quite dry the film presents a smooth, opalescent appearance of some density, and perfectly free from grain; it adheres strongly to the plate, and if forcibly rubbed with the finger comes away in powder. When moistened its transparency returns.

But the greatest difference is noticeable in its behaviour during the process of emulsification. We were at first under the belief that No. 3 would prove to be incapable of holding the silver bromide in suspension, or, at least, that the formation of the latter salt would be so rapid that a coarse granular film would be produced. We were, consequently, much surprised to find a directly opposite result. Compared with Nos. 1 and 2, which when salted and sensitised with similar quantities of bromide and silver formed a rich, dense, ruby emulsion, it presents a totally different appearance. The silver bromide actually formed much more slowly on the thin collodion than on the thicker samples, and, after allowing more than twice the length of time for the completion of the sensitising, the No. 3 emulsion was still far thinner, more transparent, and of a peculiarly intense orange colour without a tinge of ruby.

Poured upon glass and washed, the first two samples gave films of rich colour and great density when dried. No. 3 while wet gave a very clear and transparent film, possessing great intensity of colour, rivalling in that respect a piece of dense orange glass; when dried, however, it became absolutely opaque, forming in the two stages the strongest possible contrast in appearance. The formation of the silver bromide in the sample of collodion appeared to exercise a very great effect upon its tenacity; for, unless the film be allowed to "set" very thoroughly before immersion in water the whole will be washed away in minute particles, just as we might expect in the case of a film of silver bromide without collodion or other matter to render it cohesive. When properly "set," however, the film is capable of withstanding any ordinary treatment, but will not bear much *rough* usage.

The working qualities of these three emulsions are very good, the image developing crisp and clear and full of detail, with a very short exposure. In all these cases density is obtained with the greatest ease either with alkali or silver, No. 3 surpassing the other two in this respect. When dried, however, the latter image becomes much more opaque, acquiring a density two or three times as great as when wet. This is not a merely trifling increase, such as may be noticed in the drying of any plate, but so great that detail which is little more than visible in the moist plate acquires almost sufficient density to form a high light. The transparent portions also assume the same opalescent appearance mentioned previously, and which seem to be identical in character with the phenomena described by M. Davanne in his communication to a recent meeting of the Photographic Society of France. Both the opalescence and the increased density disappear under the operation of varnishing—the former completely, the latter almost so. Moisture of any description has the same effect, which, however, ceases upon desiccation. We have not tried the effect of gelatine in removing this opalescence; but a strong solution of albumen (one part albumen to one of water) only partially destroys it, while its action upon acquired opacity of the image is feebler still.

We next turn our attention to the precipitation of the emulsion we have described, as in that is centered the chief interest of our experiments. We chose precipitation in contradistinction to washing, on account of the great saving both in time and trouble which it brings to the preparation of a washed emulsion, and because we believe that the future practice of that process lies in the direction indicated. We need not go minutely into the details of our mode of operation; suffice it to say that in each case we secured a good result, but properties of the various samples differed in some material points, chiefly bearing upon the physical properties of the collodion. Thus the films obtained from Nos. 1 and 2, after re-solution, exhibited a tendency to structure and to mottling. No. 1 appeared to have acquired a greater degree of glutinosity, with a tendency to flow in crapy lines. No. 2 flowed more smoothly but set very slowly, and great difficulty was experienced in preventing the film mottling at the instant of setting. No. 3 gave a most peculiar result; when poured upon glass a thin layer of powder absolutely without coherence was left, which while moist exhibited an orange colour, but, when dry, became opaque and showed no colour at all. From the nature of this emulsion previous to precipitation we had some doubt as to its capability of resisting the action of that operation, and took the precaution to divide it into two portions before redissolving; the second portion was now dissolved in plain collodion containing three grains of cotton to each ounce. The result was a beautiful emulsion without the slightest trace of grain or structure, and possessing the peculiar properties which marked the sample before precipitation.

The working properties of all the emulsions were but little altered in the process of precipitation; the same clearness and brilliancy of result were obtainable, and, in the case of the first two, no appreciable increase in the difficulty of obtaining density. With No. 3 the density appeared to be more easily attained, owing probably to the film containing a large quantity of sensitive material in proportion to the cotton. The dried film became opalescent, but not to such a degree as it had previously done, and unfortunately it showed a great tendency to drying marks.

We have gone thus minutely into the description of these samples of papyroxyline, because we think that a new power is developed in at least one of them. Moreover, we may say that the formulæ we have given are merely representative ones, selected from a large number of others giving, in a general way, corresponding results. The feature to which we wish to call special attention is the peculiarity of the results obtained with No. 3. It is obvious to the most inexperienced of our readers that the general properties of this sample do not recommend it as the basis of collodion for general work; but its peculiar action in emulsion fits it, we think, for use in connection with a sample of a different character.

Thus, we have employed No. 3 (or a sample corresponding to the description we have given) in several ways in combination with others. First, by mixing in certain proportions with a more horny sample in making the collodion; second, by adding a certain quantity of plain collodion prepared from a tough cotton to the emulsion made with No. 3 papyroxyline immediately previous to precipitation; and, thirdly, by using plain collodion in redissolving the pellicle as before stated. In each case we find we gain the full advantage of the organic nature of the papyroxyline.

It is possible that the same course may be adopted in the case of an extremely organic pyroxyline, but not, we think, with so much advantage. The conditions as regards both temperature and strength of acids are more easily conformed to when paper or similar material is used, besides which we have reason to believe that the product itself is more "organic" in its reactions owing to the peculiar re-arrangement of the various conditions of manufacture.

LIQUEFACTION OF OXYGEN.

We are able, in our first issue of the year, to announce a recent scientific achievement of startling interest which may not impossibly be ultimately of use to photographers. On the 22nd of December last oxygen was for the first time liquefied by M. Raoul Pictet.

Little more than a century has elapsed since the first discovery of this gas (by Priestley, in 1774), and vast has been the progress of science since that time. The whole modern structure of chemistry has been raised, and photography was then undreamt of. Gases at one time were looked upon as uncondensable vapours; but, within the century, first one and then another has given way to the persevering efforts of experimentalists, till at last the number of incompressible gases, by the liquefying of nitric oxide about a month ago by M. Cailletet, was reduced to three—oxygen, nitrogen, and hydrogen. Now that oxygen has succumbed two only remain unliquefied; and we may hope to look forward to the time when sufficient oxygen to make an enlargement by, or even to suffice for an evening's entertainment with a magic lantern, may be condensed sufficiently to be able to be carried in one's pocket.

We do not, of course, mean that the new process will enable us to obtain cheap liquid oxygen; but it generally happens in commerce that, whenever a substance has been made, readier and cheaper means are discovered for producing it in quantity. For example: we know that hyposulphite of soda can now be purchased at less per hundredweight than it cost per pound when its use in photography was first shown, and liquid sulphurous acid gas—at one time a chemical curiosity—is a recognised article of commerce. There are many other similar cases which we need not here repeat, and for this reason we are not without hope that liquid oxygen may be one of the usual *impedimenta* of the future magic lantern exhibitor.

We have said how, by degrees, the number of incompressible gases has been gradually diminishing. We owe to the illustrious Faraday the reduction to the liquid state of all known gases except the four we have named, with carbonic oxide and marsh gas. The method he employed was a combination of enormous pressure and extreme cold, further enhancement of the effects being produced by evaporation *in vacuo* of the cooling agent, a temperature of—110 being obtained with the air pump—76·6 in the open air. The extreme pressure was 50 atmospheres.

Since that time Professor Andrews has made important contributions to this branch of science; but even he did not succeed in liquefying either atmospheric air, oxygen, hydrogen, carbonic oxide, and nitric oxide with a cooling bath of liquid carbonic acid and ether as a temperature reducer, and at such enormous pressure as reduced their volumes respectively to $\frac{1}{675}$, $\frac{1}{554}$, $\frac{1}{500}$, $\frac{1}{278}$, and $\frac{1}{680}$ of their bulk.

It is remarkable that under the method so recently successful with oxygen neither the pressure nor the temperature of the cooling bath were so extreme as those we have just recorded, and hence we are quite justified in hoping that still improved methods of obtaining liquid oxygen may be discovered, for the incentive will be enormous now that it is known that the feat can be accomplished. It would be impossible to give a list of all the uses to which such a substance could be applied.

The process adopted by M. Raoul Pictet was designed rather differently from those usually employed, and is remarkably ingenious. The oxygen is made in a large generator of immense strength, so as to resist any pressure it would be subjected to, and is in form somewhat like a large shelf. The cooling agent is carbonic acid, which is liquefied under a pressure of four to six atmospheres and a temperature of 65°. It is conducted in this liquid state into a tube four meters long, and is then solidified by means of a vacuum produced by two combined pumps. Attached to the oxygen generator is a tube, narrower than the one named; it is passed through the tube of frozen carbonic acid, and the apparatus is then ready for use. The oxygen which has been kept confined in the vessel that generated it (thus allowing a pressure of 800 atmospheres, if necessary) has had its temperature reduced so as obtain the utmost cold. When the connection is complete the oxygen is turned on. The conditions thus carried out on the day named were—cold compressed oxygen ready to expand, and so produce a still lower temperature, passing through an extremely cold tube. When it reached the orifice it emerged as a jet of liquid, and the most remarkable product of modern ingenuity and perseverance was obtained.

The pressure was by no means great nor so extreme as had been obtained by other experimentalists with no success, as it only reached three hundred atmospheres. The temperature is not given in the account which has reached us, but it must have been remarkably low, for the carbonic acid was liquefied at 65° and then frozen in a vacuum, which would probably give the temperature Faraday obtained, as above stated; and, finally, the expansion under the atmospheric pressure only must have produced a still further reduction of temperature.

The experiments were to be repeated under slightly different conditions, and we look forward with great interest to further details of this most remarkable achievement.

RECENT PATENTS.

No. I.—PHOTOGRAPHIC PLATES FOR PRINTING.

In the following patent, which has been granted to Mr. William Howard Mumler, of Boston, United States of America, it will be seen that the leading feature consists in the substitution of acetic acid for hot water as a solvent of an impressed gelatine film, from which is eventually to be produced a surface block for printing.

Starting with an acknowledgment of what was effected by Mr. Mungo Ponton in 1839, and by M. Poitevin in 1855, in connection with the rendering of organic matter insoluble in water by its exposure to light when mixed with bichromate of potash, the present patentee, in order to impart a clear idea of his invention, gives a brief summary of the main features of the more prominent of the processes founded on the discoveries of the gentlemen named, and now in use:—

In photolithography and photozincography a transfer is made on stone or zinc by means of gelatine, and the printing is done from the surface of the stone or zinc by means of lithographic ink and a press.

In photogalvanography the gelatine film or plate after having the picture printed thereon, and the parts not acted upon the light swollen by water, is made to serve as the basis of electrotyping.

In the Woodburytype process a sheet of gelatine, from which the parts not acted upon by light have been washed away, is used as the means for obtaining by hydraulic pressure a metal mould. This mould is filled for every impression with gelatine containing colouring matter, and the print is really an embossing of coloured gelatine on the sheet of pager.

In photocollograhic printing, or the heliotype process, the printing is effected directly from the flat level surface of the sheet of gelatine in the same manner that lithographs are printed from stone, the superflous chemicals contained in those parts not previously acted upon by the light having been washed out without washing away the gelatine.

The patentee then continues:—

My improved process differs from all these processes, and will be best understood by a description of the various operations in detail which go to make up the complete process as follows:—In the preparation of the gelatine plate I use the following ingredients in about the proportions stated, namely, gelatine, one ounce; fresh water, seven ounces; glycerine, two drachms; saturated solution of bichromate of potash, two drachms. These ingredients are placed in a vessel and subjected to a gentle heat, and when thoroughly dissolved and mixed the mass is poured upon a smooth level metal or glass plate provided with ledges raised about one-fourth of an inch above its upper surface around its outer edge until the fluid mass is even with the tops of the said ledges, the surface of the said plate having been previously prepared by rubbing it with tallow to prevent the gelatine from adhering thereto. The plate with the gelatine thereon is then put away in a dark room to dry. When thoroughly dry the gelatine film is removed from the glass or metal plate, and placed under a photographic negative, and exposed to the light under the direct rays of the sun a sufficient length of time to print thereon a picture from the negative in contact therewith; it is removed from under the negative and secured to a base of glass, metal, or other suitable material, with the face or printed side uppermost, by means of liquid glue, or any other suitable adhesive material that can be used in a cold state. The upper surface is then made level and true by grinding the surface with emery paper or cloth, or other suitable abrading material attached to a block of wood or other suitable material having a true and level surface.

To prevent scratching by the emery or other abrading material I rub the surface with tallow until all the insterstices are filled. The plate of gelatine with the picture printed thereon is then treated with acetic acid by pouring it upon its upper surface, and brushing such surface with a soft bristle brush to assist the acid in dissolving the gelatine not acted upon by the light. Those parts acted upon by the light being rendered insoluble thereby are unaffected by the acid, and as a consequence are left in relief by the gradual dissolving or eating away of those parts not acted upon by the light. When a sufficient depth has been obtained, or when the acid has dissolved or eaten away the gelatine as deep as the light has penetrated (which effect is indicated by a slight curving or crooking of the straight lines), the acid must be immediately washed off with water at about blood-heat. If any trace of acid should remain it may be neutralised by exposing the plate to the fumes of ammonia.

If sufficient depth has not been obtained by this one treatment the instertices or parts eaten away by the acid may be filled or coated with a paste composed of mucilage or other suitable gum and bone black; or these parts may be coated with india ink, black shellac varnish, or any opaque or semi-transparent substance which will prevent the passage of the actinic rays of light through the same, and that may be readily removed again without injury to the gelatine plate.

Up to this time in my process all the operations upon the gelatine plate, except while under the negative, must be performed in a dark room or in an anti-actinic light. The plate covered or partially covered with the bone-black paste or other protective coating may now be exposed to the actinic light without the negative, the paste or other coating preventing the action of the light, except upon the lines left standing by the acid, and which are not covered by the paste.

This exposure may continue for an indefinite time, or until the raised lines become very hard, and the light has penetrated and acted upon the gelatine to a sufficient depth. The plate is then taken into the dark room again, where the paste or other coating is removed by a suitable solvent; for instance, if the paste of mucilage and bone black be used cold water will serve as the solvent, and if a varnish be used to hold the colouring matter, to render the coating opaque, alcohol should be used as the solvent. When this has been done the paste is again treated with acetic acid as before. The plate may then be dried in the light until it becomes hard in all its parts; it is then ready to electrotype in the same manner as a woodcut is electrotyped.

It is well known that the face surface of type, woodcuts, and other plates with which printing is to be done, must be true, straight, or level, in order that good work may be produced therefrom; but this result has never been fully or satisfactorily accomplished in any of the processes of producing prints by means of gelatine plates, for the reason that in removing the gelatine from the original surface on which it was dried, and fastening the same to its base, it is very difficult to preserve the level surface; and, moreover, the gelatine film when dry is not sure to be of an even thickness, its upper surface sometimes being very irregular and uneven.

Another difficulty heretofore encountered in experiments for the production of gelatine relief plates has been that the outer edges of the lines left standing in relief, after treating the plate with a solvent, turn or curve upward, and thereby destroy the even level surface thereof, the effect of which is to make the lines when printed rough and imperfect.

This difficulty is evidently occasioned by the partially insoluble nature of the outer crust or coating of the gelatine film, which, in all the heretofore known processes, is preserved intact. This outer crust is partially insoluble, and of a more contractile nature than the other portions of the plate.

To obviate these difficulties, and give to the gelatine plate a true, straight, and even surface, and prevent the turning up of the edges of the lines, I grind the face surface of the gelatine plate after the picture has been printed thereon, and after the gelatine film has been permanently secured to its base, as previously described.

Another great difficulty heretofore met with has been occasioned by the use of hot water as a solvent for the parts unaffected by the action of light in printing the picture on the gelatine plate, which has heretofore been the practice.

Gelatine has a great affinity for hot water, and is easily dissolved therein; and in using it to cut away the parts of the plate not acted upon by the light, the heat from the water penetrates the entire plate, and partially dissolves or softens the whole plate, and throws the lines out of shape.

To obviate this difficulty I use acetic acid in a cold state as a solvent. This acid affects the gelatine plate only so far as it has not been acted upon by actinic light, acetic acid having no effect upon bichromatised gelatine that has been exposed to the action of actinic light when said acid is used in a cold state; but in the same cold state the said acid is a very ready solvent of gelatine, however hard, if it has not been exposed to the action of actinic light, therefore the lines, however fine, are preserved intact, and kept from being thrown out of shape.

Having thus fully described the said invention as communicated to me by my foreign correspondent, and the manner of performing the same, I wish it understood that I claim—

First. The process, herein described, of obtaining level, straight, and true surfaces on gelatinous films, from which to produce relief plates for printing, by grinding the surface of the said film with emery cloth, or other suitable abrading material, properly extended upon and secured to a true flat surface of wood or other suitable material, as above described.

Second. The process of producing relief surfaces upon gelatine plates by photographing or printing from a photographic negative, the picture to be reproduced upon the surface of the said gelatine plate, grinding the surface of the plate either before or after printing thereon the picture, and then treating it with acetic acid in the manner herein set forth.

Third. The process, herein described, of producing gelatine relief plates by photographing or printing from a photographic "negative" or "positive" upon the surface of the gelatine plate the picture to be produced in relief, treating the plate with acetic acid until it has eaten away the gelatine to as great a depth as possible without injury to the lines, removing the acid and coating or filling the parts acted upon by the acid with a paste made of bone black and any suitable gum, or with indian ink, black shellac varnish, or other opaque or semi-transparent substance, then exposing the plate to the direct rays of light without the negative or positive plate, and, after removing the paste or other opaque or semi-transparent substance, treating the gelatine plate with acetic acid a second time, as above described.

Fourth. In the process of producing gelatine relief plates, treating the plate after a partial relief has been produced, with a coating of bone-black paste, indian ink, black shellac varnish, or other opaque or semi-transparent substance, in the manner herein described, for the purpose specified.

Fifth. The method of preventing the scratching of the surface of the gelatine plate by the emery or other abrading material, by filling the interstices of the abrading surface with tallow or equivalent material as above described.

While much ingenuity has been displayed in carrying out the details of this invention, we nevertheless entertain a decided opinion that superior methods for effecting the same ends have been published in this Journal. But to enter upon these at present would be foreign to our purpose. We may, however, state that, in this country at anyrate, glass plates can be coated with gelatine in a fluid form, which, when dry, will possess so much smoothness as to render it difficult to pronounce at first sight as to which side of the glass has been coated.

No. II.—PRODUCING COLOURED PHOTOGRAPHS.

It is only a few months since we gave a brief description of certain pictures that had been produced by Mr. Lombardi, in which effects similar to old oil paintings had been produced—still later we noticed Mr. J. Solomon's efforts in the same direction—without being able in either case to impart information regarding the *modus operandi*, beyond stating the fact in general terms that the photographs had been rendered transparent and the colours applied behind.

Unless we are greatly mistaken the reader will find in the following specification of a patent obtained by Herr Johannes Carl Schuhmacher, of Blasewitz, near Dresden, a somewhat detailed statement of the method by which "poikilographs" are produced, or, what amounts to the same thing, a method by which pictures having an appearance similar to those named may be produced:—

This invention consists in a method or process, hereinafter described, of producing coloured photographs, to which end the photograph before being mounted is made transparent by applying copal varnish on its reverse side; it is then, by applying retouch varnish on the same side, made capable of taking oil colour, which oil colour, when the photograph is viewed from the front, becomes perfectly apparent, whilst the shadows and transitions or gradations from shade to light of the photograph itself at the same time form the shadows and transitions or gradations from shade to light of the coloured photograph.

Since the introduction of the art of photography it has been the aim of photographers to produce coloured impressions, to which end innumerable means and manipulations have been resorted to. Nevertheless, until recently the coloured photographs produced have not met the standard of higher artistic pretensions.

By the present invention coloured photographs are produced in such manner as, when taken direct from good original paintings, to satisfy the most exacting requirements in an artistic point of view.

The photographic picture, as such, remains perfectly intact, so that faults in form and drawing will never occur, the colouring operator having merely to heed his colour. Hence, and by the peculiar degree of softness given to the colours by the photograph prepared as hereinafter described, pictures of surprising effect will be obtained with but little loss of time.

In describing the manipulation, hereinbefore referred to, for effecting the object of the invention, the patentee says:—"I soak the naked photograph on its reverse side (back) with marketable (commercial) West Indian copal varnish, which I previously warm up to 25° Reaumur, and which I dilute, in case of its being too thick or clotted, with French turpentine, so that the fluid can then be easily laid on by means of a brush. When this copal varnish, applied as described, has become dry, I take common saleable French retouch varnish and cover the same reverse side of the photograph with it, this laying on of retouch varnish being necessary to enable the now transparent photograph to take the oil colour. When this retouch varnish is dry, which takes but little time, the oil colour is laid on on the same reverse side of the picture without shades, and in most cases it will suffice to apply the oil colour in the tints of light. The shades and passages (gradations) from shade to light are completely returned (shown) by the photographic picture. After the drying of the oil paint another layer of copal varnish of the same quality as above is applied on to the same. When this varnish is also dry the photograph is mounted on cartoon paper or white canvas, by means of starch mixed with a little glue and common Venetian turpentine. I will here expressly remark that all the layers and colouring as described take place on the reverse side (back) of the photograph. The mounting on card-paper or canvas being accomplished, I finally varnish the front side of the photograph by means of copal varnish. The picture thus obtained reproduces all the pecularities of good old paintings, such as the marks of the brush of the artist, cracks in the varnish, and so on."

The special claim is the broad one of "the method of producing coloured photographs, as described."

While we gladly take advantage of the specification to obtain a description of the mode of working, we are unable to say that the method of producing coloured photographs herein described is new —at least in this country—and that therefore the patent would prove valid were legal measures resorted to in order to punish anyone for its infringement.

It is an almost superfluous task at the present time to attempt to write anything about a "new" preservative, as the inevitable result will be the subsequent discovery that it is *not* new. We shall, therefore, preface our description of a modified organifier by the simple statement that is not new in one sense, while it has claims to be considered so in another. Some little time ago we spoke of the action of a feebly-alkaline solution when applied to the sensitive film before exposure in assisting in the formation of a vigorous image, or in aiding in the acquirement of density. The ordinary coffee preservative, admirable though it is in most respects, fails with certain descriptions of plates to give such an amount of vigour as may in some subjects be desirable; hence we were led recently to attempt the combination of coffee with an alkali with results not only gratifying, but surpassing our expectations. The solution is simple and easily made. Take a tablespoonful of ground coffee and half a teaspoonful of bicarbonate of soda, and pour upon them a pint of boiling water, and, when cold, filter. The quantities given may be considered rather indefinite, but for all practical purposes are sufficiently accurate. Such a solution we have had in use for a period of five or six weeks without the appearance of any tendency to decomposition. It gives a plate possessing great sensitiveness (other conditions being favourable) and the usual delicacy and colour of coffee plates, with the additional advantage that full density may be obtained with the greatest ease either with ammonia or silver. We have tried the addition of gallic acid, but cannot recommend it, as, though it works very well when freshly prepared, a few hours suffice to bring about a complete change in its action.

THE ART OF PAINTING ON THE PHOTOGRAPHIC IMAGE.

No. XVI.

Autotypes may be excellently worked upon in black and white crayons by the following method:—Take two pieces of bath-brick and rub them together over your print, so as to cover it with an impalpable powder. Remove all large pieces, and then with the palm of the hand rub firmly but gently in a circular manner all over the autotype, until a mat surface is produced. Now (having carefully removed every trace of bath-brick) sprinkle over the surface powdered white chalk, which must be *briskly* rubbed in all over; then blow away all loose chalk, and you have a surface that will take crayon either from the stump or the crayon itself.

There are several different methods of using crayons. One is by using lines and dots only, and not using the stump at all, and very beautiful effects are got in that way. There are pencils sold which seem particularly adapted for the purpose; they are called "Binns' carbon pencils." Sometimes a slight suggestion of red in the cheeks and lips is introduced; this is best given by the natural red chalk. It does not look well to use too positive a red for this purpose.

The management of the cross-hatching and lines can be well studied from some of the excellent lithographed studies for two crayons sold in the shops, especially those by Julien. A soft, white crayon should be lightly touched on the high lights on nose, forehead, &c.; then the rest carefully cross-hatched, so managing the lines as to aid the rounding of the features. There is much art required in managing the drapery, and for this kind of finish vignettes are best. The drapery must be so lined as to match the face and keep up the character of a crayon drawing throughout; the background also gives great scope for taste.

If red be introduced it should be put on immediately after the white and before the black. If red be used it will also be requisite to give just a suggestion of the colour of the eye with a suitable crayon; such as are sold in round, upright card-boxes will suffice. Should the artist like a tint all over his paper, so as to get an effect somewhat like a Mulready study, a suitable tint may be got by dipping the autotype in a bath of a strong solution of coffee; or, if a bright straw colour be required, a decoction of saffron answers admirably. Perhaps Judson's dyes would answer, but I have not tried them.

Now that stumping is allowed in the schools of art it will probably become commoner than formerly. The stump is a short, round instrument pointed at both ends. Some of these are made of wash-leather, others of cork or paper. For general use a large wash-leather stump is the most useful; but the small cork ones are good for small, sharp touches. Sometimes, however, a piece of wash-leather folded over the forefinger is the most manageable, and if a photograph be lacking in half-tone, such a piece dipped in that very soft crayon known as "stumping sauce" may be made to do wonders. A tint should be taken all over the face, and the lights then removed with ink-eraser. Any unevenness in this tint may be removed or stippled out, as it were, with ink-eraser. The picture may then be finished off almost entirely with stumping or altogether with the crayon, or a combination of the two. J. Wake.

ON THE SAVING OF SILVER.

It is a trite saying that "it is not so much what a man earns as what he saves," and, as the margin for saving or wasting in photography is so large, the matter of saving becomes an important one.

It is well known among photographers that but a very small percentage of the silver used remains in the finished negative or print, and yet it is surprising to see how careless many are in their handling of the precious material, and how little effort is made to save where saving is possible, or where it is no more trouble to save than to waste.

Men are governed mainly, no doubt, by their interest in this matter, and unless one has had a thorough training in economical methods, or has a prospect of personal benefit in the result, he will waste as soon as save.

Most proprietors of galleries are disposed to practice saving, but the difficulty is in getting "helps" to look to their employer's interest in this direction, when it requires a little more care or an extra step to do it. The best plan I believe for all concerned would be to make those who handle silver interested in saving by giving them a percentage of all they save. The man who has been in business for himself and practised this kind of economy requires no inducements, as it has become to him a duty which forms a part of his daily practice.

The methods for saving silver vary with different operators, each adopting that which seems best adapted to his situation and the amount of silver used. The necessity for watchfulness and care commences with the first handling of the crystal nitrate, to see that no grains are scattered on the floor, and that clean, dry paper is used in the scales in weighing it out.

In making a bath the bottle should be placed on a broad sheet of paper (an old newspaper will answer) to catch any drops or drippings that might otherwise go on to the floor. One will be surprised to see in a short time how this paper will be stained. It should always be used when the bath is filtered, and the bottles kept on it. In pouring into the filter, or from one vessel to another, care should be taken to catch the last drop, otherwise this last drop runs down the side, and in handling the bottle the hands are sure to be stained. Some may experience difficulty in decanting the solution from a glass bath without waste. If not too large to be handled conveniently, it may be poured from one side with perfect safety by pasting a little strip of albumen paper close to the top of the bath where the solution is to be poured out, or a small cord tied round the bath near the top will serve the same purpose.

In the dark room the shelves should be covered with paper, and especially near the holders, where it is well to keep a sheet of thick blotting-paper. If the holders be fitted with bottles, and plates used the full size of the holders, these may catch the drippings well if care and attention are exercised; but in the hurry of work they are unreliable and much silver is lost. A bottle of the right shape has never yet been used. The only one ever made for the purpose is the traditional one with a hole in one end, which is always more ready to let the solution slop out than to let it go in. A bottle with the opening in the centre and a slight neck to it would be free from the objections which have consigned the present style to almost entire disuse. But the cleanest way of working is, no doubt, to prevent any dripping from the plate. This is done by draining the plate well as it comes from the bath, and then wiping the back till there is no solution to run, the plate being held on its edge on a sheet of blotting-paper during this operation. The solution drains from the film side, and when the plate is placed in the holder a little strip of blotting-paper under each corner will absorb all further drainage. Instead of wiping the back of the plate, it may save time to have a piece of blotting-paper the size of the plate to place against it immediately it is put in the holder. Keeping the holder in a horizontal position while it is being carried from the dark room to the camera is also a preventive of dripping.

The practice of these methods may, from the recital of them, seem too troublesome to pay, but they are not really so when once they are put in practice and adhered to. They not only save a sufficient amount of silver to pay for the trouble, but they prevent the gallery from assuming the unsightly appearance which is the result of a loose and indiscriminate dripping, and from which the operator himself usually carries, both on his clothes and his person, the indelible evidences of his profession and slovenliness.

The next important point for saving is in the development, and here various methods are used. In the early days of photography, when many of its votaries, doing business in a small way, were obliged to carry their water from a pump in the yard to the third or fourth story, the washings were all collected in a tub, and every day the waste water drawn off, to be carried down as it had been brought up, or emptied out on the roof, to find its way to the ground by the conductors. These tubs formed excellent silver savers, though their real value was hardly then appreciated; and something of the same sort answers the purpose admirably now. Where a large business is done a large tank should, of course, be used, and where there is not room to place it under the developing-tank in the dark room it should be placed in a room below, or in the yard outside, if the climate be not too cold in winter, with a pipe leading to it. Over this tank the negatives are developed, and washed just enough to clear them of the developer and whatever surplus silver may be on the plate. Into this tank all washings of vessels that have contained silver solutions are poured. The developer is usually sufficient to precipitate all the silver, and by a waste pipe attached to the tank the clear water can be drawn off every morning, or when the tank is full, provided it does not fill more than once a day. Where a small business is done a large dish or wooden tray may be used for the developer washings, or a developing tank constructed with separate apartments, one of which shall be used for this purpose. Into such a tank, or a separate dish, all the films from waste plates should be scraped while they are still wet.

The hypo. fixing bath for negatives becomes well charged with silver after a time, and if well cared for will yield a good return. When this bath shows signs of failing—which are usually spots on the negative after fixing, though they are not of such a nature as to show in printing—it should be poured into a large bottle or earthen pot; a wooden tub or butter firkin will do, and as it becomes full add a quantity of a solution of sulphuret of potash, stir well, and let settle. The clean part may then be decanted, and the vessel filled again in the regular order of business.

As this completes the routine in the negative department I will not extend this article, but leave the methods for saving silver and gold in connection with the printing to be discussed in another paper.
—*Phil. Phot.* Robert J. Chute.

ABOUT ACETIC ACID.

A few years since I was troubled with a bad sample of acetic acid, pharmacopœia strength. I did not suspect it until all the usual tests for defective collodion, bath, &c., failed; then I turned my attention to it. I tried less and less until I only used two drops to the ounce of developer; the pictures were beautifully clean, almost like positives, but without any half-tone. I procured a fresh sample and all my troubles ended. I presumed it was contaminated with sulphurous acid, and decided to use the purest I could obtain for the future.

With respect to Mr. Gilfillan's paper: if Mr. Gilfillan would substitute nitric acid, three drops to the ounce of developer, instead of acetic acid, he would obtain the delicate pearly whites of the old glass positives, instead of the unpleasant grey resulting from the use of acetic acid. F. York.

NOTES ON PASSING EVENTS.

By a Peripatetic Photographer.

Beechey's lantern is one which, from its nature, ought to become popular. It is strange how valuable hints and inventions that have been given to the world in a past period have long lain dormant, to be revived once more in these latter days. This suggests the reflection that many inventions come into the world, and numerous suggestions are made, long before the photographic world is in a position to receive them. The Beechey lantern is doubtless one of these, and I think, now that public attention has been directed towards the matter, that the instrument will be taken up and carefully "looked at." Many inventions are introduced at a time when we are not ready to receive them, and this thought suggests some specific applications. For example: what is now known as "poikilography," and for which a patent has been obtained during the year just closed, formed the subject of another patent obtained a long period back; and everyone is aware that the subject of auxiliary exposures was brought before the readers of this Journal several years ago, but a favourable time for its reception only arrived when a modern patent was obtained to bar the way.

Talking of patents: it would be very desirable if some one would take out a patent for the application of an actinometer wherewith to determine the exposure required for a negative. It is quite true that Mr. J. H. S. Ellerbeck brought the subject forward at a meeting of the Liverpool Amateur Photographic Association, and that a great deal of useful information has been placed at the disposal of anyone who chooses to read; but as photographers never seem to jump at any good thing until they are prohibited from using it, or until they are told that if they touch it they do so at their peril, it only requires such interdiction to be applied to the new application of the actinometer in order to bring it into general favour and use. The history of photographic invention and discovery affords numerous instances of the truth of this proposition. Verily, "stolen waters are sweet!"

Now that it has been demonstrated that portraits may be taken at night by the electric light, what have we gained? It has been known for over a score of years that the actinic power of the electric light was such as to enable portraits to be taken by its agency; and other lights, especially those produced by pyrotechnic compounds and magnesium, have long been employed, although very infrequently, for the purpose. Pondering over the description of the means employed by Mr. Vanderweyde for directing his light upon the sitter, I am struck by the apparent inutility of the leading feature in his patent claim, viz., the large and expensive lens which is made use of to converge the rays of light from the reflector upon the sitter. It should be apparent that if a reflector of a suitable form be selected the whole of the light which falls upon it will be condensed upon the sitter without the necessity of employing a Fresnel lens. Looking at the matter from the patent point of view I inquire—if I find that as good or, perhaps, a better picture can be obtained without the use of such a lens than with it, am I not at liberty to use such an arrangement without reference to the existence of the patent for something more elaborate? And, further, may not the magnesium or other powerful lights answer equally as well as the electric? I have seen some effective portraits taken by means of a lump of phosphorus being ignited in the midst of a small hillock of powdered nitrate of potash, still better ones taken when the chlorate of potash was substituted for the nitrate, and best of all when a bit of phosphorous was ignited in a jar of oxygen. Sulphur burnt in oxygen also yields a magnificent flame, which is very rich in the actinic rays. While it is well to know that portraits may be taken by artificial light, it does not seem to me to be a wise direction in which to push photographic portraiture.

The present dull weather suggests the time as being fitting for re-introducing an idea that was begotten of the cheapening of magnesium. In the dull weather we are now experiencing the light is often sufficiently good to enable a dull, flat portrait to be taken without any sparkle in the high lights, or what ought to be so. An excellent remedy, and one which may be easily applied, is to ignite a bit of magnesium riband, and allow the light to fall upon the face of the sitter at a suitable angle during a brief proportion of the time of sitting. This will supply the lacking high lights.

I observe that the South London Photographic Society has decided upon electing honorary members. What the world will look for with interest is a reply to the following question—What qualifications will be necessary ere a person be competent for election as an honorary member of the South London Photographic Society?

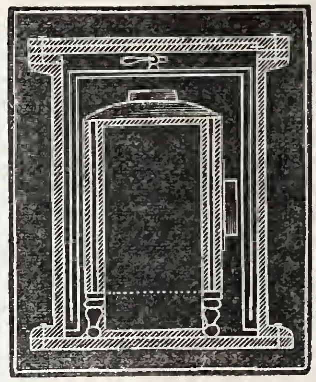
(To be continued.)

HOW TO EMPLOY PHOTOGRAPHY AND THE LANTERN AS EDUCATIONAL AIDS.

It is some years since I put pen to paper in connection with my old hobby-horse, the magic lantern, in its association with photography; nevertheless, I have not been idle in the interim, and I now wish to impart to my former readers, through the pages of The British Journal of Photography, some of my experiences.

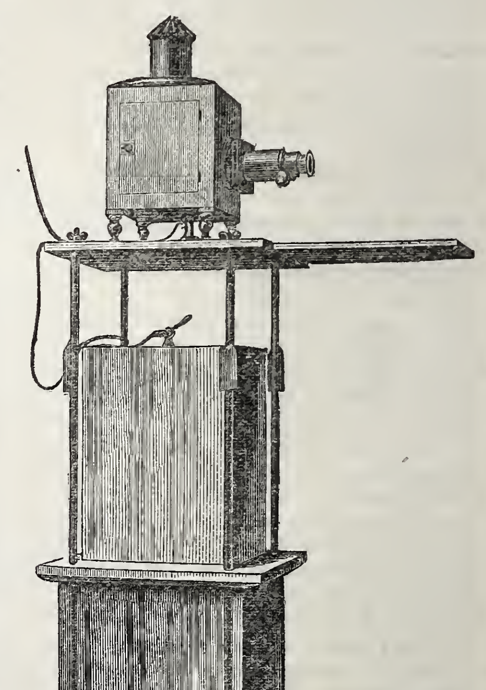
In 1856 I first employed the lantern in association with photography for illustrating the course of lectures on *Microscopes and Aquaria* I gave at my private laboratory, and since that time the educational value of this association of process and instrument has been ever present in my mind.

FIG. 1.



At the International Exhibition of 1862 I contributed some of my first educational slides, and exhibited my first attempt at making the lantern and its appliances portable. This was the arrangement shown in *fig.* 1, where the instrument packed inside a square gasometer, and when "rigged up" the gasometer formed a stand to the lantern, as shown in *fig.* 2, whilst *fig.* 3 shows my first arrangement of the bi-unial lantern. These first ideas are of interest as landmarks whereby to indicate the amount of progress made towards perfection since 1862 to the present time, when I come to describe my final arrangement of portable lanterns for travelling lecturers.

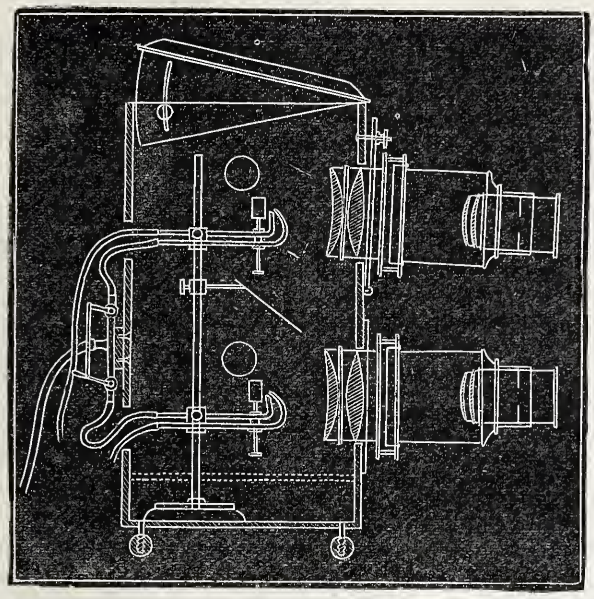
FIG. 2.



My first slide frame is shown in *fig.* 4, of which there were a pair, for interchange, one slide in and one slide out, and these in connection with grooved boxes, as my primitive arrangement for economising space for these slides and their orderly arrangement ready to the hand of the lecturer, forms another landmark, from which progress must be recorded.

My first portable screen was in the form of a wall map case, but I shall have much to say on this important item in the lecturer's outfit. Portability, with arrangements provided for quickly fitting up and removing the lecturer's outfit means economy in carriage, in assistants, and in time. The arrangement of the jet has also undergone an important change since 1862, with the object of placing the lecturer in the desirable position of being provided for any emergency in which circumstances may place him, as well as for obtaining the greatest amount of light, and that with perfect safety.

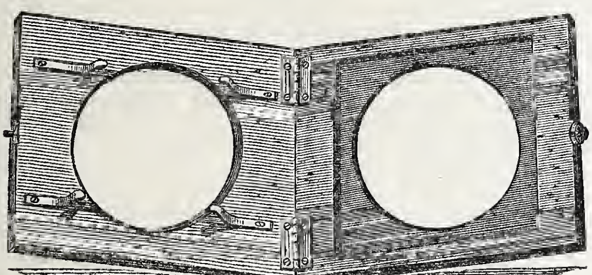
FIG. 3.



Gas-generating apparatus and gas reservoirs have also claimed my attention in the aim at making the lantern a perfect instrument for the use of the teacher.

As I have been totally unconnected with business for the last four years I contribute these articles *con amore* with the view of adding to the general store of information on this subject, and

FIG. 4.



there will be many details given which I have never yet published. Another section of my papers will be upon the production of the slide, more especially where it has to be prepared for colouring; for every lantern worker knows that if landscapes including foliage are taken from nature by photographic agency it is impossible to convert the dark deposits into brilliant green by the most skilful colouring. So where for natural history, historical, or other purposes colour is a *sine quâ non*, then we must bring the draughtsman to our aid, and he has a lesson to learn as to how he can best apply his art so as to play into the hands of the photographer and colourer and assist their efforts in their several departments. This is a department I have made a special study, in which I trained my eldest son. As we have had some varied experiences in carrying out the magnificent historical series ordered by the Russian government, the Gilchrist Trust geological series employed by Dr. Carpenter in the Royal Society and British Museum lectures, and Ernst Griset's comic series ordered by the Nabob of Bengal, I trust I shall be able to give my readers some hints on matters I have hitherto treated as trade secrets.

The production of what are known as "effects" for the dissolving-view lantern have not, so far as I am aware, ever yet been treated of in relation to the means of photographic production, and on this subject I shall have some hints to offer.

Samuel Highley, C.E., F.G.S., &c.

MY DISCOVERY.

From my youth upwards I had been of an inquiring disposition, and when late in life I took to photography the problem of how to photograph in colours absorbed my principal attention. Days and nights of hard study had some time since deprived my head of its natural adornment, and for my good looks in this particular I must confess indebtedness to the *perruquier*. But pray, intelligent reader, do not run away with the idea that I was vain by any means. A youthful appearance was of considerable importance to me from a business point of view, especially with the unmarried portion of the opposite sex. The little time I could devote from the money-getting portion of my labours was devoted to experiments with the end in view to which I have already alluded, but, I am bound to confess, without any direct success. However, a look on the focussing-screen at the marvellously-beautiful and evanescent images thereon depicted sufficed to make me return with fresh vigour to my study and experiments.

It had been a terribly wet season. Rain, rain, day after day and week after week, continued, and on this, the day of my discovery, it was, if anything, worse than its predecessors, varied by heavy thunder and lightning. I was sitting down in my glass room, watching the hail as it viciously pounded the skylight, expecting instant damage, and that my last new idea of glass-room construction would be carried by assault and battery, when my thoughts ran into their old groove of colour photography. "No fear of interruptions today; much too bad for sitters," I thought. "One more trial, and if I don't succeed; well, try again—perseverance overcomes," and all the rest of it. So I lit a spirit lamp in my laboratory, over which I suspended a glass flask containing an elaborate mixture of chlorides and bromides, with due precautions as to the degrees of heat, and was just on the point of testing a solution out of which I had great hopes something good would come, when, to my surprise, the studio bell rang a vigorous peal, and my assistant ushered a gentleman into the room. I say "a gentleman;" but what with wraps and waterproof it was rather difficult to be assured. After some time spent in disrobing and apostrophising the weather, he stood before me—a little man with the most unpleasant expression of countenance I ever recollected seeing. I had flattered myself on being a shrewd physiognomist, but I had to own myself baffled this time. His address was not much more prepossessing than his appearance. "Take my portrait full length, and let it be good or I shan't pay," were the first words he spoke to me, or rather snarled. Now it was much too dark to take any portrait, good, bad, or indifferent, so I politely told him portraiture was entirely out of the question—there was absolutely no light, &c., &c. "No light!" he snapped out. "You arn't burning the gas yet, and you can see me. What do you mean? Isn't there Godellari's method with coloured media? Then there is pre-lighting and after-lighting, and continuating action; there is Misonas's method, and there is the nitro-sulphur light, the oxyhydrogen light, the pyro-hydrogen light, the magnesium light, and the deuce knows what lights besides! Yet you pretend you cannot take my portrait because there is not enough light, and, besides, there is *my* method, by the side of which the rest are absolute failures!" Then he paused and looked at me.

"Really I am at a loss, not having the advantage of knowing your name," I ventured to remark. "Never mind my name," he replied, "I know yours. Moreover," he continued, patting the side of his nose with his forefinger, "you would like to know how I do it, wouldn't you?" Thinking I had possibly some eccentric character to deal with from whom I might pick up some crumbs of information, I said I should much like to know, if he would kindly describe his method. "Very well; yes. Put in a plate for two pictures, and scratch it with a diamond so that we can divide it after exposure and before development; then I'll show you."

I did as directed. "Now take my portrait and expose as if it were the best light imaginable. How long should you give it, eh?" "Till tomorrow morning," I replied. "And then, if the light didn't improve till dinner time, then wipe it off, and put another plate in." "That's what you think, eh? Well, do as I tell you. No head-rest!—No, no! I can sit half a second quite still, and that will be full exposure, in my opinion. You photographers will over-expose your negatives so much! I never see any of your new-fangled dry plates that are not spoilt from over-exposure. Even in the shadows—over-exposure! Want of detail—over-exposure! Harsh contrasts—over-exposure. In fact, not one in a thousand of you know how to expose. Now, then, I'm ready."

I removed the cap for the half-second directed, smiling to myself at the absurdity of the thing, and we went into the laboratory. "Develope one half *your* fashion." So I developed, or tried to do so, but, as I expected, not a vestige of an image made its appearance. "Now," he said, "do it *my* way. Bring a saucer here and put into it a teaspoonful of spirit." I obeyed. He then pulled out a small bottle of some dark liquid from his pocket, carefully added a few drops to the spirit, and directed me to light it and expose the other half of the negative to the flame at a few inches distance. The flame thus made was of a very singular character.

It was not a monochromatic flame, nor yet like that of burning alcohol; but consisted of every imaginary colour, each colour predominating for an instant, then giving place to its complementary colour of the most intense and beautiful description, This continued until the alcohol had burned itself out. "Now," he said, "I will add a drop of this to your ordinary developer, then proceed to develope as you usually do." To my intense surprise out came an image, which gradually obtained printing density, and was not only a good negative, but one of the best I ever remember taking. Noticing the effect produced by me, which was one of astonishment and delight, he asked—"Should you like to know how it's done?" "Oh! very much indeed!" I enthusiastically exclaimed. "Will you tell me the secret?" "It's no secret; the simplest thing imaginable. An old process and old materials used with the knowledge of experience—nothing more. Tell you? yes! This solution is composed of—but stay. I have the formula and particular directions for mixing in my note-book. You shall copy them; but, by-the-bye, you, too, have interesting matter to communicate with regard to colour photography. I take quite an interest in the matter myself, having done some tolerably successful things, and will show you them when we go out of these vapours."

Taking a small leather case from his pocket he selected some dozen pictures from it, and handed them to me. Could I believe my eyes? Here were the very transcripts of nature in all the glory of colour and detail. Sunset views, with all the brilliant and gorgeous colours of the western sky. Early morning, with all its pearly greys and atmospheric effect. The brunette and the blonde—each and every one in its own true and varied tints, and no heaviness or artificial appearance—nature and business itself. At what marvels of science and consummate skill was I looking? and who was this skilful operator? All *my* years of study and sleepless nights had helped *me* to nothing like this—the very ultimatum of all my wishes; and here was a stranger showing me such triumphs merely as small successes!

I was positively in raptures—too affected to speak at first. When I could find words I said—"Will you teach me to do this?" "Yes, I will," he replied, "for a consideration. I'm a poor man, and money is an object." "Name your price!" I almost shouted. "I will give anything, everything, to be able to do it." "Good!" he said, and placed in my hands a sealed paper. "If when you have read this you still desire the knowledge and continue still of the same mind—well; but, mark me! you will have to make great sacrifices." He laid his hand impressively on my arm and said—"Tomorrow, not now, I will call for your decision. Now help me on with my wraps."

I was not long in opening the paper, but the contents were so extraordinary, and such a systematic jumble of science, theory, and speculation that for the life of me I could not make it out. I read, for the writing was lawyer-like and distinct, and couched in the most seemingly explicit and clear manner for a few pages, when a sentence would occur that had the peculiar effect of confusing all that had seemed so clear to me before. All that night I sat up, and the greater part of the next day, with a wet towel bound round my temples, worrying at this puzzle, and was hard at it when my visitor returned.

"Ah!" he exclaimed, as soon as he entered, "it is useless trying to understand that without the key I omitted to give you." At the same time he placed a diminutive box on the table, from which he took several bottles and a small glass flask. "I have a plate here that has undergone a preliminary preparation, and will, to prove my good faith, obtain a photograph upon it in natural colours of any object you may desire." There was a pretty view from my window, and I pointed to it. He adjusted the camera and rapidly exposed the plate. On entering the laboratory, to which I accompanied him, the first process was to expose the plate to certain vapours in a closed box, wash with spirit, and expose again several times to other and different vapours, with the intermediate wash of spirit.

"Now, observe!" he exclaimed, as he superposed a piece of prepared paper upon the film, "all you have to do is to strip it off—like this," and, suiting the action to the word, he placed in my hands as perfect and beautiful a *facsimile* of the view from my window as I had ever seen on the focussing-glass, and the time occupied did certainly not exceed twenty minutes. "Now I think I have satisfied any doubts of my ability that you may have entertained. Oblige me by fetching that flask from the table in the adjoining room and I will show you something more; but, for heaven's sake! be cautious and don't remove the stopper."

I went on the errand in a nervous state of excitement, and had just raised the flask from the table when, horror! it slipped from my fingers. Crash! the room was instantly filled with dense vapour. Part of the contents were projected over me and trickling down my face and neck, and, with a disappointed cry, I started up to find the skylight broken and the rain soaking me in a copious stream from the aperture. This was "my discovery," and, to make certainty more certain—"How much longer do you mean to keep supper waiting?" came echoing up the stairs. I had only been asleep after all, and am as far off the wonderful discovery as ever. Oh! dear! E. D.

COLLODION EMULSION AND OTHER MATTERS.

Those who do not care to prepare their own will find the "Liverpool" emulsion quite up to the mark. I do not always use it, but keep it for a photographic treat, as I find it easy to work and very satisfactory. I expose pretty long with it, and develope with an eight-grain solution of pyro, adding to it, twice, six to ten drops of bromide (ten-grain solution) and the same quantity of dilute ammonia (one to eight). I simply mention this because I find it much better than adding the bromide and ammonia drop by drop, as has been recommended by some. The predevelopment organifier gives an extraordinary density to these films—far too much, in fact. I find, however, that adding a small quantity of tincture of quinine to the alcohol, for moistening the plates, gives a very fine colour and generally improves the negatives.

Emulsion plates show an uncomfortable inclination to obliterate the distance, from over-exposure. I often give the foreground three minutes and the distance twenty to thirty seconds. The best way to do this is to cut a piece of card of the requisite size, "dentillate" the edge like a postage stamp, only much larger, and place it before the lens as close as possible. You will now see on the ground glass that only part of the picture is there, and also that the line of junction between it and the dark part of the glass is invisible. I am indebted to Mr. W. B. Woodbury's kindness for this, as also for putting me in the way of working successfully the emulsion process.

I have always worked with a very deep orange light in the dark room, often using a ruby-red glass in the window. I have sometimes wondered how anybody could manage with the almost white quality of light they have used.

Once I went into the room of a professional photographer and saw white light coming through chinks between the boards, enabling the operator to have dispensed almost altogether with the yellow window! He complained of the bath or something else being out of order; but, considering that professional photographers should know far better than amateurs, I wisely said nothing. This was at Sorrento, where I passed some time last summer. Seeing the beautiful "bits" that there were on the mountains and by the sea, I asked one man there why he did not photograph them, and got for answer that they were only good for painters to take; and this sentiment seemed to pervade nearly all the photographers here. Fortunately Americans and English consider just those little "bits" eminently adapted for the camera, and so take them.

The photographer must acquire something of the art of the artist if he wish to excel. We want a little more than simple manipulatory skill; we must cultivate artistic taste if we wish to turn out proper work.

There are a great number and variety of pretty views round Naples; but in the shops there is nothing but the commonplace "tourist-sights" that *must* be taken, and nothing more. They are sold at about five shillings the dozen, whole-plate size. Of course at such a price nothing can be done; but I fancy it is the photographer's own fault, for the public generally pay well for first-class work. There are photographs of the last carnival in several of the stores, but they are all most admirable examples of "diffusion of focus," and shadows as black as *Erebus!*

I have not seen more than two or three formulæ published for preparing sensitised paper that will keep, and these are hardly practicable. I found rather a good one in Monckhoven's book. It is this:—

Nitrate of silver	12	parts.
Nitrate of magnesia	12	,,
Water	100	,,

For amateurs especially it is now almost indispensable to have paper that keeps well.

One day, when out with the camera, I was exposing a plate, and had sat down to count the seconds required, when, looking up, I saw a man intently watching me. He was a common field-labourer, and such a thing as a photographic apparatus with a glittering eye he had doubtless never before seen, and the fact of my lips moving clearly proved to him that there was some magic connected with it all! After exposure I let him look at the picture on the ground glass, but it required some time for his curiosity to overcome his superstitious awe. Even yet, in this country, among the peasants anything strange is put down to miracle; but the national intellect is emancipating itself in science, as in other matters, from the tyranny of superstition and ignorance.

I should like to write more about the beauties of the country around, but it would be misplaced here. Let me say with my illustrious namesake, Samuel Rogers :—

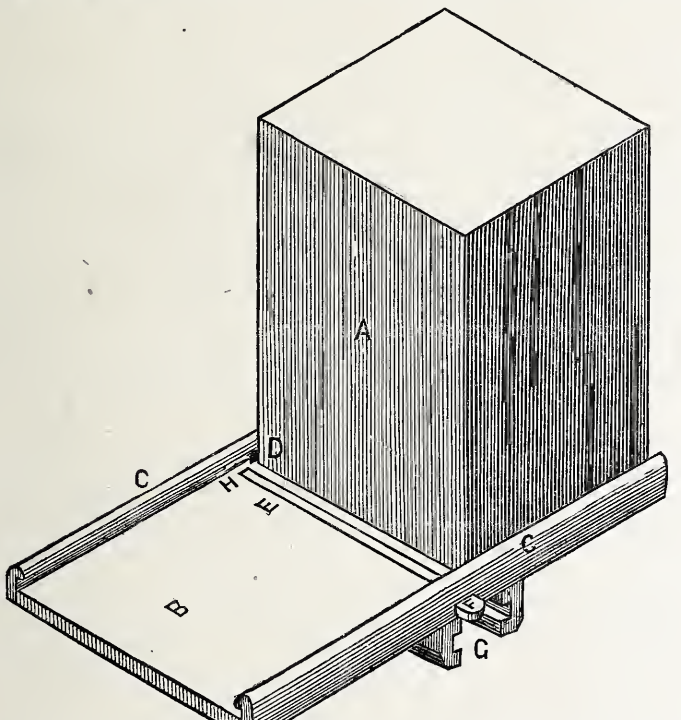
> "This region surely is not of earth.
> Was it not dropt from heaven? Not a grove—
> Citron or pine or cedar—not a grot,
> Sea-worn and mantled with the gladding vine,
> But breathes enchantment."—*Poem on Italy—Naples.*

Naples. HENRY G. ROGERS.

DRY-PLATE BOX.

HERE is a sketch (quarter full size) of a dry-plate box, to be used with the ordinary dark slide of a half-plate square camera), which I made about four years ago and found to answer admirably.

First: the Dry-Plate Box.—Take the dark slide and mortice a hole into the side to admit of a half-plate endways without scratching, and fit a sliding cover into the same, light-tight. Now refer to the following diagram, in which A represents a box fitted with grooves to hold fifteen



half-plates, open under and sliding to and fro on the base B, of which C C are the sides, grooved to allow a piece of brass to slide each side, which, being fastened to the box, keeps its mouth close to the base. Notch the piece at D to catch with the spring H, as each plate stands over the opening E, which is opened by drawing out F. Fix two cheeks across the bottom of the base, grooved to admit of two slips which are fixed on each side of the dark slide. Finally, make a plate-carrier with three sides only, two of which must be rebated to allow the plate to slide. Reverse the spring in the door, and fix a piece of brass to it, passing it through the door so that the spring may be drawn forth from the outside; put an india-rubber washer round the same between the spring and the door, fastening it to each to keep out the light. Work it in the following manner:—Fill the box with prepared plates, and slide it on the base as shown in the diagram; when required shift it forward until the first plate is over the opening E, which you will know by the click of the spring (remember when once pushed over the spring you cannot get it back without going into the dark room). Next slide the dark slide between the cheeks G, draw out the shutter in the side of the dark slide, also the shutter F in the base of the box, and the plate will commence its fall, which it will complete on your drawing forth the spring of the door. Close the little shutters, draw out the dark slide, expose the plate and return to the box the same way, and move forth for the next. The above box is easily made, and if made nicely will answer well without injuring the dark slide.

JAMES HARRIS.

ON POSING.

MANY photographers recommend their sitters to smile, to keep themselves steady, and to look at some fixed point. This is the reason why we see so great a number of portraits wherein the expression is ugly and false, and which show for the most part but forced contractions of the facial muscles, producing an unhappy grimace. In others it is an awkward stiffness which replaces gravity, or where the expression of the eyes should be fine and spiritual it is vague, trembling, pitiful, and paltry. The air of good nature and kindness is replaced by stupidity. All these defects come from the artist not having mastered his model sufficiently, or that he fails in the necessary talent to produce a complete and successful work.

There is an equally important point—that is, the truthfulness of the photographic image. Dimension, or rather proportion, ought to be given to the portrait. It is easy to understand that a large and strong person should occupy in the frame traced out in advance a place more considerable than one who is smaller and more delicate. It would give a false idea of a child ten years of age, for example, if in a full-length portrait he was made to fill the same place as a stout man of six feet. The one would have the air of a giant, and the other of a little man or a dwarf, which would certainly not give a just idea of either of these individuals.

The corpulence and size of the subject ought to serve as guide, and it would not be suitable to give the same proportion and size to the portrait of a great and illustrious person as to that of a child playing. In the two cases the picture ought to be treated differently, and the backgrounds, as well as the furniture and accessories, ought to be in harmony with the character of each of the subjects. For full-length portraits the personage will appear so much taller and slighter by leaving less space or air and background above the head; the relative position of the image on the picture has therefore a great importance as to the real proportions of the sitter. A. LIEBERT.

Paris.

HIGHER EDUCATION OF PHOTOGRAPHERS.

IT is a mere truism to say that real practical life-education commences where school education ends, and it is then that those intended for what are called the learned professions commence the studies required to fit them for their practice. As a rule the *curriculum* is extensive enough for any one mind to do full justice to it, and yet I venture to say that not one of those professions demand an acquaintance with so many different branches of knowledge as does the proper and intelligent practice of photography.

How this knowledge is to be acquired is a question of considerable importance. In most of our large towns the necessary machinery already exists, but in a form hardly suitable to the requirements of the apprentice or assistant photographer. Under the present circumstances it is true that here and there we find one who, in virtue of his thirst for knowledge, has overcome difficulties and obstacles, and climbed the ladder of learning to a height far above his fellows; but such cannot in the nature of things become general till more suitable provision has been made for the kind of teaching required. What that ought to be is not difficult to understand. What is wanted is not a perfect, or even extensive, knowledge of the various branches of science and art, but a thorough acquaintance with just so much of them as is involved in the operations in which they are engaged, and applied in the apparatus which they employ.

Neither do I see much difficulty in organising the machinery necessary for the purpose. In most of the larger towns in the kingdom—in fact, wherever there is a photographic society—the matter could be faced and successfully carried out by a few of the more energetic members. One of themselves, or, if need be, an outsider apt to teach, could surely be found willing to undertake the necessary study to qualify himself for the office of teacher. A suitably-equipped lecture-room might fairly be made a charge on the funds of the society, or defrayed by a small subscription; and a little personal dealing with those for whose benefit the college had been instituted would result in the formation of a class that ought to include everyone anxious to succeed in his profession.

The love of learning and a desire to rise high in the profession ought to be sufficient stimulus to bring the students out; but in this utilitarian age the *cui bono* cry will doubtless be heard. It is, however, easily answered. Masters who undertake to teach the mysteries of the craft to apprentices, and expect during the latter years to be repaid for the early trouble of such teaching, would find it to their interest to pay the fees, as the pupils would sooner become valuable assistants, while they would be saved from much drudgery in teaching; and assistants would soon find that the man who knows most and can best apply that knowledge will always command the highest salary. Then, although the fees should of necessity be low, they would in the aggregate amount to a sum sufficient to pay the lecturer well, as the lectures, taking place at night, need not interfere with his ordinary avocations; while, if he should possess the knack of making the lectures and demonstrations sufficiently brilliant and attractive, the class might be largely increased by the attendance of amateurs and outsiders.

JOHN NICOL, Ph.D.

Correspondence.

DOUBLE-COATED PIGMENT TISSUE.

To the Editors.

Gentlemen,—I am pleased to see by the article by Mr. H. Cooper, in the Journal of November 30th, that the above subject is again occupying his attention, and that its merits are again advocated after lying dormant for so long a time.

You will remember that in March, 1871, I sent a communication to the Journal, and that an article of mine also appeared in the Almanac for 1873, in which I broached the idea, quite unconscious, till I read Mr. Cooper's letter, that he had before that date proposed the same improvement. The obstacle at that time to obtaining tissue so prepared was that the company holding the monopoly of the carbon processes did not seem to see their way to making the suggestions I gave them available in a mercantile sense.

The feasibility of preparing such tissues was demonstrated by me at that time, and the fact of the improvement lying so many years dormant is a convincing proof of the obstructiveness of a company holding such comprehensive patent rights. It seems clear that, so long as they can make money by their ordinary routine system, they have no inducement to enter upon a new field of work. The evil is want of competition. The patent holders *will not*, and the other makers *cannot*, advance; but it is most injurious to the interests of pigment printing, and indeed to general progress, that such a dog-in-the-manger policy should be upheld.

Mr. Johnson's process is ingenious, and looks like an improvement so far as it goes; but I think a two-tint tissue would be better. I suppose Mr. Johnson's patent is, or will be, absorbed by the same comprehensive concern; if so, it may fail to be a blessing to the profession or the public.—I am, yours, &c., G. S. Penny.

Cheltenham, December 29, 1877.

ART PORTRAITS.

To the Editors.

Gentlemen,—When I was honoured by the request to write a short paper for the Almanac I stated my inability to do so for reasons satisfactory to myself. I hold that "deeds are better than words," and I now intend giving you a tangible proof of my goodwill towards all men in general and yourselves in particular.

It has been suggested by friends and others—amongst whom are metropolitan artists of repute—that I ought to publish a series of cabinet portraits which to them seemed worthy of notice, and might prove useful to others. Had I no other object in view than that of parading before you what I can do, and otherwise expect benefit from your goodwill, I would refrain; but I hope you will credit me with better motives, and it will be for you to determine to what extent I justify them.

From publications sent to me I find that our American friends complacently "lay the flatt'ring unction to their souls" that they do everything photographic very much better than we do; and it is this "idea" that has suggested to me a few remarks which I intend making for the good of all whom it may concern.

There are three points to which I wish to draw attention in the cabinets I have sent you:—1. That pictures should not be made of backgrounds. 2. That retouching should be an aid only. 3. That expression is an all-important object in portraiture.

In the first place, do not imagine that I object to a suitable background as a valuable property for the studio. What I wish to point out is that it should be what its name indicates, and appear quite subserviently to the subject. I object to the pawnbroker's-shop appearance when the furniture is piled on. I want the subject first, the surroundings next, and finally the background behind. "Distance lends enchantment to the view" is a good motto for photographic backgrounds, and when in use should be placed at from one to one and a-half yard from the subject, as circumstances require.

Secondly. That retouching should be an aid only, and particularly confided to hands skilled in the art of drawing, and even painting, is a fact which forces itself more and more upon the artist-photographer's attention every day. But, I would ask, how many retouchers are there who have ever held a pencil or a brush? Very few indeed, I should say, if we are to judge from what we see every day as we go along. Look at all the portraits of celebrities, and note particularly those of a certain "Diva," who is made to appear as being always "sweet seventeen." What a pity it is to behold otherwise excellent productions of our transatlantic friends so completely done to death by the pencil, and to find that all real beauty, character, and even resemblance have been "licked entirely out of creation!" Away, I say, with these French polishers, photographic planers, smoothers, and levellers of all things to be respected! I protest against this wholesale "massacre of the innocents," because it is not artistic, and there is too little of truth left in it to be acceptable. Flattery may go a certain length, but it becomes the "food of fools" if carried too far; and, as our witty neighbours say—*s'il en faute, pas trop n'en faute.*

My third point—that expression is all-important in a portrait—is so patent to everyone that it may appear superfluous to insist upon it, were it not that we so seldom see that "revelation of the soul," so to speak, depicted on the countenances we study as they appear "photographically." To arrive at the best results many little things should be observed; for instance, rapid arrangement, avoiding all causes of annoyance or fatigue to the sitter, such as entrenching with furniture and the aggravation of trying many attitudes to arrive at effect. Simplicity both for effect and attitude always produces the best results. It may be objected that in our climate it is often very difficult both on the part of the sitter to "retain," and that of the photographer to "catch," a good expression, because the time of exposure is generally too long. That is quite true, but the evil suggests the remedy: study this point!

In conclusion: I will now ask you whether the evidence I have laid before you bears out all that I have said? If I have failed to satisfy you that pictures can be made without backgrounds, that faces can retain their character, cheeks be fleshy without coarseness, and honest wrinkles respected without harshness, and, finally, if I have failed in securing happy or appropriate expressions, allow me to say, in the words of the great poet, "Lay on, Macduff!" But I will not "damn" you, neither will I cry "enough!" Should the expectations have been realised I shall not object to your singing a hymn of praise in the sweetest tones. You know that we are very vain—we knights of the camera. In fact, some of us even go the length of saying, which is very much worse than *thinking*, that they alone can photograph—evidently an "optical delusion." Some might even hint at something loose in such cases. On the other side of the pond they call it "high flying." The true definition, I think, is "brag;" but, as this is the time of peace, let us say that it is simply a "weakness!" And yet I don't altogether dislike those brothers who may have too long inhaled the intoxicating perfume of the collodion bottle; they are generally clever fellows, and should content themselves with being "cocks" among their peers. I have a much greater dislike to those *theorists* who flood photographic literature with their visions of what would be very delightful if we could only discern one grain of sound practice as a basis for their lucubrations. I am of the same way of thinking, on that subject, as a great man who has truly said that a little common-sense is worth all the learning in the world. As a last word, I would say to our theorctical friends that, so long as they have not fully tested their theories by abundant practice and satisfactory results, they ought not to allow themselves to be troubled with the *cacoethes scribendi*, of which they may have read, and should desist.—I am, yours, &c.,

Liverpool, December 29, 1877. C. Ferranti.

[Until we read the foregoing we were unaware that our American friends imagined "that they do everything photographic much better than we do." It is quite true that there are some photographic art-giants in America—to wit, Gutekunst and men like him—but they have ever been exceedingly reticent in speaking of their own works. The three points—namely, backgrounds, retouching, and expression—which form the theme of Mr. Ferranti's communication will necessarily commend themselves to every photographer acquainted with, or who has any appreciation of, art or even fidelity to nature. We must confess our inability to discover what is meant by "those theorists who flood photographic literature with their visions of what would be very delightful," &c., &c., to whom he confesses to have a "dislike." Is Mr. Ferranti alive only to practice, ignoring principles? On the subject of the cabinet portraits which accompanied this communication, we are entirely of the opinion of the artist's friends, viz., that he should publish them. We shall by-and-by give a detailed notice of these pictures.—Eds.]

FOG IN THE STUDIO.

To the Editors.

Gentlemen,—Will you kindly allow me a small space in your columns to give expression to a perplexity which must be felt at this season by nearly all photographers—I mean fog in the studio. How can it be quickly and easily expelled?

I remember that Mr. G. Watmough Webster, in one of his very practical articles, once called attention to it, and recommended a short-focussed lens for winter work; but even this is not sufficient. We get such an amount of fog between lens and sitter that anything like a brilliant negative is out of the question. Can Mr. Webster, or anyone else amongst your readers, suggest anything further?

I am sure that this is a subject of interest to all professional photographers, and hence I trust you will allow me to give expression to this in your columns.—I am, yours, &c., Pylos.

Northampton, January 1, 1878.

THE LAW RESPECTING STILLS IN PHOTOGRAPHY.

To the Editors.

Gentlemen,—Is a person using a still in photography bound to take out an excise license? This is a question of some importance to all who are interested in the art of photography. After much inquiry, the conclusion I have arrived at may be shortly stated as follows:—While manufacturing photographers are bound to take out such a license, amateur and operating photographers are not so bound.

Until August, 1846, persons not being licensed distillers, rectifiers, or compounders of spirits, or vinegar-makers, were not required in England to take out a license to use a still; but previously to that year a license duty of ten shillings was imposed upon every such person in Scotland or Ireland not being a distiller. In 1846 a statute was enacted imposing one uniform duty for the United Kingdom. Thus England was placed on the same footing as Scotland and Ireland. No doubt the legislature looked after the two latter component parts of the United Kingdom at an earlier date than it did England in consequence of the enormous amount of illicit distillation of whisky which once existed. There was another act passed in 1861 which gave power to any officer of excise to enter at reasonable times the premises of such persons "taking out a license, or who shall use or keep any still or retort."

The amateur photographer who exercises his art simply for his own pleasure cannot be said to be occupied in the business of photography, and therefore, in my estimation, as the acts referred to do not apply to him, there seems no objection to his keeping a small still for water.—I am, yours, &c., ARGUS.

Strand, London, January 1, 1878.

JOHNSON'S NEW CARBON PATENT.

To the EDITORS.

GENTLEMEN,—In your issue of the 9th of November appeared a specification describing Mr. J. R. Johnson's new improvements in carbon printing. I read it carefully over at the time, and fancied I was not entirely unacquainted with some of the processes therein contained. Being busy I left the matter just then; but, having put on the cap of cogitation during Christmas leisure, it struck me that perhaps the Autotype Company, finding their ground of monopoly slipping away from them by the efflux of time (their tissue-making patent expires in February), had concocted this new patent with a view to somewhat reinstating their position.

I am not going to argue for or against the patents of the company. It may be that no person could have been found to provide the capital and spend so much money as has undoubtedly been spent upon carbon printing unless with some sort of protection. However, that is neither here nor there; Swan's patent being on the point of lapsing it behoves all photographers to see that they are not further burthened without very good reason.

At present I shall pass over Chapter I. of Mr. Johnson's specification, which I confess is beyond my powers, and pass on to Chapter II., which opens as follows:—

"Chapter II.—My first and chief improvement under this head of my invention consists of a new method of obtaining reversed negatives, without which, as is well known, prints produced by the single transfer process of pigment printing are themselves reversed, as when an object is viewed in a mirror or looking-glass," &c.

[Here follows the remainder of the chapter, which we cannot reprint, but must refer the reader to the Journal of November 9, 1877, page 533, in which it is contained.—EDS.]

And now, gentlemen, we will turn to the columns of your Journal of June 1st, 1864, and there will be found the following communication from Mr. Wenderoth:—

"The process, I think, is now complete, and is as follows:—First.—The preparation of the gelatine sheet. Dissolve gelatine or isinglass (gum arabic produces plates more pure even than glass itself, and I would decidedly prefer it if it were not so easily attacked by water, as well as being insufficiently tenacious) at a low heat in water, and do not make it too thin. When dissolved, strain and add to each ounce of this solution *ten drops* of glycerine; mix well and keep warm, or warm again when you want to use it. In my first communication I recommended the use of honey, but I found that it made the gelatine ferment, whereas the glycerine keeps it sweet and makes it more pliable too. Then take a plate of glass of the desired size, wash, dry it, rub over one side a solution of white beeswax in sulphuric ether, and then coat it with plain collodion. When this is dry pour the gelatine solution on, and lay it quickly down on a *perfectly horizontal plane*. To become perfectly dry will take from twelve to twenty-four hours. When dry, cut loose around the edges, take it carefully off the glass, and put it away between sheets of paper in *a dry place* to keep for future use. These plates might be made advantageously as a distinct branch of industry, and kept for sale in photographic material depôts.

"Secondly.—Take the negative in the common way on any kind of glass, but do not omit to rub over the side destined to receive the collodion some of the wax solution in sulphuric ether. To apply the gelatine sheet the negative may be dry or still damp.

"Thirdly.—Immerse the gelatine sheet for one or two minutes in a bath of three parts of alcohol and one part of common water; but be careful to notice which is the collodionised side, as that side should be kept uppermost during the immersion of the sheet. Take some of the alcohol and water bath and pour it over the collodion of the negative, and drain without leaving too much on it; then lay it down horizontally, and put down on the negative the gelatine film with *collodion side uppermost*, commencing at one end, lowering it by degrees carefully, so that no air gets underneath, when it will be found to attach itself very closely and without blisters, which are obviated by the immersion in the alcohol bath, in which the sheet expands, the small quantity of water dissolving just enough of the gelatine to make it adhere to the collodion without softening the sheet too much. To dry will take about one hour; but care should be taken not to cut it off before the plate is perfectly dry.

"By careful attention to these instructions no failure is possible. With this I send you a few samples.

"Besides the convenience of being able to put away such negatives in portfolios, they have the advantage of being printable from both sides, and to be used for composition printing; in which case parts of negatives can be cut out with a sharp knife or a pair of scissors, and joined with others by being carefully in a few very small places fastened down with a little gum on to a plate of glass."

["Mr. Wenderoth will perceive by the report of the North London Photographic Association meeting, page 189, that we recognised the fact of his independent discovery of the process, and we may here add that the clever adoption of the film of beeswax is as original as it is ingenious and effective. We consider this process for the removal of negative films invaluable to all, and especially so in connection with the practical application of Mr. Swan's carbon process.—ED."]

I think any person who carefully studies these two extracts must see that to all intents and purposes the two processes are absolutely identical, and that Mr. Johnson's claims in this direction are worthless. It is well known that if any portion of a patent can be upset the whole of it goes, and, if so, any comment on the value of this particular patent is superfluous.

Mr. Wenderoth's invention was published in 1864, the year of Swan's patent, and was exactly the thing to render Swan's patent of great value by enabling prints to be obtained by the single transfer process instead of the troublesome and disagreeable method of double transfer with india-rubber-coated paper; but, somehow, like many other useful inventions, its value was unheeded and it dropped out of sight.

In 1869 Mr. Johnson brought out his method of double transfer, and his interest in the reversal of negatives would very naturally subside; but now that the lapse of the tissue-making patent is close at hand, and carbon printing by single transfer will be free and open to anybody who likes to take it up, it will not do to have so useful a method of producing negatives suitable for single transfer work fettered by unfounded pretensions. Mr. J. R. Johnson—at anyrate in his "first and chief improvement"—can have no claim to priority of invention.

I must apologise for trespassing at such length upon your space, but believe the importance of the subject will be considered a sufficient excuse.—I am, yours, &c., W. S. MILLER.

Great Yarmouth, January 1, 1878.

PHOTOGRAPHY IN COURT.—At the City of London Court, on Monday last, the case of Wright *v.* Müler was heard before Mr. Commissioner Kerr. The plaintiff, a picture framer, carrying on business in the City, sued the defendant, a photographer, of Kingsland, to recover the sum of thirty shillings for mounting a certain number of photographs by the defendant's orders and upon an estimate given. The defendant set up a counter claim of £5 for damage done to the pictures sent to the plaintiff to mount and frame. Before going into the case the learned commissioner asked the plaintiff why he had not sued the defendant under section 1 of the new act, as he (the commissioner) was determined not to allow a plaintiff any costs who would sue under the old act when the new one was framed for the benefit of the plaintiffs and for the convenience of the court and the public; however, the case must go on, but no costs would be allowed to plaintiff, even if he won the case.—The plaintiff said the orders were given by the defendant and were executed in accordance with that order, and no notice had been taken of application for payment until the present summons was issued, when he was met by the counter claim in question. The plaintiff had no witnesses to call.—The defendant said he entrusted the proofs now in court to the plaintiff to mount, and when they were returned he had to take other proofs and send them elsewhere to be mounted, as those the plaintiff had done were wrinkled in mounting and discoloured by some preparation or other which had been used, and which he (the defendant) supposed to be lime. He never heard of the plaintiff's application for payment, and if he had done so he should have returned the work on his hands.—His Honour asked to see the two specimens of work, and unhesitatingly said that the plaintiff's work was bad in comparison with that the defendant had got done elsewhere. He could not say from what cause the defect had taken place, but "there it was." He should, therefore, give judgment for the defendant, but without costs, as the defendant had also set up his counter claim under the old act. His Honour hoped in future people would avail themselves of the first section of the new act.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
Jan. 7	West Riding of Yorkshire......	Oddfellows' Hall, Bradford.
,, 8	Photo. Society of Great Britain.	5A, Pall Mall East.

,, 9	Cheltenham Amateur (Annual)..	Savings' Bank.
,, 10	Manchester....................	Memorial Hall, Albert-square.

EXCHANGE COLUMN.

Wanted, 10 × 8 bellows camera with doublet lens, in exchange for large tent and other things.—Address, C. Mason, Dobwalls, Liskeard, Cornwall.

Wanted to exchange Grubb's patent aplanatic view lense, A°, 2 inches diameter, $8\frac{1}{4}$ focus, for a *good* half-plate portrait.—Address, F. S., Whitley Brow, Melksham.

First-class magic lantern, $3\frac{1}{2}$-inch condensers, will be exchanged for anything useful in photography; a quick-acting *carte* lens preferred. Address, E. J. Holmes, photographer, Cranbrook.

Wanted in exchange, a studio camera and Dallmeyer's 1B lens for any of the following:—52-inch bicycle, Woodward's solar camera, 9-inch condenser, cabinet burnisher, five quires albumen paper. Difference adjusted.—Address, Photographer, 11, Grove-terrace, Victoria Park, London.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

Notice.—Each correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a *nom de plume* as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

⁂ With our next number we shall present the title page and index for the last year's volume as a supplement.

Jas. T. Cowie (Troy, N. Y.)—Yours, with enclosure, received.

G. F.—We should imagine that rain water would be best for your purpose.

Argus.—We refer you to our forthcoming Almanac, in which you will find an article on the subject of collodion transfers.

A. D. N.—Vitrifiable pigments, prepared for ceramic painting, may be obtained in a shop near the Piccadilly end of Regent-street.

Permanency.—You will have observed from an advertisement in last number that the information is now accessible under very easy conditions.

W. B. Fisher.—An ordinary film of iodised collodion may be converted into a *bromised* film by immersing it (after being washed) for about a minute in an aqueous solution of bromine.

A. M. Wood.—The verses possess an even flow; but do you not think their publication would serve to damp the joyous feelings that we desire to see pervade photographers during the "glad new year?"

J. Y. (Manchester).—There is no chance of obtaining the information in the manner you suggest, inasmuch as trade interests are involved. Tannin when mixed with gelatine will prove useful as a basis for experimenting. Why not try the addition of albumen as suggested in these pages some time ago?

Dr. R. H.—In one vessel make a saturated solution of sulphate of copper, and in another a solution (of medium strength) of bromide of potassium. Pour the latter into the former. The resulting mixture is an impure solution of bromide of copper, which will, however, answer the purpose of your experiment in connection with intensification.

Omega inquires—"What is the best way by which to prepare plates by the gelatino-bromide process which shall be more sensitive than wet collodion?" ——We reply: while much useful information concerning the preparation of very sensitive gelatino-bromide has been published, we should not be warranted in saying which is the *best* process.

T. G. W.—Why not obtain one of the lenses on trial? You err in supposing that we possess an intimate acquaintance with the various classes of lenses manufactured in London; for, on the contrary, our knowledge of them is in many instances a mere *catalogue* one. However, as we have the various catalogues at hand for reference, we are enabled to offer all the advice you will probably reqnire.

H. W.—For painting magic lantern transparencics a retouching desk forms one of the very best appliances we have seen, for all the conditions demanded by that class of work are fulfilled in such a desk. The transparency should be laid npon a well-selected plate of opal glass, by which the effect of even the most delicate touch with the brush will be plainly perceptible. We are, of course, alluding here to retouching desks of the most perfect and improved class.

G. M. D.—By "intensity" we meant the diameter of the lens compared with its focus. In the instance you give, No. 3 has nearly five times the intensity of No. 2; that is to say, the image is formed by nearly five times the number of rays, or the light power, transmitted by the other. In reply to the third question: for photographing by artificial light select a lens having a large aperture and a short focus, and let it be such an one as will work without a diaphragm.

Thomas Chilton (Manchester).—Our correspondent directs our attention to the fact that he has in his paper *On the Gelatine Emulsion Process*, published in our issue of last week, page 618, omitted to state the focus of the lens he employed. This omission he now supplies by stating it to be six inches. But if Mr. Chilton will glance at his paper again he will find that he has really given much fuller information than he imagines, for he states that he employs a single lens with a stop $\frac{f}{24}$. Knowing the ratio of the aperture to the focus, one does not require to be told the focus of the lens, because $\frac{f}{24}$ is a definite degree of luminous intensity, no matter what kind or focus of lens be employed.

Thos. Stuart.—A "line" is the twelfth part of a French inch. This latter being a little longer than an English inch, you may very safely estimate thirteen lines to our English inch. We are aware that dealers in French optical goods roughly estimate twelve lines to the inch; but this is slightly incorrect, unless coupled with the foregoing explanation. Forty-five lines equal about four of our inches. This measurement, although not absolutely precise, is sufficiently so for your purpose.

J. W. Kirby.—1. We are trying some experiments in the same direction, and hope to publish the results very soon.—2. The special kind of lime light mentioned will prove totally inadequate for the purpose of taking portraits. It will be a good plan for you to initiate your experiments by igniting a piece of magnesium of a definite length, and holding it a certain measured distance—say thirty inches—from the face of the sitter, of course making use of a reflector to prevent any of the light being lost. The results obtained under these conditions will serve as data for extending your basis of action. In the early days of magnesium photography Mr. Brothers introduced a large reflector made of tin, having a handle conveniently fixed behind it, and an arrangement in front, by which to suspend tapers, formed of twisted magnesium wire or riband.

An Actonian inquires whether, when in using a 10 × 8 old Voigtländer lens (which is considerably over-corrected) for copying a map, it will give a copy the precise dimensions of the original. He does not state his requirement very plainly, but we quite well understand what is meant.——In reply: If the visual image—that is, that which is seen in sharp focus upon the ground glass—be adjusted so as to be of the same dimensions as the map, as the picture would not be sharp owing to the over-correction of the lens, it would become necessary to remove the sensitive plate to a greater distance from the lens than the focussing-screen was; and as the rays of light diverge from the lens, so would the finished picture be larger than the original. If "An Actonian" has access to an Almanac for 1870 he will find the subject there treated of, and also a method by which such a difficulty as that here stated can be obviated.

Received.—George Lawrence Burge, W. A. Brice, and J. P. D. In our next.

Photographic Society of Great Britain.—At the next meeting of this Society, to be held on Tuesday next, the 8th inst., at 5, Pall Mall East, Mr. Edward Viles will read a paper on *Microphotography*.

RECENTLY-PATENTED INVENTIONS.

October 29, 1877.—"Certain Improvements in the Production of Typographical Etched Plates, Reproducing Photographs from Nature or from Copy. No. 4009."—E. Capron, L. Duvivier, and N. Ponsolle.

November 9, 1877.—"Photographers' Head Rests or Supports. No. 4196."—T. P. White.

November 21, 1877.—"Improved Arrangements or Means applicable to Producing Enlarged Pictures and for Taking Pictures by the Agency of Light. No. 4367."—F. H. Warlich and J. W. J. Cadett.

November 21, 1877.—"Improvements in Photographic Printing Frames, and in Apparatus used in connection therewith. No. 4380."—T. G. Hemery.

December 22, 1877.—"An Improved Method of Taking Binocular or Space Photographs. No. 4877."—C. H. Lehmann.

No. 923. Vol. XXV.—JANUARY 11, 1878.

ON THE ACTION OF VARIOUS BROMIDES AND CHLORIDES IN EMULSIONS.

The recently-published researches of Captain Abney upon fog-producing emulsions, and the fading of the impressions upon exposed films, have called our attention once more to the subject of the salts employed in forming the silver haloid. Though it was at one time supposed that the base of the soluble haloid used in salting the collodion produced little or no action upon or variation in the nature of the sensitive film, the impression has long been gaining strength that such action is produced, and that, in fact, the question of the proper salts to employ for the purpose is one of the greatest importance.

Some few months ago, at page 362 of our last volume, we devoted an article to the subject, since which time we have repeated and varied the experiments therein described, and now that the matter has once come under notice we propose to give a further account of the results thus obtained. As will be seen by reference to the article in question our experiments were divided into two classes, having as their bases the correction of emulsions fogged respectively by excess of silver and by exposure to light, and these may be taken as representing the two classes of phenomena treated by Captain Abney in his separate papers. We do not intend here to go into the question of the actual cause of the fog in either case, simply remarking that it may be due in each instance to the formation of sub-bromide of silver; but it is evident that the *whole* conditions are not identical in both cases, hence we have continued to follow the two distinct lines of experiment.

In the first course we have varied the conditions only to the extent of reducing the excess of silver to such a point that it required several days for the emulsion, even without restraining acid, to develope unmistakable fogging propensities; but the result at that stage was such that under some circumstances of subject and exposure the fog produced would not prove sufficient to seriously interfere with the quality of the result. The character of the emulsion was, indeed, such that if a sufficiently full exposure should be given to render the development rapid and to require no "pushing," the fog had not time to make itself apparent; but the slightest prolongation of the action of the alkali, whether from under-exposure or difficulty in gaining density, was sure to produce a veil of more or less opacity. In this manner we obtained an emulsion more easily susceptible, we think, to the weakest action which might be exerted by any of the salts used to remove the fog than if its fog-producing power had been greater.

This emulsion was divided into several portions, which were treated respectively with the chlorides of zinc, copper, cobalt, and ammonium, and with the bromides of copper, zinc, cadmium, and ammonium, in the proportion of half a grain of each to the ounce of emulsion. The various samples were set aside and examined at intervals in order that we might note the length of time occupied by the different fog-removing agents, the rapidity of the two classes of which was found to be in the order we have named them. Of the chlorides that of zinc acted most rapidly. Our first trial, made six hours after the addition of the chloride, showed that the emulsion had sustained a decided improvement; it gave no sign of fog, as we are accustomed to accept the definition, but the image failed to exhibit the clearness and brilliancy we like to see in an emulsion. A general softness, accompanied with a slight but not objectionable veil, marked the early stage of the development, while a strong tendency to fog under the intensifier rendered it almost impossible, except with a long exposure, to obtain printing strength. Subsequent trials proved that the maximum effect of the chloride had been obtained within the first six hours, as no further improvement was afterwards noticeable.

The chloride of copper continued its improving action during a further period of seven or eight hours, when the maximum was reached. The emulsion was then in a far better working state than that treated with zinc chloride, but still failed slightly in the same respects as the latter. Chloride of cobalt attained its maximum effect in about forty-eight hours, but was then inferior in working qualities to either of the preceding. Chloride of ammonium appeared capable of producing little or no effect, even after several weeks' action, the emulsion being at the present time in such a state that to obtain a clean image of moderate density a very long exposure and strongly-restrained developer are necessary.

Turning now to the bromides, we have to record a different class of results. Anticipating greater rapidity in the fog-removing power, we commenced testing these samples one hour after correction; but it was not until three hours had elapsed that the first emulsion became clear. In this case the copper salt was the most rapid in its action, zinc following next, its function being performed in a little over four hours. The image obtained from these two emulsions after the times named was all that could possibly be desired as regards freedom from fog and the various good qualities directly or indirectly connected therewith, while as regards rapidity and power of giving density they were in no respect wanting. The emulsions were, in fact, in every way as good as could be obtained with the same materials and the same formula.

The sample treated with bromide of cadmium cleared much less rapidly, but after two days' rest gave a clear, bright image, possessing great delicacy and that peculiar "bloom" or veil which some prefer. It continued to gain in clearness for some days, but so gradually that it was impossible to decide when it reached its maximum; at the end of a fortnight, however, it was perfectly indistinguishable from the last two samples. Bromide of ammonium appeared to act but little differently from its corresponding chloride, and after a lapse of several weeks has proved incapable of removing the slight fog originally existing in the emulsion, though if it be possible to so speak of a practically useless result it shows greater promise than the chloride.

In a second series of experiments an emulsion was prepared with excess of silver, and restrained by the addition of one drop of nitric acid to each ounce. It is noticeable that in this case it required a larger excess of silver and a much longer time to produce an emulsion in which the fogging propensities were sufficiently marked to render the experiments of any value. In the previous course the original excess of silver was extremely small—probably not one-fifth of a grain to the ounce—but just sufficient to completely convert the whole of the soluble bromide, after allowing several hours for complete combination. In this instance, however, the excess reached as nearly as possible two grains in each ounce above the theoretical equivalent required, and the emulsion did not then arrive at the fogging stage until forty-eight hours after sensitising.

In all probability by employing a smaller excess of silver and allowing a longer time the same result would have been arrived at—that is, the production of fog—for we believe that an acid *per se* is incapable of altogether *preventing* fog, but only acts temporarily in restraining or retarding its production. However, for our present purpose, that point is immaterial. At the time of adding the "correcting" agent it suffices that the emulsion was in a "foggy" state, and our object was to compare the effects of various salts in restoring it to its pristine brightness.

For this purpose the emulsion was divided and treated as in the last case with varying proportions of the same series of salts, the quantity of each being calculated to leave an excess of about half a grain above the exact quantity necessary to neutralise the excess of silver. The first and chief difference in the results obtained with the acid emulsion was that the whole of the salts were effectual in removing the fog. Next their order of rapidity was altered, the chlorides performing the clearing in the following order:—Copper, zinc, ammonium, cobalt. The bromides: copper, zinc, ammonium, and cadmium. There was less difference in the proportional rapidity of the various salts than in the case of the neutral emulsion, the chlorides occupying a longer time than the bromides. The latter produced their maximum effects in from fifteen to thirty-six hours, the former requiring between twenty-four and forty-eight, with the exception of cobalt, which required nearly three days and a-half, or about eighty hours.

Since reading Captain Abney's paper we have tried iodine and bromine in the free state, as suggested by him, with, in each case, the total elimination of the previously-existing fog. The experiments having been, however, made with a different sample of emulsion from those already recorded, and at different times, can scarcely be placed in comparison, It may be remarked that we failed to detect anything in the behaviour of the bromine-treated emulsion which would indicate the formation of bromal; on the contrary, we are inclined to give bromine the preference over iodine, as not only performing its function more rapidly, but as producing less injurious action upon the sensitiveness.

We shall be compelled to hold over until next week the remainder of our experiments and the deductions we have made therefrom.

LIQUEFACTION OF ALL GASES ACCOMPLISHED.

With respect to the event we dwelt upon last week—the liquefaction of oxygen—which has been of the most surpassing interest to *savants* over the whole civilised world, further particulars by M. Raoul Pictet are now to hand of the circumstances under which his experiments were conducted; but all are cast in the shade by experiments conducted before some of the leading chemists of the day at the Ecole Normal, by M. Cailletet. M. Pictet sounded the knell of "permanent gases," and M. Cailletet was at their death.

On the last day of the old year the remaining two "permanent gases," hydrogen and nitrogen, were liquefied by means of the apparatus the latter had erected; and the assembled chemists saw for the first time in the history of science actual drops of nitrogen, and, finally, liquefied hydrogen, which emerged more in the form of a misty cloud. A new epoch in science dates from these startling and marvellous events, which afford the most convincing truths of some of the grandest theoretical conceptions that have illumined the present century,

It is a very remarkable fact that some of the greatest discoveries in science have been announced almost simultaneously by two different workers. Just as the priority of the discovery of oxygen by Priestley has been called in question, so the first liquefaction of the same gas has given rise to rather angry discussion. M. Pictet publicly liquefied oxygen, but it appears that a sealed note had been delivered to the Paris Academy by M. Cailletet on December 2nd, stating that he had liquified that gas, and describing the process he made use of.

It is evident that equal honour is due to each of these learned investigators, though as an absolute matter of fact the process described in the sealed packet only allowed the production of a cloud of oxygen. This, of course, must be composed of minute drops of liquid, yet it hardly comes under the category of liquids, while the other experimentalist obtained actual jets of liquid. True, they were not confined and collected; but they were seen by every one present as unmistakable drops. The next feat to perform will be to collect these drops, and make a portable liquid of them, and this we do not doubt will be very soon done.

The actual present connection from a practical point of view of these great events with photographic operations may not be clearly seen, but they are pregnant with possibilities the date of whose realisation cannot be predicted. Many ideas connected with this aspect occur to us as we write, but it is rather early to give them journalistic form.

[By a misprint in our last the gas generator in the form of a *shell* was termed a "*shelf*."]

FILTERING MEDIA.

The introduction, not long since, of a new filtering medium in the shape of the so-called "glass-wool" led us to think that a short disquisition on the various media suitable for purposes of filtration would be useful to some of our readers—the more so as the glass-wool, though of considerable utility, does not possess sufficient corresponding advantages to set against its price, which at present is something close upon ten shillings an ounce.

The chief materials used at the present time are—dividing them into two classes, organic and inorganic—various fibres of animal or vegetable origin in the first; and, in the second, glass, sand, rock crystal, asbestos, and charcoal, all in various states of fineness.

Foremost among all these useful materials is to be placed the indispensable filter paper, which is now rarely to be seen in any shape but that of the circular pieces obtainable from all the dealers. Few of our younger readers, to whom the circular form seems a matter of course, can imagine the trouble and waste that was experienced in the laboratory or dark room prior to the advent of this most useful mode of selling and storing filtering paper. It is to be obtained of various qualities—the hard, firm-textured being the best to select, and the kind with a radiating water-mark is rarely made other than of good quality. Up to about ten or twelve inches diameter they may be folded and placed in the funnel without special precaution being taken, beyond being careful, while folding, not to crush the point too much, as it is liable to burst in use if at all weakened in that part. Beyond twelve inches in diameter some support is needed for the point; and in all cases the liquid should be poured in so as not to fall upon the point. At the late exhibition of the Photographic Society of Great Britain an ingenious filter was exhibited, which combined the strength of a woven fabric and the filtering power of paper by combining the two, the ordinary circular filter being backed up with strong muslin. We are inclined to think, however, that this method is inferior to one brought out by Mr. Waters, of Troy, New York, some years ago, which consisted in embedding, in the *centre of the filter*, in the process of the paper-making, a piece of lace between two thicknesses of the paper, the fibres of the latter intermingling with the lace so as to form a practically unbreakable sheet. The same gentleman also introduced a method of so strengthening the point as to make it impossible to break by folding.

Next in order after paper come raw fibres, such as cotton wool. This material has many advocates for its superseding every other medium; but, though it is useful enough in its way, it is only so in a minor degree. A pledget of cotton wool inserted in the neck of a funnel is useful for clearing grosser particles from a liquid; but if it be required to render a turbid liquid thoroughly clear it will take a day to perform what a piece of filter paper would do in a few minutes. Further: it will almost soak up as much fluid as the latter, so that it possesses little claim to attention on the score of economy. Again: it requires very careful placing in the funnel. If too tightly pressed in it will entirely stop the flow of liquid; if too lightly placed the fluid will descend round it and remain unfiltered, and it is by no means always an easy matter to hit the happy medium.

There is, however, another fibre which is infinitely to be preferred to cotton wool in every way. It is fine tow. We do not remember attention having been called to this material at all before, but for all purposes it at least equals cotton wool in usefulness, and in many it far surpasses it. It does not require such nice adjustment to prevent the fluid running away without filtration on the one hand, or not passing through it all on the other. A small plug of this material, pressed rather firmly into the neck of the funnel, filters excellently, and a glass rod passing through the fluid may be used to press or loosen the closeness of packing with the greatest nicety. Let any of our readers try this who have not done so already, and we think they will require no more cotton wool.

It must, of course, always be remembered that quick filtration does not at all imply the most efficient filtration; as a rule, the slower the liquid passes through a filter the clearer it comes out. But cotton wool forms an exception to the rule; for it is very easy to filter a quart of liquid through tow in as short a time as a few ounces through cotton wool and yet be equally clear, the pressure in packing the wool doubtless causing all filtration to stop in the chief bulk of the mass.

Coming to the inorganic filters, we first name the new glass-wool. We have referred to its price. As to its working capacity, it is more allied to the tow to which we have just been referring; but being, unlike the latter, inorganic, there are no combinations of circumstances in which it could, for instance, act upon a bath passing through it beyond that solution of the glass itself which on a former occasion we dwelt upon. We do not, however, think it at all likely to be useful to photographers; its best place is in the laboratory of the chemist.

Next we have asbestos, which is quite as practically useful as the glass-wool and not a twentieth of the price. It is a natural product, found in an aggregation of brittle, fibrous-looking crystals which are unacted on by most chemicals. (There are many kinds of abestos, the name really being given on account of the form rather than the chemical constitution.) It may be used with advantage for filtering anything, from the strongest acids or the nitrate bath to pure water. Glass and rock crystal, powdered, and sand form in effect a single class, their action being alike. They are very efficient when large quantities of liquids are to be cleared; but for occasional use paper is to be preferred unless the same filter be employed; and this we think hardly worth while from the trouble that would have to be taken to preserve the filtering bed from disarrangement and contamination with dust and other foreign matter. Rock crystal, which can be easily obtained from the clippings of the spectacle-makers, is therotically preferable to glass on account of its insolubility in water.

Sand requires to be well washed to free it from salt, and to be treated with hydrochloric acid to remove various lime salts and other materials deemed necessary to be expelled. It is not an easy matter to pound glass fine enough for the purpose; but if it be made red hot and then thrown into water it becomes very brittle, and capable of being broken up with the greatest facility.

To use these materials it is necessary, first, to prepare a bed of larger pieces of glass in the neck of the funnel, covering them with a layer of finer, and so on till the uppermost layer consists of the finest powder. It filters well and quickly, but is open to the objections we have named.

There remains now only charcoal to be treated. Its chief use is as a purifying material, in which direction it is more employed than for its mechanical properties. It forms an ingredient in many commercial filters, which, however, can scarcely be brought within the scope of this article; but there are not so many cases where it would be used in photography, seeing that distilled water should not require its aid, and the other waters where it would ordinarily be useful are not thought to require special filtration. In ending our brief survey we think our readers will agree with us that filtering paper still forms, and will for some time to come, the staple filtering medium for photographic purposes.

RECENT PATENTS.

No. III.—A VIOLET-COLOURED VARNISH FOR PHOTOGRAPHY.

Seeing the name of Sig. Scotellari appended (along with that of M. Puttemans) to a patent headed "Photography," we naturally concluded that it would have something to do with the violet-coloured, translucent lens caps associated with the name of the former gentleman. In this, however, we find we were mistaken, for the specification (for which provisional protection only was obtained) is confined to a certain method of—or, more correctly speaking, a violet varnish for—enamelling or varnishing glass, paper, and other materials, the connection of which with photography is stated to consist in causing the light to pass through them "for the various manipulations in photography."

The violet varnish is made as follows:—

Take two ounces of powdered copal gum, six ounces of essential oil of lavender, two grains of camphor, and essence of turpentine in quantity according to the consistency of the mixture wished; mix dragon's blood infused hot with the varnish, and add prussiate of iron—these two ingredients according to the shade of violet colour required. The mixture is then to be put into a thin glass bottle, or other convenient receptacle, with the lavender oil and camphor, adding to it the powdered copal in small portions as each is dissolved in the liquid, stirring the mixture continually with a stick of white wood or other material. When the copal is incorporated with the oil add by degrees the essence of turpentine in a boiling state. The mixture must be filtered, and when cold is ready for use. It can be applied to glass, paper, linen, metals, and other materials.

Bearing in mind the fact that this received provisional protection only, photographers will not be sorry to be put in possession of what appears to be a good formula for the preparation of a transparent violet varnish.

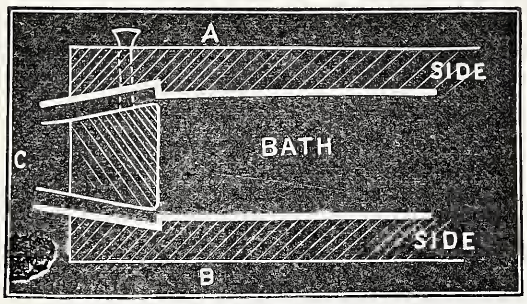
Our readers will remember that in the course of a paper read before the last meeting of the Edinburgh Photographic Society, by Mr. Norman Macbeth, the author spoke very favourably of the use of emulsions, both of collodion and gelatine, for portraiture. In the course of his paper Mr. Macbeth gave his experience with washed collodion emulsion, and spoke of the organifier of alkaline albumenate of silver, recommended some little time ago by Mr. J. C. Roche, as an accelerator when applied to the wet emulsion plate. It is well known that a very high degree of rapidity is claimed by many for the wet emulsion plates—a rapidity, indeed, far surpassing the ordinary wet process; while, again, others declare that there is no gain whatever as regards sensitiveness in employing the emulsion in the moist state. Possibly each side may be correct in speaking as they do from their own experience, for there is not the slightest doubt that the original character of the emulsion has a very great deal more to do with the rapidity than many suppose. A merely *moderately* sensitive emulsion, whether washed or unwashed, cannot by any subsequent organifying or "accelerating" be made to yield the extremely rapid results claimed by some; it is necessary that it be in the highest possible state of sensibility previous to such treatment. Again: it is optional whether the plate be merely immersed in water before exposure or whether it be treated with an organifier; and here another element of importance is introduced. If a simple immersion in water be adopted, or an organifier of plain albumen or gelatine, some emulsions show a large increase in rapidity over the dry plates, others no difference, except, perhaps, in the ease of development. But when an alkali is introduced into the organifier the increase of sensitiveness occurs in all cases, though it varies in extent according to the nature of the emulsion. After a number of careful trials we have arrived at the conclusion that Mr. Roche's organifier owes its accelerating effect *solely* to the alkali it contains and not to the silver, the only action of which is upon the colour of the deposit, while it has a strong tendency towards the production of stains and spots, especially if the plate be kept long before development.

PRACTICAL HINTS FOR PHOTOGRAPHING IN HOT CLIMATES.

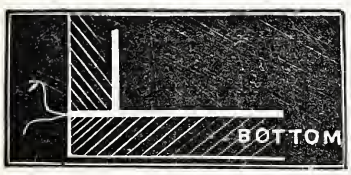
Every groove in photography seems to be well explored and the results published in all sorts of ways and by-ways, and if one be short of this kind of knowledge it is the fault of either not reading the journals attentively or not reading them at all. Simple little matters connected with the photographic outfit are recorded as very important subjects to be acquainted with; and so they are, particularly when you are a few hundred miles away from a photographic ware dealer, and perhaps thousands from the particular thing immediately wanted.

The photographer who wants an almost imperishable "field piece" must look to the ALMANAC for 1876, where I have shown how to put together a wooden bath with sheet india-rubber lining. I have one in use, and a serviceable article it has proved. But out here, where the normal temperature of the atmosphere is about equal to the inside casing of a "Howarth's patent hot-air stove," just replenished with fuel, the menstruum for rubber, such as benzole, naphtha, &c., is very difficult to obtain in the first instance, and equally so to keep when you gain possession of it; hence my india-rubber lining idea loses some of its simplicity of construction. I have, therefore, looked about for a substitute for sheet india-rubber, and found it in wax cloth.

Waxing the wooden bath is an old idea (I beg Mr. Stillman's pardon—it was new once), but it came off just where you don't want it. The dipper dislodges a little, which floats on the silver solution waiting to be received on the next collodionised plate. The other place where it also comes off cannot often be found; but it is evident enough it does so, or the silver solution would not drop from its receptacle so copiously. My notion of a perfect bath is this:—



The diagram shows the front, *a*, and back, *b*, with one end, *c*; depth, &c., according to requirement. Take white wax and use the flat iron unsparingly on it in driving it into the pores of the wood; then lay a piece of strong calico, which is here represented by a thick black line; apply more wax and the flat iron again, and it will then adhere to the wood like a skin that was born with it. Screw altogether and afterwards trim the ragged edges of the cloth, leaving the bottom a little long, so that the bottom wood can be screwed on, as in the diagram.



The Aryian brethren of this country are not born philosophers as a rule, but my table servant wakened me up to a sense of my ignorance on one scientific point. In very hot weather, with a scorching wind, the bottles of bitter beer are cooled by being placed in either wet grass or wet cloth. Evaporation goes on quite rapidly, as the wind blows strongly upon it. Acting upon this hint I wrapped my nitrate of silver bottle in a shroud of flannel, placed it in a dish of water an inch deep, and opened the window to catch the breeze. Call this "Gough's refrigerator" when you are delighted with it, and my ambition seeks no greater distinction as an "inventor."

Warming the Bath.—A hot "bath" is about as unnecessary as hot grog, one would think, in a climate like this. To know how to do it when coals are scarce is a wrinkle worth attending to. Put a black cloth round the bottle and place in the sun for a few minutes. Now blow through a glass tube dipped into the solution till it bubbles and up violently. In two minutes all ether and alcohol have departed, you have that article much commended "as better than a new bath."

Cool Collodion.—Wrap a piece of wet flannel round the bottle, and as sure as it dries so sure will the collodion become cooler. If I extend this article in length I might affect your readers with something like chilblains. J. W. GOUGH.

Darjeeling, India.

NOTES ON PASSING EVENTS.

BY A PERIPATETIC PHOTOGRAPHER.*

WRITING by the light of the triple-wick lamp, recently patented by Mr. Hughes, I inquire whether he has adopted the best form of chimney that might be devised for the twofold purpose of effecting combustion and transmitting light. A glass cone in proportions similar to a sugar-loaf may answer quite well for surrounding the wicks, but would not its proximity to a flame possessing such an intense degree of heat as a triple-wick must give cause it to run a constant risk of being fractured? To this it may, perhaps, be replied that if the glass cone be sufficiently large in diameter it will not get over heated. True; but neither could the flame be brought sufficiently close to the condenser to yield its light properly. It seems to me that every end would be secured by making the glass cone of metal (forgive the Hibernicism), such as thin brass or tin, and having an aperture in one side to allow the light to pass out to the condenser. This aperture might be closed by a small, flat plate of glass, say of the dimensions of the transparencies, and if this were allowed to drop loosely into a guide or groove in front, or even be inserted in the same manner as that in the sciopticon, all the advantages of the present cone would be secured *plus* the further additions of freedom from breakage and facility of replacement. I have spoken of a "cone," but the suggested metallic chimney need not be a cone at all, but be perfectly cylindrical in form. I am glad to see a more powerful lamp being applied to the lantern; for, as every exhibitor is too well aware, something better adapted for drawing-room or small school-room exhibitions than ordinary oil lamps, and yet possessing their simplicity and facility of management, was badly wanted. Query: seeing that a triple-wick lamp gives a light so much superior to one having only a double wick, is there any reason why a still greater number of wicks—say four or five—should not be pressed into the service of the lantern? The heat would be very great, but that would be a small matter in connection with a well-ventilated lantern and room.

The idea of providing "adapters" for camera dark slides is so excellent that I trust to see some of the well-known ingenuity of our camera-makers expended in that direction. Like the "friend" of whom the editors have spoken, I, too, am the possessor of a number of sets of slides which I should like much to be enabled to use in conjunction with a certain camera for which they were not made, and yet which I dare not have altered to suit them. If such an adapter were available, many photographers would be very glad indeed to embody them among their *impedimenta*, and I hope, at no distant period, to find that among the various ingenious pieces of apparatus which from time to time are exhibited at meetings of the photographic societies this one will also be found.

A simple piece of apparatus, devised by Mr. J. H. Taylor, for cutting a pair of carefully-trimmed stereo. prints out of a large binocular negative, will be welcomed by those who use a cabinet-landscape size of plate for taking binocular views of subjects which cannot so well be represented in the single or monocular form. To ascertain the *full* value of this apparatus, however, it will be necessary that the manipulator acquire the art of being able to view a stereoscopic picture by the operation incorrectly designated "squinting." This will enable him to place the apparatus or guide plates down upon any uncut binocular picture, and, having placed *one* of the apertures over that portion of the picture selected, a "squinting" glance at both will show whether the conditions of correct stereoscopic projection will be properly carried out; for, if not, the width of the two masks can be almost instantaneously adjusted so as to produce *any* effect. For this reason, the apparatus to which I have referred will prove very useful.

In a paper read before the Manchester Photographic Society, Mr. Thomas Chilton complains of "frilling of the film during development" as being one of the drawbacks attending the practice of the gelatino-bromide process. This is a disease that appears to be very little understood. At one time I had several plates "frilled;" *now* I never see such a defect. This is all very well so far as it goes; but here lies the special annoyance—I am quite unable to say by what means I have obtained immunity from the evil in question. I work precisely (so far as I am aware) in the same manner as I have always done, but whereas in my earlier trials of the process I occasionally got a negative which had a little frilling round the margin, I have long ceased to be troubled in this respect. My method of development is exceedingly simple. Fixing the plate upon a holder I allow water from the tap to play upon the surface until it is made thoroughly wet; I then apply a four-grain solution of pyrogallic acid, containing one drop per ounce of a very much diluted solution of carbonate of ammonia. The picture appears with quite an easily-managed degree of rapidity, and is checked or aided by bromide or ammonia according to its appearance. When the details are all out, but still very thin, I wash, fix, and intensify with acid-pyro. and silver. I prefer

* Concluded from page 6.

this method to bringing the picture up to its full intensity by alkaline pyro.

Concerning the Kennett patent Mr. Chilton does not appear to be quite conversant with the facts when he speaks of it thus:—"Owing to the non-validity of Kennett's patent, it having been declared void," &c. The patent in question was not "non-valid" in the ordinary acception of this term; it was simply allowed to lapse at the termination of the three years for which it was obtained. True, Mr. Kennett might easily have extended the duration of his patent for four years more, and after that for a further period of seven years, but these extensions are attended with the somewhat stiff fees of fifty pounds and one hundred pounds respectively. This course he, wisely, did not adopt, but allowed his patent to *lapse*. This, it will be seen, is a very different thing from its having been "declared void" through "non-validity"—a term which conveys an erroneous impression. The patent authorities would have been only too glad had he not allowed it to lapse, as they would thereby have been a hundred and fifty pounds the wealthier.

HOW TO EMPLOY PHOTOGRAPHY AND THE LANTERN AS EDUCATIONAL AIDS.

No. II.

At the present day, when our students have to "cram" for, if not master, many more subjects than were required at "exam's" in olden days, the teacher, if he would go with the times, must seize upon every available "tool" that can be made to do service in the cause of education.

"Sight knowledge," or that which can be imparted to the brain through the eye, plays a very important part in every person's education, whether it be scientific, technical, or worldly. Thus, if once we have well examined a specimen of natural history, we readily recognise it again or any other specimen of the same species. Again: if we have visited any place, at home or abroad, on its being named we can at once conjure up "in the mind's eye" all its characteristics as if we were looking upon a photograph of the spot; and, more familiarly, if Jones has once been introduced by Brown to Robinson, both Jones and Robinson ever after, through sight-knowledge, mutually recognise each other whenever they may meet. Further: the shop windows make us familiar with the photographic portraits of men great in the political, literary, scientific, religious, legal, or financial world, and if by accident we meet any of such celebrities the chances are we at once recognise them, through the sight-knowledge we have acquired from their photographs.

This gives us the key-note as to how we may make *truthful* delineations of rare objects, of far-distant places, or of events long since passed away important implements of education, as they afford the necessary sight-knowledge, which in many instances could not be imparted in any other form. But that word "truthful" means a very important element in the whole story; for no pains must be spared to procure accurate data, even to the most minute detail, if we wish to do justice to the student and give this system of teaching a fair trial.

Here I must protest against the employment of *very* cheap slides, for, as a rule, such must mean poor drawings and worse colouring. An *educational* slide ought not to be one of those things in which the maker has, like "Caleb Plummer," the doll-maker, "to go as near to natur' as he can for sixpence." Careful drawing with due attention to data, good negatives, clear positives, and artistic painting must be paid for, as sound teaching will not admit of the ship being spoilt for the sake of the ha'porth of tar.

It may be asked—"Are slides to take the place of objects in teaching?" To this question I think the answer must be—"As a rule slides should supplement, rather than take the place of, objects, unless the desired objects are unattainable by reason of their rarity, great money value," &c. Thus, if I had a school museum, I should not wish to disarrange carefully "displayed" specimens placed in the cases, but I should employ a set of counterpart slides when lecturing on the contents of the museum cases; for, on account of the large size of the lantern diagrams, I could better point out to a greater number of students the characteristics of the specimens than if I employed the specimens themselves, and, having thus "primed" each student as to *what to look for*, I should request my class to examine the specimens themselves in detail and with due care.

If I wanted to show the skeleton of an elephant, on account of the size and cost of a real specimen I should make a slide play substitute in the museum as well as in the lecture room. If, on the other hand, I were travelling on a lecture tour, then specimens would be an incumbrance, and I should employ lantern diagrams alone. Undoubtedly it is always desirable for a student to examine the absolute object itself, and the next best thing is to be taught from a truthful delineation of the same. That this may be done with advantage I need only refer to the success of Dr. Carpenter's Gilchrist Trust and Sweeny's Geological Lectures, which were entirely illustrated by lantern diagrams of fossils, restoration of extinct animals, and of the probable aspect of the surface of the earth at different geological periods, of the physiognomy of mountain masses of various mineralogical constitution, glacier regions and action, coral reefs, &c., which otherwise would have required an extensive museum and field excursions to all parts of the globe for their equivalent illustration.

It has been asked—"At what point in the education of a scholar should the use of the lantern be introduced?" I think those who are conversant with the value of this system would make answer—"At the very beginning, so as to supplement the *Kindergarten* of the primary school, as the latter should supplement the museum of the collegiate school."

I never could understand the necessity for making instruction a matter to be abhorred by the pupil, through being presented in form so dry that it became difficult to swallow; nor could I ever understand the necessity for the teacher assuming a high and dry, stilted aspect of extreme severity that destroyed all sympathy between pupil and teacher, and simply made the pedagogue one to be dreaded instead of loved as a friend of youth. Nor could I ever understand why the youthful mind should be so overloaded with task work that, if honestly mastered, it would keep the brain on the strain from nine o'clock in the morning till twelve o'clock at night, with the exception of the hour given to dinner and play and the half-hour given to the evening meal. I say, "honestly," because we all know that such over-tasking never was done thoroughly, but by hook or by crook the work was "fudged," though apparently gone through. Such a system of teaching must lead to superficial knowledge, whilst "thorough" ought to be the motto of the skilled teacher. A moderate amount of instruction thoroughly mastered by the pupil will (what in the slang of the school is termed) "stick," whilst the over-cramming system will produce nought but Dead Sea fruit.

The manner of carrying out illustrations in each department of education for which this system is adapted will next claim our attention. Samuel Highley, C.E., F.G.S., &c.

NOTES FROM AMERICA.

Curiosities of Science.—Lighting the Studio with Yellow Glass.—Talbot's Engraving Process *Redivivus*.

Under the heading of "Curiosities of Science" the *New York World* describes how, at a recent meeting of the New York Academy of Sciences, Professor J. S. St. John illustrated a new application of dry-plate photography in preparing without a camera glass transparencies of sections of fossils for projection. Slides of sponges and corals prepared by this method were exhibited, and showed the delicate sections with great accuracy. Professor St. John did not fully explain his application, but Professor Newberry, president of the society, said that the discovery, which it really was, would prove to be of great benefit when Professor St. John should see fit to make it public.

All this is correct enough, but we imagine that it will scarcely in this country be classed as a "new application" of photography. It is a long time since sections of fossils for projection by the magic lantern were prepared in the following manner, which, so far as we can see, covers the ground referred to:—The section, which may be one of a fossil or any other partly or wholly translucent mineral, having been mounted upon a glass plate is used as a negative for printing upon a dry-plate by superposition, in the same manner as leaves, lace, and other flat objects which have been used as negatives to print upon *paper* ever since the earliest experiments of Mr. Fox Talbot. It is certainly ten years since fossil sections were applied to a similar use—not merely upon paper but upon sensitive dry plates; and we are aware of several sections of this kind having been photographed upon glass in the manner indicated with the view of their being submitted for examination at an early meeting of the Royal Microscopical Society. It may here be observed that by making use of the bromised emulsion process the resulting picture may be either a negative or a transparency, according to the way it is treated after its primary development.

"And what next?" inquires the *Photographic Times*, who, in speaking of the interposition of yellow glass between the sitter and the light by which he is to be illuminated, continues:—

Not content with blue, purple, and rose-coloured glass, some brave personage has suggested that if the glass in the skylight be tinted a pale bright yellow that it will be just the thing. We have as good a right, we suppose, as any one else to make a suggestion, and, therefore, we suggest that those who so continuously hanker after colour would do better to paint their studio glass entirely black, then shut up shop, and clear out of the business. We guarantee if this be done that their models will never complain of the light hurting their eyes, although the tears may come to them before the exposures are sufficiently long. The effect could be increased by scratching star-shaped apertures through the black. We are prepared to defend this method on scientific grounds.

This is the manner in which Mr. F. A. Wenderoth, in the *Philadelphia Photographer*, gibbets a photo-engraving process which has been "resurrected" by Mr. Jose Julius Rodrigues. Under the heading *Honour to Whom Honour is Due* Mr. Wenderoth says:—

It is astonishing with what coolness, expressing it mildly, some people appropriate the labour of others. In last month's number of this journal there is published an article headed *Photographic Process Giving Half-Tone*, a translation of a paper presented to the Belgian Association of Photography by Jose Julio Rodrigues.

This *new* process was invented and patented in England *only twenty-five years ago*, in 1852, by none less than the great Fox Talbot, and in Muspratt's *Chemistry* (English edition) under the article "Photography," division "Photo-Engraving," one can find the process given in almost the same words as published in this translation; also, in Ure's *English Cyclopædia*, ditto in Appleton's, under the head of "Photography," and in the opening article of last month's number, in an obituary of the late Fox Talbot the same process is alluded to.

If Mr. Rodrigues had introduced a new feature or improvement, no matter how small, he would have been entitled to some consideration, but as it is it is an unblushing "steal." If it was not for the fact that this process introduced the use of gelatine in combination with chromic salts for photographic purposes it would not merit consideration, as it is valueless for the purposes for which it was intended, being based on an impossibility, viz., to etch the metal surface underneath the gelatine film without detaching it, when, in fact, as soon as the etching agent has penetrated the gelatine film to the surface of the metal plate, and its action has commenced, the support of the film is removed, and it is lifted off, when the action of the etching agent has to be stopped. This explains why only a very delicate impression on the plate is obtained, not deep enough to print from. And of what use is a printing-plate which cannot be printed from? This defect Mr. Talbot was unable to overcome, and that has been the reason for its twenty-five years' slumber. But what use is it to resurrect a process of which Mr Rodrigues himself says, "does not appear to me to be the most useful," and to send a paper all the way from Lisbon (if I understood right) to Belgium to be read about a process he says himself does not accomplish its end; the less so when we have in successful operation photolithographic processes by which half-tones are produced. To cover the metal plate first with the resin powder was rejected by Talbot as preventing the rendering of the half-tones, instead of which he applied the resin after exposure and before etching.

Having made a few experiments in this same direction as long as six years ago, I would advise experimenters that this process is not worth the gelatine to be used, much less the labour necessary to conduct operations so delicate.

FOREIGN NOTES AND NEWS.

A New Paper for Filtering Collodion.—The Inauguration of a Society for the Encouragement of Art Manufactures in Berlin.—A Method of Fixing the Retouched Parts of Negatives without Re-varnishing.—Dr. Monckhoven's Photometer.—On the Conversion of Chloride of Silver into Nitrate of Silver.—A Method of Recovering Silver from a Solution of Cyanide of Silver.

Herr Schröder, the optician, has lately used a peculiar sort of paper, imported from Japan, with much success for filtering varnish, and recommends it highly as a filter for collodion, which runs through it almost as rapidly as water through ordinary filter paper.

For some time back there have been in Munich, Frankfort, and Brunswick societies for the encouragement of art manufactures, under whose protection and superintendence libraries, drawing-class rooms, and other establishments, in which instruction is given to the public in the various art manufactures, have been carried on with much success. In Berlin there was no such society, and its want was much felt in many quarters; so in October last Dr. H. Vogal undertook to organise one. He called a meeting, which was attended by the representatives of the most important manufacturing houses in Berlin, but his proposal did not meet with much favour. It was maintained that the Gewerbe Museum already fulfilled all the functions of the proposed society, and by a majority of voices the project was abandoned.

Some seven of the gentlemen present, however, determined not to let the matter rest there, and accordingly a second meeting was called, consisting of the members of the societies of painters, sculptors, and engravers, and on the 5th of November the society, numbering 200 members, was constituted, Dr. Vogel being chosen president. On the 5th December the society held its first ordinary meeting, 400 persons being present, when Professor Döpler made a valuable opening speech, and a variety of interesting articles bearing upon the objects of the society were exhibited. Photography, as an employer of art manufactures to decorate its studio, to furnish it with backgrounds, frames, &c., was represented by the well-known names of Dr. Vogel and Herren Prümm, Reichard, Liebmann, and Frisch.

In a very long article *On Negative Retouching*, in the *Mittheilungen*, Herr Belitski, of Nordhausen, mentions that for the last ten years, instead of revarnishing retouched negatives to prevent the particles of lead from being removed by the duster or by friction in the course of printing, he makes use of alcoholic fumes to fix the graphite, but does not fume the whole surface of the plate by holding it over a vessel containing heated alcohol, merely conducting a stream of alcoholic vapour over the retouched parts. The contrivance he uses for this purpose is both simple and cheap, consisting, as it does, of a small square tin bottle, having a wooden handle fixed to one side. The bottle is five and a-half centimetres in diameter and ten centimetres in height up to the mouth, in which a good seltzer-water cork should be inserted so as to be quite air-tight; and the cork being bored, a glass tube of about one centimetre in diameter, outside measurement, must be inserted through the hole. The glass tube should have an internal diameter of six or seven millimetres, and the end which passes into the bottle must be cut straight off. About fourteen centimetres from the bottle the tube should be bent almost at right angles so as to form a knee, and at about fifteen centimetres from the knee the free end should be brought to a point having an opening of three millimetres. To use it, the bottle is half filled with absolute alcohol and brought slowly to the boiling point upon a spirit or other lamp. At first the alcohol will condense in the tube, but by canting it carefully backwards it may be made to run back into the bottle. As soon as the condensation in the tube ceases hold the hand flat in front of the opening of the tube at a distance of about a centimetre, and if the apparatus be in proper working order one would feel, as it were, a soft blowing upon the palm of the hand. The plate upon which the retouching is to be fixed should then be placed, varnish side uppermost, at an angle of 45° from the horizontal, and the stream of vapour issuing from the mouth of the pipe one centimetre from the upper slope of the plate. The plate is then moved so that the vapour can be seen to condense upon the retouched parts, which, being matt, become shiny and disappear, or sink into the varnish. If the stream be too strong or the plate be placed too near the opening, or if the current be allowed to play too long on the same place, the varnish, instead of merely softening, becomes partially liquefied and runs, carrying the retouching with it, and there is no other remedy than to wash it all off and revarnish and retouch. With practice this mishap will rarely happen, but the beginner would do well to practice upon some old and useless negatives until he has acquired considerable dexterity. A few minutes after the "burning in," as Herr Belitski calls it, has been safely accomplished the plate may be put in the printing-frame, but it should not be retouched upon again immediately.

In the *Photographisches Archiv* there is an illustrated description of Dr. van Monckhoven's photometer. It consists of a seven-centimetre cube-shaped box E F G H, to which a lid A B F E is attached by hinges. This lid is divided into two parts at C D (*fig.* 2), held together by two hooks at J and J (*fig* 1). At the top of the box there is a flat piece of wood

FIG. 1.

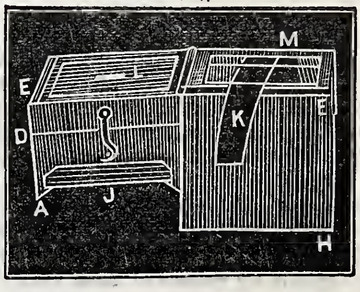


FIG. 2.

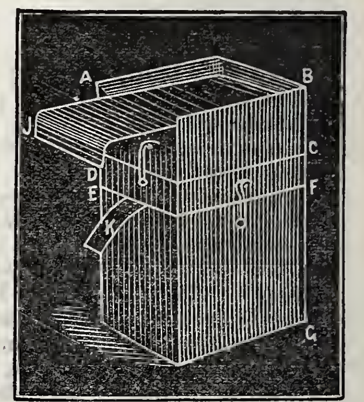

gummed to a piece of cloth, and two india-rubber bands, under which, by the aid of a strip of silver paper K, one centimetre in breadth (see *fig.* 1), which lies rolled up in the interior of the box, may be passed. At M beside the strip of paper a piece of paper (something of the colour of blue litmus paper) is placed, and which forms the tint. A plate of glass is let into the lid at L, so that when the instrument is closed it lies flat upon the strip of paper K. Upon the plate of glass a piece of black paper is pasted, from the centre of which a piece one centimetre long and half-a-centimetre wide had been cut. The strip of paper K peeps out through a small opening in the box, and may be further drawn out at pleasure. A piece of ground glass is let into the lid at A B; and above it the sides of the lid are grooved to allow of a metal slide J *(fig 2)* being slipped in and out. The grooves are divided lengthways into ten equal parts, so that when the slide is pushed up to No. 5, as in the diagram, the ground glass is half covered. If the silvered paper be drawn forward, and the photometer exposed to the light until the paper K has assumed the colour of the paper M, which lies beside it, the time required to get a carbon print from a negative is ascertained. If the negative be thin then draw the slide further out, and if the negative be dense push it further in.

The silvered paper for this photometer is prepared in the following way:—Take some good raw Rives or Steinbach paper (44 x 57 centimetres). Dissolve 100 grammes of sodic chloride in two litres of distilled water, and place the paper in it for two minutes. In this way prepare from ten to fifteen sheets of paper successively, and dry in a dark place. Then dissolve in two litres of water 200 grammes of nitrate of silver, and dip the sheets of salted paper into the solution one after another; then turn the whole bundle over, and place it sheet by sheet in the vessel with clean water to wash out the free silver salt. Finally, hang the sheets up again to dry in the dark. The dry sheets are then cut into strips one centimetre wide, and running the whole length of the sheet (57 centimetres), each of which is rolled up separately. Every time that a new roll of paper is placed in the photometer a piece of carbonate of ammonia the size of a pea rolled in a small piece of tissue paper should be put in beside it. The new paper should be placed in the photometer the evening before it is to be used, so that the ammonia may have time to act upon the silver paper, and thus render the paper more sensitive than albumenised paper. Too large a piece of ammoniac carbonate would make the paper yellow.

In the *Journal für Practisches Chemie* Herr Von Bibra says that the following is a good process for changing chloride of silver to nitrate of silver:—Mix one volume of freshly-precipitated chloride of silver with three volumes of freshly-prepared hydrosulphide of sodium, add water and boil for an hour, then filter. Now fuse the whole of the silver containing black residue, and wash it well with water, when a white mass having a metallic lustre will be produced, which, when treated with nitric acid, gives a solution of pure nitrate of silver.

In the above periodical the same writer gives the following as a method of recovering the silver from a solution of cyanide of silver:—Treat the solution with sulphuric acid. The resulting precipitate contains all the silver in the form of cyanide of silver, and should be made red hot and then digested for a short time with nitric acid. From this last solution perfectly pure chloride of silver is got by muriatic acid.

Meetings of Societies.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

This Society met on Tuesday evening last, the 8th instant,—Mr. J. Glaisher, F.R.S., President, in the chair. The following gentlemen were elected members, namely, Messrs. W. S. Hobson, Carl Norman, and William Cobb.

In anticipation of the forthcoming annual meeting Messrs. F. Beasley and Robert Murray were elected auditors.

Captain Abney read a paper *On the Theory of the Destruction of the Photographic Image by Time.* This paper was supplementary to the one he had read at the previous meeting, and it had been, meanwhile, sent to the two weekly journals for publication [see our last volume, page 617]. On the present occasion he still further supplemented those remarks by another paper, which will appear in our next. With respect to the latter portion of Captain Abney's paper, some remarks were made by Mr. T. J. Pearsall and Mr. T. Sebastian Davis, which, however, would be very imperfectly understood without the paper, and the publication of which we accordingly reserve till next week.

A paper on *Microscopic Photography*, by Mr. Edward Viles, was then read by Captain Abney.

The Chairman said that the paper was one of great interest, and while they were sorry that Mr. Viles had not been able to be present with them on that occasion, it would give them great pleasure to have him with them at their next meeting, at which he would exhibit his negatives and enter more fully into details.

Captain Abney observed, for the benefit of any member who desired to practise microphotography, and who had got object glasses which were not quite achromatic, that all difficulty would be obviated by using a monochromatic light.

Mr. Dallmeyer (regretting the absence of Mr. Viles) said that he had in his possession numerous microphotographs, many of which had entirely faded. To Mr. Viles was due the credit of having produced not only the largest picture of that class that he had seen, but one produced in unchangeable pigments; while with regard to quality the one for which he had been awarded the medal was superior to any he (Mr. Dallmeyer) had ever seen. In illustration of the importance of microphotography he might state that Colonel Woodward, of America, had photographed things which, owing to the physical constitution of light, could not be seen. The chemical ray would show closer separations of lines than the human eye was capable of distinguishing.

Mr. Edwin Cocking then read a paper entitled *Thoughts on the Recent Exhibition.*

No discussion followed.

The Chairman announced that the next was the annual meeting of the Society, for the election of officers, &c.

Mr. R. Kennett exhibited a choice collection of negatives by the gelatino-pellicle process.

Mr. Harman made some observations on his estimation of the advantages of the wet over the dry process.

Mr. J. L. Lane exhibited a new camera embodying a reversing back, as described by us a few weeks since, the double back being remarkable for its simplicity of construction.

After a vote of thanks to all who had contributed to the interest of the evening, the proceedings terminated.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

The meeting of this Society, which was held on Thursday, the 3rd inst., was devoted to a magic lantern entertainment. Mr. Frank Howard presided, and the large room in the House of the Society of Arts was well filled. Keevill's lantern, under the direction of Mr. F. York, was the medium by which numerous fine pictures by Messrs. York, England, Woodbury, Dunmore, the Chairman, and others were thrown upon the screen. Upon these we purpose making some critical remarks next week. Mr. W. M. Ayres exhibited, on behalf of Mr. Baker, a curious mechanical lantern slide designated "Beale's choreutoscope," the object of which was to produce lifelike motions of figures upon the screen.

The proceedings were varied by the reading of the tale of "Gabriel Grubb," by Mr. Statham, Jun., and Dr. Croft's poem of "Jane Conquest," by a young lady.

The meeting proved a very successful and agreeable one.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

The Board of Management of the above Association held its monthly meeting on Wednesday, the 2nd inst., at 160a, Aldersgate-street, E.C.

The following gentlemen, having been proposed by Mr. Lavender and seconded by Mr. Hall, were elected members of the Association:—Messrs. Staples, Pember, Howard, and Hackett.

The balance sheet and Secretary's report for 1877 were approved. The board then prepared the report for the annual meeting, but, owing to the number of members present being insufficient to constitute a general meeting, it was postponed till February 6th, at 8 p.m. The members are particularly requested to note the date, to be present on that occasion, and to invite friends to further the object of the meeting by their presence.

Correspondence.

Intensification of the Weaker Portions of Negatives.—Tcha-Oma, a New Retouching Medium.—Death of M. Braun, of Dornach.—Emulsion Negatives by M. Balaguy.—M. Gobert's Process of Photolithography.

The usual monthly meeting of the Photographic Society of France was held on Friday last, the 4th instant. M. Davanne occupied the chair in the absence of M. Peligot, the President, who was indisposed, so that it would seem that the two societies of England and France are entitled to sympathy for being both deprived of their able presidents—let us hope but for a short time.

M. Girond was unanimously elected a member of the Society. M. Pector, in the absence of M. Perrot de Chaumeux, detained in the provinces by the general communal elections, read the extracts from the foreign journals, among which were the remarks at the Berlin Society's meeting upon the advantage of rubbing powdered lead upon the parts of a negative under-exposed.

Mr. Stebbing said that in his experience the application of a stump with red powder on those parts of a negative feebly visible was very efficacious, and made half-tints appear which otherwise would be scarcely apparent.

M. Davanne added, with respect to redeveloping, that if they intensified the feeble parts with pyro. and silver, they rendered other parts more vigorous also, so that in obtaining printing force in the feeble parts of a *cliché* they made the remaining portions too intense, and hence produced hardness.

M. Gobert preferred a film of bichromate on the negative, and, after a short exposure, applying, with artistic judgment, the brush charged with graphite.

M. Alfred Chardon said that in the emulsion processes (and wet collodion had a certain analogy) intensification did not really create any image—the silver deposited only gave more force to what there was, but did not make anything new. If the original exposure did not—as it should—give a harmonious picture, intensification on local parts could not make a perfect whole.

M. Carette submitted to the Society a new product which he calls "tcha-oma"—a Japanese paste to replace gum arabic as the material of the retouching surface of negatives. The instructions for its use were as follow:—Boil 1000 cubic centimetres of water in a porcelain or varnished earthenware pan, and plunge the stick of paste into it as soon as the water commences to boil, then stir with a wooden spoon until completely dissolved. Now remove the pan from the fire, and filter into a bottle. The solution must be cold when used. Keep the bottle well corked. As soon as the negative is taken, and while still wet, pour upon it the above solution, so as to produce an even film. Allow it to dry naturally upon a grooved draining-stand, so that the excess may drain off at one corner of the plate. In the event of the negative from any cause becoming dry before pouring on the solution of tcha-oma, the plate must again be made wet and the rest of the operation performed as above stated, and it will answer as perfectly as if poured on before the negative was dry, which is not possible when gum or dextrine has to be used. This new product he (M. Carette) said would supersede the use of varnish for retouching purposes. In a word, tcha-oma gave the best surface for retouching, cost the least, united all the good qualities desirable for facilitating the production of good work and preserving the varnish of negatives, and had the double advantage of equally permitting the use of the point, needle and pencil without fear of injury. It was impossible to desire better *materiél.*

The order of the day announced the presentation of photographic proofs, in printing ink, by M. Braun, of Dornach.

The Chairman was very sorry to have to state that M. Braun died on the 31st ult. They had thus lost the man who first popularised Swan's carbon process in France, and whose name would be for ever honoured by the publication of his unrivalled collection of reproductions, after the old masters, from every celebrated gallery in Europe—a labour of love to M. Braun, who was himself an artist. His wonderful grouping of flowers for the textile fabrics of Dornach and Alsace, and his enlarged photographs of very considerable dimensions, would not be easily forgotten by those who had the good fortune to see them in the Exposition Universelle, held in the Palais de l'Industrie, in the Champs Elysées, Paris, in 1855, and which, for beauty of the lines and harmony of the conception and design, have never since been equalled, much less surpassed.

M. Mouilleron exhibited a magnificent portfolio of reproductions from the old masters in the Museum of Munich, by Hafenstangl, printed on albumenised paper in silver. The prints were much admired. They at once gave the impression of being faithful representations of old paintings.

The competition established by the Society, under the patronage and with the pecuniary aid of the Minister of Public Instruction, for the best photographic camera and complete equipment for use for official missions and travellers in foreign countries, has been responded to by four competitors. A representative commission of travellers and photographers was named, consisting of MM. Clouzan, Derogy (optician) Ferrier, Franck de Villecholle, Haincque de St. Senoch, de la Noë (commandant) and Janssens (de l'Institut), with M. Davanne, *ex officio*, as President of the Council.

The competition for a substitute for glass for emulsion and dry processes was postponed, there being only one competitor.

M. Balaguy exhibited two negatives, one being a view in the Forest of Fontainebleau, 14 × 10 inches, and the other a view in Auvergne, 9 × 7 inches, obtained by the collodio-bromide emulsion process. The larger one, sensitised with the usual solution, was excellent. The smaller one, which was sensitised with the same emulsion, but to which had been added a double proportion of alcohol, thus reducing the relative quantity of powdered emulsion, gave a much more sensitive film than the other and more transparent. Both negatives possessed equal effects as respects contrast; but, although the smaller negative was somewhat less vigorous it gave relatively as good a print as the other. There was no blurring even in the most trying parts. A backing of burnt sienna, mixed in dextrine and water, was used (according to the practice of M. Peuch for the last fifteen years), and wiped off with a sponge before commencing the development.

M. Chardon said he was pleased with the experiment, which showed that there was great latitude in the formulæ for emulsions.

M. Gobert observed that that was so much the better, there being a wide margin within which could be produced a very presentable image.

The Chairman laid upon the table a publication by Braun and Co., called *La Lumiere.* He then read the report of the committee on emulsions. [The substance of this was given in a previous communication, at pages 586 and 599 of last year's volume of this Journal.] He (the Chairman) gave the additional recommendation to colour the back of the plates to be exposed for landscapes and interiors with some non-actinic colour, to prevent blurring.

The Society thanked the commission for its labours, and reappointed it to continue its experiments, adding to its number the name of M. Alfred Chardon, in recognition of his talent. This was passed by acclamation.

A vote of thanks was passed to Captains Champenois and Rapatel for taking charge of the experimental boxes which had passed twice under the equator. A special vote of thanks was given to Captain Rapatel, a distinguished photographic amateur, for the exposures given to plates sent out to China by M. Audra, which were brought back to Paris and successfully developed. Thanks were also offered to M. Audra for his great kindness and services rendered to the commission.

M. Gobert (on being called upon by the Chairman) said that in the process of photolithography, which he had the honour to bring before his colleagues, there was nothing new under the head of photography, but there might be something new under the title of lithography, for by his method of working they could replace the lithographic stone by glass—a great advantage, for the present quarries were nearly all worked out, and would be entirely so at no distant period of time, while the materials for making glass were unlimited. Such was still the blissful state of ignorance amongst the mass of lithographic printers of the advantages that already might be secured by the aid of photography that one was really astonished at the slow spread of information; and he had made the otherwise really intelligent and clever lithographic printer attached to the Bank of France "jump out of his skin," when he (M. Gobert) proposed to substitute glass for the lithographic stone, as a support for the photographic image consisting of lines. That, he said, was impossible; and, looking at his (M. Gobert's) face, inquired:—"M. Gobert, are you ill to-day? or have you got your stomach so deranged that your mind is affected?" "Oh! no; not in the least. I was never more serious than at the present moment, as you shall see. I will myself print you a proof from a glass to convince you of the practicability of what I tell you; 'for seeing is believing, is it not?'" He then showed the printer a plate of patent glass about three-sixteenths of an inch thick, which he would call his child, and would caress it as such and wash it. Now, if he put water on the polished side, it would not run evenly, as if the glass were greasy, which was not the case. He would turn over the plate and pour water on the ground side, made rough by acids, and they would observe that the water would flow perfectly even, like collodion; that was, therefore, the side on which to pour a film of albumen, containing three per cent., by weight, of bichromate of potash, the whole being beaten up together and left to repose, then carefully drawn off without bubbles, froth, or residue. A pipette was now charged with the necessary quantity of the clear bichromated albumen, according to the size of the glass plate, and carried across the further top end. By inclining the glass, the albumen was spread with the pipette lengthwise towards the operator, and the excess drained from the nearer corner. The glass, they saw, was sustained in his hand by the aid of an English pneumatic holder, having a hook at its lower end. Now he would turn the glass upside down, and suspend it by the hook of the holder to one of a series of wires hanging from the ceiling of the work room, which would enable him to rotate the glass to secure an even surface of the albumen, and to render the film as thin as possible. They would observe by the increased rotation that he caused the albumen in excess to be projected from the edges of the plate in drops; he also avoided dust by the reversal of the glass, which all albumen workers knew must be avoided. He then detached the glass from the holder, and in the course of a minute or two dried it over a gas-heated metal plate, when it was ready for exposure. The exposure varied with the amount of light, from one to ten minutes in diffused light. The plate he had experimented with had had ten minutes' exposure. That, he said, was enough; the image would be apparent then without any after-exposure or other nonsense. He would now begin to make the "black table," and ink over with common lithographic or transfer ink the whole of the albumenised surface of his "child," and thus thoroughly blacken her face, as they saw, to their great amazement—*ne'st ce pas?* Well! let them pass the inking-roller once more, as it would repay them for the trouble. Now to wash the face of his "darling!" He would place it in a tray of clean cold water for a bath! At the very instant of contact—in the twinkling of an eye—it was clean. Eureka! "By Jove!" exclaimed the lithographic printer, "there's my image already inked! Really I must ask your pardon, M. Gobert; for you neither suffered from illness nor indigestion, as I imagined, and, as you justly said, 'seeing's believing.'" Yes, he might rub it with his finger, but it would not move—the insolubility was too strong for that. He might, without sponging, print off the first proofs, and then in the usual manner print two hundred copies that day and two hundred the next day. He (M. Gobert) said he had not himself printed more than two hundred from one glass, but did not know how many more might be pulled off through the press; for as yet he perceived no loss of sharpness nor softening of the film from water or from wear or tear. So long as they kept off acids or vinegar, which would carry off the inked image and film altogether, he did not yet see any danger. If the first inking should not prove sufficient the image might be strengthened afterwards and copper plates obtained therefrom.

The demonstration, of which the above is a description, was so striking and so successfully performed that it was received by the members with well-merited acclamation. W. Harrison.

Asnières (Seine), Paris.

JOHNSON'S NEW CARBON PATENT.

To the Editors.

Gentlemen,—Having read the letter of Mr. Miller, in your last number, and the article to which he refers, I have no hesitation in saying that my claim to the use of spirit in transferring negatives, made in my recent patent, is an erroneous one, and that I shall take an early opportunity of doing that which the law provides for when such a mistake has occurred.

I am surprised to see in the letter of any respectable man the vulgar imputations made by Mr. Miller. He ought to know that no person can be possibly injured by a patent being taken out for a published process but the patentee himself, who not only thereby records his ignorance of the subject upon which he presumes to teach others, but throws away his money wholly or in part into the bargain. Even a disclaimer cannot be made except at considerable cost.

I am only pleased, as an excuse for my ignorance, that I was in a foreign country, had not the English journals to refer to when I took out the patent, and that my agent here does not appear to have made the usual search.—I am, yours, &c., J. R. Johnson.

January 8, 1878.

FRILLING.

To the Editors.

Gentlemen,—In your number for December 28th is an article on *The Gelatine Emulsion Process*, by Mr. Thomas Chilton, in which he says:—"The frilling of the film has been, and is still, my greatest difficulty, and is one which has been experienced by most gelatine workers; but I am glad to know there are some who say it is a thing of the past." Having experienced the same difficulty myself, allow me to say a few words on the subject.

In the autumn of 1874 I took with me, on a photographic tour into Somersetshire, a few dozen of gelatine plates. The emulsion was from Kennett's dried pellicle. The locality was the town of Dunster, in the neighbourhood of which is some very beautiful scenery. I was in hopes I should have been able to return home with a few good specimens of that scenery; but you may easily imagine my disappointment when, after a journey of some three hundred miles, I was scarcely able to save a single plate, all being more or less puckered or frilled. I was at a loss at the time to know the cause.

In the year 1876 I thought I had discovered the cause of my failure, and, therefore, determined to try again. I had some of the plates left which I had prepared in 1874, and I had also some of the pellicle left, with which I prepared a few more plates. The town of Dunster is supplied with water from the surrounding hills. Now this water is as soft, or nearly so, as rain water. Taking this into consideration I felt convinced that the softness of the water was the cause of my failure. What I had to do, therefore, was to get hard water. Now, although the water from the hills is soft, the water from the wells sunk in the town is hard. I therefore made use of the hard water both for the developing solutions and for soaking and washing the plates. The result was perfectly satisfactory—not the sign of a frill. In washing one of the plates I poured on it by mistake some soft water, and the consequence was that it frilled immediately.

It appears, therefore, that to ensure success hard water must be used, and the harder the better. This will explain why some have succeeded, while others have entirely failed. Those who live in places where the water is hard meet with no difficulty in the development of gelatine plates; while others who have nothing but soft water, or something approaching to it, meet with nothing but disappointment.—I am, yours, &c., George Lawrence Burge.

Barton-on-Humber, January 7, 1878.

To the Editors.

Gentlemen,—Mr. Chilton seems to despair of getting a gelatine film that will not frill; but with some films, I can assure him, "it is a thing of the past."

The last two years I have worked Kennett's gelatine plates, and I have not had one frill or slip. Small blisters come up sometimes, but they go down again on drying.

As an amateur of short standing I have worked these plates with the greatest facility. Of course in my ignorance I have over-exposed and under-exposed.

I have written this to show that there is a remedy for the evils of which Mr. Chilton complains, although I am sorry to say I cannot assist in the matter.—I am, yours, &c., W Adkins.

268, *Oxford-street, London, W., January* 8, 1878.

DOUBLE-COATED CARBON TISSUE.

To the Editors.

Gentlemen,—Whenever any ingenious gentleman who has dabbled a little in pigmented printing wishes to bring his name before your readers the first thing that suggests itself to him is to have a fling at the Autotype Company.

Mr. G. S. Penny does us the honour this week. He informs your readers that he "broached" an idea in March, 1871, this idea being the production of a tissue with two coatings. Now, considering that a sheet of paper can be coated once with gelatine and pigment, it does not seem to us an extraordinary flight of imagination to "broach the idea" of a second coating, or in fact as many more as may be required.

Mr. Penny may have made his wants known to the Company in 1871; however that may be, he certainly has not applied lately for double-coated tissue. He seems to be strangely in ignorance as to what is or has been done. Double-coated tissue has been made for years. Four years ago a frame of *Liber* prints were contributed to the Photographic Exhibition by the Company, *labelled* as being made from double-coated tissue.

In an address upon *Pigmented Tissues*, delivered before the Photographic Society of Great Britain by Mr. J. R. Sawyer, the following remarks occur:—"Far from presenting difficulties, my decided opinion is that in pigmented tissues we have means of modifications and adaptations perfectly unknown to photography before. Not only have we colour—that is to say, the power of using almost any pigment that may be desired—but we have the means of combining pigments, and of getting effects that are impossible in any other way. Take, for instance, Turner's *Liber*. It is well known that the deepest portions of these are absolutely dug out of the plate with all the vigour of a master's hand. In the impressions—partly, no doubt, from the skill of the printer, but mainly from the boldness of these lines and touches—they appear almost black upon the sepia ground of the picture. An ordinary photograph would be totally inadequate to represent these—it would make the picture all one tint; but a judicious method of combining colour in the tissues, giving a coat of a suitable dark colour, then upon that imposing a layer of picture colour, enables us to render these dark touches with a fidelity rivalling the best original. The same principle holds good in many other cases. Given, for instance, landscapes: is it possible, I will not say to produce natural colours, but to produce a harmonious and artistically-tinted photograph simply by the superposition of colours over each other." Double-coated tissues are not, therefore, the novelty supposed, and if they have not been supplied as articles of ordinary commerce it is simply because there has been no demand for them. As a rule, our clients find the difficulties of single-coated tissue sufficient for them.

But to have a *proper* fling at the Autotype Company it is always necessary to write in an offensive style; so Mr. Penny talks about our "dog-in-the-manger" policy. Mr. Penny is not, perhaps, aware that we have no monopoly in tissue making—that we granted months since to Messrs. Marion and Co. full right to manufacture tissue quite independently of ourselves, and duly advertised this fact in the journals of July, 1877. Mr. Penny will note that we ourselves provided the very competition he so much desires. He avers that we "will not," and other makers "*cannot*," advance; but if they are *makers* at all why cannot they advance? If they make tissue at all, why cannot they coat it twice as well as once? This reasoning is unintelligible to us. And to what does Mr. Penny's letter amount?

In 1871 he "broached an idea"—that his suggested improvement has been lying dormant, and that the Company pursues a "dog-in-the-manger-like policy." We reply: double-coated tissue was known long before his idea was broached; that it has been made and used extensively for certain work; that had it been demanded by any of our licensees it would have been supplied; and that when Mr. Penny runs into offensive phrases he draws on his imagination for his facts.

In concluding permit us an allusion to a letter in the same number o your Journal from Mr. W. S. Miller, who imagines that we had some hand in the "concocting" of Mr. J. R. Johnson's new patent. We have only to say that we have no interest in Mr. Johnson's patent; that our first acquaintance with it was through the printed specification; and that the ingenious and experienced gentleman referred to needs no assistance in the "concoction" of a patent from—Yours, &c.,

January 8, 1878. The Autotype Company.

Obituary.—The death is announced at Dornach, Alsace, of M. Adolphe Braun, the head of the celebrated photographic establishment which first applied photography to the reproduction on a large scale of the masterpieces of Michael Angelo and Raphael.

EXCHANGE COLUMN.

No charge is made for inserting these announcements; but in no case do we insert any article merely *offered for sale*, that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a *nom de plume* be thought desirable), otherwise the notice will not appear.

About five dozen lantern slides will be exchanged for anything useful in photography.—Address, N. MAY, 16, Chestnut-walk, Worcester.

I will exchange a Harrison's head-rest for albumenised paper or chloride of gold.—Address, S. ARLIDGE, photographer, Northampton.

Wanted to exchange, three dozen coloured lantern slides—Scripture subjects by Carpenter and Wesley—for anything useful in photography.—Address, F. SHAW, Willowby-street, New Lenton, Nottingham.

Wanted to exchange, a $3\frac{1}{4} \times 4\frac{1}{4}$ bellows-body, rising-front, and folding tail-board camera, with three double backs, new, for a wide-angle lens.—Address, J. SCHOFIELD, Heaton Mersey, near Manchester.

A quarter-plate camera and lens, glass bath, tripod stand, and frame for dark tent will be given in exchange for a watch or magic lantern and slides.—Address, R. W. YOUNG, 3, Stoke Hills, Ipswich, Suffolk.

Wanted, in exchange for a large cylinder electrical machine, cylinder about 15×10 inches, and a stereoscopic camera with lens, changing-box, &c., a water-tight bath, or anything useful in photography. — Address, F. CROSLAND, 55, Bold-street, Liverpool.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

NOTICE.—Each correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a *nom de plume* as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

REGISTRATIONS.—In our next.

LUX.—Try the proportions of six ounces of hyposulphite of soda to a pint of water.

H. G. BOX.—Thanks for the cutting, but we have already taken notice of the photographic feat therein recorded.

A THEORISER.—We must refer you back to page 579 of our last volume (December 7, 1877), where you will find a detailed account of the trinoptric lantern of Canon Beechey.

A PHOTOGRAPHER (Manchester).—We regret to find photographers resorting to such practices, but sooner or later they must recoil upon the heads of those who indulge in them.

S. G. F.—Of the various lenses in your list that marked A will prove most useful, inasmuch as it possesses all the properties of the others, together with other features peculiarly its own.

R. S. P.—From your description it appears probable that too great a proportion of carbolic acid has been added to the gelatine solution. Bear in mind that *very* little suffices to prevent decomposition.

BETA.—Your letter having been wrongly addressed has only been delivered by accident. The only advice we can offer is to precipitate the gold from the solution by means of protosulphate of iron.

R. O. P. (Dalston).—The red discolouration on the plate is owing to the presence of nitrate of silver in the film. The preventive consists in giving the plate a *thorough* washing before applying the tannin.

T. O. G.—Try the following to prevent the film from splitting after drying:—As soon as the negative has been fixed and washed pour over it a little weak gum water, after which dry and varnish. Diluted albumen may be employed instead of gum water.

OBLIGED READER.—You may prepare the varnish by dissolving twelve ounces of sandarac in a quart of strong methylated spirits of wine. Place in this about a quarter of an ounce of camphor and a quantity (say half a pound) of coarsely-crushed glass.

LIVERPOOL.—No special strength of chloride of copper is necessary for intensification; let it be such as to produce the required effect in half-a-minute. This will whiten the image, which must then be well washed, and afterwards flooded with the ordinary alkaline developer.

T. F. F.—Your letter was duly received, but up to the time of going to press we have not received the photograph, nor, indeed, have we heard of it. Possibly you may have omitted sending it, but until it is received we cannot offer any opinion as to the nature or cause of the defects to which you allude.

ALFRED S.—When we first saw your prints we concluded that water had been used in which were suspended particles of dirt; but upon subjecting the specks to microscopic examination we have dismissed this idea. It is possible that the employment of a different sample of collodion for facing the prints would give a better result, especially if it had a better and tougher body. Are you certain that the plates were made thoroughly clean previous to applying the collodion?

GEO. SMITH.—Yes; the preparation of plates in the light is far from being the impossible thing you imagine. Try the following:—After collodionising and sensitising remove the plates from the bath in daylight, give them a thorough washing, and then place them aside to dry. Then, in a dark room, immerse them in a solution of tannin for a few minutes and dry them. They will be found to answer as well as if the whole preparation had been conducted in a dark room.

DR. MANTELL.—The preservative may be applied either by immersion in a bath or by pouring a little on at one edge and allowing it to flow over the surface. The plate thus treated may be dried, either spontaneously or by heat. The development may be conducted by either the alkaline or acid pyro. process. For lantern transparencies the latter seems the better method. Previous to the application of the developer rinse the surface of the plate with water.

J. WILLIAMS.—It is of no use to attempt taking landscapes, or any other kind of photographs, with the back lens of a portrait combination; for under no circumstances whatever would you succeed in obtaining presentable pictures by such means. The *front* lens of the combination will, however, answer the purpose quite well if placed flat side to the scene with a diaphragm a little distance outside of it. What we have said respecting the non-suitability of the back lens must be held to apply to portrait lenses of the original Petzval form.

J. E. G.—A few days ago we saw at Mr. Solomon's, Red Lion-square, a kind of transparent muslin that would prove to be the very thing you want. It differs from the ordinary non-actinic muslin, formerly manufactured by Mr. Solomon, in being of a deep ruby-orange colour. A piece about a foot square would admit sufficient light to enable you to operate with ease in such good light as you will have in India. In reply to your last query: the quantity of light admitted is of no consequence so long as it is non-actinic. The idea of the developing sink with a glass bottom and a reflector placed underneath is excellent.

PHOTO-CHEMICUS.—We recollect, several years ago, placing upon record the results of an experiment somewhat analagous to yours. Some iodide of silver having been wanted, it was prepared by means of iodide of potassium and nitrate of silver; the precipitate was then well washed with several changes of distilled water, and allowed to settle. The bottle containing the iodide of silver having been placed in the light, the supernatant water, in the course of a few hours, became of a brown colour, evidently from the liberation of iodine; but this became absorbed upon allowing the bottle to stand in the dark for a short time.

M. H.—The method we advise for placing the diaphragm is to remove it the greatest possible distance from the lens of which the mounting will admit; then try the effect in the camera, using the *smallest* stop. What we here mean by "effect" is this:—See if the ground glass is so equally illuminated that a plate of the dimensions you purpose using is thoroughly illuminated from corner to corner. If the corners be dark owing to the area of illumination being circumscribed, push in the stop towards the lens until that area is extended so as to illuminate the plate. As a rule, the greater the distance at which the diaphragm is placed from the lens the flatter will be the field of definition when using a large stop. This rule would not apply in the case of a very deep meniscus, but it will, we believe, in that of your lens.

RECEIVED.—W. Washam and J. Schofield. In our next.

CONTENTS.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 924. Vol. XXV.—JANUARY 18, 1878.

THE ACTION OF CERTAIN BROMIDES AND CHLORIDES ON EMULSIONS.

In pursuing this subject we have now to consider a different action of the haloid salts, or more correctly, perhaps, a similar action exercised in the removal of a different class of fog. In our experiments last week the emulsion was fogged by the protracted action of free silver, and we have now to speak of one in which the same effect is produced by means of light. In the corresponding experiments made some months ago we carried the fogging to such a point, by several hours' exposure to strong light, that it became a difficult matter to restore the working properties of the emulsion. In our present experiments we exposed the emulsion to diffused light with continual shaking until, upon trial, it gave only a slight trace of an image upon development. To those of our readers who may not have tried the experiment, it will be a matter of surprise the length of time an emulsion must be exposed to light before it shows any distinctly-marked traces of fog; in the case in question between four and five hours were required, the emulsion standing exposed upon the table in a well-lighted room and about two yards distant from the window.

It is needless to recapitulate the results of the whole course of experiments; it will suffice to say that the bromides and chlorides of copper and zinc acted most vigorously in clearing away the fog, the end being attained in less than an hour. Bromide of cadmium and the chlorides of cobalt and gold required between two and a-half and five hours, bromide of potassium about seven, and bromide of ammonium longer still. In the last case, it may be remarked, the emulsion did not regain its working properties very much more rapidly than if it had been left to itself; twenty-four hours after sunning a portion which had been stored away in the dark had become spontaneously almost free from fog. The emulsion employed was a washed one, but after "sunning" and treatment with bromide or chloride the films were washed to remove the soluble haloid, and dried without preservative.

Whatever may be the reactions which occur in the formation of the invisible image by exposure to light on the one hand, and the production of fog by excess of silver nitrate in the emulsion on the other, the ultimate effect, so far as the experiments of Captain Abney and others have gone, appears to be practically identical in each case. It is generally assumed that the change which occurs under the action of light depends upon the formation of a certain quantity of sub-bromide of silver by the liberation of a corresponding equivalent of bromine; and this theory sufficiently agrees with known facts to warrant us in accepting it as the correct one. When, however, we come to apply it to production of fog in an unexposed emulsion we meet with difficulties which are not at first sight explainable. Thus, if we assume the fog to arise from the formation of sub-bromide of silver by absorption of a portion of the metal of the free nitrate, we must have a corresponding liberation of nitric acid from that portion of the nitrate whose metal is absorbed. But nitric acid is one of the substances capable of preventing or retarding fog by its action on the sub-bromide of silver; why, then, should an emulsion containing sufficient nitric acid to decompose any sub-bromide which may be formed still exhibit fogging propensities? We shall attempt to explain.

First, we will suppose the case of an unwashed emulsion containing pure bromide of silver and free nitrate, and which has attained the fogging stage, presumably from the formation of silver sub-bromide. We will formulate it thus—

$$\underset{\text{2 eq. Silver Bromide + 1 eq. Silver Nitrate.}}{\overset{\text{Original emulsion.}}{2\ Ag\,Br + Ag\,NO_3}} = \underset{\text{1 eq. Silver Bromide + 1 eq. Silver Sub-bromide + 1 eq. Nitric Acid.}}{\overset{\text{Emulsion in fogging state.}}{Ag\,Br + Ag_2\,Br + NO_3}}$$

That is to say, the metal of the nitrate combines with an equivalent of the bromide and forms sub-bromide, setting at liberty the equivalent of nitric acid.

If we now add any of the usual salts employed in correcting foggy emulsions the action is tolerably plain. Let us take for example cupric bromide. The latter salt parts with half its bromine, which goes to the silver sub-bromide, reconverting a portion of it to the state of bromide; the copper salt does not, however, remain in the state of sub-haloid, for it is attacked by the free nitric acid and converted into nitrate, its halogen being liberated. This, then, combines with the remainder of the silver sub-bromide thus:—

$$\underset{\text{1 eq. Silver Bromide.}}{Ag\,Br} + \underset{\text{1 eq. Silver Sub-bromide.}}{Ag_2\,Br} + \underset{\text{1 eq. Nitric Acid.}}{NO_3} + \underset{\text{One-half eq. Cupric Bromide.}}{\frac{Cu\,Br_2}{2}}$$

$$= \underset{\text{2 eq. Silver Bromide.}}{2\ Ag\,Br} + \underset{\text{One-half eq. Silver Sub-bromide.}}{\frac{Ag_2\,Br}{2}} + \underset{\text{1 eq. Nitric Acid.}}{NO_3} + \underset{\text{One-half eq. Copper Sub-bromide.}}{\frac{Cu\,Br.}{2}}$$

Then, the free nitric acid reacting upon the copper sub-bromide, the formula is rearranged thus:—

$$= \underset{\text{3 eq. Silver Bromide.}}{3\ Ag\,Br} + \underset{\text{One-half eq. Cupric Nitrate.}}{\frac{Cu\ 2\ (NO_3}{2}}$$

The emulsion after correction thus contains only silver bromide and nitrate of copper. If a chloride be used for the purpose of clearing the emulsion the only difference would be the replacement of one equivalent of silver bromide in the above formula by one of silver chloride.

We may now consider the action of nitric acid, which, according to Captain Abney's experiments, is one of the products capable of destroying the image formed upon the sensitive film by the action of light. If, as it has been assumed, the effect of light and the action of free nitrate on the production of fog are identical forces, it might be reasonably calculated that nitric acid would prove effective in eliminating the latter; but such is not found to be the case. Free nitric acid—that is to say, nitric acid added to the emulsion over and above the quantity it may contain in the shape of silver nitrate—is capable of preventing fog in the presence of excess of silver for a considerable time, though not indefinitely; but its addition to an emulsion which has already reached the fogging stage is insufficient to clear it, except with the assistance of a soluble haloid. This would point to considerable difference between fog and exposure to light, yet we must not lose sight of the widely-different condition which exists between a thin dried film of sensitive material and a mass of the same in the state of emulsion; and it is very possible that extraneous circumstances intervene in the case of an emulsion to prevent the occurrence of a reaction which proves entirely successful with an exposed plate.

In attempting to trace the action of nitric acid in this direction we seem to be irresistibly driven to adopt Major Russell's opinion, published many years ago, that bromide of silver, except in the presence of a trace of soluble haloid, is photographically useless. It would appear that, in sensitising a bromised film or emulsion, as soon as the soluble haloid is fully converted the further action of silver nitrate tends to the formation of a compound (call it "sub-bromide" or what you will) of silver, which produces the effect of fogging, and that the function of nitric acid is merely to retard the formation of this substance; but when once formed it is powerless, *per se*, to reconvert it or to prevent fog upon development.

So far we have spoken of an unwashed emulsion containing free nitrate; but, if we change the conditions, a little clearer light is thrown upon the action of nitric acid. Let us take the case of a "washed" emulsion—washed or precipitated while in the foggy stage. We have then to deal with the bromide and sub-bromide of silver alone. The emulsion in this state is restored to working condition by certain salts (as bromide of copper) which are capable of acting directly upon the fogging material, whatever it may be; but others, such as bromide of ammonium, which do not possess the power of direct action, fail to produce any change. Nitric acid, acting upon the sub-bromide, may be supposed to abstract a portion of the silver, converting it into bromide and nitrate of the metal without removing the fog. If, however, one of the inert haloids (ammonium bromide or chloride, for instance) be present, the nitrate is at once converted into bromide or chloride and the emulsion brought into working condition.

In point of fact, nitric acid appears to act merely as a go-between; it is incapable in itself of forming any combination which will remove the fog, but it places the partially-reduced material *en rapport* with other substances which are also, *per se*, incapable of such action. This view may, we think, be extended to its action in removing or destroying the undeveloped image. Captain Abney's theory on the subject of this destruction is that it is due to oxidation, and from the experiments brought forward in its support we cannot doubt that oxidising influences do exercise a destructive action; still we are not prepared to accept that as the sole cause, or even as the actual one, under ordinary circumstances. In the case of the emulsion fogged by exposure to light, we can well understand how the atoms of the decomposed bromide rearrange themselves with omparative rapidity, the circumstances being eminently favourable to recombination. Nor is it difficult to imagine that when the change takes place in a dried film the dissociated atoms may remain for a very considerable time locked in the film but chemically separated, and incapable, from adverse conditions, of recombination. If we treat a film in this state with nitric acid the latter, we may suppose, acts upon the sub-bromide, and liberates the extra atom of silver, which at once recombine with the loose atom of bromine. It would be interesting to note the effect of the presence of moisture in destroying the image, all other influences being as far as possible removed. Obviously, if the theory of simple recombination of the elements be correct, the mere presence of moisture, which would favour combination, should hasten the disappearance or destruction of the developable image.

The practical conclusions we have arrived at, after a careful study of the facts connected with this subject, are—that fog, from whatever cause arising, is invariably capable of removal by suitable treatment; that, while certain of the haloid salts possess the power of acting directly upon the fogging material, others do not, but that in the presence of nitric and, probably, other acids the inert salts become active, hence the importance of an acid in the emulsion during sensitising; finally (and we speak with a due regard for the opinions of others), that free silver in emulsion—that is, a *real* excess after the total conversion of the soluble haloid—is a practical impossibility.

THE PHOTOGRAPHIC USES OF COAL GAS.

There are many practical applications of the heating and illuminating powers of coal gas to photographic use which might be extended considerably with advantage, and the apparatus in connection therewith greatly improved. At some future period it is our intention to enter fully into the subject of the possibilities of coal gas in the direction of heating rooms, but at present we merely allude to it. For some time past it has been seen that a first-rate and economical stove was a desideratum, and numerous have been the efforts to supply it, some of the later apparatus having special advantages and peculiar contrivances to increase the benefits derived from the heating; but we do not think we shall be contradicted when we state that a perfect stove is not yet made, and that a nearer approach to it than any hitherto brought before the public will yet be produced. At the same time there are already some most useful ones to be had, and under many conditions they are, for not over-large rooms, effective.

At the outset we must call attention to a very serious drawback to the use of gas in most towns. It is the great inefficiency of pressure in the day time—just that portion of the twenty-four hours in which we require its aid. This is brought about from motives of economy on the part of the gas companies. There is so small an amount of gas burnt that its profits do not cover that loss by leakage from the mains which occurs in the best-regulated gas works; and is a very serious item, reaching from five to twenty (and sometimes more) per cent. upon the total amount supplied to consumers; and this leakage increases in proportion to the pressure. The excuse usually offered by the company is that if the day pressure equalled the night the pressure upon every individual burner in use would be so great that complaints would be made of flaring and ultimately of too large a gas bill. To a certain extent this is right; but the opposite extreme is reached, and from the cause named, with the consequence of leaving our furnaces, our Bunsen's burners, even our gas lights where required, with a most insufficient supply.

This is a fertile source of disappointment in the use of the gas furnaces, now to be had so cheaply, for melting, reducing, enamelling, &c. One of them is bought, put into position, gas turned on and lighted in the proper way, and left for a while to grow hot. We return to it to find either the light blown down or the heat utterly inefficient, and are usually inclined to blame the furnace, if not return it upon the maker's hands. We have seen very many instances of this kind. We know at the present time a provincial laboratory of importance where the proprietor informs us he can never have more than two or three Bunsens burning at once, owing to the low pressure, notwithstanding his repeated complaints to the gas company's officials.

Again, too, in comparing results with these and other furnaces and burners, a considerable allowance has to be made for differences in the composition of the gas, some varieties (witness Scotch gases) being so much richer in carbon than others—a difference which tells strongly when questions of illuminating power are under considera-tion.

While dwelling upon furnaces we must not omit to mention another point often lost sight of—the larger the furnace or the greater the amount of consumption of gas required to keep it going the larger must be the supply pipe from the meter, as, if that be too small, no amount of day or night pressure of the usual description will suffice to keep the furnace properly alight. The india-rubber tubing used for connecting the furnace or burner to the supply pipe must be of good quality, thick, and without the usual spiral wire support running through it. If too thin the gas will find its way through and contaminate the air; and the same effect will be produced if the quality of the rubber be not good.

In the Bunsen burners, as usually sold, there is room for improvement. We recommend none to be used but those with the late J. J. Griffin's improvement in it. The air-holes in the base are covered by a ring of metal, having apertures to correspond; this arrangement enables the amount of air supplied to the burner to be regulated with the utmost nicety by turning round the ring and so covering more or less the base apertures. When the supply of air is much too great—or, in other words, the pressure of gas not strong enough—the flame will run down the tube and ignite at the gas jet inside, producing a flame all soot, and useless for any purpose. When the air is still in excess, but not to so great an extent, the gas burns with a penetrating, disagreeable odour most offensive to everyone in its vicinity. A perfect Bunsen flame should have a small, scarcely visible, white tip.

Attention has often been called to the usefulness of a wax match in developing, one being struck and then held under the negative undergoing development to warm any part deemed too weak or under-exposed. A very efficient substitute is a small jet on a foot attached by a thin india-rubber tube to a gas standard or supply-pipe.

There are some photographers who use a gas flame in the dark room in preference to daylight for developing and intensifying; and there is very much to be said in favour of the plan, as, comparatively speaking, the flame would be constant and uniform, and have a tendency to lead to the production of greater uniformity in the intensity of the negatives. Experienced operators well know the difficulty of judging with exactitude the right moment for arresting the action of the developer when their light has that fluctuating character so common to our climate. When gas is used special care must be taken to prevent the vapour of ether coming too near, or an explosion would soon result. True the vapour of ether is heavier than air, and has a tendency to fall; but beyond the action of specific gravity there is that power of diffusion which carries the heaviest vapours, if present in sufficient quantity, in all directions—upwards as well as downwards. Where the cost of suitable globes would stand in the way, we can suggest a very inexpensive mode of converting an ordinary glass shade into an "adiactinic" one. Let a small quantity of the *best* quality of Brunswick black be obtained from the drysalter and one or two coats laid on the globe. The result will be an excellent screen, through which no light will pass to injure the most sensitive emulsion or wet plate. The same liquid is an excellent material with which to coat the glass for dark room windows; it is cheap, efficient, and durable.

We had purposed making some remarks on recent inventions for producing powerful illumination by the aid of gas. They must now be left for future treatment.

By the kindness of Mr. W. S. Ashley Oakes we have been enabled to renew our acquaintance with some of the finest productions of the late Mr. Chas. Breese, who stood alone in his particular branch of photography. Mr. Oakes, who is an enthusiast in photography, has set himself the task of reviving the rapidly-waning interest in stereoscopic pictures, in which attempt he has our cordial good wishes for his success. In another column will be found the first of a series of articles in which he proposes to make public the hitherto "secret" methods, processes, and formulæ used by the late Mr. Breese in the production of his unequalled transparencies, and which Mr. Oakes purchased, together with the negatives, shortly before that gentleman's decease. Certainly, if any thing is calculated to once more bring into favour the now neglected stereoscope, it is the popularisation, if we may so term it, of a branch of our art hitherto undeveloped; and we greatly misjudge our amateur friends if a large section of them do not avail themselves of the information which Mr. Oakes generously proposes to place at their disposal. It is needless for us to enlarge upon the beauties of glass pictures or their immeasurable superiority over paper prints; but it is only in carefully studying a collection such as that presented to our notice by Mr. Oakes, that we are able to fully realise their value in connection with the stereoscope in rendering effects not otherwise attainable by any means. Be it ever so perfect, from a technical point of view, a photograph when examined without the aid of the stereoscope fails to convey a natural impression of the objects depicted; not alone from the absence of colour—for the same may be said of the majority of paintings—but from the impossibility of adequately representing "texture." Taking, for instance, a photograph of a lady in a robe of white silk or satin, who can say, from the majority of photographs, that her robe is not of homely linen? Or who, except by its surroundings, could distinguish an expanse of smooth water from the asphalte floor of a "skating rink?" In Breese's slides, as viewed in the stereoscope, the rendering of texture is perfect; the transparent brilliance of glass, the metallic glitter of polished silver, and the dead whiteness of Parian, are reproduced with a truth which no tricks of colour could equal, much less excel; whilst other substances lack but the suggestion of colour to render them perfect. In the department of combination printing, and in the production of atmospheric effects, Mr. Oakes has much to relate which will be new to most of our readers; and we can only repeat our hope that he may succeed in infusing new life into the practice of stereoscopic photography.

EMULSION EXPERIMENTS.

I HAVE read your leader on the subject which is akin to that on which I have been working lately, and am much interested in the results you have obtained; more particularly when I see that your results with the ammonium bromide and chloride coincide so exactly with what I should have theoretically expected, and that they also agree with my own experience.

In reference to your experiments, I wish to call your attention to a phenomenon that will result from the employment of nitric acid in the emulsion. Supposing we are preparing emulsion from zinc bromide and from copper bromide, we may have two effects produced. The zinc bromide is generally contaminated with zinc oxide, whilst the copper bromide, being very unstable, is almost always associated with copper sub-bromide (cuprous bromide). So unstable is the copper bromide, in fact, that I very much question whether a solution of it in alcohol will not specially decompose, forming bromal and the sub-bromide.

In some recent experiments I have had this reaction unpleasantly brought home to me, when boiling an alcoholic solution for a short time. Relying on Mr. Warnerke's experiments I anticipated that the bromal would give a precipitate when treated with silver nitrate; but, much to my astonishment, it did not do so. When the bromal was destroyed by nitric acid, in the presence of silver nitrate, a precipitate was at once obtained. From what I have seen lately, and from experiments I made some time back, the results of which were embodied in a paper on the albumen emulsion, I am convinced that there is an appreciable time elapsing before alcohol, when treated with bromine, is converted into bromal; and this coincides with your experiments.

Now, with regard to the emulsion made with the zinc and the copper bromide, the effect of the nitric acid would be somewhat different. In the one case we should have the formation of zinc nitrate and water; in the other we should have copper nitrate, water, and nitric oxide formed. *Nitric oxide destroys fog* as well as the other bodies I have experimented with; in fact, better than nitric acid. It will thus be apparent that, with such metallic compounds as those of copper, the elimination of fog may take place, perhaps, more easily than with those, such as zinc, which are dissolved with merely an evolution of hydrogen.

It has been asserted that nitric acid will destroy the image on iodide of silver; and it has been a difficulty to me to understand how I got results which differed from what other workers obtained. I find that the image has only been proved to be destroyed when strong nitric acid was employed, and when its application was of long duration. The reason of the destruction of the image in this case is now clear; for the nitric acid will act upon the organic matter in the film, and produce this very nitric oxide which I have shown can destroy it.

Apparently there are many agents which have the same destructive effect, and some of them may be worth following up. Let me say that it seems to me that the best way to destroy fog though exposure to light on a bromide plate is to treat it with a dilute solution of potassium bichromate or potassium permanganate. It is a safe way, and certainly does not affect the sensitiveness of the film. Take two grains to the ounce of the former salt, or half-a-grain of the latter, and immerse an exposed bromide plate in it for a couple of minutes, and wash. When dry it will be found to be ready for exposure in the camera, and to develope without any trace of fog. For a bromo-iodide plate a little chromic oxide may be substituted for the bichromate. I think the addition of the manganese salt to an emulsion will be found to be efficacious; in fact, the changes may be rung with these compounds pretty much as one likes.

W. de W. Abney, F.R.S.,
Capt. R.E.

[Since our leading article was written we have received the above communication, our remarks upon which we must hold over till next week.—Eds.]

ON THE PRODUCTION OF ENLARGED PHOTOGRAPHS OF MICROSCOPIC OBJECTS.

[A communication to the Photographic Society of Great Britain.]

The photograph of the *Proboscis of the Blowfly*, which is now before you, has the dimensions of 30 inches × 24 inches, and is, I believe, the largest microphotograph which has yet been produced. The difficulty of photographing this object is, doubtless, well enough known to several present.

First let me direct your attention to the fact that the photograph shows the object entire, as it appears when viewed under a power magnifying 200 diameters; or, rather, I should say, it is absolutely 40,000 times larger than the object is in reality, as may readily be shown by a pair of compasses and a rule. And, moreover, that the whole of the proboscis is under the eye, on a scale large enough to show all the details fairly well; but with a magnifying power of 200 diameters the whole of the proboscis cannot be seen at once in the microscope, for this power requires a quarter-inch objective—a lens with a limited field of view.

Wishing, however, to obtain a photograph showing the entire proboscis, and not a portion of it, I selected a microscopic object-glass whose angular aperture was sufficient to comprise the whole of the object within its field, and attempted to secure the enlargement direct by removing the sensitive plate to a great distance from the lens. Theoretically this should give all the amplification required; but in practice there was not only the difficulty of deficient illumination to contend with, but a limit was soon reached beyond which sufficiently sharp definition could not be obtained. The result of "straining" a lens is familiar to most photographers, and needs no further explanation. I may mention that in practice I have found eight feet to be the greatest possible distance which can intervene between the microscopic object and the sensitive plate, but it is much better not to exceed three or four feet.

But the image at that distance, where the definition began to break down, was far from being large enough for my desires; so I endeavoured to get rid of the difficulty by using an amplifying lens—analogous to an eyepiece. This gave all the magnifying power wanted, but, comparatively, the enlarged image was a mere blur. I was, therefore, under the necessity of reverting to the plan of making a small perfect negative, and afterwards enlarging it as much as the sharpness of the photograph would allow. The results are now before you.

By means of a $\frac{2}{3}$ O.G. a negative was taken on a quarter plate; this to the eye appeared beautifully sharp, and was an enlargement of twenty diameters.

A four inch O.G. (power about twelve diameters) was now screwed into the microscope, and a negative placed on the stage; as it was to be enlarged ten diameters it was necessary that it should bear this power. At a glance, however, it was seen that the sharpness was "nowhere," and that in spite of all the pains taken the negative was very much out of focus.

It was not until after many trials that a sufficiently sharp negative was obtained; but at length success crowned my efforts. Close examination will show that the large picture is not absolutely sharp; this is due not to any want of definition in the small negative, but to a cause which will be presently explained.

The enlargement was made by means of a solar camera fitted with a condensing lens of twenty inches diameter, and, therefore, commanding an immense power of light. As specimens of this method of enlargement these prints—absolutely untouched in every respect—will have an interest to photographers over and above that which may attach to them from a microscopical point of view.

Time will not allow me to describe the apparatus any further than to say that the sun's rays are made to fall continuously upon the condenser by means of a heliostat, which consists essentially of a mirror mounted on a polar axis in a manner similar to an equatorial telescope. As in the latter instrument clockwork keeps a star constantly in the centre of the field of view, so in the former clockwork serves to make the mirror turn from east to west with a velocity equal to the rate of the earth's rotation. By this means the negative is kept constantly illuminated by the condensed sunlight. The slight want of sharpness alluded to as existing in the print was due to a little irregularity in the motion of the clock—a defect which has now been completely rectified.

Should sufficient interest be felt in this subject I shall be happy, on a future occasion, to give a detailed description of the automatic solar camera, as well as an account of my working with it. At present I can only say that a piece of carbon tissue was pinned up to the focussing board, and, after an exposure of about half-an-hour, was developed and finished in the usual way.

As a matter of course the enlargement can be made by any other method which is found to give good results, though I do not imagine that as good a result is likely to be got by making an intermediate transparency. The solar camera method has the advantage of being a direct enlargement. Most now present know that while it is easy to make on glass a large satisfactory transparency from a small negative, it is most difficult to produce a correspondingly successful enlarged negative. This, however, by the way.

We come now to the important question of illumination. Except for the smallest degree of amplification I have not been successful with anything but sunlight. This is a matter of great regret, because microphotography is just such an occupation as one would like to follow on winter days, or evenings, when there is most spare time on hand.

Paradoxical as it may sound, better enlargements can be made of objects from an inch in diameter down to half-an-inch without a microscope at all than with one. Nothing more is needed than a good magic lantern, preferably fitted with lime or electric light. Care must be taken that the condensers are good ones. For the amplifying lens a small portrait combination, stereoscopic size or smaller, will answer best. It must be a lens giving a flat field, and must have no central stops. The microscopic slide, fitted into a frame, is pushed into the lantern in the ordinary way, the light adjusted as usual, particular care being taken to obtain a perfectly equally-illuminated disc. The focussing will require the closest attention, and is better done on a piece of cardboard than on the ground glass of the camera. Objects must be chosen that are moderately transparent and not of a non-actinic colour, as most entomological preparations are. If there is much opacity the concentrated lime light will not be found sufficiently powerful. With properly-selected specimens the exposures will be very short. Some otherwise intractable subjects can be managed by masking portions during the exposure. But when we come to really minute objects, and comparatively high powers are needed, the sun alone can produce a successful negative. In most cases the exposures are very rapid.

To use sunlight to advantage, a dark room, with one side exposed to the south, fitted with an adjustable mirror or a heliostat is requisite. The operator then sits, as it were, within his camera, and has all things immediately and easily under control. A condenser is necessary, and nothing answers the purpose better than the front lens of a portrait combination; the larger it is the better. Supposing now that we have a beam of sunlight entering the darkened room, and condensed by means of the lens above mentioned. If we place a sheet of white paper in a suitable position, and cause a microscopic object-glass to slide to and fro in the cone of light, we shall find that there is just one point, and only one, where we have a perfectly-illuminated disc of white light. This, then, is the position the lens ought to occupy in relation to the condenser. The microscopic slide must now be placed in the cone of rays at just the focal length of the enlarging lens. If too much light surrounds the object a higher power must be used; if, on the other hand, the whole of the object is not illuminated then recourse must be had to a lower power. From this it will be seen that the solar microscope—for, in effect, any apparatus for producing microphotographs is nothing more—requires to be managed in a manner different from that which the ordinary table microscope requires. With the latter the slide is placed on the immovable stage and the objective moved nearer or farther till vision is distinct. In the latter it is the object-glass which is fixed in its proper position and the stage made to move. Between the condenser and the amplifier there is a certain relation which must always be observed; there is no better way of discovering it than by moving the amplifier to and fro along the optical axis of the condensing lens.

As a rule little trouble will be found arising from the heat of the concentrated solar rays. Of course, if an object remained long near the burning point of the condenser it would be damaged, but during focussing it is more agreeable to diminish the light by slipping an annular diaphragm over the condenser; sufficient light will be left for focussing by, without any fear of damage by heat. During the brief period of exposure it is necessary to avail oneself of the full power of the light.

The importance of using a condensing lens of the kind described cannot be over-estimated. Strange to say, the use of it completely gets rid of diffraction, while the exposures are reduced amazingly, thus rendering it easy to photograph animalculæ in motion. To avoid diffraction some writers have recommended the interposition of a piece of ground glass; this does not answer so well as the condenser, and has, moreover, the effect of immensely increasing the time requisite for the exposure. It also exercises a detrimental effect upon the definition.

I am now engaged in fitting up a dark room for microscopic photography and like uses. I shall be happy to furnish full particulars of it if desired.

The negatives from which the present enlargements were produced were made by sunlight. A brass bar, with a rack on the top of it, carries various brass holders; one of these contains the condensing apparatus, the other is a stage, and another is the holder for the object-glass. A connection is made from this last to a 5×4 camera, by means of a cone of leather bellows; the entire apparatus rests in a mahogany box composed of the bottom and one side only. This box is screwed on to the bar of an equatorial stand, where the telescope is generally. The object of this arrangement is that one movement of the Hooke's joint keeps the condenser pointed to the sun. The exposures were practically instantaneous, and while they were made of course the handle was not turned. By this means reflection from mirrors is done away with, which is an advantage.

A good magic lantern is valuable for the exhibition of microphotographs; but instead of making the negative by the ordinary wet process, use a bromide emulsion instead. After development pour over the plate strong nitric acid; a transparency, instead of a negative, is then produced, and as this is done at one operation there is a manifest superiority in point of sharpness over those which are produced by printing from a negative, as is generally done. Full working details of the production of these transparencies will be found in an article which I contributed to the *Year Book* for 1877.

Considering the importance of recording what is seen by the aid of the microscope, and bearing in mind the facility with which the generality of objects can be photographed, it seems a matter of surprise and regret that there are so few workers in this field. It is an easy matter to adapt a camera to a microscope, and plates can be purchased all ready for exposure, leaving nothing but the development and fixing to be attended to. Under these circumstances a great number of microphotographs ought to be produced; for though as representations of what is actually seen there may be some shortcomings, yet they are better than nothing, while the drawing of microscopic objects on paper is a proceeding so difficult and so tedious that we must not expect many observers to produce them, and then, if ever so perfectly finished, they could not compete in fidelity and usefulness with even a tolerable photograph which would be produced with a thousandth part of the labour.

With regard to the production of the negatives themselves, I have only to say that they were made upon selected glass—flat, thin, and absolutely free from specks, blisters, and scratches—coated with a collodion giving a structureless film, sensitised in a normal silver bath, developed with iron, fixed with cyanide, and neither intensified nor varnished. Of course the utmost care was used to secure cleanliness in all the operations.

As to the microscopic objectives made use of, their only peculiarities are that they have an arrangement by which suitable stops can be inserted for the purpose of increasing the depth of definition, and that they are furnished with an extra lens—a double convex of suitable focus—which screws into the place usually occupied by the back stop. The purpose served by this extra lens is to bring the visual and actinic foci into coincidence. This arrangement is Mr. Wenham's, who recommended it many years ago. In my hands it has answered perfectly.

In conclusion: I have to express the hope that increased attention will be given to this fascinating branch of the photographic art, and that next year, if a medal is offered for microphotographs, that there will be a goodly number of competitors for it.

E. Viles.

THE PROGRESSIVE RESULTS OF THE PAST SESSION.

[A communication to the Edinburgh Photographic Society.]

Year by year the "progressive results" of each passing session is becoming more and more difficult to write; perhaps I ought to say it is becoming more and more easily written, as most certainly there is year by year less progress to record.

If it be true that charity ought to begin at home, it is equally true that any local progress that may have been made should be first noticed; and therefore I commence by reminding the members of the great measure of success that attended the exhibition held under the auspices of the Society twelve months ago. This, I think, we are fairly entitled to include under the items of progress, as many attempts at photographic exhibitions had previously been made in Edinburgh, but in no case had they been pecuniarily successful, or attained to anything approaching the magnitude or technical excellence of that of last year. As, however, I hope shortly to bring the history of the recent exhibition before the Society in another and more satisfactory form, I shall leave it for the present and pass to other, though probably less important, items of progress.

Those who think with me that perfection in photographic manipulation is to be looked for in an emulsion process, in which the bath with all its troubles is discarded, will recognise the contribution of Mr. Gray as one of considerable importance in that direction. It is no doubt true that for commercial reasons Mr. Gray keeps his process a secret; but we have abundant evidence that by it dry plates may be made much more sensitive than the ordinary wet collodion film, and that the image may be developed to full printing density without any tendency to fogging, although no bromide or other restraining agent is employed. But, although the process is kept secret, I am at liberty to say that the principle involved is the use of an organic body, which, by emulsifying a large excess of free silver, enables its accelerating influence to be brought into play without the ordinary drawbacks of fogging or the production of thin images.

Next in importance, perhaps, is the method of washing the emulsions by precipitation, introduced in the case of collodion by Mr. W. B. Bolton, and of gelatine by Mr. Wratten. By this means the operation is shortened and simplified; and, as washed emulsion is the direction in which perfection is to be looked for, this improvement is undoubtedly a step in the right path.

Taking the emulsion process as a whole, although, except in the points already indicated, no very marked improvements have been made there has been considerable light thrown on some of its more obscure phases, and the united results of many ardent experimentalists have swept away many difficulties and shown how some of its most objectionable qualities may be got rid of.

Carbon or pigment printing has, as usual, continued to make rapid progress—not so much in the direction of any new improvement as in the overcoming of prejudice and the increase in the number of those practising it; and I think it is a matter for congratulation that we have now in Scotland two houses which turn out for the trade work of the highest class. I mean Messrs. G. W. Wilson and Co., of Aberdeen, and Mr. Annan, of Glasgow. In this connection Mr. Johnson, whose name has long been connected with carbon printing, has patented some improvements, the principle of which is the getting of tissue the colouring matter of which varies, being denser, or in larger particles at the bottom and smaller towards the surface. Whether this is an improvement remains to be seen; but, doubtless, such tissue will soon be in the market, and carbon printers will not be slow to avail themselves of it should it be all that is claimed for it.

In addition to substantial improvements, there have, as usual, been claims advanced for some things that, to say the least, are of doubtful value. Foremost amongst those is the attempt of Sig. Scotellari to extract the "needful" from the pockets of photographers for his patent "*opturateur sensible;*" and I can only hope that Scotchmen, at least, will be too sensible to take the bait, as even fifteen shillings is too much to pay for a cardboard cap with a hole covered with a bit of violet-coloured paper.

Mr. Vanderweyde is one of those clever, restless people who are never content with things as they are, but must always be trying to improve them. His last venture may probably turn out to be his best. Be that as it may, he has undoubtedly shown how portrait work may be carried on with artificial light. By the electric light he brilliantly illuminates the interior of a white painted box, and passes the rays through an annular lens, such as is now used in lighthouses, and under such a light very fine portraits are said to have been produced in a few seconds. I hope by next meeting to have some specimens for exhibition, and the members may then judge for themselves as to their quality.

In connection with this matter I would throw out a hint which, if acted on, may be of advantage to all concerned. It is generally admitted that at present photography as a trade is very dull, and that a novelty of some kind is wanted to give it an impetus. Such a novelty may either be one by which, from its popularity and cheapness, sitters would be attracted to the studios throughout the country, or something that would revive the interest in photography by making it for a time, at least, the general subject of conversation. To the latter class the successful introduction of photography by night would certainly belong, and if properly worked could not fail to largely increase the ordinary business. The cost, however, of fitting up the necessary plant, involving as it does a powerful electro-magnetic machine and suitable gas or steam engine, is too great to be undertaken by a single individual, and as the benefit is likely to be felt by all it should be a joint-stock concern. I would suggest that the principal photographers in the city join together in securing a suitable suite of rooms in a central position, and fit up a studio with all the necessary appliances for the proper carrying out of Vanderweyde's system of night working. If properly advertised the novelty would produce an amount of enthusiasm that could not fail to largely increase the ordinary trade, while, *per se*, it would yield a handsome profit, which, of course, would be divided amongst the shareholders.

On the whole, although nothing very striking has occurred during 1877, photography has not only kept its ground, but has made considerable progress, especially in the artistic direction. Retouching—the bane of the profession in some previous years—is gradually giving place to the production of negatives so perfect as to need no such aid, the result being truer and better work, which, probably, after all, is the direction in which we must look for the permanent improvement of the trade. JOHN NICOL, Ph.D.

EXPERIENCES WITH DRY PLATES AND EMULSIONS.

[A communication to the Glasgow Photographic Association.]

WHEN our Secretary asked me to read a paper I was at a loss for a subject of sufficient interest to bring before your notice. After deliberation it seemed to me that every known process of any moment has been from time to time ably treated and thoroughly exhausted. However, on second consideration I thought it would not be out of place to give a brief retrospect of my own experience and experiments, and also their results in connection with dry plates by the bath processes in general and emulsions in particular. I cannot promise you anything original, and trust you will not be disappointed, for I can only offer you the following remarks with the laudable object of promoting investigation and experiments in a like direction, and producing discussion thereby.

I.—THE BATH PROCESSES.

My first experiments with dry plates were with the Fothergill process. In turn I have tried, with varied success, coffee, collodio-albumen, gum gallic, hot water, tea, and tannin. They all, with one exception, present in my hands an insurmountable difficulty, namely, want of rapidity—requiring, as they do, from seven to thirty times the exposure of wet plates. The exception referred to was the tannin process. To give you detailed formulæ of all the processes enumerated would be a sheer waste of time, as they may be seen in the photographic almanacs. I will simply give you my modification of Major Russell's tannin process, as the plates are reliable, and only require a little longer exposure than wet plates.

Collodion.—Add four grains of bromide of cadmium, one drop of distilled water, and half-a-grain of nitro-glucose to each ounce of ordinary negative collodion.

Silver Bath.—Eighty-five grains to the ounce, neutral; wash the plate well until greasy lines disappear, then flow over the following—

Preservative.—Tannic acid, ten grains; gum arabic, four grains; sugar candy, four grains; syrup of squills, two drops; water, one ounce; then set up to dry. These plates keep well for three weeks, but should be developed as soon after exposure as possible and by the alkaline method.

I may here give my process for cleaning, edging, and backing plates, applicable alike to all dry processes:—

For Cleaning.—Immerse the plates in a solution of bichromate of potash, one ounce; sulphuric acid, eight ounces; water, one gallon. Allow the plates to lie in this for several hours; wash under a tap thoroughly, and set on the draining rack to dry. When dry, dust over the marked side of the plate a little powdered talc, and polish off with a wash leather or piece of flannel. As an additional precaution against the film slipping an edging of india-rubber solution, a quarter of an inch round the margin, applied with a camel's-hair brush, may be used. In my experience I find that albumen as a substratum is next to useless. The developer permeates the film, and the ammonia used in it being a solvent of albumen the substratum is dissolved as a natural sequence.

Backing.—It is judicious in all cases to use a non-actinic backing, to absorb the light that passes through the sensitive film and prevent its being reflected from the back surface of the glass again on to the film, which would produce the kind of blurring known as "halation." The usual backing is burnt sienna mixed with mucilage and glycerine applied with a piece of rag to the back of the plate. A much neater and cleaner method, and which I prefer, is to coat the back of the plate with chrysoïdine matt varnish. In passing I would draw your attention to the advantages derived from the use of chrysoïdine varnish for dark room windows and globes. The most sensitive bromide plates can, I find, be manipulated without fear of fog in a light sufficient to permit everything to be freely seen, which is of very considerable importance.

II.—EMULSION PROCESSES.

The emulsion process is what I might term a more concise and scientific form of manipulation—doing away, as it does, with the silver bath and its attending disorders. This process has of late years made gigantic strides, which is mainly due to the energetic investigations of experimentalists—chiefly amateurs, who have always been the pioneers of improvements in photography. It seems to me, therefore, that we have every reason to believe that ere long we will have standard commercial emulsions quick, stable, and reliable, and I can unhesitatingly predict their universal adoption by the profession. I may also state that I am at present working out an emulsion process of which I have great anticipations. Should my efforts be ultimately crowned with success I will communicate full details at some future time.

My first experiments were with uranium dry plates, using Colonel Stuart Wortley's strong alkaline developer. They are very sensitive, particularly adapted for foliage and dark subjects, easy of development, but difficult to intensify.

The ordinary dry plates and washed emulsion issued by the Liverpool Dry-Plate Company are slow but sure, requiring from five to eight times longer exposure than wet plates. The extra-sensitive plates issued by the same Company I find require about double the exposure of wet plates, but are more difficult to develope and intensify than the ordinary plates.

My attention was next directed to the beautifully-delicate and sensitive gelatino-bromide emulsion. It is, without doubt, one of the most sensitive dry processes known. The colour of the film, being of an olive-green tint, is very deceptive. At first I had great difficulty with blisters, but overcame that trouble by using sulphate of magnesia in the washing water. Another difficulty is the frilling, which I have as yet only partially overcome by coating the plate with a one-grain solution of india-rubber in chloroform as a substratum. One of the drawbacks of this process is the length of time required for drying the film, which has been reduced to a great extent by the use of alcohol in making the pellicle.

One of the most simple and sure, although slow, of the emulsion processes I have tried is the formula published by Canon Beechey, to which I have but one objection—instability. If the plates are kept more than a week after being made they lose detail. I find them exquisitely adapted for lantern transparencies, without toning.

In experiments with Young's Philadelphia washed emulsion I find it much quicker, but in other respects similar, to the Liverpool emulsion.

During the past season I have chiefly experimented with Newton's American emulsion, which I considered, at first, to be the *ne plus ultra* of all emulsions I had tried. After keeping it for three or four months I found its sensitiveness gradually diminishing. The reason I ascribe for this, being an unwashed emulsion, is the excess of silver left in it undergoing a chemical decomposition, thereby deteriorating its sensitiveness. The preservative recommended for these plates, which I consider excellent, might be applied to other dry processes with advantage. It is as follows:—

Tincture of nux vomica	1 drachm.
Tincture of opium	1 ,,
Syrup of squills	1 ,,
Alcohol	2 ounces.
Water	10 ,,

Filter.

In my first attempts at portraits with this emulsion, used moist, I gave the same exposure as for wet collodion. On developing—using, of course, Newton's new sal soda developer—the image flashed out at once, and the plate immediately blackened all over. After repeated experiments I found that two-fifths of the exposure given to the first plate was quite sufficient. In comparative experiments with Newton's against other dry plates, using the ordinary alkaline developer, I find them even slower than the average of the other plates I have tried. On the other hand, in trying the sal soda developer with other plates I find it reduces their exposure about thirty per cent., and brings out the image clear, round, and strong, without the hard effect peculiar to dry-plate photography. In short, I consider it a great impetus to alkaline development; and it has placed a wonderful force in the hands of the photographer. While possessing all the good qualities inherent in the ordinary alkaline development, it possesses the additional advantages of iron development, viz., the continuous strengthening of the image which distinguishes iron from alkaline pyro.

The formulæ for the sal soda developer are as follow:—

Water	16 ounces.
Sal soda (washing soda)	2 ,,
Bromide of ammonium	40 grains.

Take the quantity of above that may be required to cover the plate (say an ounce), flow over the plate, return to the cup, and add four to six grains of pyrogallic acid. The image will appear and development go on as with a bath plate. If greater strength be required use more pyro. If the plate be under-exposed the energy of the developer can be greatly enhanced by adding, before the pyro. is put in, six drops of the following solution:—

Water	1 ounce.
Liquor ammonia	1 ,,
Bromide of ammonia	40 grains.

Wash thoroughly in clean water; intensify, if necessary, with acid silver and pyro. Fix with the following:—

Water	4 ounces.
Hyposulphite of soda	1 ounce.

The soda developer has a tendency to loosen the film, causing blisters when an edging of india-rubber only is used. To obviate this use a substratum of india-rubber over the plate.

Before concluding I would draw your attention to one of the many advantages collodio-bromide plates have over the usual wet plates, viz., that a transparency can be taken in the camera, direct from the sitter or other subject, at one operation, suitable either for the lantern or enlarging purposes. The following is the *modus operandi.* Take the negative and develope in the usual way by alkaline development; wash well, and pour off and on the following solution:—

Nitric acid	1 part,
Water	1 ,,

until the picture seems to bleach. Wash well, but gently, as the film is very tender after this powerful application. The result will be a thin transparency, which will acquire sufficient intensity by redeveloping in the usual manner.

Instead of occupying your time with any theoretical speculations as to the relative merits or demerits of the above processes, I prefer to give you a practical proof in the shape of negatives, transparencies from negatives, prints, and lantern transparencies, which I will show by means of the sciopticon. JAMES M'GHIE.

THEORY OF THE DESTRUCTION OF THE UNDEVELOPED PHOTOGRAPHIC IMAGE.

[A communication to the Photographic Society of Great Britain.]

IF I may be given permission, I will read a letter from myself, addressed to the *Journal* of the Society, as it was also to the other photographic periodicals, in which certain important additions were made to the paper I had the honour to read at our last meeting. I wish to obtain this permission, as I think that any matter which bears upon photography should, if possible, be brought before the members, that they may have an opportunity to discuss it, and also that the author or discoverer, whichever the case may be, may have an opportunity of explaining any difficulty which may seem to others to require it.

I am particularly anxious to hear any remarks that may be offered on this subject, as it seems to me that it affects the theories held in certain particulars.

The following is the letter:—

"I wish to make a few remarks on a subject kindred to that of my last paper which was read before the Photographic Society, and which appeared in your issue of last week. Since its reading I have undertaken further experiments with a view of ascertaining the cause of the fading away of the undeveloped image impressed on dry plates by long keeping after exposure. It will be quite evident that none of those agents that I previously used for eliminating fog or destroying the image could cause this gradual fading away. Reasoning from the fact that nitric acid was effective with silver bromide, it struck me that it might be possible to oxidise the loose atom of silver in the sub-bromide (Ag_2Br) and even in the sub-iodide (Ag_2I) of that metal, if the chemical theory of the photographic image held good. Films of pure silver iodide and of pure silver bromide, after exposure under proper conditions, were washed and treated with potassium bichromate, potassium permanganate, and chromic acid. With the first-named silver salt *all* were effective in destroying the image. With the latter silver salt the last two oxidising agents alone were effective, the permanganate requiring a longish application.

"Now if this destruction were caused by an oxidation of the silver atom, it should also be capable of being oxidised by ozone, since metallic silver when moistened can be per-oxidised by it. To test this plates were prepared, exposed, and left to the action of ozone, and in every case when proper precautions were taken the image was entirely destroyed. The oxidised films (however oxidised) were all capable of receiving fresh light images which could be developed free from fog.

"Is it too much, then, to assume that the effect of time on the image impressed on a dry plate is *to oxidise an atom of each of the molecules* forming the image; particularly when it is found that *nascent hydrogen* is capable of restoring it to a certain extent, though its perfection is marred by the reducing action of the hydrogen on the whole of the salt in the film?

"I wish, also, to note an experiment which I made some short time ago, and which struck me forcibly at the time. Two plates were prepared with rather thick emulsion, and exposed to a gas flame behind a negative for equal times; one was immediately developed and gave a good picture, whilst the other was put away in my dark room for a couple of months. On attempting to develope this latter, the image refused, apparently, to show at all; but on turning it over and looking through the glass an image was seen developing next to its surface. Eventually the image worked its way up to the top surface, and remained as an under-exposed picture. The atmospheric influences had evidently not had time to penetrate so far as the light, which latter must have been much enfeebled as it arrived at the back of the film; and hence on developing showed signs of under-exposure.

"Is it not probable that the keeping qualities of certain plates, when washed over with gallic acid, may be due to an oxygen absorber being present, which the atmosphere must first saturate before it can hope to attack the silver image? Apparently a preservative for a dry plate should be impervious to the air, and for double security it may be presumed it should contain some substance more readily oxidised than the atoms forming the image. I am keeping some plates in hydrogen and nitrogen, which, after a couple of months, will be developed in competition with some exposed to the air in the usual manner."

As an addendum to the above letter, I should like to make a few remarks. Firstly, the action of ozone is not confined to the destruction of the invisible photographic image alone; but it is also remarkably distinct in photographic prints. I have here a specimen of its action. The end of this toned silver print was kept dry, the middle portion *slightly* damped, and the other end saturated with water. I would have you specially remark the result. The damped portion is very much faded; the wet portion shows a decided loss; whilst the dry print is almost unaffected. Now we know that moistened silver is per-oxidised by ozone, but from what I can see by having tested a portion of it we have a distinct change, not in the metallic silver alone, but in the organic compound of silver forming the image. Now the print was as well washed as most prints are, and you will notice that in one spot, where a drop of sodium hyposulphite has been placed on the paper, we have a marked effect on the image, even where it was wet. I am not in a position at present to say definitely what has happened in the compound forming the image; but this I can say—that what will happen in ozone will generally happen by exposure to the atmosphere. In our climate, where we are exposed to so much damp, the very best state apparently for destroying the silver image is to be found.

My friend, Mr. Pearsall, in a conversation I had with him the other day, incidentally mentioned that in an old experiment made by Sir W. Grove, he found that the electric spark, when allowed to pass over the surface of a sensitive plate, did not cause any developable image where the spark had passed, that remaining a blank, but outside it developed. Mr. Pearsall was unaware of the experiments I was at that time carrying on, and it immediately struck me that the strongly-ozonised air, which would be in contact with the plate when the spark passed, would prevent the formation of an image, whilst beyond that space the light from the spark would be free to act. I may say that this oxidising action of ozone on the undeveloped photographic image opens out a great field of inquiry into coloured spectra, photography of the least refrangible end of the spectrum, and the reversal of the action of actinic light by the red rays. I also may say that in my succeeding researches on these points I have met with encouragement to proceed; and at some future date hope to lay the results before the Society. W. DE W. ABNEY, F.R.S., *Capt. R.E.*

COMBINATION PRINTING FOR THE STEREOSCOPE.

PART I.

[A communication to the Manchester Photographic Society.]

THE subject of which I am about to speak to you tonight is the one nearest to my heart, so far as photography is concerned. I am but an amateur; so I come before you with all due deference as far as my opinions are concerned. I feel how unworthily I have performed the task I set myself in writing this paper—a task I looked forward to with some pleasure and no little anxiety; for my object in doing this is a very ambitious one—no less, indeed, than a hearty desire on my part to awaken in the photographic world, and through it the world outside, a fresh interest in one branch of your business you have sadly neglected, and a branch that, not only in my opinion but in the opinion of many others, deserves a better fate at your hands. I cannot reasonably hope to accomplish this tonight, or even in many nights; but I am satisfied that the stone only requires to be set rolling down the hill and it will accomplish its own end.

I see by the announcement that I am down for a paper on *Transparencies.* As this may be somewhat misleading, I must first of all inform you that I am about to tell you what I know of *stereoscopic transparencies,* and more especially about Mr. Breese's work in this direction. I trust I shall not tire you by constant reference to that gentleman's name. But I look upon myself as occupying the same position with regard to him that Boswell did to Johnson, and I look upon Mr. Breese as occupying the same position as a photographer that Johnson did in literature; but if I can only be of as much service to his memory I shall be satisfied. Boswell, you know, was abused wholesale as a bore and a toady; but he bored and toadied to some purpose, for, thanks to him, we have one of the finest biographies that has ever been written.

At the risk of taking up a portion of the short time at my disposal this evening in telling you what most of you know, or should know, already, I propose to run over, as briskly as I can, a short description of the instrument I am about to deal with. In doing this I shall not mind making use of the language of others where I believe they have expressed themselves better than I could do. I have little scruple in going into details that may appear at first sight unnecessary; but I have found that most people, though rejecting with scorn the idea of their ignorance of the principle of the stereoscope, really know very little about the matter when asked to explain the principle in question—people, too, tolerably well informed on scientific matters generally.

When we look at an object a picture of that object is formed on the retina of each eye; but each picture, being observed from a different angle of view, differs to a slight extent, and the nearer the object is to the observer the more marked the difference is. If the right hand be held at right angles to the face and a few inches from the nose, the back of the hand will be seen by the right eye only, and the palm of the hand when viewed by the left eye, if you close each eye alternately. Hence the images formed on the retina of the two eyes must differ—the one including more of the right-hand side, and the other more of the left-hand side of the same solid or projecting object,

Perfect vision and perfect representation of solid objects in monochrome cannot be obtained without two eyes and without two pictures taken at a suitable angle of view; and it is by the combined effect of the images produced in the retina of each eye, and the different angles under which objects are observed, that a judgment is formed respecting their solidity and distances. You will observe that I am talking of pictures in monochrome, because the artist proper has special advantages in representing objects with regard to solidity and distance in the use of colour apart from light and shade, or, rather, in addition to light and shade.

It is well known that blind men who have been restored to sight cannot tell the form of a body without touching it until their judgment is matured by experience, although a perfect picture may be formed on the retina of each eye. A man having only one eye cannot readily distinguish the form of a body which he has never previously seen; but he quickly and unwittingly moves his head from side to side so that his one eye may alternately occupy the different positions of a right and left eye. It is, in fact, quite an amusing joke to request a friend to take the snuffers and snuff the candle with one eye closed. He is bound, in the ordinary course of things, to make several bad shots before he succeeds in trimming the wick.

It may be asked—"If the use of two eyes be so valuable in judging of distances why do people who are taking aim with a gun invariably close one eye?" But, in this case, the gun being placed against the right-hand shoulder, and the barrel being so immediately in a line with the eye with which aim is being taken, the effect of opening the other eye would be to apparently throw the end of the gun at least a yard to the right hand. If you are not satisfied that this is the case it is almost worth your while to try by holding up the finger as if you were taking aim, then closing the left eye, as you would naturally do, make a careful observation of the spot covered by the end of your finger. Now suddenly open the left eye and close the right one, and mark the apparent difference in the position of the end of your finger. Another instructive experiment is to look at an object and then press one of the eyeballs slightly, thereby diminishing or increasing, as the case may be, the angle of view, and the result is you get the object in duplicate.

Drunken men are said to "see double," because they have not the sense or sufficient command of themselves mentally to concentrate their sight or mind on one object. The consequence is they see the same object in the retina of each eye, and, the mind not working in unison or sympathy with the eyes, they see two objects for every one they look at; and the distance between the object seen with one eye and that with the other would probably be the distance between the observer's eyes, or about two and a-half inches. In playing billiards this must be very awkward, for the drunken player would see two tables, two cues, six balls, and twelve pockets.

In order, then, to deceive the judgment, so that flat surfaces may represent solid or projecting figures, we must cause the different images of a body as observed by the two eyes to be depicted on their respective retinæ, and yet to appear to have emanated from the same object. Two pictures are, therefore, taken from the really projecting or solid body—the one as observed by the right eye only and the other as seen by the left. The picture is then placed in the stereoscope, which is furnished with lenses so constructed that the rays proceeding from the respective pictures to the eyes should be refracted at such an angle as each set of rays would have formed had they proceeded from a single picture, occupying the centre of the instrument, to the respective eyes without the intervention of lenses. No human hand could draw or paint sufficiently accurately to produce any but geometrical figures for the instrument, but photography kindly steps in and does the work for us.

In former days the pictures taken for the stereoscope were daguerrotypes; and, by the way, let me remark that next to a glass transparency I have reason to believe the daguerreotype is the process most suited to the purpose. I sincerely wish I could induce some one present to try a few of these pictures for the stereoscope of still life—such as dead game, flowers, or fruit—by way of an experiment. I am sure it would repay him for his trouble if they were only done for private use. I regret I have neither the time nor the money to experiment, as I long to do at times. The advantage of the daguerreotype over paper slides in the stereoscope are many, and the disadvantages are not so great that they may not be overcome with a little ingenuity. Paper is simply abominable to any one who knows and can appreciate the tenderness and delicacy of a well-toned transparency. (You must not think I am abusing paper photographs wholesale; but bear in mind that I am speaking only of paper used in making slides for the stereoscope to be viewed either by reflected or transmitted light.) No paper has yet been made that will stand the test of the stereoscope. Who ever saw a sunlit cloud properly represented on paper, with every bit of detail from the highest light to the deepest shadow? Who ever saw water represented on a paper photograph that would bear the slightest comparison to water in a transparency? Or who ever saw anything on paper that gave one the feeling that atmosphere existed between the foreground and distance? You may see a fuzziness, but fuzziness is not atmosphere.

Now, as paper is not a suitable material for pictures that have to undergo the test of the stereoscope, and glass may be considered to have serious drawbacks commercially, I make a suggestion which is quite at your service. It is to print your slides, or transfer them to gelatine or tough collodion films or tissue, and use them with some arrangement akin to Mr. Warnarke's roller dark slide, so as to bring a succession of pictures into the field of view instead of the somewhat clumsy arrangement at present in use, which is always getting out of order. I mean the boxes to hold from 50 to 100 slides. You have tissue negatives; why not tissue or pellicle transparencies? I have made experiments in this direction that warrant my recommending this to the serious notice of those in the trade.

The four slides you will find on the table are glass subjects taken by Mr. Breese. It may not strike you that there is anything very much out of the way in these slides, or that they are superlatively good of their kind. They are, however, as near perfection as possible, and you will find they are all composed of as difficult a combination of things that could be brought together to test a photographer's skill; but you will find every bit of tender, reflected light, and half light is present as in nature itself—every bit of detail, from the highest light to the deepest shadow. Nos. 1 and 2 were photographed on Mr. Breese's own drawing-room mantel shelf. His brother being in the glass trade accounts for his having so many beautifully-cut glass and other ornaments. The exposure for the negatives, Mr. Breese told me, was twenty minutes.

I may as well mention here, once for all, that Mr. Breese's transparencies are camera printed, and that he invariably used pyro. development. He worked with the ordinary three-grain pyro. developer reduced three times, or a one-grain pyro. developer. For his very quickest pictures (no man ever did quicker ones) he used a developer no stronger than the usual three-grain pyro. I could never induce him to give the iron developer a fair trial. Once, indeed, he tried it at my urgent request; but the quality of picture he got did not satisfy him, and I could not get him to try again.

Mr. Breese kindly spent four hours in colouring me a duplicate of No. 7 slide, for which I paid him a guinea. I regret to say it has since come to grief. It was most beautifully coloured—not both sides alike, as I have seen some transparencies done; but in colouring one of the lustres, for instance, he would proceed thus:—He would put on a dab of perfectly-transparent yellow on one side of the stereo. picture, and on the corresponding portion of the lustre on the other side he would put a small dab of Prussian blue and a small dab of red, so that the blue and red should partly overlap the yellow when seen in the stereoscope; and he would proceed thus with either side of the slide till it was done, in no instance painting the two sides alike. Suppose he wanted to paint a tree or a field, he would paint one side of his slide with broken yellows and the other with broken blues, and the result when seen in the stereoscope would be various shades of green. The difficulty is in getting colours sufficiently transparent and pure for the purpose, otherwise most charming effects may be got, especially when prismatic hues are to be represented.

A silver ewer figures in three of the slides on the table. This ewer was given to Mr. Breese by Mr. Elkington as a present, in acknowledgment of some service he had rendered that gentleman in photographing his family and house at Croggan, North Wales, and for which Mr. Breese refused to accept payment. Inside the jug was a ten-pound note, with the following words written on it:—"To pay for the collodion"—a very handsome and neat acknowledgment on the part of your respected townsman.

You will find on the table two moonlight views. These are favourite subjects with Mr. Breese, and he is the only man who has had any real success in rendering moonlight effects for the stereoscope. Sometimes Mr. Breese took negatives on purpose to convert them into moonlight transparencies, and these are generally his best productions; but if it so happened that he found he had got an under-exposed negative he would not allow the development to go too far, and would put it by to make a "moonlight" of it at some future time. The negatives when taken with a view to be turned into moonlight pictures were carefully studied beforehand, and a favourable opportunity of taking them was patiently waited for from day to day. They were then taken with short exposures in full sunlight, and the development stopped before too much detail made its appearance.

Now, in printing a transparency for a moonlight picture the moon has to be printed in where the sun really was in taking the picture. This is done as follows. I am now about to come to the pith of my paper, and to tell you what no living man besides myself knows anything about, and this is combination printing for the stereoscope, though I should not be at all surprised if some one crops up in future who knew how it was done all along. As, however, at least two months will elapse before I am able to give the second part of my paper, a good opportunity occurs for people to say what they may have to say about the matter. I have no fear of being anticipated in what I have to say. In giving this information I do not wish to take any credit to myself. I did what any man might have done under the circumstances. I bought the information with the negatives, and I bought the negatives for the information. I gave Mr. Breese for the negatives a cheque for £80, intending some day to go into the matter commercially (which I may do yet, as far as I know), but at present the information is of no service to me, and I thought it might give a fresh spurt to the trade if I tell you what I know about the matter.

I find the time is slipping away, and that I must bring my paper, or, rather, the first part of it, to an abrupt conclusion, as I wish to afford you sufficient time for discussion and to answering any questions that may occur to you. I think I can promise you a more interesting paper next time. I shall begin by telling you how moons, seagulls, clouds, animals, figures, &c., may be printed into transparencies stereoscopically—that is the rub. Combination printing for paper work is comparatively child's play. I shall tell you, as far as I know, Mr. Breese's pet solutions and formulæ. I shall show you my printing apparatus, made according to Mr. Breese's pattern, and shall, if possible—but this I cannot promise—print a combination picture in your presence. S. H. Ashley Oakes.

Meetings of Societies.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

As we are publishing the communication of Capt. Abney *On the Theory of the Destruction of the Undeveloped Photographic Image* in another page, we are now enabled to redeem the promise made last week to give the short discussion that took place, which we do from the official notes of the report:—

Mr. Pearsall observed that, in the Society's rooms, some years ago, after speaking of the philosophy of photography, Sir William Grove referred to several experiments, which he thought had not been sufficiently followed out, and recently he (Mr. Pearsall) had, at the request of Sir W. Grove, searched for the records of these experiments for this purpose. In these experiments Sir W. Grove had taken a sheet of glass, on which he placed, in letters of tinfoil, the word "Volta." He then passed the electric spark through the word, thinking to get some particular effect from the discharge. Greatly to his surprise, when he removed the tinfoil there was no development where the letters had been, but a development in every part of the glass not covered by the tinfoil, the pictures on which the latter had been placed being clear while the remainder was cloudy. Sir W. Grove thought that these experiments might be pursued with advantage, and for this purpose he (Mr. Pearsall) had mentioned the fact to Capt. Abney as a thing which ought not to be allowed to stand alone, and the result of Capt. Abney's further researches they had had that night.

Mr. Sebastian Davis said that he wished to make an observation in reference to a fact which, in his opinion, seemed somewhat to militate against the theory of fading which had been advanced that evening. He referred to the action of tannin, or tannic acid, and gallic acid upon sensitive plates. It was well known to photographers in the days when tannin was much used as a preservative, that the plates, when washed with the usual ten or fifteen-grain solution, had to be developed very soon after exposure, as they soon deteriorated, although the time between preparation and exposure might be considerably extended without any bad effect following. But it was also noticed that the contrary was the case when a wash of gallic acid was applied, and plates so prepared could be kept for a lengthened period between exposure and development. He (Mr. Davis) had brought this before the photographic world many years ago, and that it was true had been established, beyond a doubt, by a great many experiments. Indeed, there was no chemical agent which had a greater power in regard to the preservation of the image than gallic acid. But instead of its being an oxidising agent it was a reducing agent, and he (Mr. Davis) thought it would be well if some explanation could be given of this apparent contradiction, why gallic acid, a reducing agent, was capable of preserving the image on the photographic plate for an indefinite time.

Captain Abney observed that the end of the letter would furnish an answer to Mr. Davis's objection.

"Is it not probable that the keeping qualities of certain plates, when washed over with gallic acid, may be due to an oxygen absorber being present, which the atmosphere must first saturate before it can hope to attack the silver image? Apparently a preservative for a dry plate should be impervious to the air, and for double security it may be presumed it should contain some substance more readily oxidised than the atoms forming the image."

The fact was he had tried both tannin and gallic acid. Tannic acid had certainly not the same effect as gallic and pyrogallic acid. Gallic acid when flowed over an exposed plate preserved the image from the action of ozone. Sugar of milk also preserved the image, but he did not attribute the effect in this case to the same cause. Oxygen absorbers preserved the image from fading, but he was not inclined to agree that tannin was an oxygen absorber.

Mr. Davis: I should rather term it a reducing agent.

Mr. Spiller remarked that the subject was one upon which he had had a little discussion with Captain Abney. He was rather inclined to agree with Mr. Davis, and use the term "reducing agent"—at all events, in the sense in which he applied it, rather than "oxygen absorber." A reducing agent was not necessarily an oxygen absorber, since it might have an affinity for chlorine.

Captain Abney: In the case of a bromide film gallic acid is *not* a reducing agent at all.

Mr. Davis: That is scarcely borne out by experiment. A plate can be developed by gallic acid, though I admit its action is very weak, and not nearly equal to pyrogallic acid.

Captain Abney: I fancy we are rather at cross purposes as to what we actually do mean. Pure bromide of silver exposed to light and treated with gallic acid for months, whether *in vacuo* or not, certainly does not show the slightest reduction.

Mr. Spiller: And still it is an oxygen absorber.

Captain Abney: Yes, but it must not be regarded as a reducing agent in the presence of pure iodide or bromide of silver. If you introduce silver nitrate you get a different state of affairs altogether.

Mr. Spiller: That is so; in this case then gallic acid is not a reducing agent.

The paper of Mr. Viles and other matters were then proceeded with, but as we referred to these in our last issue further allusion is not now necessary. The papers by Capt. Abney and Mr. E. Viles will be found in our present number. We have been compelled to leave over Mr. E. Cocking's paper till our next.

EDINBURGH PHOTOGRAPHIC SOCIETY.

The third ordinary meeting of the session was held in 5, St. Andrew-square, on the evening of Wednesday, the 9th inst.,—Mr. John Lessels, President, in the chair. Fortunately there was not a large attendance, as, in consequence of the change of the day, the meeting had to be held in a small upper room, the ordinary large room being occupied by another society.

Messrs. John Jackson, John Terras, and J. K. Tulloch were unanimously elected ordinary members of the Society. Dr. John Nicol then read a paper, entitled *The Progressive Results of the Past Session* [See page 27], in the course of which he solicited the indulgence of the members, as he found that every recurring year rendered such a paper more difficult to prepare, and he found the journals for the past year specially barren in matters of interest.

Mr. W. Neilson remarked that all anniversaries were pleasant, and as Dr. Nicol had always written the annual summary it was pleasant to find him still doing so, though he could not agree with all he had said. In connection with the electric light for nocturnal portraiture, he considered there must of necessity be an overpowering glare, rendering the pose far from comfortable to the sitter. He had some first-rate carbon enlargements produced for him by Mr. Annan, of Glasgow, and recommended that the original small negative should be slightly under-exposed, as it then in a great measure rectified the flatness always apparent in enlarged prints.

The Chairman, in the course of his remarks, spoke very highly of the plates prepared by Mr. Gray, saying they could be thoroughly relied on for producing really good negatives of the most difficult subjects. He had himself procured valuable records from the very dimly-lighted interiors of ancient edifices on the continent and elsewhere by means of them, and, indeed, for interiors or exteriors he did not know of any plates that could surpass them.

Dr. Thompson was gratified to find, from his own observation, that in the average work turned out during the past year there was a return to a more healthy condition; there seemed to be a greater determination to produce perfect negatives, and less dependence was placed on the work of the retoucher. At one time retouching was much overdone; but he was glad to find that the main effort seemed to be to get as good a negative as possible in the first instance, and do as little as possible by way of hand-improvement afterwards. His own experience had not been altogether favourable to carbon work, as he found that he could not get prints in pigment equal to those in silver; but he believed a reason for that might be found in the fact that his negatives were specially suited for silver printing.

Mr. Alex. Nicol had noticed that for carbon enlargements produced by the Autotype Company a slightly under-exposed negative always produced the best results. In his ordinary work he sought to get fully-exposed negatives, so as to secure soft silver impressions; but when such were sent to be enlarged the resulting prints were always flat. He had even noticed that a negative giving hard, black and white silver prints, when enlarged produced very satisfactory results.

Mr. Balmain said that in his experience he always found that "like produces like." If the original negative were under-exposed the same effect was reproduced in the enlargement. His general plan, when he intended to produce an enlargement, was to strengthen the small negative so as to get a carbon transparency exactly to suit the picture he desired to make, and then enlarge the transparency in the usual way.

Mr. Turnbull, after remarking that the tendency of all enlarging was to flatten, gave some information concerning an apparatus for generating the electric light, in the erection of which he had recently been interested. The machine gave a light of 1,000 candles at a cost of about £80, and was worked by a three-horse-power engine.

The conversation then turned on gas-bags.

Mr. Aird (whose experience gave weight to his remarks) said that a bag belonging to the Society, supplied by a well-known maker, and which had so unexpectedly broken down, had been made of india-rubber improperly prepared in the firing. As a rule it would be found that cloth which had only sufficient india-rubber to render it air-tight would be more serviceable than that which had a thick layer.

At the close of the meeting a number of copies of that useful annual, *The Photographer's Pocket Almanac and Reminder*, presented by Messrs. Cussons and Co., of Southport, were distributed to the members present.

GLASGOW PHOTOGRAPHIC ASSOCIATION.

A meeting of this Association was held on Wednesday evening, the 9th instant,—Mr. John Stuart, President, in the chair. There was a good attendance.

The minutes having been read and approved,

Mr. McGhie read a paper *On Emulsions* [see page 28], and afterwards exhibited a large number of transparencies by the sciopticon. The negatives and transparencies from them had been produced by a variety of processes. After the paper was read and the pictures exhibited the members expressed themselves highly pleased with the paper, and hoped Mr. McGhie would soon favour the Society with another paper with his extended experience on the same subject. He was awarded a hearty vote of thanks, as also was Mr. Bell, who assisted with the lantern.

The Secretary showed one of Fletcher's (of Warrington) instruments for producing lime light without oxygen. It gave a pretty good light, but much inferior to the oxyhydrogen. On account of the air which is used instead of oxygen requiring to be forced through the common gas with a powerful blower, there is a hissing sound which is not very agreeable; but the members were very much pleased at having the opportunity of seeing the light and examining the instrument, and thought it was a move in a direction from which other improvements might yet be expected.

Mr. Fletcher was awarded a hearty vote of thanks for showing his apparatus, and after a vote of thanks to the President the proceedings terminated.

MANCHESTER PHOTOGRAPHIC SOCIETY.

The ordinary monthly meeting of this Society was held on Thursday, the 10th inst.,—Mr. A. Brothers, F.R.A.S., President, in the chair.

The minutes having been read and passed, Mr. George Gregory was unanimously elected a member of the Society.

The President said it was in contemplation to hold a *soirée* and exhibition at the end of the year, and that a lantern exhibition, including other objects, would form the chief feature of the February meeting.

Mr. Hellawell said he had brought the negatives he had alluded to at the last meeting for the inspection of the members.

The President said experience had led him to the opinion that there really was something in supplementary exposure to coloured light.

Mr. W. J. Chadwick exhibited an instantaneous shutter made by himself many years since.

Mr. S. H. Ashley Oakes read a paper on *Combination Printing for the Stereoscope.* [See page 29.] He showed some charming specimens, including a number of views by the late Mr. Breese, many of which had been separated to show how they were built up.

The thanks of the members were voted to Mr. Oakes for his interesting paper, and the meeting was adjourned.

BRISTOL AND WEST OF ENGLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

The ordinary monthly meeting of this Society was held in the Theatre of the Bristol Museum, Queen's-road, on Tuesday, the 8th inst.,—Mr. W. W. Stoddart, President, in the chair.

The minutes of the previous meeting having been read and confirmed, the entertainment announced for the evening was commenced, viz., "a trial of lanterns."

Two lanterns which were expected did not arrive, namely, Hughes's triplexicon and a stella light of the old style. The three shown were, therefore, as follows:—Steward's institution lantern, and pyro.-hydrogen light, by Mr. Brightman; Woodbury's original sciopticon, by Mr. T. Davey; and the euphaneron with Newton's refulgent lamp, by Mr. H. A. H. Daniel.

A number of slides were exhibited, and the verdict was that the first place was taken by the sciopticon; the second by the euphaneron and Newton's refulgent; and the third by Steward's lantern and pyro.-hydrogen light. It must, however, in fairness be remarked that neither the owner of Newton's refulgent nor Steward's had possessed their lanterns beyond a very short time, and were not sufficiently experienced in the use of them; also, that they had, on a former occasion, a most successful trial. It was understood that a new trial would take place. The testing was most interesting, and occupied the whole evening.

Correspondence.

FRILLING OF GELATINE NEGATIVES.

To the Editors.

Gentlemen,—The frilling of gelatine negatives evidently troubles a few of your readers. If your Journal was made more of a manual there would be fewer failures.

Many months ago the Rev. H. J. Palmer reported upon this subject at a meeting of the Liverpool Amateur Photographic Association, and stated that, by the use of a small quantity of Hunyadi water, he had overcome this tendency. A rough qualitative analysis of this water shows it to be impregnated with sulphate of magnesia (Epsom salts) and chlorides; and there is no doubt that where the water is too pure (*i.e.*, soft) the addition of a small quantity of soluble mineral substance would be beneficial.

If I might make a suggestion without appearing presumptuous, I should like to point out the great assistance it would be to readers and workers if the formulæ so often given in French weights and measures were first translated into English; the work of one would then help all, whereas, now, each has to search out for himself the equivalents if the matter is to be of any use to him. Apologising for troubling you,—I am, yours, &c., J. H. T. Ellerbeck.

7, *The Elms, Peel-street, Toxteth Park,*
Liverpool, January 14, 1878.

JOHNSON'S NEW CARBON PATENT.

To the Editors.

Gentlemen,—I think Mr. J. R. Johnson scarcely understands his position when he speaks of the "vulgar imputations" contained in my letter. He appears on the photographic stage with a portentous new patent covering a wide field of carbon operations, and making prodigious claims. I attack, in the public interest, one of these claims, and point out that Mr. Johnson has appropriated almost literally for his personal ends the process of reversing negatives given years ago to the profession by Mr. Wenderoth. Instead of making an apology for having appropriated (however unwittingly, another man's ideas) he coolly says he will "take an early opportunity of doing that which the law provides when such a mistake has occurred."

Mr. Johnson's name is perfectly well known in the photographic world. He has been one of the most controversial of contributors to the journals. He has been keenly interested in carbon printing from the commencement, and is about the last man one would have expected to plead ignorance. However, he has raised this plea, and I unhesitatingly accept it. His name is honourably known in photographic annals, and he has simply mistaken in this Wenderoth matter faint stirrings of memory for the inspiration of original ideas. My contention, however, is that having through ignorance attempted to restrict the rights of the whole body of the profession in a process which may shortly be of peculiar value, the least Mr. Johnson could do was to have expressed regret that he had so erred, and not attempted to pass as an injured inventor.

I feel the majority of the profession will coincide with me in the opinion that all attempts to extend the carbon monopoly should be jealously watched, and if patents are attempted embodying preposterous claims their exposure in the plainest language is fully warranted. I am pleased to note the disclaimer of the Autotype Company as to any foreknowledge or interest in the Johnson new patent, and to apologise for the imputation made in my previous letter.—I am, yours, &c.,

Great Yarmouth, January 14, 1878. W. S. Miller.

[We embrace this opportunity of correcting a clerical error in Mr. Johnson's letter last week, and to which the writer has directed our attention. In that letter Mr. Johnson is made to say (see last paragraph) "*I am only pleased*, as an excuse for my ignorance, that I was in a foreign country," &c. For the first four words, which we have italicised, *read*—"I can only plead," &c.—Eds.]

CLEANING POT OPAL.

To the Editors.

Gentlemen,—I see in your issue of December 28th, 1877, a query from a correspondent for a method by which pot opal may be cleaned after it has been used.

The stains caused by nitrate of silver or the article used in development may be removed by a solution made of equal parts of nitric and sulphuric acid, and well washed. After such treatment I have always found the glass clean and equal to new.—I am, yours, &c.,

25, *Williamson-street, Liverpool,* Richd. Crowe.
January 12, 1878.

COLOURED VARNISH.

To the Editors.

Gentlemen,—In the last number of the Journal I see described a method of making coloured varnish.

The formula there given is, no doubt, very good, but if you will permit me I can inform your readers of a much simpler one which I have often used, and which has also the advantage of being able to obtain any colour. It is prepared by simply adding any of the liquid dyes to the ordinary spirit varnish, a very few drops being quite sufficient.

I have used some of those colours to impart a warm tone to lantern slides, and also stereoscopic pictures on glass, and it produces a very pretty effect. The objection in using it with the former is that where slides for the lantern have to be coloured the tint is objectionable.—I am, yours, &c., W. England.

London, January 16, 1878.

THE NEW ALMANAC—A CORRECTION.

To the Editors.

Gentlemen,—Kindly excuse my taking up space in your columns with a personal explanation; but, as some misunderstanding has arisen through a mistake of your printer, I shall be obliged if you can find room for this correction.

In your Almanac for this year, an article by Mr. H. Cooper, of Northampton, is credited to me, whilst one of my contributions is attributed to my namesake.

As the article which I did *not* write is entitled *Hints from Practice in a Small Studio*, and as the author speaks of his sixteen years' professional experience, many of my friends have been sorely puzzled. I should be sorry to deprive my namesake of the credit of his suggestive article, and also wish to assure the readers of the Journal that I have not been sailing under false colours for these many years past. As most of my friends know, I have never had any professional or commercial connection with photography in any way whatever.

My own contribution (which has been attributed to the wrong writer) is a short epitome of an improved method of printing on textile fabrics.

The formulæ I have recommended have given most satisfactory results, and I can cordially advise all those interested in this branch of photography to give the method a fair trial.

A modification of the same formulæ gives a good process for "plain" paper prints.

The only novelty is the use of the lactate of silver. This salt is a great favonrite of mine. I have proved its usefulness in emulsion work for the camera, in collodio-chloride printing on glass, and in printing processes generally; so I ought to speak well of its merits.—I am, yours, &c., Henry Cooper.

Homehurst, Torquay, January 16, 1878.

[The mistake alluded to by Mr. Cooper, which is regretted, is one which arose from one of the officials in the printing works having unfortunately misinterpreted our instructions relative to the means of making the distinction clear between two contributors bearing the same name, one of whom is a professional photographer, the other being one of our best-known and ablest amateurs.—Eds.]

DOUBLE-COATED PIGMENT TISSUE.

To the Editors.

Gentlemen,—The letter of the Autotype Company last week, in stating that I "broached an idea" in 1871, though quoting my own words, does not fairly state the case, because I was thereby calling attention to two former articles of mine, which detailed the fact, supported by proofs of my having at that date practically carried out the idea.

Having done so, and desiring more perfect tissue than an amateur could make, I applied to Mr. J. A. Spencer, then associated with the Autotype Company. He very courteously promised to assist me; but, from some cause or another, the suggestion was never carried out. I have still in my possession a letter from Mr. Spencer, which, being a private one, I am not at liberty to quote without his permission; but this I may say—that, from the tenor of it, one might legitimately draw the conclusion, which I did at the time, that no such tissue had been made at the Autotype Works before that date.

I am willing to make the confession that I was not aware the license to Messrs. Marion and Co. extended to manufacturing tissue. I regret having overlooked the announcement of this recent limited concession. Still my ignorance is not more strange nor more inexcusable than that of the Company, who might reasonably be expected to know everything connected with the subject, in ignoring the fact of my having originated much more than "an idea" in 1871, and throwing a doubt upon the well-established fact of my having "made my wants known" at that time.

However, I am now informed that the monopoly has been relaxed in favour of one firm for six months past, and the deduction attempted to be drawn from it is that they could have made double as well as single tissue. This is rather a *non sequitur*. At the rate of progress of the Autotype Company one would hardly expect a new concern in so short a time to bring out a novelty, or to do more than supply ordinary tissue in competition with an old-established firm. If they do not do so in less than six years it may justly be said of them, also, that they have allowed an improved process "to lie dormant."

The quotation from Mr. Sawyer's address has no date given; but, as the "*Liber* prints" exhibited four years age are alluded to, it may fairly be inferred that his words were used several years after my experiments had been published, and therefore no claim can be made for them of originality, and the evidence of the letter above alluded to tends to the belief that no such tissue had been made by the Company before I described it. I admit that "the idea" might have existed at an earlier date "*in nubibus*," and even within reach of an ordinary flight of imagination.

Had the Company done more, when Mr. Sawyer delivered his discourse, than apply the invention to the particular case given? It would seem not, from the expression of doubt used by Mr. Sawyer when he says:—"Is it possible to produce a harmonious and artistically-tinted photograph simply by superposition of colours over each other?"

If the Company had already invented and made such a tissue, why was no notice taken of my publication in 1871? It was again brought forward, without challenge, in your Almanac of 1873. Why did they not *then* say what they now assert, namely, that they were prepared to supply double-coated tissue? Why not advertise it the same as other improvements? *These* are not "hid under a bushel," or left to be "demanded" by the public.

I had no intention of writing in an "offensive" style. The expression objected to was used as being emphatic and concise. I should not have supposed this Company so thin-skinned. Companies generally are not noted for extreme sensitiveness or delicacy of feeling, and the present one, if so constituted, might have long since exhibited it by acknowledging their indebtedness to amateurs.

After the above statements your readers may judge whether my expressions were more severe than are warranted by the facts of the case.—I am, yours, &c., G. S. Penny.

Cheltenham, January 14, 1878.

EXCHANGE COLUMN.

Wanted to exchange, a first-class one gallon copper still, with worm and iron furnace, for anything useful in accessories.—Address, H. Buttrum, 17, Wolverton-road, Stony Stratford.

A brass-bound 1-1 camera, by Meagher, swing-back, new; 10 × 8 water-tight mahogany and glass bath, in good order; new tourist's quarter-bellows camera, three double backs and stand, and No. 1 Steinheil lens; an excellent head and body rest, Harrison's pattern, very firm; a firm, folding tripod, good as new; a sporting Snider carbine sighted to 600 yards. Wanted, Dallmeyer's 4D and 12 × 10 W. A. L. lenses, in good order.—Address, S. G. F., maker, Devonport.

ANSWERS TO CORRESPONDENTS.

Photographs Registered—

J. Rae, Dumfries.—*Portrait of Rev. J. Hope.*

E. Debenham, Weymouth.—*Group entitled "The Italian Band."*

W. Child, Leeds.—*Two Views of Statue of late Alderman Marsden.*

Rouch and Co., Strand.—*Two Photographs representing respectively Graphic Art and Piscatorial Art.*

☞ *Correspondents should never write on both sides of the paper.*

*** Owing to pressure caused by the unusually large number of communications connected with the meetings of the various photographic societies included in our present issue, a considerable number of interesting articles are crowded out this week.

J. Starre.—To the mixture of albumen and gallic acid add a little caramel; but you must not expect that this preservative will retain its good qualities for more than two days.

J. Schofield.—For certain samples of pyroxyline the proportions of ether and alcohol given will answer; but when making use of an average quality of pyroxyline it will be much better to increase the proportion of ether.

Obliged Reader.—While we are aware of such a patent as you describe having been obtained, we do not think the invention was even tried by the patentee, who allowed his patent to lapse after the termination of six months.

T. W. T.—If the diameter of the lenses be three and a-quarter inches (the usual *French whole-plate* dimensions), and be free from scratches or other defects, the price mentioned is moderate. The name on the lens is that of a dealer.

George Hercus.—You can ascertain for yourself the effect produced upon a sensitive dry plate by vulcanised rubber by the simple expedient of slipping an elastic rubber band over the plate, and allowing it to remain for a few days or weeks.

Elsie.—When a sitter has overhanging eyebrows care must be taken not to have a dominant top light. Retouching may be resorted to as a palliative, but it will be better to use a more judicious mode of lighting as a preventive of the evil of which you complain.

Tourist.—We have no access at present to such information as would prove valuable to you; but we understand that at a distance of about three hundred miles from Alexandria are to be found several remains of temples which may, perhaps, satisfy your requirements.

J. E. G.—What we *now* advise is the use of collodion (any old and otherwise worthless sample will answer) containing, in solution, such a quantity of aurine as will give a film of a very deep orange colour. This film may be protected, and its colour intensified, by means of a spirit varnish also coloured with aurine. This we have tried, and can strongly recommend.

W. S. inquires—"How can I stain the surface of boxwood white, or nearly so? I do not want any powder to be on the surface. And what is the best way of attaching a carbon image on wood for the engraver? Alum and gelatine is not good enough. What way is the best known? I should like something twice as adhesive as gelatine."——Can any reader give the required information?

Vitromaniac.—To photograph upon such articles of porcelain as cups and saucers, you may either adopt the dusting-on process or the more easily-managed one of toning a collodion transparency and transferring it to the article into which it is to be burnt. The process for doing so has been frequently described in former numbers of The British Journal of Photography.

Tom.—The proportion of nitrate of potash is too great. Reduce it to the proportion of two parts of sulphuric acid to one of nitrate of potash, and immerse the cotton when the temperature is about 130° Fah. See that the cotton has been pulled out in small tufts previous to immersion. Allow them to remain submerged for about eight minutes; then remove the pyroxyline thus formed, and wash it thoroughly.

W. W. (Gibraltar).—Regarding the markings on the gelatine film, we are not yet in a position to elucidate the mystery, but the matter is receiving attention. A brief notice of Bainbridge's tent was published in our volume for 1875. We are at present uncertain under what circumstances the notice appeared; but we imagine that it will be found as one of the interesting things that were exhibited at the meeting of some society.

E. Varvaisse.—The pose is graceful, although the arm is not sufficiently plump to admit of such a special display as is there exhibited. But so long as your fair sitter adopts a spangle-bedecked dress, of the description shown in the picture, it will be simply impossible to produce a high-class photograph under the circumstances. The day has now long gone by when photographs having round, white splashes (we must so designate them) all over the dress would be tolerated.

X. Y. Z.—The work to which you allude was never published. We are not aware of the reason why. After being advertised its non-appearance was determined upon. We believe it would have been useful and have proved a commercial success. If you decide upon taking up and working out the idea, not only would there be nothing to hinder its being done, but, on the contrary, you might calculate upon receiving aid from a number of sources. It would be unwise to let the price exceed a guinea.

Received.—*The Photographers' Pocket Almanac and Reminder.* By D. H. Cussons and Co., Southport.—This *Almanac*, as usual, contains a complete list of the various novelties in the way of accessories and studio furniture manufactured and sold by the above firm. It contains two nice illustrations by the Woodburytype process.

S. S. (M.D.).—A stop having an aperture like a slit has been previously proposed for lenses. Indeed there is scarcely an end to the funny forms that at some time or another have, by various individuals, been proposed for these apertures. Some have imagined that a vertical slit is that which ought to suit a tall building, others that a keyhole-shaped aperture would be better adapted for the general run of subjects. All, however, are wrong; the proper form of aperture for a diaphragm is a simple circle.

Chromo-Photography.—On this subject Mr. T. Bodley, 18, Wood-street, E.C., writes as follows:—"Having recently found that the chemicals used by myself for the production of coloured photography were used by an eminent French photographer in the same pursuit, I thought it worth while to suggest to experimentalists the use of electricity on a warmed copper plate, with a film of chloride of copper, phosphoric acid, and sulphuric acid. By aid of a thirty-shillings' electric battery and the above chemicals, combined with *nitrate of silver*, I obtained a distinct 'red' and 'blue,' which withstood exposure half-an-hour. For any substance to exhibit colour it is necessary for its atoms to be held in suspension till they are in thorough sympathy with the different vibrations of light. The sulphuric acid will, perhaps, fix the colours as the film dries, and white of egg may prevent the copper from crystallising. I feel confident of the utility of a powerful electric battery in the development of colour; and perhaps some of your readers that have the time and money might like to try the experiment."

Iron writes as follows:—"In your next issue of The British Journal of Photography, in your "Answers to Correspondents," please answer the following queries:—1. How can I render a piece of plain Saxe or Rives paper transparent?—2. How can I take out the cracks that have taken place in some wax-paper cloud negatives? They were frightfully cracked when they arrived here by post; in fact, they are useless in their present condition, and I don't care about sending them back again to the dealers.—3. How can I remove the silver from some of Warwick Brookes's "Academy negatives" that has shown itself? I expect it is from leaving prints on them over night during the present damp weather.—4. This query is one of great importance, and I am afraid that it will take a very long time to master. I have for years past been dabbling in making transfers (collodion), and I have always found it very difficult to get any such fine *warm* tones as you can with chloride prints. The collodion transfers always present a very dull and disagreeable grey-black or slate-blue. What I want to know is how can I get at making some warm tones? I have tried both toned and untoned transfers; I have also tried gold for toning; but still there is something left wanting. Do you think that any modification in the collodion would attain this object?"——In reply:—1. By applying castor oil, or a solution of Canada balsam in spirits of turpentine.—2. Place the waxed-paper negatives between sheets of plain paper and go over them (singly) with a laundress's hot iron; or, hold them in front of a hot fire.—3. This query we cannot answer definitely until we know something concerning the nature of the negatives to which you refer.—4. An answer to this query will be found in The British Journal Photographic Almanac for the present year, in the course of an editorial article on *Collodion Transfers*, page 27, to which our correspondent is referred.

The Late Mr. Thomas Lampray.—With regret we learn of the death of Mr. Lampray, which took place at his residence, 25, Gaisford-street, on the 5th inst. Mr. Lampray was at one time a member of the now non-existent firm of Ordish, Lampray and Co. Mr. Lampray's name has long been known in connection with the manufacture of albumenised paper of various kinds, and, among others, of Sutton's patent paper. He died at the early age of forty-nine.

Not So Bad.—A friend makes an inquiry as to how we have overlooked any notice of the process mentioned in the following cutting from the *Newcastle Chronicle*:—"A few nights ago, at one of the Birtley 'meeting corners,' the 'crack' turned upon photography, when a bystander heard the following remarks:—Dick: 'Hes thoo ivvor hed thy likeness ta'en, Geordie?' Geordie: 'Ay, aa yence hed it ta'en on glass; it's abune ma mothor's chimley piece noo.' Dick: 'Wes thoo ivvor ta'en, Ned?' Ned: 'Ay, aa was ta'en on cairds at Newcasile yence.' Dick, to Tom (who is a bit of a wit): 'Wes thoo ivvor ta'en?' Tom: 'Ay, aa was yence ta'en on suspishon!'"—The process (our friend says) is evidently such as could be easily practised, and is very simple:—Go into a pantry or dark room and take the first plate that comes handy—silver plate preferred. On coming out expose to the light of a policeman's bull's-eye lantern, and a full-length portrait will be taken immediately.

OXYGEN EXPLOSIVES.

To prevent the formation of any misleading ideas respecting the heading of this article, we commence by making the assertion that oxygen does not, and cannot, explode.

It is only a month since we recorded the occurrence of one of those terrible explosions which sometimes take place—happily at distant intervals—when oxygen is being prepared. On that occasion one of the readers of the Journal, when about to prepare some of this gas, finding himself short of oxide of manganese, obtained a supply from a neighbouring chemist. Having mixed this with chlorate of potash in the proportion of seven ounces of the former to twelve ounces of the latter, he placed it in the retort; in about three minutes after the application of heat an explosion of such a violent nature took place as to blow out the windows and create an alarm in that quarter of the town where the accident occurred. The experimentalist was experienced and careful, and the only conclusion that could be arrived at respecting the cause was that some impure material had been mixed with the oxide of manganese. A sample of the latter was sent to us for examination. Such was its impurity that under no circumstances could an explosion have been avoided, the principal impurity present consisting of graphite in large proportion—than which a more dangerous substance could scarcely be found.

Every preparer of oxygen is well aware that when a mixture of chlorate of potash and oxide of manganese is heated it is the latter salt which becomes decomposed and yields the oxygen; and the knowledge of the fact that the manganese acts a merely mechanical part has often led to the inquiry as to its advantage over other substances which, it is alleged, would answer the purpose equally well without introducing any element of danger from being contaminated with a foreign body. On the assumption that the sole function of the manganese is to separate the particles of the chlorate and prevent its becoming too quickly fused into a solid mass, and yielding up its oxygen with an unmanageable degree of rapidity, other bodies having a recognised chemical inertness—such as sand—have been proposed, and in many cases adopted, as a diluent of the chlorate. If it can be shown—and this is a subject which oxygen experimentalists seem not to have investigated—that as much oxygen can be obtained from a given quantity of chlorate when mixed with sand as when manganese is the diluent, then it would become a fit subject for consideration whether, in view of the accidents that occur, it would not be well to discontinue the use of manganese. We are aware of more than one experienced oxygenist who for this reason has long since adopted sand in lieu of manganese.

We should not wish it to be inferred from what we have said that there is any, even the slightest, danger in preparing oxygen from a mixture of manganese and chlorate; for, in reality, there is no operation in the whole range of practical chemistry that is safer. But the danger lies in the unintentional mixture with the manganese of other bodies having a similar appearance to it; and it happens that the substances most likely to be used as adulterants are those whose presence leads to the most deadly results. Here let us state that we entirely acquit chemists and dealers of all *intentional* adulteration of this substance in the ordinary sense of the term, its cheapness being a complete safeguard against that; but, when allowed to lie stored away in corners of cellars, where it is not infrequently kept it is apt to get mixed with coal dust or graphite lying in juxtaposition, and the presence of which among the manganese can with difficulty be detected; it is then it becomes an engine of destruction. Again: chemists—especially those in country towns—who do not make a leading feature of supplying this article, or whose acquaintance with it is but limited, are apt to mistake it for graphite, and *vice versâ*, allowing the two to become intermixed.

We have spoken of a sample of the impure manganese which was sent to us. The following results were obtained when subjecting it to trial:—Two test tubes were charged with chlorate of potash—one containing, in addition, a fourth of its weight of manganese that we knew to be pure, the other containing an equal proportion of the impure manganese. On applying heat the former liberated oxygen in the usual manner, while the latter behaved as if it were "possessed" by a gunpowder demon of intense violence. It was fortunate for ourselves that the quantity upon which we experimented was very small.

It will still be in the recollection of many readers that, thirteen years ago, Mr. Crowther, of Manchester, lost his life—his child being also killed—by an explosion which was afterwards known to have occurred through the accidental admixture of lampblack with the oxide of manganese he was using. In that case, as in the more recent one to which we have alluded, the cause of the explosion lay in the ignition of a large quantity of gunpowder—for such the mixture really was—confined in a strong iron vessel.

To ascertain whether any sample of manganese binoxide be sufficiently pure for use in the production of oxygen, mix a little with chlorate of potash in an iron spoon and place it over the fire. If it explode or deflagrate it is impure; if not, it may be employed with safety. It is well that it should be known that the manganese may be used over and over again; for, when the oxygen-producing mixture has been spent and is removed from the retort, the washing with water to dissolve away the chloride of potassium leaves the manganese ready to be again mixed with a fresh supply of chlorate of potash. In drying it—which is frequently done on a shovel over a hot fire—special care must be taken that no soot fall into it.

It is well to remind the reader that, among the various substances which introduce danger into the oxygen retort, one of those possessing a special degree of virulence is the otherwise often-used cyanide of potassium—a fact first pointed out by Dr. George Kemp.

In conclusion: we should be glad if those readers who have had experience in the production of oxygen would give us their opinions as to the comparative merits and advantages of the following (or any other) substances used for mixing with the potassium chlorate, namely, the oxides of manganese, iron, and copper, sand, brickdust, or powdered pumice stone.

ON THE CORRECTION OF EMULSIONS AND THE REMOVAL OF FOG.

So far as we have dealt with this subject in our two previous articles our remarks have been almost entirely confined to the treatment of emulsions, in which branch only have we made any systematic course of experiments. Capt. Abney, however, has extended his researches to the treatment of dried films, where, it is needless to say, the existing conditions are in many points widely different. It is of the utmost importance, not only in attempting to trace the reactions which occur in connection with the sensitive media, but also in applying the knowledge thus obtained, to bear well in mind the minute differences of conditions under different circumstances; and we may take this opportunity of supplying an omission by calling attention to the varied conditions which prevail with different emulsions.

We dwelt at some length in our article of last week upon the reactions which occur in sensitising and correcting an emulsion, tracing step by step the changes which take place, or which we suppose to take place, in the formation of the sensitive material. For the sake of clearness we spoke of such an emulsion as containing only silver bromide and free nitrate in a certain proportion, ignoring the decomposition salts present, as well as the constituents of the collodion or other organic matter. As regards the proportion between the bromide and free nitrate that is a matter of no moment, because whatever small quantity of silver nitrate might be in excess it would find a sufficient quantity of bromide upon which to react, and any superabundance of the latter would obviously remain as silver bromide. The decomposition salts (nitrates of cadmium, zinc, ammonium, &c.) are scarcely likely to interfere with the calculations; but we cannot, perhaps, predicate as much of the organic matter. Though the latter undoubtedly plays an active part in the formation of the image under development, it is just possible that it may not participate in the formation of the latent image, or in the reactions which occur between the soluble haloid and the silver. The opinion has been expressed that the function of the organic matter is to aid the development in giving density to the image, but that it is incapable of itself receiving any developable impression. If this be so it is not difficult to understand that the reactions which produce the organic silver compound may be entirely distinct from those involved in the formation of the sensitive haloid. In the absence of any direct evidence in favour of the participation of the organic matter we have, therefore, omitted it from our calculations.

We showed last week that, in correcting an unwashed emulsion with bromide or chloride of copper (or any similar salt capable of forming an insoluble sub-salt where the conditions happen to be favourable), there is no danger of introducing complications or irregularities into the emulsion by the formation of sub-bromide or sub-chloride, owing to the immediate decomposition of the latter substances by the nitric acid set free in the previous reactions. Thus, the corrected emulsion contains only nitrate of copper which is washed out, in company with the other soluble matters, in the course of the after operations. It is immaterial, therefore, what mode of correction be adopted. When, however, we turn to the case of an emulsion which has been already washed, and still exhibits fogging tendencies, the conditions are altered. It must be understood that, whatever may be the treatment to which such an emulsion is subjected, it will be, after correction, scarcely in a fit state to be used as a washed emulsion—that is, the films will require washing previous to exposure to remove the soluble matter. If bromide or chloride of copper be used a trace of sub-salt will remain in the film, owing to the absence of any active matter capable of removing them. Nitric acid, either added to the emulsion or to the washing water, will effect the removal if such a result be desirable, though from the extremely minute quantity present little injury is to be anticipated. We are inclined to think that the presence of even a much larger proportion than could be expected to remain in the film after correction for fog would produce little, if any, effect upon the quality of the image, though we cannot speak as regards sensitiveness. A plate exposed for a brief period to light, and developed by means of alkaline pyro., so as to reduce the whole film, was treated with cupric bromide and thoroughly washed, being allowed to soak for three hours in several changes of water. One half of it was then treated with dilute nitric acid, again well washed, immersed in a preservative of copper, and dried. Upon exposure to gaslight, under a negative, a clean, bright transparency was developed over the whole plate; it was possible to trace the line of demarcation between the part treated with nitric acid and that merely washed; but, as regards clearness, density, or rapidity of development, it was impossible to choose between them.

It should be noticed, however, that in applying the bromide or chloride of copper to a plate in this manner only a portion of the sub-salt is formed in the film, a large proportion forming in the solution itself. This is especially the case with the chloride, which, as anyone who has used it for intensifying purposes knows, rapidly becomes turbid from the formation of the white sub-chloride. We have for some time employed an addition of nitric acid, in order to keep the solution clear, and cannot detect the faintest difference in the intensifying action of the acid solution. The sub-chloride and sub-bromide of copper appear to be, in fact, merely so much inert matter. In order to be "on the safe side" it would, perhaps, be as well in treating such an emulsion to use nitric acid in addition to the bromide, or to set aside the bromide salt altogether, for others act equally as well in the presence of acid.

Nitric acid we stated last week to be incapable of eliminating fog except with the assistance of a soluble bromide, or rather the latter was the only agent mentioned as possessing the power of completing its action. We believe, however, we are correct in saying that any substance capable of entering into combination with silver nitrate will serve the same purpose, unless possessing some property especially injurious to the film. Tannin and gallic acid possess this power if added to the emulsion together with nitric acid, but the film *must* be washed before exposure. Albumen gives a still better result if the plate be immersed in a dilute solution directly it has set. We have not tried the addition of the albumen to the emulsion. It is probable that the list may be greatly extended, but such are the materials of which we can speak with certainty.

Owing to extreme pressure on our space this week, we are compelled to break off at this point, but shall resume our notice of Captain Abney's and Mr. Berkeley's communications next week.

A NEW DEVELOPER FOR DRY PLATES.

It is the fortune of those placed in editorial positions that they not infrequently have imparted to them items of information in their private capacity which they are not permitted to utilise in their position as editors. An instance of this occurred some time ago, and we now allude to it inasmuch as we have been released from the promise we then gave.

On the 20th of March last year Mr. W. Willis, jun., who was then on the point of paying a visit to America, gave us information regarding a certain new iron salt which he had discovered to possess a wonderful influence in the development of dry plates. We were quite at liberty, he said, to try the method as much as possible, but he requested us to delay its publication till his return. The method in question is exceedingly simple, and we are now in a position to describe it:—

The developer is ferrous oxalate; but, as this is an insoluble salt in all the ordinary menstrua, Mr. Willis makes use of the neutral potassic oxalate as a solvent.*

The ferrous oxalate is easily prepared by mixing together a solution of oxalic acid with ferrous sulphate; a copious precipitate takes place, which is the salt in question, and which must be well washed with numerous changes of water, to remove the result of the decomposition. The ferrous oxalate thus prepared will keep for an indefinite period. As we have said, it is easily soluble in a solution of neutral potassic oxalate, and this solution is the developer to which we have made allusion.

It may be premature to say much at present respecting this new developer; but during certain experiments, in which we have seen it pitted against development with alkaline pyro., its behaviour was such as to elicit the highest encomiums upon its energy. Upon plates having received a short exposure the application of this developer brought to light images full of detail and free from fog, with a degree of rapidity only comparable with the action of an ordinary iron developer upon a wet collodion plate.

* We are here bound to recognise Mr. M. Carey Lea's suggestions and experiments described on page 305 of our last volume.—Eds.

To experimentalists in the direction indicated, it may be stated that a soluble bromide does not appear to exercise any retarding power upon the development of the image; the restrainers, so far as at present known, should consist of acids, among which the oxalic has been tried with great success, and appears to be the best on theoretical grounds, although a more extended experience may suggest one still more suitable.

PRECIPITATES *VERSUS* PRECIPITATION.

Certain peculiarities in the process of precipitation and the qualities of precipitates are known to photographers, though their possible application to certain theories has been lost sight of. Yet the various phenomena attending this class of chemical processes deserve the closest study, forming, as they do, the very groundwork and substratum of the whole photographic structure. The familiar sensitive plate—be it wet or dry, iodised or bromised or both, gelatine or collodion—owes its existence to an act of decomposition, followed by precipitation. The old daguerrean film could scarcely be justly classed under the same head; but every film since has been essentially a precipitate embedded in a more or less porous film.

To take the commonest instance: it is known to many that when a precipitate is thrown down in a solution it often carries with it a certain portion of the organic matter that may be present; in fact, with silver solutions the fact is turned to practical account. If the printing bath get discoloured it is the common practice to throw into it a few grains of citrate of ammonia, extemporised by neutralising a little citric acid with ammonia. A deposit at once forms, and soon settles on the bottom of the glass, and not only does it contain an equivalent quantity of citrate of silver, but it has carried down with it all the colouring constituents of the solution which had caused it to assume the appearance of port wine. But we are not aware that this peculiarity is turned any further to account; for we never heard of any method of imparting a foreign substance to the sensitising bath with the object of its being abstracted by the chloride of silver, though it is obvious that a large number of matters would be available, but whether they would be serviceable or not experience alone could determine.

Although the use of citric acid is well known, it is less commonly known that almost any insoluble salt of silver at the time of formation carries down with it dissolved organic matter in a similar manner. The cyanide process for clearing baths—which, since its first proposal by Mr. Tully, has grown much in favour—may, and most probably does, owe its efficiency to some such abstraction, though, of course, it is impossible to indicate what the substance is which is withdrawn. Indeed, although the fact of there being organic matters present in old baths is indisputable, nothing but the barest guesses have been made as to their constitution.

Then, again, those who use carbonate of soda for keeping their printing baths neutral know there is never any necessity to do anything further to keep them free from colour. Some have supposed that a neutral bath does not discolour; but this, we believe, not to be the true mode of stating the case. It is the addition of the carbonate of soda or the presence in the filter of the carbonate of silver, to which the absence of colour is due. And so with regard to chloride, tartrate, and many other salts, we have in our own experience found the same effect to be produced.

The question naturally arises—Is it not possible that to abstraction by iodide or bromide of silver of *dissolved* matters during the process of precipitation may be due many peculiarities special to certain places? Or may not even the very sensitiveness and the power of development itself be explainable on these data?

So far we have dwelt only upon organic matters, and of course if none were present it is evident that our question would need no answer. Some very striking light has been thrown on the subject by a communication, by Professor H. E. Roscoe, from Mr. C. F. Cross to the Manchester Literary and Philosophical Society. He points out another well-known case of a precipitate carrying down with it other matters—ferric oxide, which not only abstracts organic matters from solution, but likewise takes up a quantity of fixed alkali if present. He then points out that, though the inference that *saline* matters might be so abstracted is obvious, there yet exists no statement in print relative to such a case. He therefore made a series of experiments to ascertain the truth or falsity of such an hypothesis, and has obtained some most remarkable results, showing incontestably that such abstraction does take place, and that its amount is capable of determination by weighing. This is a result so unlooked for that it offers most pregnant suggestions to photographers; and if the insoluble silver salts could be examined with equal exactitude it is possible that much light might be thrown upon both the theory and practice of bath and emulsion work.

The following is a short epitome of Mr. Cross's results:—Ferric oxide was precipitated by ammonia from ferric chloride. The precipitate was washed from fifteen to thirty times with boiling water, till the washing gave no alkaline reaction. Sodium chloride was found in all the precipitates examined. A similar experiment was performed with ferrous ammonium sulphate oxidised by nitric acid; the results obtained were identical.

When caustic potash was used as the precipitant enough was absorbed to cause an error of 3·65 per cent. Special experiments were then made with great exactitude to discover the limits of error, the precipitate being washed with boiling water till absolutely free from chlorine. When ·2080 grains of iron was taken the abstraction of chloride of sodium by precipitate, thrown down from its solution, was ·0023 grains—more than one per cent.—with extraordinary care, taken to wash everything away, and only small quantities operated upon—precautions which, we think, have not often been taken with silver precipitate experiments.

Similar results were obtained with other alkaline chlorides and with salts of the alkaline earths, and the results all showed that if in an analysis these facts were not taken into consideration errors of grave magnitude would be made.

In another column will be found a brief note by Dr. Eder on the double bromide of cadmium and ammonium, which has recently come very much into use in emulsion work. Dr. Eder's remarks upon the instability of the ordinary commercial bromides of cadmium and ammonium are quite just, but we fear he is claiming a little too much for the double salt. We were some time ago under the impression that the latter was constant in its character, anhydrous, and not liable to absorb moisture from the atmosphere. Such, indeed, were the characteristics of the sample upon which we based our opinions; but we have since then made other samples which vary very considerably in composition, and exhibit, no matter how carefully dried, extremely hygroscopic properties. The two salts have been in all cases mixed in equivalent proportions, and it seems difficult to account for the difference in the results. One thing, however, is very certain, that, as Dr. Eder points out, the practice of strongly heating the salt to expel moisture is not to be recommended, as the ammonium salt is thus partly volatilised. We have until recently been in the habit of *fusing* the mixed bromides, which would sufficiently account for want of uniformity in the combining equivalents; but the exhibition of hygroscopic propensities would seem to depend upon some other cause. Possibly the double salt is only permanent when the cadmium and ammonium are mixed in certain definite proportions, and if the balance be destroyed instability is the result.

ON THE DESTRUCTION OF THE LATENT IMAGE AND THE ACTION OF SILVER NITRATE ON SILVER BROMIDE.

While I quite follow Captain Abney in his opinion that ozone, probably, may form Ag_2O (or Ag_2O_2?) with one atom of the Ag from each of the molecules of Ag_2Br, produced by the action of light upon Ag Br—especially as nascent hydrogen restores the image to some extent—I do not incline to the belief that an exposed plate, kept in a plate-box, would in any way be affected by ozone, especially in London, where the latter commodity is unluckily exceedingly scarce.

Then, granting its presence, is it not doubtful whether ozone, in its exceedingly diluted state, would practically affect the sub-bromide forming the "invisible image" in the way stated? It seems to me one thing to submit plates to an atmosphere of ozone, and another to place them where only traces of ozone may occasionally get at them. But this is reasoning from a negative point of view. I will, therefore, try to explain how, in my opinion, the effect of exposure to the actinic rays is obliterated.

When a washed emulsion—that is, silver bromide in contact with a halogen absorber—is exposed to light, the bromine ejected enters into combination with the pyroxyline; how I cannot pretend to say. If the necessary quantity of organic matter be not present the bromine may continue in the free state, unless, indeed, the action of the light be counterbalanced by the desensitising effect of the organic bromine compound.

After keeping the emulsion in the dark for some time the emulsion is found, speaking generally, in its normal state again—a fact evidently due to the action of the organic bromine compound. If anyone doubt the fact that the bromine is engaged by an organic substance, I would ask how he supposes the organifier acts as enhancing the sensitiveness—notably tannin with iodide plates.

However, to supplant theory as much as possible—though that is all very well as a leading string—I would ask such doubters to coat a plate with bromide emulsion (washed or otherwise), and to soak it, when set, in a dish of distilled water, until no cloudiness is observed in a portion of the water on acidifying with nitric acid and on the addition of silver nitrate. Then, taking the plate on a clean plate-holder, let him pour a little distilled water over both back and front of the plate, and then hold it before a lamp or gas jet for a much longer time than would be necessary to print a positive by superposition. Now take in a clean cup enough distilled water to cover the plate, and flow it over the latter several times, allowing it to soak for a minute or two. After this test the water contained in the cup in the same way as before, and if no cloudiness result I think he will be entitled to come to the conclusion that the bromine, though probably disengaged—that is, the action is chemical—remains in immediate contact with the sub-bromide, $Ag_2\,Br$, only in *combination.*

Now, just as a soluble bromide, when present in quantity in a bromide film, destroys the effect of the light in the course of several weeks (gallic acid having the opposite tendency to reduce the $Ag_2\,Br$ to metallic silver), so the insoluble organic compound of bromine parts with its bromine, *only much more slowly*, to restore the $Ag_2\,Br$ to Ag Br. This action is slow, and accounts for the good keeping properties of plates prepared with emulsions made with excess of silver nitrate; indeed, the silver organic compound formed may bind permanently a large portion of the liberated bromine; and I much doubt whether such an exposed plate would appreciably lose any of the results due to exposure to light, even in the course of years, much less of months, if kept in a pure atmosphere of the best kind of country air.

With reference to your leading article in last week's Journal, there are still some points on which I am not satisfied. To begin with: by the action of silver nitrate on silver bromide you set free "NO_3," which you call "nitric acid." Now, if we had a H in combination with "NO_3" we should have nitric acid. What "NO_3" in the free state would look like I really don't know; but I presume that you consider it would be apparent on keeping some pure silver bromide in water in contact with silver nitrate. Granted we can isolate "NO_3," then we may suppose that it would combine with the copper, as by the following equation, which is a transcription of your own:—

$$\begin{aligned} &2\,Ag\,Br + 2\,Ag_2\,Br_2 + 2\,NO_3 + Cu{\cdot}Br_2 \\ &= 4\,Ag\,Br + Ag_2\,Br + 2\,NO_3 + Cu\,Br \\ &= 6\,Ag\,Br + \begin{matrix} NO_2 \\ NO_2 \end{matrix} Cu\,o'' \end{aligned}$$

But as "NO_3" is not nitric acid, and I do not see how NO_2 Ho could be formed, I think we must give up this theoretical method of forming Ag_2 Br, though free NO_2 Ho, added to a fogging emulsion, may aid the formation of the Ag Br after the manner suggested in your article; but then H_2 must be set free, or water and nitric oxide be formed, the latter being the action of nitric acid on *metallic* copper. On which reaction would take place I am not able to give an opinion.

Of course I do not mean to infer that nascent NO_3 could not enter into combination with the copper of cuprous bromide without any such evolution of gas; but you, by your fogging theory, have to dispose of NO_3 in a fogging emulsion, and what have you got for it to combine with? With organic matter? If so, I can imagine that, on the addition of cupric bromide to the fogging emulsion, it would perform a part in the reaction in the way stated by you. Granting, however, the possibility of the NO_3 combining with organic matter, we would be led to suppose that no fogging action can take place with pure silver bromide, silver nitrate, and water, in the manner stated by you, as there is nothing for the NO_3 to combine with.

I at one time thought I "had it" when *on paper* I set out the mystic formula—

$$Ag\,Br + Ag\,NO_3 = Ag_2\,Br + NO_3;$$

and, if I remember rightly, I suggested some such action to Capt. Abney. He soon, however, dispelled my illusion; and, though the action of cupric bromide has been made plain to me for some time, I still fail to understand how the Ag_2 Br is formed.

I am not quite certain whether a solution of pure nitrate of silver has been proved to have a fogging action upon pure silver bromide. I refer to what would happen if pure silver bromide were acted on in this way, and were then washed thoroughly, ground up with collodion, and "developed," irrespective of image, quality, and soforth. Would such emulsion fog? And would it fog more than another prepared in the same way, only with free bromide?

I could never understand why an emulsion may be made with gelatine and excess of silver nitrate without any "restrainer," and yet, instead of getting into a fogging state, it will rather work cleaner on keeping. The free silver is washed out, and proved to be present, previously to coating the plates.

The reader may say:—"Of course the gelatine acts as a restrainer." Well, I do not doubt that gelatine is a "restrainer" in a certain sense, as restraining the action of the developer and preventing abnormal reduction; but I cannot go so far as to allow that it would be a restrainer of the supposed action of silver nitrate on silver bromide, since, if it do not prevent the total conversion of soluble bromide into silver bromide, there seems to me no reason to expect that it would successfully prevent the Ag of Ag NO_3 from taking hold of one atom of bromine from 2 Ag Br (or, as the true molecule *may* really be, $Ag_2\,Br_2$, the Ag in this case being a pseudo-dyad, this latter formula may give a better insight into the supposed action of either light or silver nitrate).

It may be said that the gelatine, though powerless to prevent the formation of the silver bromide, may yet be sufficiently powerful to restrain the more feeble affinity of silver nitrate for bromine in combination with silver. If this be so, we must allow that gelatine exercises a greater influence than nitric acid, as we generally add the latter; for nitric acid, undoubtedly, as you yourselves state, does not prevent the formation of the supposed sub-bromide. Gum arabic also prevents the formation of fog, and yet it cannot be considered a powerful restrainer of abnormal fog produced on development; and if we attribute its retraining power in emulsion to the presence of organic acid, produced by incipient decomposition, we must allow that an organic acid may be a more powerful restrainer of silver nitrate than nitric acid itself. Reasoning in this way has often suggested to me the idea that it is an organic compound in the pyroxyline to which we owe the fogging action of excess of silver nitrate.*

Besides, though the affinity of bromine for silver may not be great, there seems hardly sufficient reason why bromine should leave the fully-saturated bromide to go to an atom of the same metal (or to two atoms, if formulated as above)—

$$2\,Ag_2\,Br_2 + 2\,Ag\,NO_3 = 2\,Ag_2\,Br + Ag_2\,Br_2 + 2\,NO_3),$$

especially as the NO_3 has no base to combine with, unless it enters into combination with an organic body; and even then would remain the question of what becomes of it when no organic body is present, as when silver bromide, silver nitrate, and pure water are used, as suggested above.

I hope that I have made my meaning plain, though I am aware that some points have been almost unavoidably reiterated in the course of my argument. I need not say that I shall only be too glad to be set right on any point on which I may hold a mistaken view; and I therefore hope that those whose judgment is far more worthy of consideration than my own will not think it time wasted to do so. HERBERT B. BERKELEY.

ON THE PRACTICAL USE OF VARIOUS SALTS OF BROMINE IN EMULSIONS.

ONE principal thing which is required of bromides used for emulsions is that they be stable in their composition, as it is from their composition that the exact bromine contents of the salt is calculated, and the maintenance of an exact and due proportion between the bromine and the silver is of great importance.

* In this case I would suppose that an organic substance holds the NO_3 in combination, while the Ag combines with Br.

It is, therefore, to be recommended that the precaution should be taken of drying the crystallised bromide of cadmium until free from water before weighing it, because it usually loses a part of its water by efflorescence, when the bromine contents of crystallised bromide of cadmium, as calculated from the formula, does not agree with the actual contents. Then bromide of ammonia absorbs a varying quantity of moisture from the air, and should, therefore, be also dried before being weighed.

The ammoniac-cadmic bromide, which I described at more length on a former occasion, and which is much used in bromine emulsions, is quite stable in the crystallised, in air-dried, condition. It neither absorbs water nor gives any off by efflorescence; its bromine contents are always the same, and it may be weighed out and used for emulsions without any further precautions. To dry it is superfluous; indeed I rather advise its not being dried, since I have observed that at 150° C. the double salt loses a part of its bromide of ammonium, and that its composition then becomes less stable and likely to produce failures.

This salt should, therefore, only be dried on the water bath at 100° C., and not over an open, even if gentle, fire, as previously recommended. Thus the drying of ammoniac-cadmic bromide is not only superfluous but may be injurious.

I recommend this crystallised, spontaneously-dried salt as a bromide excellently adapted for emulsions. J. M. EDER, Ph.D.
—*Photographisches Archiv.*

NOTE UPON THE SOLAR PHOTOSPHERIC NETWORK, AND ON PHOTOGRAPHY REGARDED AS A MEANS OF DISCOVERIES IN PHYSICAL ASTRONOMY.

THE application of photography to astronomy has an importance which becomes each day more marked, and at the present time several branches are distinguished in this admirable application.

From its origin photography has been considered a truthful means of obtaining a durable record of any phenomenon, being free from all personal intervention. Here was already a very important field open to this new branch of science, and it was quickly recognised that the photographic image, when taken wlth the necessary precautions, might be used to obtain accurate measurements. It was thus that in the observatories of physical astronomy, already numerous on the surface of the globe, and of which the number increases each day, a series of images of the sun, the moon, and even of the constellations were taken, and because photography now attacks the construction of celestial maps there is every indication that it will obtain in this direction the most brilliant success.

In a few lines I shall not have the necessary space to fully treat of this recent progress, and still less to give the history of the important applications of an art born in France, and which we ought to strive and labour to maintain in our country in its greatest perfection; and I therefore only desire now to inform my readers of a new point of view of the application of photography, which is that of the astronomical discoveries to be obtained by its means.

After studying the facts of which I am going to speak, one can easily be convinced, indeed, that under peculiar circumstances the photographic image is able to reveal certain phenomena which would not be perceptible with the present instruments used for celestial exploration. I do not here wish, be it well understood, to allude to the photographic impressions based upon the intervention of ultra violet rays, which appear to have so feeble an action upon the organ of sight, and, on the contrary, so active upon whole classes of photographic substances. These phenomena are well known, and I have no need to speak of them here, where I have to treat of quite another subject.

Since its establishment in 1876, the Observatory of Physical Astronomy, not being yet supplied with great instruments for celestial exploration, has specially occupied itself with solar photography. The photographic telescope, constructed by the eminent optician, M. Prazmowski, for our expedition to Japan to observe the transit of Venus, has been very precious for these researches, which have been conducted not only from the point of view of the formation of a series of solar images giving the history of its surface, but more especially in view of the progress to realise in this branch of science the new and important one of physical astronomy.

Up to the present time solar photography, considered as a means of ascertaining the nature of the surface of the sun, has remained very subordinate to optical observation with great instruments. The negatives, of which the images were not greater than four to four and three-quarter inches, could not show the details of the photospheric structure, notwithstanding the study of the real formation of the photosphere is today indispensable if we wish to make progress in solar knowledge.

The study of solar markings or spots, which for more than two centuries and a-half have furnished nearly the only data upon the constitution of the photosphere, appears nearly worn out, or at least it must be sustained for the future by the study of the photosphere itself. Now, this study has only been aided to the present by optical observation, and it is well known how many difficulties this kind of observation presents.

The rareness of favourable conditions, and even the fatigue and danger, are not here the greatest obstacles. The principal circumstance which has hitherto especially opposed the success of these studies is the impossibility, in the midst of the incandescent photosphere, to well recognise the form of the granulations—the power of measuring them, especially to identify them, so as to follow their transformations. It is only near the markings and the little and obscure nuclei that attempts have been made to study the photospheric constitution, but these conditions are no longer normal.

The questions respecting the variations of structure which the different regions of the photospheric surface may show have not been even commenced. There was, therefore, a great step for science to make; and if photography could give images of the surface of the sun, and with details secured with sufficient sharpness to allow of such study unobtainable by the optical observation only, it is clear that a grand advance would be made in our knowledge of the sun, and the way would be prepared for the future precious elements for progressive discoveries. It is the solution of this question which has occupied me since I commenced my labours in solar photography.

Permit me a few words on the considerations which have guided me in my researches. In studying the conditions under which solar photographs have until now been obtained, I have been led to recognise that the principal cause which opposed the reproduction upon these photographs of the details of the solar surface was a phenomenon which may be called "photographic irradiation" (without in any wise prejudging its cause), and in virtue of which a photographic image when it is formed by a very brilliant light gives upon the negative dimensions larger than the reality. This phenomenon is very striking in all the photographs of total eclipses which have been obtained since 1860, and the images of the protuberances encroach upon the lunar disc by a quantity which exceeds sometimes more than ten or twenty seconds of the arc. It is understood that if the details of the solar surface—the granulations, for instance—are of an order of size inferior to the value of this irradiation, it becomes impossible to obtain them with any sharpness. Now it is known that the granulations have in general an average diameter of a second of an arc; and I have been able to see the irradiation attain, even by the very much more feeble light of the protuberances, a value twenty times more considerable.

It appeared to me that the solution of this difficulty was in the enlargement of the image, combined with a diminution in the time of the exposure of the sensitive plate to the action of the light. In this way there was a triple chance of success. On the one hand the irradiation diminished rapidly with the augmentation of the diameter of the image, especially if the period of exposure diminished at the same time. On the other hand, the dimensions of the details to be reproduced being augmented, such details ought to be obtained much more easily; while, finally, the imperfections of the sensitive film had less relative importance. But there is especially a circumstance which then becomes very favourable to the production of very precise images: I have recognised, in fact, that in very short exposures the photographic spectrum reduces itself to a very narrow band; that is to say, that the rays which then go to form the photographic image belong to a group nearly monochromatic. If it be considered that the visible spectrum is, on the contrary, very extended, it is easily understood that photography can give, under these conditions, images very much more precise than ocular observation.

It is true that photographic difficulties augment with the size of the images; but they may be surmounted with care and perseverance. Thus, since the commencement of these studies in 1874, I have constantly striven to obtain the solar images larger and larger, and the diameters of our images have been increased successively from four and three-quarters to six, eight, and twelve inches; at the same time, in increasing the dimensions, the formation of the sensitive film and the manner of the development of the negative was perfected. Upon these last points I will say that solar images demand a photographic process of very great perfection, and the least faults are revealed in all their crudity. As the details to be shown possess extreme delicacy, it is indeed necessary that the film should be without structure and of irreproachable purity. The cotton ought to be prepared at a high temperature, so as to give a film of great fineness.

The development of the image should be gradual—commenced with iron and terminated with pyrogallic acid with silver added thereto. I have been assisted in my photographic operations by M. Arents. The focussing must be rigorously exact. It varies with the season and even with the hours of the day, which is caused by the variation of the lens and the tube which carries it. In my instrument the ocular is movable, and its position is obtained by a circle finely divided.

The time of the exposure is regulated by mechanism, by which the regularity of the movements is rigorously obtained so as to secure an equal time of exposure on all parts of the image. The duration of the exposure ought to be extremely short. In summer the time of action for the images of twelve inches is comprised between $\frac{1}{2000}$ and $\frac{1}{3000}$ of a second of the direct light of the sun which falls upon the sensitive film without either being concentrated or dispersed by refracting medium.

It is the extremely short duration of the action of light which necessitates the slow and continued development; but then the image, free from sensible irradiation, appears with all the details and shows the phenomena with which we have now to occupy ourselves.

The photospheric surface has been much studied with the great optical instruments, and the study has led to the admission in the solar film of the presence of granular elements, but upon the form and dimensions of which learned men are not agreed. My readers will recollect the discussions which have arisen upon the forms resembling rice grains, willow leaves, &c. I will not continue this discussion, for photography has now served to solve the question. Thus, in the labours I pursue, and of which I give here only the generalities, I attach myself especially to the study of the negatives, which are for the future the documents most important to consult. My photographs show the solar surface generally covered with a fine granulation. The form, the dimensions, and the disposition of these granular elements are very varied. The sizes vary from several tenths of a second to three and four seconds. The forms resemble those of the circle and the ellipse more or less elongated; but frequently these regular forms are altered. The granulation shows all over the image, and it does not appear at first sight that there is a different formation at the poles of the sun. It will be necessary, however, to return to this point. The lighting power of the granular elements, considered separately, are very varied; they appear situated at different depths or levels in the photographic film—the granular elements the most luminous; those in which are contained especially the luminous power of the photosphere only occupy a small fraction of the surface of the sun.

But the most remarkable result, and which is due exclusively to the intervention of photography, is the discovery of the *photospheric network*. In fact, the attentive examination of these photographs show that the photosphere has not an uniform constitution in all its parts, but is divided into a series of figures more or less distant one from the other, and showing a separate constitution. These figures have their outlines generally rounded—often nearly rectilinear, and resembling polygons. The dimension of these figures are very varied. They attain sometimes one minute and more in diameter; while in the intervals of the figures of which I speak the grains are sharp and well terminated, although of a size much varied. In the interior the grains are as if half effaced, pulled out, and troubled; but most generally they have disappeared to make place for currents of matter which replace the granulations. Everything indicates that in these spaces the photospheric matter is under the influence of violent movements, which have confounded the granular elements.

I will not today touch upon the consequences of this fact, which enlightens us upon the forms of solar activity, and, as I have said some time ago, show that this activity in the photosphere is always very great, although it does not exhibit any mark at the surface. The photospheric network could not be discovered by any optical means which were directed at the sun; in fact, to observe it on the proofs it is necessary to employ a magnifying power which embraces a certain extent of the photographic image. Then, if the magnifying power be really appropriate, if the negative be very pure, and especially if it have received the full exposure necessary, it is seen that the granulation has not everywhere the same sharpness—that those parts of well-formed grains are disposed as currents, which revolve in such a manner as to circumscribe the spaces where the phenomena represent the aspect which we have described. Now, to corroborate this fact it is necessary, as we say, to embrace a considerable portion of the solar disc, and it is just that which is impossible to do when the sun is observed through a very powerful instrument, the field of which, by the very fact of its power, is very much restricted. In these conditions it may be stated that there exist certain parts where the granulation ceases to be sharp or even visible; but it is possible that this fact does not form part of a general system. Already the examination of the photographs extending over a few months show certain differences in the constitution of the photospheric network—differences which will instruct us upon the variations in the forms of solar activity.

I direct attention also to the very important fact placed in evidence in quite a special manner by the photographs—that of the very numerous and obscure prints shown in the regions of regular granulations, and which indicate that the photospheric film is extremely attenuated.

Thus solar photography is from the present moment placed in the condition that it reveals to us the most important facts connected with the constitution of the sun. It is a new method which opens itself before us, the results of which we can associate with those of spectrum analysis and the old optical observation, and to resolve definitively at last the important problems connected with the great luminary of the day. M. Janssen.

PHOTO-ETCHINGS.

In your issue of November 30th your article on the so-called photo-etchings exhibited by Mr. Gutekunst, of this city, directed special attention to the character of the collodion employed in their production.

Your experiments were evidently conducted directly on the collodion film—a method we consider impracticable, as no known sample furnishes a sufficiently structureless and adhesive film to procure satisfactory results. In our practice we employ no special collodion, and only the ordinary sandarac varnish as used on all negatives made in this establishment. For etching purposes the varnish should not be too thick, and preference ought to be given to a freshly-prepared plate, though we have worked successfully on old negatives, the varnish containing sufficient oil of lavender to retain its elasticity.

After sketching the design lightly on the negative, lay in the lights with crayon, india-ink, or any opaque material, and proceed to etch or scratch away such portions as may be desired, using a coarse needle and firm strokes for the foreground and strong shadows, and a finer point for the more delicate and retiring effects—hatching, cross-hatching, and knitting together, as it were, with irregular markings, and blending into the parts to be left untouched with a delicate stippling process, care being taken to avoid a patchy or wiry appearance. The successful manipulation of the print can only be attained by practice; and, although a careful study of good engravings will materially assist the student, yet an attempt to imitate their character would entail too great an amount of labour, and result only in failure and too harsh a contrast with the texture of the untouched portions of the negative.

As operator in the establishment of Mr. Gutekunst, my duties in the studio afford me but limited time to devote to this interesting branch, and the specimens exhibited were some of my efforts, made in spare moments and in most cases from negatives not specially intended for the purpose, the design being suggested by the character and pose of the subject.

Considerable tact and inventive genius may be displayed in arranging and adapting accessories and grounds to negatives on hand; but the beauty and value may be enhanced where a subject is posed and arranged for a fixed design, and in the hands of an intelligent operator very beautiful and artistic results may be achieved.

There is here certainly an immense field for the display of talent; and the process. in the main, not being difficult, with an unlimited scope, from the slightest alteration in a negative to the finishing of the most elaborate design, according to ability, we unhesitatingly encourage the attempt in any enterprising student whose taste may be in this direction. Wm. Osborne.

Philadelphia.

THE ART OF PAINTING ON THE PHOTOGRAPHIC IMAGE.

No. XVII.

Photographs may be very effectively treated with coloured crayons, and very rapid effects are got in this way. There are two distinct methods—one by the use of hard crayons, or *creta lævis* in wood; and the other by the use of soft crayons or pastels, as they are sometimes called. The latter are capable of producing very sweet and soft effects; but they are very liable to be damaged. Methods have been proposed for fixing them. One way was to apply some penetrating, glutinous solution to the back of the picture, intended to soak through to the front, and so fix the small particles of colour; another was to prepare the paper with a gummy solution, then paint upon it with the crayons, afterwards subjecting the surface to the steam from a kettle; and the third mode was to blow a sticky solution on to the front of a picture from a spray diffuser. But one and all are subject to the objection that they slightly sully the picture. The best way is to frame it at once when done, first seeing that the glass is securely papered into the frame by narrow strips running all round the edges at the back, and, when the picture is in the frame, pasting some waterproof material all over, such as thin gutta-percha or tinfoil.

If the hard or dry crayons be used they should be applied in cross-hatchings or stippling, or the two combined. Take an orange crayon and cross-hatch the darkest shadows with it, and between those may be stippled some warm maroon or Indian red colour. Next take a flesh-coloured one and cross-hatch all over the face. If a good photograph the pearly greys will now be found to have taken their place, and the medium shadows should be warmed up with a raw-umber-coloured crayon, just as if it were water-colour. Pound a small piece of greenish colour in powder; dip a piece of wash-leather into it and rub all over the background; then take various-coloured crayons and cross-hatch and stipple all over until a pleasing effect is got, applying the rules already laid down, which I need not repeat. The drapery should be treated in the same manner; but here, again, vignettes are the most suitable. The hair may have some appropriate colour now stumped over it, and then carefully lined to suggest the flow of the different portions of it, remembering that the lights are generally cold or neutral tinted, the deep shadows rich and warm, and the real colour of the hair most discernible in the middle tints.

Touch up the high lights on the face with a light buff crayon; put the carnation deftly on to the cheeks and lips; and, finally, mark out the nostrils, line between the lips, and put sharp touches about the eyelids, &c., &c., with a deep maroon crayon.

Next week I will endeavour to explain the soft crayon or pastel painting, and then for the present take leave of my indulgent readers. It occurred to me that some might wish to address me by letter on any part of my subject upon which I had not made myself quite clear, or in which they had met with special difficulties. Such readers I would refer to the advertisement columns of this and the next issue.

JOSEPH WAKE.

ON THINGS IN GENERAL.

THE New Year, with all its hopes and promises, has begun. Photographers by this time have made up their balance sheets for the old year, and reckoned up their profits and losses. That they may all have a big balance in the right direction I fervently wish, though if all I hear as I travel about be correct, the year that has just gone has been the worst for a long time past in a commercial sense, except to the process-mongers, and to them I opine many have despairingly fled in the hope of drawing clients by the latest thing out.

Instantaneous photography is not yet accomplished, though I see that with the kindness and generosity becoming the season a gentleman who has made a noise in the photographic world for the last twelve months has reduced the price of his apparatus designed to this end. I don't know whether the Editors will put a veto on this paragraph on the ground of its being an unpaid advertisement; but with the new year I am informed that the renowned Scotellari apparatus can be had at the reduced price of thirty shillings. Of course it will now be in the hands of every-one!

I see the powerful pen of a well-known provincial photographer has been at work to prove that—really it is rather difficult to gather *what* from his flowing periods and classical style—however, I may translate him by saying that three things are bad—too much retouching, too much background, and absence of expression. Photographers cannot be too much obliged for the information thus prominently given:—"Away with levellers and French polishers," I further read. I never before heard of the term "French polishers" applied to photographs, though it could be very appositely done to that class of pictures of which this gentleman is the redoubtable champion—the highly-glazed carbon pictures. As this, however, cannot be his aim, I can only imagine it to be a sly hint at one of his professional rivals who, if reports may be believed, was at one time connected with the French polishing interest. I cannot admire the taste displayed if this be the *motif* of the expression.

I have found much to amuse me in the correspondence columns of late. What a perverse fate it is that constantly impels the Autotype Company into defending its actions in print! They don't deserve it; but they are quite able to hold their own, and he who crosses swords with them needs to put forth all his skill. One gentleman was not "let down softly" by them in their last communication. I must, however, say that their idea that "it does not seem an extraordinary flight of imagination to broach the idea of a second coating of pigment, seeing that a sheet can be once coated," savours rather of the egg that Columbus made stand on end. However, pigment printing is now well to the fore, and I wish it every luck. A good deal has been said of late, in connection with carbon printing, of the use of alcohol in the bath; wherever it is used it is to be hoped that such samples may not be come across as appear to be found in the north, where, as I learn from the report of the Glasgow Photographic Association, fusel oil is sold in place of methylated spirit. It is a very remarkable exchange, but not near so remarkable as the manner of doing business on the continent, where I gravely saw put into print a week or two ago that such goods, for instance, as chocolate were sold by the kilometre. Fancy in England a shopkeeper asking whether you would have a mile or half-a-mile of chocolate!

Among other things of note I have read that some of the German *savants* have discovered that when transparent parts of the negative were worked upon with a pencil further detail would frequently make itself apparent. I should have thought that that was the object of the alteration; however, they manage these things so much better abroad!

America must come into the category of "abroad," and one of those things they manage so well there is the saving of residues—at least so from an article in the *Philadelphia Photographer* one is given to understand. The writer says that "most proprietors of galleries are disposed to practise saving, but the difficulty is in getting 'helps' to look after their employers' interest in this direction when it requires a little more care and an extra step to do it." That is all right and good so far, but he goes on to say that the best plan for all concerned would be to make those who handle silver interested in saving by giving them a percentage on all they save. Now I am afraid that those men who would throw valuable residues down a sink to save the trouble of taking a step, would not hesitate now and then to put a sly ounce or two of silver into the receptacle to increase the amount of their percentage.

In connection with nitrate of silver I have read one of the strangest communications I ever looked at. The writer is grumbling at the high price of ready-sensitised albumenised paper, and thinks it ought to be sold for less, proposing ten shillings and sixpence as a suitable charge. He estimates it to cost nine shillings, and this, he says, would leave a profit of one shilling and sixpence for labour. What he means by a *profit* to go in paying for labour is beyond my comprehension. No allowance in his estimate is made for rent, and the profit—fourteen or fifteen per cent.—is truly very moderate. The Editors of the Journal very kindly declined to print his effusion *in extenso*, and hid its absurdities in three or four lines of "Answers to Correspondents;" but others have not been so kind, and the whole tissue of his absurdities is gravely paraded by them for all to deride.

FREE LANCE.

STRAY THOUGHTS ON THE EXHIBITION.

[A communication to the Photographic Society of Great Britain.]

UPON these walls have recently been seen specimens of the results of one of the most wonderful operations of nature that we, who live in the present epoch, have been privileged to discover and make known; and, unlike most other discoveries which arise from scientific investigations, this one, from the moment of its birth, became closely allied, as a matter of necessity, with one of the emotional faculties of the human mind, viz., the pleasure arising from pictorial representation, and thus were brought together in a perfectly new combination, to be for ever united, emotional feeling and scientific fact; hence we designate our work the art-science of photography.

And whilst so much has been said respecting the claims which photography has made to be admitted into the temple of fine art, it would be as well just to arrive at some definition of the capacity which this art-science possesses for the production of pictorial works. I think it will be admitted that, in fine art, the materials are so plastic that they follow and obey the also plastic emotional feeling which guides their use, and hence, in fine art, an imitation is something independent of, and different from, the sentiment of the object imitated. In photography the materials are not plastic, being unyielding scientific facts, which, in their working, are not subject to plastic emotional feeling, and hence an imitation is a something dependent upon, and cannot differ from, the sentiment of the object imitated.

Assuming this proposition to be correct, it will be evident that the results in each case must always have a separate individuality, and so should not be brought into comparison with each other. It is as well to have some definition, such as this, strongly impressed upon the mind, because, if the actual capabilities of photographic art are clearly understood, I think we should hear less of that spirit of condemnation which delights in looking down upon photographic results from the high standpoint of fine art, as if the two were identical, instead of being quite different; for photography is a new pictorial power, which, although requiring artistic cultivation for carrying out its highest aspirations, can never come into direct contact with fine art, by which is meant that it starts as a new and distinct phase of art. Photography runs its own separate course, and so must be judged entirely on its own merits.

Having thus cleared the way by stating my views of the capabilities of photography, I now propose to see whether, from a study of the pictures that have been exhibited, any lessons can be gained which may, in however slight a degree, help forward the artistic side of our art-science.

In looking at a collection of pictures, where absolute nature has been the model, one cannot help being struck with the singular fact of the more or less absence of abstract beauty, and this applies with most force to the human face. Why should this be so? One would have thought that where it was the intention to produce a picture it would be the main desire and object to secure such models as possessed in themselves beautiful forms. I cannot see why, with the knowledge which everyone has of the impossibility of the scientific portion of our work being able to alter what is given it to do, better, if not perfect, models are not selected. Possibly it may be that abstract beauty, when photographically depicted without some kind of expression, becomes devoid of interest, and this leads into another phase of our work, wherein it differs from that of the painter, viz., that the photographic art student has to bring into play a moral power, which works by influencing and bringing out of the model the mental, or rather sentimental, expression which the subject is intended to convey. This, of course, implies that the model is capable of enacting the part; at the same time there is room for much skill and judgment in deciding when the expression is evident, and it is just the possession and cultivation of this faculty, in conjunction with a knowledge of the laws which govern art-composition, which will determine the ultimate art-value of the work done.

Then, again, in the composition of the leading or prominent lines of a picture there is too often the absence of beauty—not so much in this instance the absence of beautiful form as a want of knowledge of some of the simplest or elementary rules of fine art, the result being that the educated eye becomes irritated, and cannot derive pleasure from other qualities in the picture which may possess value.

Too often we found that the head was placed in a position completely perpendicular in relation to the body. This almost always suggests a want of purpose in the object; but there were many works exhibited where great attention had to be given to this matter, and the result was a pleasure to the beholder, arising from both the artistic faculty and the mental sympathy being satisfied.

Another thing was the tendency to place figures too low down on the space apportioned to the picture. No doubt this arose from our scientific facts being found somewhat difficult to be made subservient to artistic requirements; nevertheless, the result was not pleasing, the balance of parts and quantities not being satisfactory; and this leads to a most important section of our subject, viz., the subordination of one part to another. Now, this is one of the most difficult things in photographic art. We either see the entire surface of a picture rendered with equal minuteness, or else some parts so glaringly deficient in outline that the result is not in artistic keeping, and, consequently, does not give pleasure; also, why should it not be possible to arrange the component parts of a picture in its light and shade, so that we could have one extreme dark and one extreme light, all the rest being in proper gradation of tone? In other words, not the absence of sharpness, only the placing of it in its right position as to retiring or coming forwards. Something of this kind has been attempted where backgrounds, occupying a large portion of the picture, have been made dark, or in comparative gloom; but this is not satisfactory or in keeping, because it frequently has the effect of making the figures appear as if taken when the sun shone direct upon them, whilst the background and accessories were taken without the sun shining at all.

In the exhibition were some works which afforded excellent examples of what I have endeavoured to explain, viz., subordination of parts. I refer to some specimens of mechanical printing—the originals being engravings from paintings—which very decidedly possessed all the attributes that I think ought to be attempted in photography. And it is from engravings and reproductions in black and white that photographers can gain many practical suggestions, by a careful study of the light and shade which such works so clearly reveal to us.

One very singular fact must have forced itself upon all who were capable of being moved by pictorial expression—that as photographic records of the human face must so decidedly reveal what is passing in the mind of the model at the moment, unless the exact expression desired is portrayed, what is done may not only be just something else, but also may really look like some inanimate object which has no capacity to express anything; hence the picture presents an anomaly, inasmuch as the figures appear to have got into the wrong place and mean nothing.

This matter involves on the part of the photographer a peculiar faculty—that of reading character and determining the exact moment when the model, having responded to his influence, appears to him to express the sentiment he wishes, and here again is met one of the great difficulties in the way of the photographer who aspires to depict any incident of an emotional nature; he has to choose models who not only may look like and enact the character to be portrayed, but who also must be subject to the sympathetic influence of the art operator in working them up to the desired expression.

The difficulty of securing models, more especially where several figures are required, makes it a matter of necessity that several negatives should be employed to make one picture. This, which is called composition photography, requires so great an amount of manipulative skill in the subsequent joining together of the separate parts for each individual copy that it would almost appear not to be the way by which future works can be produced. However, when the capabilities of the flexible materials which we have now at our command for making negatives are well understood, and which seem from their very nature admirably adapted to the requirements and necessities of composing one picture from many parts, let us hope that a new era will dawn upon us, and that we shall see the walls of our exhibition well covered with pictorial effects which will raise the status of photographic art in the estimation of the picture-loving portion of the world.

Naturally, as an artist and painter myself, I look at the art side of our work with more interest than at the scientific; because at a public exhibition it is the emotional faculties we appeal to, and success must depend upon the amount of interesting works we submit to this feeling, which leans to the pleasurable rather than to the instructive. And hence it is I see that photography, being a new pictorial power, must in future be taken up by those who, cultivating their artistic faculties to the greatest extent, will make their works not only take rank in photographic status from their own inherent art completeness, but also supply the evident want of the age, viz., pictorial works which illustrate the various phases of nature in its human interest, and which, from the necessity of their always presenting *facsimiles* of what has been in existence (and the originals, therefore, capable of feeling the sentiment shown) must command the sympathy of all who can respond to what is evidently true, and thus our art-science will fulfil one of its missions in conferring pleasure upon mankind. EDWIN COCKING.

FOREGN NOTES AND NEWS.

PHOTOGRAPHY IN SWITZERLAND.—THE TRANSPORT OF COLLODION IN AUSTRIA AGAIN.—DR. VOGEL'S TRAVELS.—DR. HUSNIK'S TRANSFER PAPER.—COMPARATIVE EXPERIMENT WITH COLOURED SCREENS.

THE *Photographisches Wochenblatt* has a letter from a Swiss correspondent giving an account of the condition of photography in Switzerland, from which we learn that trade is dull there at present as well as everywhere else, and that an attempt made to found a Swiss photographic journal has failed completely, as has also a petition to the Bundesrath for a law to protect the possessors and producers of original photographs against unauthorised reproductions. The proposed law of copyright was similar in substance to the new German law which has just come into force. In Switzerland photographers devote themselves almost exclusively to portraiture, the exceptions being a pair of landscape workers, who own flourishing studios at Geneva and Lausanne, while carbon is entirely neglected, the public showing little interest in that branch of the art-science. There is, however, one establishment near Zurich where licht-drucks are produced, though it has been but recently started.

At Zurich or Berne an enterprising portraitist announces that one fine day he threw all his head-rests out at the window, and that he has ever since worked without them, to the great comfort and satisfaction of his sitters.

The oppressive restrictions that hinder the transport, in Austria, of collodion cotton by rail is the subject of a long article in the current number of the *Photographische Correspondenz*; but the subject is not of much interest to British readers, and has, besides, been already touched upon in these columns, so that a passing mention is sufficient as long as no definite result has been obtained by the ventilation it has already received.

The *Photographischen Revue* speaks highly of an account by Dr. Vogel of his travels in the four quarters of the globe, published under the title of *From the Indian Ocean to the Land of Gold*, and forming a volume of the *Scientific and Literary Library* (*Bibliothek für Wissenschaft und Literatur*) of Theobald Grieben.

In the *Photographische Correspondenz* an extract is given from a letter of Professor Husnik's on the best way of using his photographic transfer-paper. It runs thus:—

"It often happens that one has not time to transfer at once to the final support a fatty picture developed on Husnik's transfer-paper, or that in the course of the day one has still a number of similar pictures to finish, so that it is not until evening or the following day that one has time to transfer them to stone or metal. In such a case it is best to remove all superfluous water from the pictures by means of blotting-paper, and then to let them become quite dry. When ready to transfer them place the pictures for a short time in damp and treat them like ordinary prints. In this way the press can be screwed up tighter at the beginning, and the success of the transfer is much more sure than when this operation is undertaken with the still fresh and softened paper pictures."

M. Durand, of St. Etienne, in the *Moniteur*, gives an account of some experiments made in conjunction with M. Blachon, with various descriptions of coloured glass and paper used as non-actinic screens for the illumination of the dark room. As the trials were made with the object of finding a coloured screen sufficiently non-actinic for use with rapid emulsions, the tests were applied to ordinary gelatine plates, and the following examples were transmitted to the editor of the *Moniteur*:—No. 1. A positive obtained by exposing a plate (in contact with a negative) for twenty minutes to the light of a taper protected by an *Appert* coloured glass. The image perfectly visible. No. 2. A positive obtained in the same manner and with a similar exposure, but substituting for the taper a lamp, the light of which was turned down pretty low so as not to have a too powerful light. The result was a positive scarcely so vigorous as No. 1. No. 3. Exposed for one hour to the light of a taper, surrounded by a sheet of non-actinic paper, prepared with chrysoïdine by Professor Stebbing. The result showed no trace of an image. No. 4. Exposed for twenty minutes to a taper protected by a bell glass, both sides of which were covered with a somewhat uneven coating of varnish, holding in suspension finely-divided chromate of lead. No trace of an image was visible. It is remarked that the light obtained with this screen possessed greater powers of illumination than any of those already mentioned. No. 5. An exposure of forty minutes under the same conditions of light as the last produced a distinct image, but M. Durand is of opinion that had the coating of varnish been *more regular* this result would not have occurred. The conclusions at which the author arrives are as follow:—1st. It will be prudent *not* to employ the *verres Appert* for gelatino-bromide plates, as they are not prepared for use in emulsion work. 2nd. That as far as we can see at the present time, except perhaps in the case of extra-rapid gelatine plates, we are perfectly safe from fog in using the chrysoïdine paper. 3rd. That the chromate of lead varnish, while not offering the same security as chrysoïdine, has the advantage of giving, from the same source, a better and less fatiguing light. We may remark that the *verres Appert* spoken of are made of three different densities for lamps, gas, or tapers respectively.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
Jan. 31	Liverpool Amateur	Free Public Library.
„ 31	Oldham	Hare and Hounds Inn.

WEST RIDING OF YORKSHIRE PHOTOGRAPHIC SOCIETY.

The ordinary meeting of this Society was held at the Odd Fellows' Hall, on Monday, the 7th inst.

The minutes of the previous meeting having been read and confirmed, the members proceeded to the revision of the rules, which occupied nearly the whole of the evening.

A number of cloud negatives on waxed paper, the production of Mr. W. Perry, were exhibited by Mr. Greaves, and were much admired, being considered good examples of cloud work.

A patent filter, to be attached to the water tap, was exhibited by Mr. Sachs (for Mr. Berlon, of Bradford, the agent for the patentee). The filter was a remarkably neat and compact piece of apparatus, very ingeniously constructed. It acts either as a filter, or as a tap, a simple half-turn of the screw being sufficient to effect the change. It appeared to be well adapted to the requirements of a photographer or carbon worker, to whom a supply of water free from solid particles of matter is of considerable importance. Much admiration of the useful little contrivance was expressed by several of the members.

The meeting was shortly afterwards adjourned.

PHOTOGRAPHIC SOCIETY OF PHILADELPHIA.

An ordinary meeting was held on the 6th ult.,—Mr. John Carbutt, Vice-President, in the chair. The minutes of the last meeting were read and approved. The corresponding Secretary reported that he had sent the names of officers to the Editors of The British Journal of Photography. Mr. Samuel M. Fox was duly elected a member. The certificate of centennial stock belonging to the Society was placed in the hands of the Room Committee to be framed.

Following a motion to that effect it was resolved to send the transactions of the Society to The British Journal of Photography for publication.

Dr. Seiler exhibited some prints, showing the great latitude of exposure admissible with washed emulsion dry plates.

Mr. Bates exhibited a very convenient hot water apparatus for drying plates, so arranged that it could be kept at a uniform temperature by a spirit lamp or gas-burner.

Mr. Corlies laid upon the table a number of prints, presented by Dr. McQuillin, illustrating various scenes in British Columbia. It was resolved that a vote of thanks be tendered to Dr. McQuillin for the donation.

Mr. Zentmayer exhibited an interesting collection of prints by Mr. Robert Beneke, of St. Louis, Mo., showing various stages of progress in the construction of the bridge across the Mississippi River at that place. These views were made with the Zentmayer lens and were considered fine examples of photography.

Mr. Corlies exhibited a number of successful prints from washed emulsion plates.

Mr. Browne called the attention of the Society to a substance now used by surgeons instead of lint, and which he had found useful in many photographic manipulations; it was similar to a *very* heavy and porous blotting-paper, and was capable of absorbing a large amount of water or other liquid.

The Secretary exhibited samples of his summer's work, showing a print from every plate exposed during the season, illustrating the certainty with which washed emulsion could be worked.

The meeting was then adjourned. D. Anson Partridge, *Recording Secretary.*

BERLIN PHOTOGRAPHIC SOCIETY.

This Society met on the 16th November, 1877,—Dr. Vogel occupying the chair as usual.

Herr Prümm exhibited a number of lichtdrucks by Herr Hoffmann, of Dresden, amongst which may be mentioned a large sheet containing the portraits of the 363 republican members of the French Chamber of Deputies. Of this it was intended to print 100,000 copies, but the printing was discontinued owing to the first edition of 30,000 copies having been seized at the frontier by the French Government. A number of other articles were then shown, including a Scotellari lens shutter, constructed by Herr Reichard. Herr Prümm remarked that an ordinary shutter could be used for after-lighting, its inner surface being covered with velvet. It is held at such a distance from the negative as that sufficient light is reflected into the camera to produce the desired after-lighting.

The President then presented the guest of the evening, Mr. L. Warnerke, of London, to the meeting, and spoke of the services rendered to the dry-plate cause by that gentleman.

Mr. Warnerke then made some most interesting remarks, illustrated by his showing a number of articles which need not be enumerated here, as they are, doubtless, well known to the readers of The British Journal of Photography.

A vote of thanks to Mr. Warnerke for his interesting communication was then passed.

Herr Schwier exhibited a number of pictures produced upon ground glass by the sand-blast process. They were reproductions of woodcuts and patterns upon flashed glass having a white ground. There were, further, ornamental borders for carbon prints, which were then subjected again to the sand blast, the parts of the glass covered by the carbon picture being protected from the sand while the interstices were still exposed to its action. The process, as patented by Herr Schüler, is as follows:—A sheet of glass is ground by the sand blast, and then etched with fluoric acid. A carbon picture is now transferred on to it, after which a second blast follows. By this means the already ground parts are strengthened and the covered parts retain their fine grain.

A discussion followed, the subject of which was introduced from the question box by the query—"What would be the best plan for the construction of a glass house upon a piece of garden ground measuring about five metres from east to west, and ten or twelve from north to south—about fifteen or twenty metres to the north of the proposed site there being houses of two stories in height, while the floor of the studio itself must not be raised more than one metre above the ground?" The querist was recommended to make the glass walls of his studio face the north or north-east.

On the termination of the discussion the meeting was adjourned.

Correspondence.

STEREOSCOPIC TRANSPARENCIES.

To the Editors.

Gentlemen,—Will you favour me by inserting in the next issue of The British Journal of Photography the following remarks on Mr. Oakes's paper about Mr. Breese and his transparencies, which appeared in the number of the 18th inst.?

He states:—"No living man besides myself" possesses the whole of Mr. Breese's *modus operandi.* This is a great mistake, and if Mr. Breese led him to believe such was the case he committed an act of injustice towards Mr. Oakes, one or two others, but, above all, to myself. This I feel anxious to remedy by publishing a few facts.

From the autumn of 1865 until July, 1866, Mr. Breese was in partnership with Mr. J. Robinson, to whom he imparted sufficient knowledge to enable that gentleman to undertake the entire management of the printing and combination department, which he did for the time being. As the commercial prospect, and one or two other matters not worth mentioning here, did not satisfy Mr. Robinson the partnership was dissolved; and, on the condition that the money deposited by him should be returned, that gentleman consented to be bound in the sum of one thousand pounds not to divulge nor practise anything appertaining to the business or the process. I state this because I think it probably accounts for his silence and loss of interest in the matter. I have reason for believing he is now living in the vicinity of Birmingham.

Prior to this a Mr. Fred. Sutton was with Mr. Breese for a short time. After he left he was very much heard of in trying to monger what he knew to many photographers in this country.

Now for myself. I entered Mr. Breese's employment, as a sort of an apprentice, on the 6th of December, 1865, and was with him almost daily until the break up of his home and removal to Sydenham in October, 1868. His brother-in-law, Mr. W. Stockil, then took his affairs in hand and started the concern of Breese and Co., with myself as deputy-manager to Mr. Breese. For the greater part of this time we were quite companions, and latterly, as Mr. Breese's failing health (arising from softening of the brain) required close attention, he was, to all intents and purposes, under my charge. This state of affairs continued till the death of Mr. Stockil in March, 1872, when the business of Breese and Co., from the failing interest on the part of the public in stereoscopic work, both of the specially good and the inferior class, not being a commercial success, the studio, plant, and effects came under the hammer in the June or July following. The whole was disposed of, except a complete set of apparatus and the negatives—the latter in consequence of not being able to get a fair bid for them. It was at this time, through unpleasantness, the great trial I had with Mr. Breese took place, and owing to this, combined with failing health on my part, it became necessary for me to separate myself from the concern in order to secure a thorough change. Since then I have had neither time nor inclination to take up the subject, and had deferred publication till some transparencies had beeu produced on my own account to add more force to anything I might have had to say.

While my pen is engaged on this subject I may as well give my version as to what constitutes (as Mr. Oakes puts it) "the pith of the matter." This is the principle on which combination printing for the stereoscope is performed:—The principal pieces of apparatus necessary are a binocular copying camera, and a good tin or other simple form of lenticular stereoscope open at the bottom. The camera should be fitted with twin lenses, and the usual partition to divide the two pictures both in the portion of the camera before the lenses and also that behind. The front carrying lenses must have, besides the rising motion, a means for varying the distance between the lenses, to bring them nearer together or remove them further apart, as circumstances may require. A right- and left-handed screw motion worked by a milled head from the side is most convenient; but rack-work, or any other contrivance which will do that, fully answers the purpose.

The camera retained for Mr. Breese, by his desire, was supplied by Mr. J. H. Dallmeyer, and fitted with a pair of that gentleman's "new stereoscopic lenses," the means for separating them being the right-and left-handed screw movement—suggested, I believe, by Professor Emerson, of Troy University, during the controversy on how far the two lenses of a binocular camera should be asunder. An extra home-made sliding body was fitted to the camera, and a suitable box divided into the two partitions necessary, with an opening in front for the negative and two at the back for the lenses to enter. This was arranged on a board, to the front of which was hinged a frame holding a cast slab of plaster of Paris, the slightly yellow colour of which was corrected by the addition, when in the liquid state, of French ultramarine and a little of Judson's magenta dye. This diffuses the light splendidly for transparency printing.

Now for the principle, which I will try to put in as simple a form and in as plain English as such an abstruse subject will admit of:—If a stereoscopic slide be taken and the interval measured which separates two corresponding objects in its foreground, one in each half or picture of the slide, then the same be done with two objects in the middle distance, and likewise with two in the extreme distance, it will be found that every measurement increases in length—that of the extreme distance being longer than that of the mid-distance, and this again longer than that of the foreground, every intermediate grade of distance having an interval proportionate to its position to the points taken for measurement. To make the matter more clear:—If a line were drawn from a certain point of a tree stump or other object in the foreground to some definite point in the extreme distance on one half of a paper stereo., and a similar line were drawn between the corresponding points on the other half, the lines, instead of being parallel, would diverge, the two pictures really diverging from their foregrounds into their distance. To put in any figure or other object the interval separating the stereo. figures would have to be hit exactly with that of the points on which each one was to be placed, or in the stereoscope a curious effect would result. Pseudoscopic effect is caused by the exact reverse of the above—the lines converge instead of diverge. If the lines were parallel superscopic effect would be produced; that is, no appearance of solidity or distance whatever.

I will now apply this, and see if it cannot be made elear why we see solidity, as well as the other two dimensions, in stereoscopic pictures. It is now well known that in viewing an object with a pair of eyes the two retinal impressions only coalesce at one point at a time. The rapidity with which the eyes are moved about from one point to another, the persistence of optical impressions, or the time they require to become perceptions on the brain, together with judgment acquired by habit, prevent us from seeing all the other parts of the view double unless we have given ourselves a special training for its observance. To enable us to see any point of a near object clearly we have to converge the optic axes, or, in homelier language, turn the eyes inwards till a line drawn through their centres intersect at the point viewed. For a point a little farther off the convergence is lessened, this convergence being more or less as the point looked at is nearer or farther away. This takes place within the limits of our capacity to judge or appreciate distance.

This is just the performance the eyes go through in the stereoscope in the rapid survey of the two dissimilar images. The near objects being nearer together, as explained above, require greater convergence of the optic axes to unite the two points viewed into one—the more remote ones, being farther apart, requiring less. This constant alteration in the lines of visible direction, with the accompanying fluctuation in the length of interval between the centres of the two retinæ, the brain interprets as distance and solidity. Anyone who wishes to go further into the matter had better go to the fountain head from which Mr. Breese drew his knowledge, viz., Sir David Brewster's works on the stereoscope and binocular vision, or to Sir Charles Wheatstone's papers published in the *Philosophical Transactions* of the Royal Society, and Professor Helmholtz's works on *Physiological Optics*.

Now for the application of the above in the construction of a stereoscopic combination picture:—Suppose it be required to make a moonlight effect: two stereo. negatives will be necessary—one a negative (say) of cloud effects taken with the sun in it; the other a negative of the moon, its position on the plate corresponding as nearly as possible with that of the sun on the other. Attention to this will save trouble. If the Sun's light were very strong he would leave a tolerably clear patch in the positive transparency; if he were partially obscured, or his light weak, as in early morning or late in the evening, his limit would be well defined. Either case would not involve much trouble—the latter rather more, perhaps, because if the moon were taken with the same lines as the cloud effect it would require to be slightly enlarged to exactly fit the place occupied by the sun's image. But as there is nothing on the moon's negative but its image the operation is not a very difficult one with the aid of a magnifier.

When the negatives have been procured the next thing will be to put that of the clouds into the front carrier of the copying camera, *face outwards*, arrange its position on the focussing-screen (about 2.6 or 2.7 inches between two similar objects, one on each foreground), focus, make a transparency, dry, and varnish. Now take out the cloud negative and put that of the moon into its place, but *face inwards*. The camera slide, with its shutters opened, holding the transparency, *back inwards*, is to be put into its place in the camera till the operation of getting the moon right for size and position in it has been performed, which—with the means for enlarging or reducing that the camera should afford, and the rising, lateral, and dividing motion of its lens-carrying front—should not be very difficult of accomplishment. When this has been so far completed that it appears near the mark to the unassisted eye, view with the stereoscope for the purpose of ascertaining whether the moon is right for distance. Very likely, after all the care and trouble taken, that interesting object will appear almost on the tip of the nose, or an infinite distance in space.

The application of the principle elucidated above requires that the moon should be just the distance apart, or, perhaps, slightly farther, than that of the clouds where they are to appear. If the moon appear too near, separate the lenses slightly. The stereoscope will show, while this is being done, the extraordinary phenomenon of a moon travelling through space at a terrific rate. If too far, move the lenses nearer together. A few trials will soon give the moon its proper distance. Focus on the proper screen, try the moon again for distance, &c., make a transparency, which must be of medium strength, dry and coat with a ground-glass substitute, a little wax dissolved in amber varnish being about the best I know, and was the only one used by Mr. Breese. Some narrow strips of thin cardboard must now be gummed round the surface near the edges of the moon transparency; it is then ready to have that of the cloud effect superposed upon it. If the work have been accurately performed the two may be fixed at once; but, if the moon be too near or too far, cut a thin strip out of the centre of the upper glass, and approach or separate the two parts till the result is satisfactory; fasten securely with strong gum-water, and then put under slight pressure to dry.

What has been said about the production of a moonlight effect applies equally to the combination of clouds with landscape, the introduction of figures, &c. Greater care must, however, be taken that both pictures, or sides, of the clouds and landscape are identical in size, otherwise another curious effect arises. More, however, about this, as also the production of distance in the stereoscope between the birds of a flight which have been drawn upon, and photographed from, a plate of finely-ground glass or paper. These, although drawn in one plane, may be given the appearance as though one bird is leading the others, with an interval between each, towards the observer.

It was really for this principle that, some time during 1866 or 1867, an eminent Paris firm offered £50 or £100 each for two of Mr. Breese's negatives, viz., *The Lonely Shore* (No. 12), and *Queen of the Night* (No. 42); for the condition was that instructions should be sent how to print them. The former was not a combination picture. This proposal, I believe, emanated from M. Levy himself.

If the foregoing remarks be not sufficiently satisfactory to Mr. Oakes to induce him to modify his assertion and extricate himself from the false position it places him in, I will undertake to give him in detail the means employed for the production of any of the eighty-six or so subjects Mr. Breese published after this fashion, taking the famous *Sea Gull* (or "gull" picture it ought to be called) picture first. The sea view portion of this was taken on the south coast, near Bridport. The gulls were stuffed ones, and with their wings outstretched were strung up and photographed, while slightly in motion, in the garden. The clouds were taken from a bedroom window near Birmingham, the combination of the gulls with these, and putting them over the sea, being effected in the copying camera. One more instance—73, I believe, was its number:—This, again, is a sea view with a very heavy cloud shading the forepart of the sea, the light shining down from the clearer sky beyond upon the distant water. The gradually-increasing light from the heavy shadow into the distance was obtained by using a softened edge shade; but, then, a streak of light was wanted along the horizon to represent the direct sunlight shining there. Four picked hairs out of a camel's hair pencil supplied this want. Two of them, with their butt ends together, were embedded in copal varnish on each half of the negative just where the light was required. When this slide was carefully printed the effect was really very beautiful. A storm appeared to be passing overhead, enveloping everything in gloom. Just beyond the sea reminded one of a glorious summer's day, the scene glowing with light and warmth.

Mr. Oakes's description of Mr. Breese's method of colouring the lustre picture is not correct. The original work was not performed in such a haphazard manner, as Mr. Breese well knew that in viewing prisms, of which a lustre is composed, every slight change in the angle of view must of necessity produce a different colour, while the laws governing the dispersion of light remain as they are. He, to ensure the representation of the colours being natural, in painting the slide copied the lustre while viewing it from the point from which it was photographed, that object remaining on the mantel-piece with the conditions of light the same as when it was taken. He then looked at it alternately with the right and left eye, putting a touch of colour on the right-hand picture the same as he saw in the lustre with that eye, doing likewise with the left eye and its picture till the slide was finished. This, of course, accounts for the overlapping of the colours arising from the difference of angle being so small. The colours used were of the transparent kind, such as Italian yellow, Prussian blue, crimson lake, emerald green, &c., thoroughly ground in turpentine, and worked in a vehicle of copal varnish.

If you can find the space I may, as opportunities arise, jot down a few details respecting printing, toning, &c. I may also have something to say about photographing moons, clouds, &c., and will probably go through the process which resulted in the production of the fine slide of *The Conjunction of Venus with the Moon*, which caused so much surprise many years ago. This was a veritable photograph of the moon and star, and was believed to be at the time it was first exhibited the only star ever photographed.

Just a few words on another point. I wish to enter a protest against the use of an expression hackneyed in photographic literature. Mr. Oakes has given its substance in the following words:—"I should not be at all surprised if some one crops up in future who knew how it was done all along." Much has been said about raising the social status of photographers; but how can this be expected while one brother of the craft does not scruple to impute falsehood and meanness of a most despicable description to another? Such, in my opinion, outsiders would take as the meaning of the words quoted. If I, from illness or any other cause, had not seen Mr. Oakes's paper, how unjust the application of those words would have been to me when I made myself heard on the subject of transparencies. While we are constantly hearing of two or more investigators arriving at the same conclusion independently of one another, almost by the same means, it behoves us to be very careful how we suspect another of appropriating our ideas, or to make the assertion that we stand alone in any sphere of thought.—I am, yours, &c.,

Wick, near Arundel, January 21, 1878. JOHN HARMER.

IMPROVEMENTS IN CARBON PRINTING.

To the EDITORS.

GENTLEMEN,—Under the above heading Mr. J. R. Johnson contributes an article to your valuable ALMANAC, just published, in which he has made a statement, as a quotation from memory, so widely different from the facts that I must beg you to do me the favour to call the attention of your readers to it.

Mr. Johnson begins by stating:—"In the last or one of the later editions of the *Manual* of the Autotype Company it is stated that while carbon prints are 'undoubtedly permanent, when permanent colours are employed for the production of the pigment paper out of which they are formed, yet, if it be desired to *obtain the tints yielded by silver and gold*, recourse must be had to pigments formed from cochineal, and that such prints are no more stable than the pigments themselves,' or words to that effect, for the *Manual* is not before me." The whole of the passage between single inverted commas is given by Mr. Johnson as a quotation from the last or one of the later editions of the Autotype *Manual*. With what right or justice Mr. Johnson prints in your ALMANAC, where it could not be immediately answered, a statement so utterly untrue, the following quotations shall show:—

The only editions in which anything like Mr. Johnson's quotation appear, are the fifth, published in 1876, and the sixth, published in January, 1877. In the fifth edition, page 83, is the following passage:—"All the range of photographic tints produced by gold toning can be obtained in pigment prints, and of undoubted permanency; if more than these are required it may involve some slight loss of that permanent quality which is the very essence of pigment printing."

Here it is specifically declared that all the range of photographic tints produced by gold toning can be obtained in pigments of undoubted permanency. Compare this with Mr. Johnson's misquotation "that if it be desired to obtain the tints yielded by silver and gold recourse must be had to pigments formed from cochineal."

In the interval between the publication of the fifth and sixth editions of the Autotype *Manual*, M. Lambert appeared, and introduced that rich purple tissue known as "Lambertype tissue." This being a colour of extraordinary brilliancy, could not at first be produced without the employment of cochineal colour, and is thus referred to in the sixth edition of the *Manual*, page 82:—"Up to a very late period, the more brilliant tints in the autotype tissues could not be obtained except by the use of cochineal colour." The article goes on:—"After many efforts and failures, the Company have at last succeeded in employing the active colouring principle of madder, and by the time this *Manual* is in the hands of the public they hope to be in a position to supply tissues in absolutely permanent pigments of a brilliancy equal to those made with cochineal lake colours."

As a matter of fact, from the commencement of 1877 all the pigmented papers made by the Autotype Company, with the exception of tissues prepared by agreement to specified formulæ, have been made with pigments of undoubted permanency, and contain not a particle of cochineal colour.

As far as autotype work is concerned the whole of the single transfer prints executed by the Company since July, 1876, have been produced with the permanent alizarine without a trace of cochineal; not only so, but in the mechanical department this rich and powerful colour has entirely superseded the various fugitive lakes ordinarily employed, and, as the specimen now sent will show, giving a brilliancy leaving little to be desired.

Mr. J. R. Johnson, in your ALMANAC for 1878, would fain put back the Autotype Company to the time when he himself produced single transfer prints with salmon-coloured lights—a remarkable specimen of which, given to him by Mr. Johnson himself, now lies before—Yours, &c.,

THE EDITOR OF THE AUTOTYPE MANUAL.

[The accompanying picture is of a rich tone, having all the brilliancy indicated above.—EDS.]

PHOTOGRAPHY IN COURT.—At the Bloomsbury County Court, on Saturday, the 12th instant, the case of Henderson *v.* Lewis was heard before Mr. Judge Russell. The plaintiff sued the defendant, a photographer, to recover the sum of £50 as damages for false representations and fraud in the purchase of defendant's business as a photographer in Marylebone road.—Mr. Marcus M. Lewis, who appeared as the plaintiff's solicitor, said that his client was attracted to the sale of the defendant's business by an advertisement in June last. His client then resided in Shrewsbury, but subsequently came to London to negotiate with the defendant, which negotiation ended in his client giving the sum of £50 for the goodwill of defendant's business, his client having to pay for all rents, rates, taxes, the defendant being merely paid £50 for the goodwill, which in reality was no good at all.—The defendant's solicitor here interposed by stating that if Mr. Lewis intended establishing his case under the statute of frauds the agreement referred to must be in writing.—Mr. Lewis contended to the contrary, as this was merely a purchase of a goodwill and not of any messuage or tenement.—The Judge coincided in Mr. Lewis's view, and the case proceeded.—The plaintiff said that he purchased the business entirely on the defendant's representations. When he called to see the place in June last, several sitters were waiting their turns to be taken, and everything appeared in good working order. There were plenty of good specimens and apparatus, and he was so well pleased with what he saw that he was induced to become a purchaser; but when he commenced operations in July following he found that his receipts barely came up to his expenditure, and, considering he had been grossly imposed upon, he applied to the defendant, who merely laughed at him, and consequently he was advised to bring the present action. In reply to the Judge the plaintiff said he saw no books, as the defendant had not kept any; but he was shown a number of receipts, from which he imagined the defendant was doing a fair business.—The plaintiff's case being ended, the defendant's solicitor urged that this was entirely a case in which the axiom of *caveat emptor* ought to apply. His client merely represented what he was doing, and that the goodwill of the business was fully worth the money paid for it, his client's only motive for selling being his anxiety to settle in the country. His client was a skilled operator, while the defendant was not, and that was the cause that the defendant had not made the business succeed.—The defendant, being called, corroborated this statement, adding that he had made a good living while in the business, and that his only object in relinquishing it was to establish himself in Norwich, where he had family connections, and if the court would adjourn the case he could amply prove this to be the case, The Judge did not consider that necessary, as the plaintiff had failed either legally or in fact to prove any fraudulent intention on the part of the defendant. He should, therefore, give judgment in the defendant's favour, but it was a case in which he would not certify as to costs.

EXCHANGE COLUMN.

No charge is made for inserting these announcements; but in no case do we insert any article merely *offered for sale*, that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a *nom de plume* be thought desirable), otherwise the notice will not appear.

Will give good *carte* lens by good maker in exchange for a strong tricycle, or for photographic accessories.—Address, Mr. Argent, Mill House, Rolvenden.

Wanted, a landscape rectilinear lens, twenty to twenty-two inches focus, in exchange for two Dallmeyer's 1B *carte* lenses.—Address, T. Edge, Llandudno, North Wales.

I will exchange a plate electrifying machine, with Leyden jar, tank, and pipette, for use with sciopticon; graphoscope; or a 24 × 18 carbon enlargement, for magic lantern slides or background, or anything useful in photography.—Address, O. B. M., 30a, Flowergate, Whitby, Yorkshire.

A brass-bound 1-1 camera, by Meagher, swing-back, new; 10 × 8 water-tight mahogany and glass bath, in good order; new tourist's quarter-bellows camera, three double backs and stand, and No. 1 Steinheil lens; an excellent head and body rest, Harrison's pattern, very firm; a firm, folding tripod, good as new; a sporting Snider carbine sighted to 600 yards. Wanted, Dallmeyer's 4D and 12 × 10 W.A.L. lenses, in good order.—Address, S. G. F., Maker, Devonport.

ANSWERS TO CORRESPONDENTS.

Photographs Registered—

H. Cooper, Northampton.—*Group of Lord Clifden and Party.*

John Moffat, Edinburgh.—*Four Portraits of the Rev. Robert Stewart, four Portraits of Rev. Dr. Lees, and two Portraits of the late Mr. Fox Talbot.*

☞ *Correspondents should never write on both sides of the paper.*

Notice.—Each correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a *nom de plume* as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

*** A press of matter necessitates our leaving over a large number of articles and reviews this week, among the latter being *Design and Work* (Purkess); Illustrations for *Gabriel Grub* (F. York); Capt. Abney's *Treatise on Photography* (Longmans, Green & Co.); Dolbear's *Telephone* (Sampson Low & Co.).

Medicus.—No other test than ordinary litmus paper will be required.

W. G. H.—A glance at the back of the *carte* mount explains the cause of the spots—bronze powder.

W. H.—The addition of sulphate of copper to the developer, so far from being a new discovery, has been well known for more than twelve years.

Dalstonian.—We cannot say to what cause the fading of the prints is attributable, but it is certainly not due to their being fixed in daylight.

W. S. (Edinburgh).—If the negatives be thin print the transparencies by the collodion process; but if intense a better result will be obtained by adopting the carbon process.

Geo. T. B.—The practice is reprehensible, but the offender cannot be reached by the law. A statement of the circumstances in your local newspaper, as an advertisement, will prove the most effectual way of proceeding.

L. L. L.—The only point upon which we can suggest any alteration of, or improvement upon, your *modus operandi* is the addition of so much ammonia to the bath as will cause it to change the colour of reddened litmus paper.

S. Berry.—The sliminess upon the surface of the prints may be possibly owing to the admixture of gelatine with the albumen. We know that this kind of adulteration was practised at one time by a continental albumeniser.

S. P. S. E.—The yellow stains on the enlargement are caused by the formation of sulphide of silver. This is probably due to your immersing the print in the hyposulphite fixing bath before thoroughly washing it so as to effect the removal of the acetic acid.

T. J. Whitley.—Rest content at present with the information that the formula will be published at no distant period. It may be during the forthcoming summer; if not then, soon afterwards. This is all that we are permitted to promise at present.

Amateur.—A plano-convex lens (achromatised) would be suitable for including the smaller angle mentioned; but for the larger angle a very deep meniscus is imperative. If the lens be twenty-four inches in focus it will include on your plate an angle of a little over fifty degrees.

Geo. Smith, Junior.—Prepare the two solutions in separate test tubes and pour them simultaneously into the beaker. Chloride of platinum is very easily prepared: obtain some thin platinum foil or wire and place it in *aqua regia* (a mixture of hydrochloric and nitric acid). Solution rapidly takes place.

Old Barium.—Toughness may be imparted to the varnish you are now using by adding a little castor oil. Commence by trying the effect of three drops to the ounce. It may be better to give it an overdose at first, and then bring it back by the addition of plain varnish, which must be reserved for the purpose.

C. B. M.—If we recollect rightly a patent was applied for, but it was not granted. The invention therefore, such as it is, is public property. If upon inquiry at the patent office we find this information incorrect, we shall in next number, or by post card, let you know. We are quite certain that to one applicant, at anyrate, protection was refused.

Lux.—1. See the remarks on this subject in the Almanac. We cannot recommend you any lamp or source of illumination that will be cheaper than the four lamps mentioned by you, unless we advise you to try ordinary daylight.—2. Any powerful light may be employed in nocturnal photography. In addition to those mentioned try magnesium and the burning of sulphur in oxygen.

W. J. W.—The negative sent is much too thin to be successfully employed in the production of a photolithographic transfer. The requisite degree of intensity may be imparted by pouring over the surface a solution of chloride of copper, followed by the ordinary alkaline pyro. developer, with thorough washing intervening; or by treating it first with a solution of bromide of copper, followed by an application of a solution of nitrate of silver. For your purpose the latter will be the better method.

G. J. T.—1. The Howard tent will answer very nicely provided you have acquired deftness in manipulating, which, from your limited experience, we can scarcely imagine to be the case. Practice for a short time at an ordinary sink, until you can conduct the manipulations neatly, and *then* try the tent.—2. We advise you to purchase the emulsion ready prepared. Coat your plates with this, and when you have mastered the small difficulties incident to a first attempt, try to prepare the emulsion for yourself.

B. Proctor.—1. See reply to "W. S.," and make use of a collodion that is of a red colour.—2. Do not imagine that we are inconsistent in advising you to tone your transparencies with bichloride of mercury followed by a weak solution of sulphide of ammonium. This method of toning will impart the quality of tone desired by you; and as, for what we regard a whimsical reason, the transparencies are all to be destroyed within a month of the time of their preparation, the matter of permanence need not be imported into the question. But for this we should not have advised the use of mercury.

Peripa.—You seem to misconceive the power and capabilities of a portrait lens. If it be tried side by side with a landscape lens—a single achromatic combination, for example—both lenses having similar foci and both being "stopped down" so as to have the same working aperture, the portrait lens will not only *not* be quicker in its action, but, on the contrary, will be a little slower, owing to the greater number of surfaces of glass that impede the transmission of the light. When exceedingly rapid exposures are said to have been given with a portrait lens it is usually considered that it has been worked with its full aperture; therefore, in taking "instantaneous" street views, make use of your portrait lens without any stop. This method of proceeding is especially necessary at the present time, when the light is very weak, even when at its best. During bright summer weather stops may be used with advantage, but not at present.

LONDON GAZETTE, *Friday, January* 18, 1878.

Bankrupts.

THE BRITISH

JOURNAL OF PHOTOGRAPHY.

No. 926. Vol. XXV.—FEBRUARY 1, 1878.

ON THE CORRECTION OF EMULSIONS AND THE REMOVAL OF FOG.

We will now turn to Capt. Abney's experiments with films fogged by exposure to light. Briefly, that gentleman considers that the destruction of the undeveloped image is due to the oxidation of the loose atom of silver, and that any powerful oxidising agent will be found capable of destroying the impression formed by light. As we stated last week, we can understand the efficacy of oxidising agents in this direction, but we do not think that such destruction or fading away of the impression is solely caused in that manner. In our last volume will be found two articles upon the action of the atmosphere upon exposed films, in which it is shown that ozone is an active destroyer of the image. Our present object, however, in the absence of a distinct course of experiment, is not to criticise Capt. Abney's theory, but to point out one or two collateral facts which have an indirect bearing upon our subject.

After reading Capt. Abney's first account of his experiments with dried films, an impression formed itself in our mind that the action of the various substances might probably be not only the destruction of the impressed image, but also the destruction of sensitiveness. In order to test this we prepared a plate with a wet emulsion, perfectly free from fog. When "set" it was placed upon a levelling-stand, and a few drops of the following agents allowed to act for three minutes upon separate parts of its surface:—1. Saturated solution of potassium bichromate. 2. Ten-grain solution of potassium permanganate. 3. Saturated solution of cupric chloride. 4. Strong nitric acid. After remaining on the film for three minutes the plate was well washed—first under the tap, and afterwards by soaking for ten minutes in water—and then dried without preservative. Upon exposure under a negative the picture was impressed over the whole surface, but varied in strength in the portions treated with the oxidising agents. The chloride of copper had left behind the strongest trace of its action, potassium permanganate coming next in order, the bichromate exhibiting the faintest permanent action. It is probable, however, that by a more lengthened washing the retarding influence might, in all cases, be removed; but in any case the result sufficiently proved to us that the action of such substance does not destroy, though it may impair, sensitiveness.

In connection with the nitric acid we may mention a remarkable peculiarity. Upon developing the plate that portion upon which the nitric acid had been dropped presented a circular central spot, surrounded by concentric rings. The image on the centre portion was quite perfect but extremely thin and delicate, while the surrounding zone possessed very much greater density than the general body of the plate. The appearance was, indeed, such as to suggest that the nitric acid had dissolved the organic silver compound, and that in dropping the acid upon the film the dissolved organic matter was forced away from the centre, accumulating in a circular zone of increased density. Such is, no doubt, the correct explanation of the phenomenon, and it may, we think, be taken as evidence in support of the theory that the organic silver compound does not participate in the formation of the latent image, but only in adding density under development.

Looking at the very slight effect which the potassium bichromate exercises upon the subsequent sensitiveness of the film to which it has been applied, we conceived the idea of rendering that substance practically useful in sensitising an emulsion, or, rather, we put into practice an idea long since conceived but never executed. The original idea was simply to utilise bichromate of potash as an "indicator" of free silver in the same manner as it is employed in Guy Lussac's silver test, of which we spoke a few weeks ago in connection with volumetric analysis. But if, in addition to this, the bichromate act as a fog remover, its use becomes doubly valuable. Accordingly, to a small quantity of plain collodion we added four drops (dropped from a glass rod) of saturated solution of potassium bichromate and eight grains of double bromide of cadmium and ammonium. This was sensitised with fourteen grains of silver nitrate, which allowed for an excess of over two grains after total conversion of the haloid. Upon the addition of the silver in alcoholic solution the emulsion immediately assumed the deep red colour of chromate of silver; but with a little shaking this rapidly disappeared, owing to the decomposition of the silver chromate by the sub-haloid. The mixture then assumed and retained for some hours the appearance of an ordinary emulsion; but when the whole of the soluble haloid was converted it gradually acquired the characteristic colour of the chromate. It was allowed to remain in this state about twenty-four hours, when it was of a reddish-salmon colour—the result of the mixture of the yellow of the bromide and the red of the chromate. It was then neutralised by cautiously adding, drop by drop, alcoholic solution of cadmium bromide, until after standing some minutes the yellow colour became permanent. It was then allowed to rest for three hours, for the bichromate to exert its action.

It is evident that by adopting such a course the nicest possible balance between the combining equivalents of the bromide and silver can be secured, as the faintest trace of chromate of silver will give the characteristic red tinge, which cannot be mistaken. The chromate is immediately decomposed by any of the soluble haloids, when, of course, the colour disappears. A mere fractional part of a grain of free silver will colour a large quantity of emulsion, and a drop or two of alcoholic bromide solution will instantly destroy the colouration. But, unfortunately, the emulsion thus treated refuses to give *the faintest trace of an image*. Plates coated and soaked for a quarter of an hour in warm water, and then thoroughly washed under the tap, gave no image after an exposure five times as long as would be necessary with an ordinary emulsion. The developer was strengthened until uniform reduction of the film took place, but not the slightest appearance of an image was visible at any stage. After the result of the experiment with bichromate upon the dried film the behaviour of the same salt in emulsion appears inexplicable, unless we suppose that it reacts in some way upon the constituents of the collodion; but, even taking into consideration the small quantity present (probably less than one grain) and the very thorough washing given to the plates before exposure, we are at a loss to account for the absolute insensitiveness of the film. We shall, however, pursue our investigations on this subject.

We shall touch upon one more point and then we have finished. Capt. Abney speaks of a difference between his own results and those of others with regard to the action of nitric acid upon the iodide of silver image. In thus making a distinction between the latent image upon iodide and bromide of silver we have been accustomed to consider the difference to arise, not from the different haloids but from the different *mode of development*. Thus, iodide of silver, under ordinary circumstances, not being acted upon by alkaline pyro., is always spoken of in connection with silver development, which differs essentially from the alkaline method almost invariably employed with silver bromide. We do not go the length of stating that there are two distinct actions of light in forming the developable impression; but we believe we are perfectly within bounds in saying that certain substances are capable of destroying that image, *so far as alkaline pyro. is concerned,* while leaving it amenable to the action of silver development. A sample experiment will show the force of this:—Let an alkaline-developed image upon bromide of silver be removed by means of nitric acid in the manner so generally adopted for the production of transparencies direct in the camera. If this reversed image in silver bromide be thoroughly washed, exposed to light, and developed *with pyro. and silver*, the result will be that the transparent portions from which the bromide has been removed (and which represent the original image) will develope as strong an impression as those portions containing the full thickness of bromide; and when a certain stage is reached the image disappears entirely in a uniform deposit of silver.

If this plate, upon which are impressed a negative as well as a positive image, be now washed, and again treated with nitric acid, the reduced silver is removed, and a perfectly clean picture in bromide of silver remains, which may be developed with alkaline pyro. without any abnormal reduction in the transparent portions. It may be urged that the developed image differs from the undeveloped; but it is evident that some latent action must remain after the visible image has been removed to permit its redevelopment. We have mentioned this first in order to suggest that possibly the discrepancies in the results of different workers may arise from some misunderstanding with regard to the mode of development.

In an article in our last number Mr. H. B. Berkeley pertinently asks what becomes of the free "NO_3" set down in the formula we gave a fortnight ago in attempting to explain the *rationale* of the cure of foggy emulsion. We wrote with the full knowledge that NO_3, except in combination, is an impossibility; but we reiterate Mr. Berkeley's question—What *does* it combine with? Assuming the liberation of NO_3 in the manner indicated, there can be little doubt that it combines in some loosely-defined way with the organic portion of the emulsion, which we have endeavoured hitherto to keep out of the reaction; but the more closely the subject is studied the more evident does it become that the organic matter plays its part, but what that part may be we must confess our inability at present to even guess at. As Captain Abney suggests, the formation of nitric oxide would account for the more energetic action of the copper salts in the presence of nitric acid; but are not the circumstances entirely changed when we substitute for the direct action of nitric acid upon metallic copper the mere interchange of elements, one or both of the substances being in the act of disengagement?

If we understand Mr. Berkeley to suggest that to the formation of nitric oxide, by the decomposition of the NO_3 in our formula, may be due the removal of the fog, we can scarcely follow him, though such a reaction may take place, accompanied, however, by the formation of other substances which may possibly have as much to do with the changed state of the emulsion. The subject is so delicate a one, unfortunately, that little light can be thrown upon it by actual analysis; hence theoretical argument and suggestions become of more than ordinary value, and we shall be glad if Mr. Berkeley can clear away some of the obstructions in the way of our present theory or hypothesis.

WATER STORAGE.

The use of a copious supply of water is so necessary and accustomed a matter to the photographer, and he is so apt to overlook or make light of sundry difficulties and dangers attending its use, that we have thought it not inopportune to call attention to the subject, reminded of it, as we have been, by being recently informed of two cases which happened in the same town when sums of money not far from two hundred pounds each had to be paid as compensation for damage from overflows.

The legal aspect need scarcely be dwelt upon here. Indeed, it is difficult to raise a doubt on the question, for instance, of the photographer's liability to be cast in damages if, through a leaky pipe or an overflow of a cistern, a pellucid stream of even the most limpid water should find itself a new bed on a pile of silk velvet, or meander over a richly-decorated wall in a draper's premises below. We would rather try to indicate some precautionary measures that might render impossible any question of law. The subject is important, many other cases than those we write of having from time to time come to our knowledge.

We are afraid that, so long as there are apprentices and careless workmen, so long will there be overflows and floods; but even in such cases it is quite possible to obviate possibilities of damage. We may take a hint from some chemical laboratories where it is not uncommon in rooms, many times larger than the average photographic dark room, to have floors laid with asphalte. It would be by no means difficult nor expensive to have the whole floor of a dark room covered with asphalte well smoothed and worked to a slight fall instead of being perfectly levelled, with a ridge or ledge all round, which would retain any amount of water till it ran in the direction of the fall, where a good-sized exit pipe might be securely fastened. The operator then might leave his room with a light heart at any time, perfectly fearless of damage being done by any overflow, even after the severest frost.

It is customary in most establishments to use a reservoir in which to store water instead of taking it direct from the main, the latter source being liable to fluctuations both in the force of the supply and in its clearness and purity. It is far from pleasant to have the fact brought under our notice for the first time that the mains have been flushed by the sudden projection on to a beautiful negative of a brown mass of the colour of coffee and of the consistency almost of Thames mud—excellent, doubtless, for the variety of subjects it would offer for microscopic enlargements of lower forms of animal and vegetable life, but detestable upon a collodion film. The use of reservoirs as a provision against such contingencies is highly to be commended, the danger, on the other hand, being the great probability that the said reservoirs would become receptacles of dust and dirt. A gentleman using an intermediate cistern in this manner lately found himself in difficulties with his bath, which he had made with ordinary tap water in the same way he had done with success for years. Though he made it in the usual manner he did not get his accustomed results, and he was at last persuaded to test the water, which was found bad—we may say very bad. An investigation proved the presence of one dead rat, two mice, and a large and interesting variety of cockroaches—an injudicious mixture which we considered quite sufficient to account for any little irregularity of action.

The tank need be by no means an expensive one, an old and tight cask answering every purpose, as we know by experience, and the whole could be fitted up with a ball-cock for very little money. We know of a studio where a special alteration of the flooring in the direction we indicate has been made; but for the toning room, instead of the dark room, one-half of the floor under the troughs is laid with Roman cement slightly hollowed to form a channel, and directly on this the washing waters from the troughs and the supernatant fluids from the precipitating vessels which lie beneath are allowed to run off, the channel carrying it to the outside, where suitable arrangements are made for conveying it to the sewer.

Such a floor may be called a precautionary measure. Preventive steps consist in attention to all the arrangements for carrying off the water in the usual manner and the occasional supervision of the supply-cock, which is liable in course of time to get leaky. All reservoirs should have an overflow pipe suitably led away, and of a *greater width than* the supply pipe, so that any contingency may be prepared for.

We believe, however, that in looking into most cases of overflow it will be found that they have arisen from the exit pipes being choked. A case recently came under our notice where some old collodion bottles had been washed, and the tough, dried skin removed from the bottles had collected and formed an impenetrable plug which had prevented the passing of any water, a disastrous flood being only just averted by a timely discovery. Collodion skins and bits of blotting-paper should be scrupulously kept out of sinks under all circumstances; even the largest effluent pipes for dark-room and printing-room accommodation are generally devised for the outflow of simple liquids, and few of them have more than a three-quarter inch pipe to take off all the outflow.

In case of frost all water pipes liable to be exposed to the cold should be protected in the usual manner with haybands if outside, but, if inside, with some more sightly safeguard, such as will be found in common hemp or tow, which answers the purpose well.

Possibly some of our readers may not be aware that it is not the *thaw* that bursts the pipes but the *frost*, the burst only being rendered perceptible when the congealed water liquefies. Professor Apjohn recommended as a protection against frost the soldering at intervals along the water pipe a short length of lead piping closed at one end and open to the water at the other (the soldered) end with the object of relieving the pressure when the water was expanded by frost. Being closed at one end the water could not fill these projections, and the elasticity of the air prevented any uneven pressure. In some cases the plan seems to have answered, while in other hands no success has been obtained. Some of the failures may be attributed to the solder not being put on sufficiently thick, when, through its brittle nature, it has given way at the first sign of freezing, and thus the very means adopted as a safeguard have proved to be the source of disaster. If the precaution with respect to the solder which we indicate be carried out, we think Professor Apjohn's proposal will not fail to achieve the object in view.

RECENT PATENTS.

No. IV.—IMPROVEMENTS IN PHOTOGRAPHIC LENSES.

The name of Voigtlander was much better known in connection with photographic lenses twenty or thirty years ago than it has been during recent years. When publishing, a few months ago, the lists of applicants for new patents, we were pleased to find the name was again to be prominently brought before the public; and, with many others, we waited with no little anxiety to ascertain the nature of the new optical production for which Herr Voigtlander had sought to obtain letters patent. We are at length placed in possession of the desired information by the publication of the following specification, which we give in the language of the patentee, Frederick von Voigtlander, of Brunswick, Germany:—

This invention has for its object improvements in symmetrical lenses for photographic purposes.

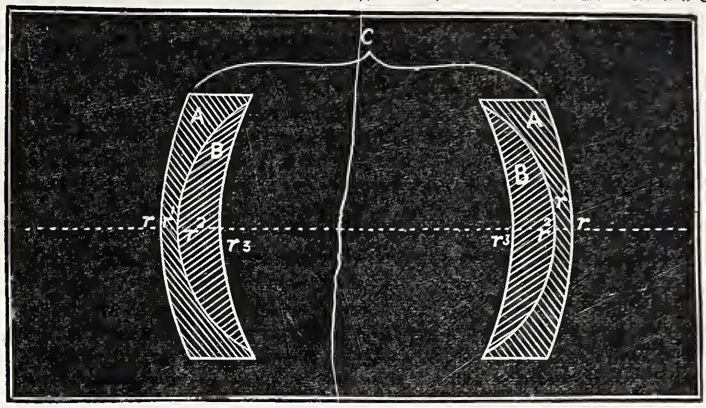
Symmetrical photographic lenses constructed according to my invention possess a considerably greater illuminating power and greater depth of focus than any other of the existing symmetrical constructions. These advantages have been obtained by the peculiarity of their construction, founded on calculations, but especially by the adoption and application of an optical principle not considered hitherto.

In every photographic lens two different kinds of rays come into action, namely, the optical or visual rays, and the chemical (not visual) rays; and from this point of view also two different pictures are obtained, namely, the optical or visual and the chemical picture.

In all photographic lenses hitherto constructed the optical picture was treated upon the same principles as the chemical; but as both kinds of rays have evident differences regarding their action, it has been my study and endeavour to make the chemical picture—which, in fact, is the only one coming into operation when making a photograph—as perfect as possible, even by somewhat injuring the visual picture.

I have fully succeeded in this respect by employing as material a flint glass of very great specific gravity and great refracting power, such as has never been used before for photographic lenses. By this means I am enabled to over-correct the visual picture—that is, give an overplus to the blue spectral rays; thus the chemical picture (the useful one in photography) is brought to that perfection which my new lenses possess. Also by this same means I am enabled to shorten the combined focus of this construction, so as even to obtain a proportion of six to one between the focus and aperture, and from this important circumstance, according to the laws of optics, the lenses derive great illuminating power.

The drawing represents a vertical section of a symmetrical photographic lens constructed according to my invention. It consists of



two exactly symmetrical object glasses. Both object glasses are exactly identical, and consist each of two lenses (menisci); the object glasses are so placed that the concave sides face each other. The lens A consists of heavy flint glass, the index of refraction being = 1·655; of the other, B, the refracting index is = 1·55.

The combined focal length of such a system being supposed to be .... = 1·000.
The aperture of the object glasses is .... = 0·666.
The ratio of curvature for the radius r ...... = 0·208.
" " r^1 ...... = 0·100.
" " r^2 ...... = 0 100.
" " r^3 ...... = 0·292.
The distance between both systems C ...... = 0·2.

The surfaces r^1 and r^2 are exactly identical, and cemented together with a permanently transparent cement. A central stop, allowing the instrument to be used with full aperture, is placed between both systems, and a number of smaller diaphragms are furnished to provide for all required purposes.

Having thus described the nature of my improvements in symmetrical lenses for photographic use, and the manner of their construction, I would have it understood that I claim—

First. The manufacture of such lenses in which the differences of the visual and chemical picture are profited of to render the chemical (useful) picture as perfect as may be, and also to obtain a considerably-increased illuminating power with great depth of focus, substantially as above described.

Second. The construction of symmetrical lenses for photographic uses with the parts formed of the densities and curvatures, substantially as above described.

The above, when reduced to ordinary photographic language, must be held to mean that the lens is one of the same form as that which in our Almanac for 1870 was described, and illustrated by a diagram, as the well-known "rapid rectilinear." From this it differs in being made of dense flint glass instead of ordinary flint and crown.

By making use of a dense flint it is undoubtedly possible to increase the aperture—a fact that was specially pointed out by Mr. J. H. Dallmeyer, at a meeting of the London Photographic Society during the same month in which the Almanac above alluded to was published; but this advantage, in the estimation of that gentleman, was purchased at too great a price, namely, the deterioration of the glass of which the lens was constructed. Presuming that Herr Voigtlander has had his attention directed to the interesting researches made by Mr. Gaffield, of Boston, with respect to the changes that certain descriptions of glass undergo after an exposure, more or less brief, to light, and in virtue of which a dense flint glass after a short time acquires a decided yellow colour, we further presume that the glass he employs in the construction of his lenses differs from any hitherto employed for this purpose in not being affected by light—a point which, not being mentioned in the specification, we can, however, only guess at.

A special feature claimed by the patentee, and one possessing interest from a scientific point of view, is that in which he boldly takes the "bull by the horns" and directs attention to the non-coincidence of the chemical and visual foci, to which he attaches much importance; for he says in the provisional specification—"I construct the lens so as to be over-corrected and somewhat imperfect for the visual picture, in order to obtain the chemical picture as perfect as possible. This I am enabled to do by making one of the glasses of each lens of a symmetrical double combination lens from a glass of greater density than has ever before been used in the manufacture of photographic lenses." On this point of the invention we may here observe that many photographers in this country have ever displayed a decided antipathy towards lenses possessing such a distinction between the two foci; while others, conceiving that by leaving the visual focus "to take care of itself" a greater number of the chemically-active rays might be brought to a focus together, have given their preference to lenses in which the chemical and visual focus did not coincide.

STUDIO FOG.

Two or three weeks ago a gentleman from Northampton, writing upon this subject, asked if I or anyone else could aid him in expelling this photographic demon. When he is once in possession, "Pylos" is perfectly correct in speaking of the difficulty in expelling him. There is not a photographic grievance at any time of the year more difficult to bear or more troublesome to circumvent. What is more disheartening than to enter one's studio upon a winter morning, the sun, perhaps, just breaking through the clouds, and giving promise of a bright, sparkling day that will bring sitters out, and then to find all over one's own quarters a dirty atmosphere fatal to any brilliancy of effect? The evil can often be palliated, and sometimes quite cured, but often as not some lowering in the transparency of the shadows has to be put up with.

It will, perhaps, be some help towards taking steps to mitigate the trouble if we consider its cause. I am not going to enter into a disquisition upon fogs in general, but only upon one phase of them. The difficulty with studio fog is that it often remains long after the external atmosphere has cleared to its normal transparency. With any apartment having windows or doors opening out upon the open air, whenever a fog arises during the night or the early morning it is sure to penetrate and fill such apartments with its thick mist, and fogs in towns always bear an immense amount of sooty flakes mixed with the minute corpuscles of water which constitute a true fog; for all the smoke discharged into the atmosphere remains suspended, and I am inclined to think the presence of the watery particles assists the sub-division of smoke particles which, instead of clotting, as it were, become smaller and smaller, and so are more difficult of precipitation. It thus follows that when the sun rises, if few or no clouds are present to obscure it, the suspended water is soon converted into invisible vapour and the fog begins to disappear, the yellowness of the atmosphere being caused as much by the fine grains of carbon composing the smoke—acting in the manner so beautifully explained by Professor Tyndall—as by the finely-divided water. In the open air, however, these smuts gradually subside, or are blown about till they coalesce, just as a finely-divided precipitate coagulates upon shaking, and drop upon the streets and housetops. But all this while in the studio the air is still, and the sun does not shine in. There is no mass of air in the higher strata which gentle breezes can cause to mix with the fog-bearing lower ones and dissolve the water drops as occurs outside.

The treatment thus indicated is to get plenty of heat in the studio, plenty of ventilation, and as many "draughts" as possible to assist in shaking and stirring about the invisible soot particles, causing them to agglomerate and fall.

If "Pylos" will be up in his studio in good time, and see that his helps "fire up" well, and, if the fog has cleared outside, open all his ventilators, doors, &c., he will soon find a change. Many studios are heated by open fireplaces and others by stoves, and the boy who usually attends to these matters is not wont to be particular in the matter of smoke, so that too frequently the studio fog owes some of its thickness to his carelessness in lighting his fires.

I used to experience considerable difficulty in my last studio from this cause; but it was to a great extent got over by making a sheet iron blower for the fire, *i.e.*, a movable screen which, when hung up before the fire, created such a draught that no smoke could come down; and, unlike many contrivances, there was no fear of the boy not making use of it, for his labour was so much facilitated by it that he more frequently went to the opposite extreme and left it on till the fuel was burnt away. Under any circumstances it was a great help, and I would advise anyone whose studio is lighted by open fireplaces to have such a screen made.

As I have on a previous occasion stated, my present studio is heated by hot water—that system under which the water is at high pressure. I like it as much as ever. Half an hour after lighting the furnace the room is perceptibly warmer, and in a little longer time is as hot as is required; it soon tells upon the fog under ordinary circumstances.

There is one other condition which may be alluded to; that is, in winter time there are so many fires going that a far greater amount of smoke is thrown into the atmosphere. I have known cases where one particular chimney-stack had been the cause of intolerable trouble, and which might have been guarded against by taking especial precautions when the wind was in a quarter which blew the smoke into the studio from that direction.

I have indicated the most practical means of curing the fog, and when all is done one can only try to evade the residuum. Thus, as I have before recommended, use short-focus lenses, and *discourage full length portraits as much as possible.*

As to the chemicals little can be said. No arrangement or selection of them will enable a clean picture to be taken through a foggy atmosphere; but particular care may be taken that the fog is not added to by the chemical manipulations. At the time of the year when fogs are prevalent, speed is of every importance, and hence old and slow collodions can scarcely be used, though their freedom from chemical fog is well known. Still, let every thing be in good order, bath and developer made warmer, the dark room at a genial temperature, and then all will have been done that is possible.

G. Watmough Webster, F.C.S.

THE ART OF PAINTING ON THE PHOTOGRAPHIC IMAGE.

No. XVIII.

One of the chief drawbacks to painting in Swiss crayon or pastel is the immense variety of separate crayons of various tints required to produce really good results; for, although the crayons are, in a sense, mixed and blended upon the paper, if too many separate ones are used on the same place (which must inevitably be the case unless you have a crayon of at least an approximate tint) a kind of greasiness arises, and the place gets polished and bright and refuses to take any more crayon.

As you are very liable to rub the lower part of your picture whilst working above, it is as well to begin at the top, working downwards, getting as much force as you can at once, and this you may the more easily do inasmuch as the colours do not change at all or run, but remain in their places. Take suitable crayons and rub in the upper part of the background; or the whole of it may be put in, as you are not so likely to disturb it afterwards, but you must first consider carefully what the face will appear when finished, and where it will require relieving by the background. Should the background be very much too light, or quite white, I should strongly recommend a deep wash or two of water colour, *without gum*, as a preparation. On vellum or proper paper this would not be necessary, but most photographic papers are not all that could be desired for crayon painting; indeed, I have sometimes found a broad washing in of the whole picture in water colours a great assistance, or the strong shadows may be temporarily warmed up with them before commencing on the high lights—for the same reason that I suggested glazing them first in commencing an oil portrait, for the crayons are very powerful, and the putting on of the high lights makes the rest look terribly grey and weak.

After having got your background to your mind, take a crayon of a suitable neutral tint and broadly map out the high lights on the hair, then the local colour, and then the deep shadows. Leave them crisp and sharp for the present; then with a light buff crayon put on the high lights on the face. Next lay a pure flesh, then the light grey, and so on precisely as in water colours. Let the strokes be broad and close together, here and there cross-hatched with slightly different tints; and when you have got the face to look tolerably complete *at a distance* you may begin to blend the different tints, commencing with the lights and working into the shadows. By this process you may get any amount of softness of outline and the utmost delicacy of tint. Should you want a few sharp touches about the nostrils or eyes, they may be got by little bits chipped off the crayons so as to get a sharp corner; or the hard crayons may be used, if preferred. The latter are, perhaps, the most manageable.

After you have softened the hair you may proceed to put in all little sharp lights and shades or matters of detail, using a stick to rest your hand on to prevent rubbing. A dark line here and there may be put on the light, or a light one on the dark, to prevent too stony or solid an appearance. After you have got the face modelled up and softened, a few broad touches here and there, scarcely perceptible, but following the lines of the face, have a valuable effect. Drapery can very easily be done with soft crayons, and most beautiful effects got with the utmost rapidity; indeed, when once the artist has mastered this mode of working, there is nothing equal to it for rapidly producing bright, clean, pleasing, cheap pictures, for club purposes, &c. The crayons completely hide the photograph, as in oil; indeed, a skilful, sharply-treated crayon head should look like oil at a little distance.

And now I must conclude these papers. Artists of old standing may (if they have taken the trouble to glance at them) have smiled at some of my recipes, and think them savouring of empiricism; but they should remember that this series of articles has been written principally for the beginner and those unused to art technics. I do not think I have said much to lead learners astray, and my aim has been to save time to the tyro in finding things out. To such I would say—Do not be discouraged by first attempts, and be assured, at all events, that the foregoing papers describe methods by which the very best results have been obtained, and such as have given satisfaction to the public. JOSEPH WAKE.

NOTES ON PASSING EVENTS.

By a Peripatetic Photographer.

The interesting account of the production of the once famous Breese "moonlight" and other pictures which is now being published is, to many, a truly delicious morsel. It was in 1861 that Mr. Breese first entered upon the stage as a photographer, and he jumped into notoriety all at once by the boldness of his conceptions; for he produced views and other scenes, mostly marine, in which he imitated moonlight effects with so much skill as even to have led to more than one editorial expression of opinion in a contemporary as to their being real moonlight views—that is, views taken by means of moonlight, as they purported to be. The "cat has now been let out of the bag," and we have what may be designated an *ex cathedra* statement as to the manner in which these "moonlight" views were taken, viz., by *sun*light, as every physicist knew all along. Great credit is due to Mr. Breese for the boldness of his conceptions and the natural and beautiful manner in which he carried them into effect. When the whole of Mr. Oakes's communication has been submitted to the public it will, I venture to believe, give a "fillip" to stereoscopic photography as welcome as it is much required. Mr. Harmer's letter on the same subject is characterised by much ability and facility of description; and it is to be hoped that he will very speedily redeem his promise of giving a few more details on the photographing of clouds, moons, &c. He may rely upon such details being received with an unusual degree of interest.

With pleasure I note the advent of a new developer for dry plates. Having experienced a failure upon my first trial of the ferrous oxalate developer, I think it well to explain, for the benefit of those who may be about to try it, the cause of that failure. The ferrous oxalate is soluble in neutral potassic oxalate; but it must be borne in mind that there are several oxalates of potash, and unless the proper one—the *neutral* oxalate—is obtained, failure is certain to be the result of the trial. So far as my experience goes this salt is not kept in stock by any of the dispensing chemists, and I have even inquired for it fruitlessly at the establishments of two or three so-called "photographic chemists." Still, it is easily procurable at several well-known chemical establishments in London, and doubtless equally so in every large town. What is required is a better and more economical method of preparing the ferrous oxalate than by the decomposition of oxalic acid and protosulphate of iron, which results in an unconscionably small quantity of the desired salt, and in the formation of "no end" of sulphuric acid as the by-product. From the little I have seen of this developer I consider it is well worthy of a thorough trial.

Apropos of explosions while preparing oxygen: there is one cause of these which, although not frequent in its action, yet does exist, and to which attention might be directed. The thread of the screw in the mouth of an iron retort not unfrequently becomes rusty, necessitating the application of a little oil or grease to cause the screw to work easily. If any of this oil be left about the tube or the retort when these are connected, woe betide the experimentalist, as the heat necessary for the production of the oxygen will also liberate olifiant gas from the oil, and the mixture of these two gases forms an explosive compound possessing great force.

I observe that one of the metropolitan magistrates has had the subject of fulminating silver brought under his notice, and in the course of a judicial trial involving its manufacture a statement was made that, with the exception of fulminating gold, this is the most powerful and dangerous explosive known. Is not this a great mistake? I have always understood that fulminating mercury was more powerful than gold, that fulminating silver was stronger than mercury, but that none of these fulminates could at all equal in explosive force the chloride of nitrogen. I have been present in a lecture room when a globule of this substance, about the size of a grain of mustard seed, was touched by a bit of phosphorus not much larger than itself. The explosion that ensued was "a caution!" It was a favourite belief of the late Rev. J. B. Reade, F.R.S., that the chloride and iodide of nitrogen, especially the latter, were yet destined to play an important part in photography; but as both these preparations are members of the same lively family, who possesses sufficient courage to go in and grapple with them? To "beard the lion in his den" is a joke when compared with experimenting with either of these pretty playthings; and yet the iodide (I can speak of this from personal acquaintance) may be rendered comparatively safe by keeping iodine in excess when preparing it. Among the useful properties of this substance is that of dissolving gold and forming a metallic crystalline vegetation of a beauty of form undreamt of by the generality of microscopists. All that I have to say is—keep the iodine in excess. I wonder if a bromide of nitrogen would not be formed by the union of bromine with ammonia, and if this would not possess similar evil, and possibly similarly useful, powers as its other relatives of the halogen family! The temptation to try is very great; but, unfortunately, the anticipated danger of such trial is very much greater.

(To be continued.)

EXPOSURE.

Photographically speaking, what is exposure? The text-books tell us that it is an indefinite "something" which can only be judged of at the time of taking a picture. In the case of the tyro this only leads to a state of bewilderment as to what exposure is, and I therefore propose to give some definite ideas upon the subject, which, I trust, may be found of service to everybody engaged in photographic pursuits.

We all know that the solar spectrum is made up of many colours, and that from violet to red, or from white to black (speaking photographically), there are many gradations or half-tones. To render these in all their force and beauty, whether from the original subject or from the negative, by any printing process should be the end and aim of the artist—not to give, as is often done, a shadowy resemblance, or a hard, cardboard outline, but the soft and delicate blending of one shade or line into the other, making the whole harmonious and beautiful. I well remember, many years ago, in a correspondence with Mr. George W. Wilson, of Aberdeen, his remarking:—"I like my pictures to be so composed, arranged, and printed that, although the centre may be the most beautiful, it shall be looked at by the observer as one harmonious whole;" and I think all must acknowledge that this is faithfully carried out in all his compositions. But to return.

A careful study of the spectrum in its relation to natural objects reveals to us this fact—that in nature there is literally very little of what we should term pure white; that white is made up of a series of tones, one of which, overlapping or blending into the other, goes to form what we call white. Indeed, if we had much white around us our lives would become unendurable; for we should be in a perpetual glare, and our brains be in such a state of activity that our existence would be considerably shortened. This we find with plants grown under blue or violet glass. They grow immensely and quickly, but they are weak and spindly; while others, grown under ordinary conditions, are healthier and better in every respect. And so it has pleased Providence to give us much green and brown and grey and red, all sombre colours, which dilate the eye and keep it in a state of rest. Further: most objects around us are flatted or dead, if I may so term it—absorbent leaves—giving us only here and there hard horny leaves which reflect light from their surfaces, the one benefiting the other in its growth.

These are points which do not often strike the casual observer, but they have a grand bearing on our art-science—far more than we have any idea of; for, when we have arranged our composition—be it portrait, or landscape, or machinery, or maps, or drawings—with many it is only a matter of guess as to what the exposure shall be, while to the careful thinker—the lover of his work, who sees more than just the ordinary end, and into whose calculations pecuniary gain does not enter—it is a matter of certainty, or nearly so, as to whether he shall have a successful issue. And so it ought to be in every case. The remarks of Mr. Wm. Bedford at the December meeting of the Photographic Society of Great Britain were very pertinent to this end, and show that he is a most careful, observant worker. See also a paper by Mr. Payne Jennings in this year's British Journal Photographic Almanac. And why is this? Because so few care to make a study of what colours their subjects are composed.

Every locality and every studio has a light peculiarly its own, due to its surroundings and formation—nay, more, due often to its soil and subsoil. The exposure you would give at the seaside would be shorter than that given inland, because the water, acting like a huge mirror, throws such a mass of light into the sky as to, in some cases, obliterate the finer details of objects that are in close proximity to it; while in localities where there are many trees and much vegetation—such as moors and heaths, and many of the rivers met with in Devon—the green light thrown into the sky lengthens the exposure to what many would call an absurd and preposterous length, and yet when pictures have been seen taken under both these conditions they have been pronounced to be clean and perfect in each case as to detail and gradation of tone and shadow.

A study of the spectrum also conveys to us a knowledge of the seasons, and when we may expect to obtain better effects at one time than another. For instance: in winter, when the Sun is closer to us, we get less light, because his rays are more parallel, and, mixing with the vapour of the earth, are more yellow or less actinic; and nature bears this out, because everywhere it is at rest. In trees, plants, and shrubs (except those of the horny nature before spoken of), the sap gone down, are in a state of repose, resting after the exertions of the past, and maturing and invigorating themselves for fresh efforts in the time to come. In spring and early summer the most rapid work may be done; but when we get into the full-tide of heat the light becomes almost *nil*. Autumn much resembles spring, and many of the finest effects are to be then obtained.

People say that photography is rapid. True; yet everything takes time, and unless all the conditions are equal, success must not be expected. It is the careful, thoughtful worker that wins the prize. If the film be very sensitive and the light very slow—say from black, brown, or green objects—unless the exposure be made in a particular way the detail in the shadows will be lost, being obliterated by the too rapid action of light on the plate. Thus the negative will be wanting in harmony, which no amount of retouching and dodging will make equal to one properly exposed.

Many forget that light, however actinic, works but slowly, and that something more than light is necessary to produce colour in the petals of a flower or the leaves of a tree—indeed, playing quite as important a part; and, unless the two be in combination, the one is powerless without the other. Temperature, therefore, must be studied as well as light in exposure—each in its volume—or success need not be looked for.

It has been urged by some that it is impossible to link the light of the interior of a church or of a large room with the spectrum. But this appears to me simple; for, by a study of the light within from the window glass and surrounding objects—whether yellow, orange, green, or violet—the exposure may be regulated, the collodion being suited to the purpose in question, and likewise the developer.

In the early edition of Hardwich's *Manual* is a woodcut of a spectrum, and it is urged that a photograph be taken of this from a coloured representation, and the effect noted of each colour upon the film. This would be of great service to all workers; and, if remembered in practice, would save much trouble and annoyance.

In conclusion: if your readers will turn to page 156 of The British Journal Photographic Almanac for 1876 they will there find an epitome of what I have here written on in detail.

W. Harding Warner.

HOW TO EMPLOY PHOTOGRAPHY AND THE LANTERN AS EDUCATIONAL AIDS.

No. III.

In my last article I stated my faith in any system which would make learning a labour of love to the young as it is to the old when trained to studious habits, and that the teacher should aim at becoming the trusted friend of every pupil instead of his or her arch enemy. In endeavouring to show how photography and the lantern may become, as I believe they will become, important aids to education, whether employed at the infant school or university, I shall be forced to discuss points in the past, present, and future systems of teaching.

I think most educationists (I believe that is the right word, though I like the term "educationalist" better, as not sounding so "hard," though it be a trifle longer to write) of the present day are of one mind as to the necessity of imparting all learning in a series of "grades" founded on logical systems, and of banishing everything in the shape of "parrot work," or learning by the method of rote instead of by reason—a system of the old school admirably contrived with the view of making the pupil believe that he or she had learned a lesson, and the pedagogue to labour under the delusion that he or she had done his duty, like a man or woman, and had "heard" the lesson of such pupils, and that he or she had imparted a modicum of extra knowledge thereby.

"God save the mark!" Was there ever a more benighted system of teaching than that of learning columns of spelling, pages of history, geography, and all the rest of it—when it "went in at one eye and out at the other?" What more horrible than to hear the drone of a pupil going through his daily purgatory, when one felt there was not one atom of intelligence, whilst they were all carrying on "the same old game!" Undoubtedly it is a matter of dire necessity that every moment of a school child's life should be devoted to acquiring a clear comprehension of all that is put before it, and to see that it masters all that is professed to be taught.

Beginning at the infant school, who does not recollect the class of books which attempted to teach the alphabet by such insanely-ingenious methods as "A was an Archer and shot at a frog; B was a Butcher, and had a great dog." Or "A stands for Ape, B stands for Bull, C stands for Cat," and so on!" But do they? If we could give vitality to A, B, C, and all their twenty-three companions, they might cry out with "Abraham Brown, the Sailor"—"I'm myself, and no one else!" They stand out clear for easy recognition by the infant through "sight knowledge," if simply placed in bold form before their eyes, without any admixture of such extraneous nonsense.

But care must be taken that the teacher, or the system he is bound to work by, does not go in for "the Gradgrind school" of *hard* facts. Facts are matters necessary for the youngest mind, but we must not impound them in a crust that is too hard for digestion.

I would advocate some such system as this:—On a young child being introduced to its teacher, it should be *made* to feel that its "pastor and master" was also its kind friend, protector, adviser, and an emblem of justice recognisable even by an infant mind—one to be trusted, not dreaded. Next, that *punctuality* to school hours was a matter worthy of notice by its friend, and also of reward in the shape of "marks." Next, that *order* is a thing to be learned, and that "a place for everything and everything in its place" gives comfort and saves time to such an extent that it is also worthy of reward.

Next, that there is One "God"—the Creator—the *Father of all*—whether they be Jew, Pharisee (observers of rites and ceremonies in the widest sense, as applicable to present days), Mahometan, Roman Catholic, Protestant, Dissenter, Gentile (according to modern meaning as applied to Deists, Pantheists, Atheists, Fire Worshippers, Savage Idolaters, and Demon Worshippers)—and that from God springs the laws of *morality* (a simpler and better term than "religion" in these multisectarian days, when the term too often means a splitting of straws over the veriest trifles), which are—I. *Reverence** for God, for Mother and Father, and for the Law of the Land. II. *Government of Temper*," so that "thou shalt do no one an injury" by act of tongue or act of violence." III. *The Law of "Meum et Tuam."* IV. *The Law of Contentment* (or non-covetousness and the wickedness of avarice). V. *The Law of Humanity*, or kindness and charity to one's fellow-creatures and to all animals. VI. *Truthfulness and Honour.* VII. *Justice*, or the necessity for punishing all who transgress the laws of God or man after fair inquiry on truthful evidence. That all the laws of morality are summed up in the Christian precept—"Do unto others as thou would have others do unto thee." Some teachers have a wonderful knack of placing the primary laws of morality in a shape comprehensible to the infant mind with the

* I think "reverence" is going out of fashion. A son nowadays speaks of his "Father" as "The Guv'nor," "The Old Boy;" and of his "Mother" (loving term as it be) as "Mater," "The Missus," "The Old Woman," and, worst of all, "The Old Gal;" whilst both are regarded as of the Rip Van Winkle type—*at least* twenty years behind the age—as to all worldly fashions, modes of thought, and expressions.

view of imparting the first glimmer of *the necessity for discipline* both in school and worldly life.

A child will also acquire, through the behaviour of its companions, in any well-managed school notions as to the *advantage* of conforming to the rules laid down for school discipline, as a school is the world in miniature, and this sort of training cannot be acquired too soon.

The next step is to acquire a knowledge of the alphabet, and I do not know of a better way than to give each child an arranged tray of large letters, and, on an assistant teacher calling out a letter, those who pick out the same correctly and hold it up the quickest being credited with a mark. All marks should be reckoned up at the end of every week, and the sum-total valued and paid for in "sweets;" for there is nothing like appealing to a child's stomach in all matters of rewards. As we grow older human vanity comes into play, and then medals, decorations, titles, and baubles of all sorts become an inducement to "go in" for work, so that we may acquire distinction amongst our fellows. In fact, I do not think we fully appreciate or, at any rate, acknowledge the part the stomach plays in worldly affairs. A well-to-do man is a giver and receiver of "feeds," and his "dear friends" will put their hands deep into their pockets to return his stomachic friendship; but should he come to grief then they would not spend five shillings to save him or his children from starvation (unless, indeed, they could have their names, with address, advertised in a "subscription list" in *The Times* to enlighten the world as to their "charity"), whilst previously they would have spent five or even fifty pounds to gorge him, when already full to repletion. Ought we not, then, to appreciate the value of appealing to the stomach as well as to the heart, even at the first beginnings of life? SAMUEL HIGHLEY, C.E., F.G.S., &c.

ON THE REDUCTION OF ALKALINE IODATES AND THEIR EMPLOYMENT IN THE PRODUCTION OF IODIDE OF POTASSIUM, IODIDE OF SODIUM, AND IODIDE OF AMMONIUM.

[A communication to the Photographic Society of Cologne.]

IN *Dingler's Polytechnischen Journal* (vol. 223, page 443) I came upon the following note:—" On the preparation of potassic iodide: Pellagri found that a dilute solution of iodate of potassium when shaken up with iron filings is completely converted, especially when warm, into iodide of potassium, without either solution of the iron or precipitation of the iodine. Chiappe and Mallesci now show that this process is also applicable to the preparation of iodide of potassium on a large scale. Iodide of sodium may also be manufactured on this plan."

This note having attracted my attention I began to experiment, and having perfectly confirmed the correctness of the statement that iodate of potassium is reduced to iodide of potassium, a portion of the iron being converted into an oxide, I extended the experiment to iodate of ammonium, and was perfectly successful in reducing that iodate also. This apparently trifling property possessed by iron of reducing alkaline iodates is of great practical value. Until now it was impossible to get pure iodide of potassium, sodium, or ammonium, from iodine in a solution of potassium, sodium, or ammonium, on account of the difficulty of removing the iodate salts which were continually being formed;* consequently a roundabout way had to be taken of attaining the end in view—a proceeding necessarily accompanied by a rise in the price of the preparation. Now, however, to manufacture iodide of sodium or potassium one has simply to use the sodic or potassic ley directly after its production from the carbonate and lime. After having ascertained the strength of the ley, the manufacturer adds the quantity of iodine proportioned to the strength and quantity of the ley, and stirs it about until the colour has completely disappeared; he then adds the iron filings and moves the whole. As soon as the complete absence of iodate has been proved by testing a small quantity, the whole is filtered off and evaporated to crystallisation.

To prepare iodide of ammonium one proceeds in the same way; but an excess of ammonia does no harm, being volatilised during the evaporation. Lastly: this preparation should be evaporated on the water bath, on account of the volatility of iodide of ammonium at a higher temperature. In order to get a colourless preparation a bright bar of cadmium is placed in the solution while the evaporation is going on, the slight formation of iodide of cadmium which may thus be induced doing no harm when the preparation is used for photographic purposes, and iodide of ammonium is scarcely used for any other purpose.

* The iodate of sodium or potassium is converted into iodides of sodium or potassium by heating to redness with charcoal.—Ed. of *Photo. Monatsblätter.*

The prepared iodide of ammonium (about five hundred grammes) which I exhibited to the Society was prepared by this method, and is perfectly free from iodate. It was allowed to stand for two days with the iron filings in it, and it was several times shaken up during that time. It is not, however, necessary for it to remain so long with the iron, as small samples tested were ready in a few minutes. The employment of heat is necessary with this process. C. BAUMANN. —*Photographisches Monatsblätt.*

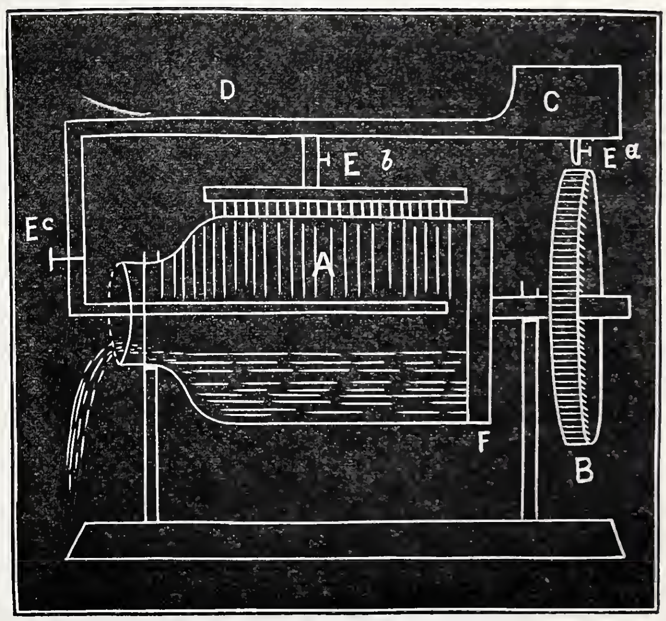
NOTES FROM THE NORTH.

IT must be gratifying to those who believe that in emulsions lie the future of photography to notice the almost universal interest which is being manifested in that method of manipulation. Here in the north we stood out against the innovation for a considerable time; but fact proved stronger than prejudice, and for landscape works, at least, the bath is rapidly becoming a thing of the past.

How best and most conveniently to remove the soluble and useless salts from the emulsion is still a question among experimentalists, and Mr. John Ogilvy, of Brechin, has just sent me a valuable contribution towards its solution in the shape of a drawing of a simple self-acting apparatus that he has devised for that purpose.

It consists of an ordinary Winchester quart, to the bottom of which has been cemented a disc of wood carrying a spindle, on the end of which is fixed a simply-constructed water-wheel. This is supported, free to revolve, at one end on the spindle, and on the neck of the bottle at the other, by two uprights firmly morticed into a base of inch-and-half wood measuring about 18 × 10 inches. Fixed in any suitable way—depending, of course, on the position in which the apparatus is to be used—is a tube bent twice at right angles, having one end connected with the house cistern or other water supply, while the other passes through the neck of the Winchester, reaching nearly to the bottom, and being pierced by a number of fine holes. On the portion of the tube exterior to the bottle, and immediately over the wheel, there is a tap, the water from which keeps the apparatus in motion, and a second tap and ┬ piece, also perforated, is intended, when necessary, to cool the bottle, while a third tap just before the tube enters serves to control the supply of water to the interior.

The annexed diagram will more fully explain the apparatus, and the method of using it will be obvious to emulsion workers. It is as follows:—



A Winchester quart.
B Water-wheel.
C Cistern.
D Water pipe.
E a, E b, E c Water taps.
F Disc cemented to bottle.

In the case of gelatine the bottle should be slightly warmed to prevent too rapid setting, the emulsion poured in and the apparatus placed *in situ.* The tap E *a* is then opened, which will cause the bottle to revolve, and the emulsion will be evenly spread over the interior in a thin film. As soon as this is accomplished the tap E *b* should be opened, when the water escaping from the perforations in the ┬ piece will, by lowering the temperature of the bottle, cause the emulsion to set. When this is done E *b* should be closed and E *c* opened, and if the head of water be sufficiently high it will be projected in fine streams and in considerable force against the film on the upper side of the bottle. When the water reaches the level of the neck of the Winchester it will run out as fast as it goes in, and the whole may be left to take care of itself until every trace of soluble matter is removed. This, Mr. Ogilvy finds, is accomplished in about four hours; but, as the machine is self-acting, it may safely be allowed to go on all night.

No doubt an ingenious photographer will find other purposes to which the apparatus may be applied; but I have reason to believe that for that for which it has been designed it is admirably suited, and need cost only a few shillings for its construction.

I have inserted the diagram as it was sent to me, but would suggest as an improvement that the uprights should be extended so as to support the water pipe, the bearings on which the neck of the bottle and axle of the water wheel revolve being attached as brackets.

The difficulties connected with the successful photographing of paintings, especially when the canvas is large, are well-known to all who have tried that kind of work; and, as during a recent visit to the establishment of Messrs. Doig, McKechnie, and Davies, Edinburgh, I saw how Mr. W. H. Davies had overcome them, I think a brief description of the method adopted may be both interesting and useful to the readers of The British Journal of Photography.

The conditions were somewhat as follows:—The canvas measured 9 × 5 feet, and the copy was required to be exactly 36 × 20 inches. The light at this season is none of the best, and experience showed that with wet collodion an exposure of about three hours would be necessary, and the floor (at least that portion of it on which the camera stand is placed) of the otherwise excellent studio, recently erected, vibrates under the tread of those moving about to such an extent as to interfere with the sharpness of the image.

The first requisite was a suitable camera. As a bellows camera is apt to bulge in when on a long stretch, and is otherwise objectionable for very large sizes, Mr. Davies adopted the telescopic form. With a view to easy sliding and inexpensive work, he ignored the idea of making the slides light-tight, and made each some five-eighths of an inch smaller all round than that into which it goes, trusting to black cloth thrown over the whole to keep out light. With a view to reduce the friction to a minimum, each sliding part rests, not on the bottom of that into which it slides, but on two narrow strips of wood; and in this way a very slight pressure is sufficient to lengthen or shorten the camera. The dark slide, which is made for plates thirty-seven inches square, is reversible, the flap and back fitting either side, and so arranged that for ordinary work the image may be received directly on the film, or after passing through the glass, when a reversed negative for carbon printing by single transfer is required; and, for convenience and economising space, the flap comes out at the side, is in several pieces, and hinged so as to fold in opposite directions.

The vibration was overcome by ignoring it altogether and suspending the camera from the roof. Four strong frames, each about four and a-half feet square, are hinged to the roof, so as to be folded up when not in use, and when hanging down are braced together by angle-tie rods, so as to be perfectly rigid. On any two of those frames two strong battens or wooden rails are laid, and on these the camera rests, and can easily be moved backward and forward till the image has been adjusted to the proper size. I do not know whether this arrangement is new, but I can recommend it as very cheap and thoroughly efficient.

With this apparatus, so arranged, the painting was placed in position and the operation of focussing tried; but, from the angle at which the light fell on it, some troublesome reflections were produced. This was easily cured by slightly inclining the picture forward, with the result, of course, of throwing the image off the square. A swing back, therefore, was a necessity, and this Mr. Davies rapidly improvised. Acting on his faith in the efficacy of a black cloth, he withdrew the dark slide (which is also used for focussing) out at the top till it lay in the same plane as the picture, and held it in that position by a slip of wood into which he had cut a slot a few inches in length. One end of this was fastened to the camera by a picture ring, and the other in the same way to the slide, a cloth over all perfectly excluding the light.

Focussing and adjusting was a somewhat troublesome operation—an exact size, a true square, and perfect sharpness being required. The first was got by calculation, the focus of the lens being known; the second by careful measurement of the image—not, however, from top to bottom and from side to side, as is too frequently trusted to, and which, except in the case of a direct square, cannot be relied on, but diagonally, from upper right to lower left corner, and *vice versâ*. When the two measures are absolutely alike the square must be true. For the focussing no such mathemetical rule can be applied; it is simply a matter of perception, and those only who have tried such work know how difficult it is. With the more pronounced portion of the picture it is easy enough, but in the deeper shadows and plain parts of the background there is little grip to be got; and, as the focus must be as equal all over as the lens will allow, something more marked is generally resorted to. A piece of printed paper is frequently used, but if moved from place to place much time is wasted in putting various portions out and in. Mr. Davies overcame this by fixing such pieces of printed matter at short distances all round the margin of the picture, and in this way was enabled to see at a glance the relative condition as to sharpness of every part.

Many and varied are the plans that have been proposed for the drying of sensitised tissue or plates. Here is one that is, to me at least, quite new, and which for cheapness and efficiency is equal to any that I have seen:—An upright box, four feet by three, the front of which is a light-tight door. The bottom is pierced in the centre by a hole four inches in diameter, and the top in the same way by one of one inch. Closely fitted into the opening in the bottom is a tube of sheet or tinned iron of the same diameter and eighteen inches long, where it expands to twelve inches for a length of a like distance. Here it contracts to four inches again, and in the form of a cone reaches the one-inch opening in the top. The box, which is provided with light-tight ventilators at top and bottom, stands on four feet, sufficiently high to admit of a large rose Bunsen burner or paraffine lamp being placed so that it shall burn a few inches up the tube, and the apparatus is complete. In this way a current of heated air is maintained, which, in consequence of the contraction of the upper end of the tube, fills the enlarged portion thereof, and from the whole surface sufficient heat is radiated for either plates or tissue, without the possibility of the drying atmosphere being contaminated with the products of combustion—a provision especially necessary in the case of sensitive tissue. To make the apparatus really complete it only needs a thermometer so arranged as to be read without opening the door, and then by increasing or diminishing the flame any required temperature could be steadily maintained.

John Nicol, Ph.D.

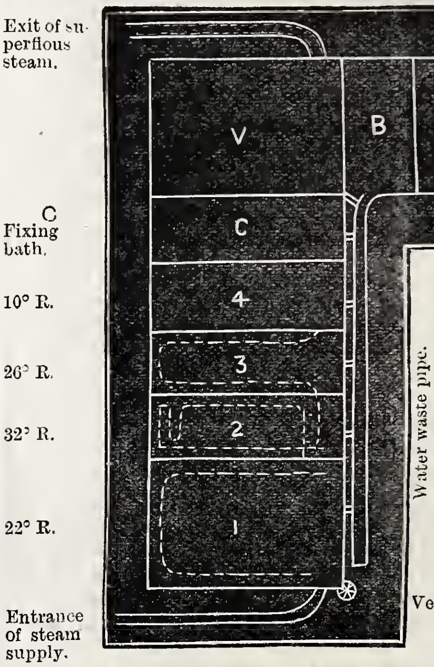
FOREIGN NOTES AND NEWS.

Dr. Reichard on the Uses of a Steam Engine in a Carbon Printing Establishment.—The *Wochenblatt* on Portraits which are not Likenesses.—The First Prosecution for Infringement of the New German Copyright Act.—Photography at Brussels.—On the Decoration of *Cartes-de-Visite* and Cabinet Portraits.—A German Photographers' Directory.

In the *Archiv* Dr. Reichard, of Maennendorf, has an article on the carbon process, in which he describes the arrangement of his tanks and how he makes use of steam in his establishment both in the form of steam power and for heating water and drying paper.

When he has sensitised his tissue he hangs it up, like albumenised paper, by the corners to dry in a room kept for the first two hours at a temperature of 16° R. (as when the temperature is higher the colouring matter is apt to drip off). For the succeeding four hours the temperature is raised to from 12° to 15° R., during the next four from 18° to 20° R., and during the last two it is lowered to 16° again. The drying of the paper is thus supposed to occupy twelve hours, and if this plan be carried out fully Dr. Reichard guarantees that there will be no failures in the prints traceable to this part of the preparation of the tissue. The temperature of the drying-room in his establishment is regulated by steam pipes which are completely under control.

In the washing-room the tanks are arranged as in the accompanying diagram:—



Each of the tanks is the size of a sheet of paper, is fifteen centimetres in depth, and holds exactly fifty litres of water.

N.B.—The tanks I., II., and III. are of the same size.

A. Zinc tank in which the prints are placed to soak when taken out of the printing-frame.
B. Porcelain tank containing the transfer paper (single transfer).
I. Zinc tank containing warm water of a temperature of 22° R.
II. ,, ,, ,, ,, 32° R.
III. ,, ,, ,, ,, 20° R.
IV. ,, ,, cold ,, ,, 10° R.
C. Fixing bath containing 10 litres of water and 250 grammes alum.
V. Washing up and developing tank.
Q. Glass plate upon which the squeegee is applied.

When all the tanks have been furnished with a sufficient quantity of water the operator turns on the steam to Nos. I., II., and III. until they are heated up to the required degree, which is, most probably, indicated by a thermometer fixed to some part of the interior of each tank. While the water in Nos. I., II., and III. is thus being prepared he goes to Q, and, taking up a print with his left hand, he dips into A, and at the same time lifts a piece of transfer-paper *b* with the right hand, putting into B. Both papers are kept under water until they have flattened out and begin to be soapy, when they are placed together, the prepared sides being next each other upon the glass plate Q. The operator, then, holding the papers in their place with the thumb and forefinger of his right hand, passes the squeegee across it from left to right. That the desired result of simultaneously detaching the gelatine film from the paper of the tissue and attaching it to the transfer paper, without causing either blisters or creases, may be safely accomplished by a single application of the squeegee, it is absolutely necessary that the pressure should be equal. This equality Dr. Reichard ensures by applying the squeegee pressure by steam power transmitted from a small steam engine. The pictures being properly squeegeed are placed in tank No. I., where the development only proceeds so far as that the transfer is floated off from the original support, and a considerable mass of pigment falls to the bottom of the tank. It is scarcely possible to assign an exact time for the prints to remain in each tank; but, taking the average, they may be removed at the end of five minutes to No. II., where they are left floating, face downwards, for another five minutes, and then, being pretty clear, they are removed to tank No. III. In No. III. they are left a couple of minutes or so until they are perfectly clear, and are only removed to be placed in cold water in No. IV.

In the tanks Nos. I., II., and III. three things have to be arranged for, namely, the clean cold water, the steam, and the waste pipe to carry off the dirty warm water. During the period of development there is a strong current of water in the tanks and a proportionately strong current of steam, which may be turned off or on to each tank by means of a cock. The steam is also controlled by means of the ventilator at X, and this facility of control makes it possible for two men to develope a thousand carbon prints in an afternoon.

From No. IV. the prints are placed in the alum fixing bath for five or six minutes, and after being moved about are removed to No. V., where they are washed up for half-an-hour in a current of fresh water previous to being dried. Dr. Reichard's steam engine is of English manufacture, and, besides feeding the steam boiler and the water reservoirs, it supplies the motive power to the burnisher and the squeegee.

The *Photographisches Wochenblätt*, in speaking of the frequency with which portraits are rejected—not on account of any technical failure in manipulation on the part of the operator, but because the portraits were not considered to be likenesses—thinks that photographers might do a little themselves to remove a fruitful cause of disputes by pointing out to their customers a frequent cause of failure, namely, that the unlikeness of portraits is generally the result of sitters not wearing their ordinary clothes, but coming more "dressed" than usual. This, besides giving an unfamiliar impression, helps to deepen the self-conscious and unnatural expression of countenance so often assumed by sitters in front of the camera. The *Wochenblätt* thinks that women are almost exclusively the offenders on this point. That may be left an open question, but that this matter of dress is a large factor in the failures in likenesses there can be no doubt. Of course the remark is not new, but it is one of those truisms which are often lost sight of and which will bear repetition.

The working of the German law of copyright is illustrated by the following story, taken from the *Archiv*, which gives an account of the first prosecution under the new act of the 10th January, 1876:—In the beginning of last year, Herr Hanfstängl, 69, Unter den Linden, Berlin, took a portrait of the Princess Charlotte, of Prussia, of which he printed and published great numbers. The defendant did the same, but furnished his prints at a tenth part of the price charged by the former, whereupon Herr Hanfstängl brought the present action for violation of his copyright. The defendant pleaded that, by the seventy-eighth section of the Copyright Act, the copyright of a portrait was vested in the sitter, unless any special agreement to the contrary had been made, and that, as Herr Hanfstängl had not obtained any formal authorisation to publish the portrait, he was incapacitated from bringing the action, as the copyright belonged to the Princess, and she alone could prosecute for its infringement. The judges took this last view of the case, and pronounced judgment accordingly; but Herr Hanfstängl appealed, and produced a document dated the 1st October, executed by the Princess's *ober-governante*, granting him the exclusive right of publishing the Princess Charlotte's portrait. The date was, however, long after the time when the complaint was made, and could not be held to have a retrospective action; besides which the judges thought it questionable whether the authorisation to be valid should not have been obtained from the Crown Prince. They, therefore, gave judgment in favour of the defendant.

A course of lectures on the theory and practice of photography, under which heading the carbon process is included, is given annually, under the auspices of the Belgian Government, in the *Musée d'Histoire Naturelle*, Brussels. The teacher is Professor Rommelaere, the Secretary of the Association Belge de Photographie, who has recently translated Capt. Abney's book into French for the use of his class, which is well attended by amateurs as well as professional men.

In the *Archiv* Herr Neidhart relates how he made a pleasant-looking picture of a portrait the plate of which was broken off short across the neck. He chose a white mat with a small oval opening coming pretty close round the head, but then too much of the white ground showed, so he added just outside the oval line a garland or arabesque of larch or heather twigs. The effect of the garland was so good that he prepared a number of other mats decorated with twigs of ivy, oak, pine, juniper, or with tufts of ferns, garlands of hop or of vine leaves interspersed with corn flowers, lily of the valley, and blue bells. Herr Neidhart's idea is not, however, so new as he, being an amateur, seems to imagine; for, not to mention the mats in which flowers and ferns in splash work are introduced, there are now many mats and albums ornamented by pictures of flowers in their natural colours, though the taste of this style of ornamentation is questionable. Ten or twelve years ago an attempt was made to introduce mats having several small ovals for *carte* portraits, the spaces between being filled up with chromos., in colours, of groups of birds, fruits, insects, &c., but the attempt did not meet with much success. Herr Neidhart, however, does not mention whether the flowers composing his garlands were natural flowers, or photographs, or etchings, or chromos., so it would not be fair to attack him as suggesting the admixture of a photograph in monochrome with the brilliant hues of flowers.

The *Deutschen Photographen Zeitung* intends to bring out a photographic directory, in which the name and address of every photographer conducting business on his own account in Germany, German-Austria, and Switzerland shall be found. The directory will also give the names of photolithographers, lichtdruck printers, and manufacturers and dealers in photographic goods. The publication, if well got up, is likely to supply a much-felt want.

Our Editorial Table.

A Treatise on Photography.

By W. de Wiveleslie Abney, F.R.S., Capt. R.E., &c.

London: Longmans, Green, and Co.

This volume forms one of the *Text-Books of Science* adapted for the use of artisans and students in public and science schools. Its aim, as stated in the preface, is chiefly to give a rational explanation of some of the different phenomena to be met with in photography, and with this to impart sufficient practical instruction to enable the student to produce a landscape picture which shall be technically good.

Its contents are varied. Commencing with a *brief* historical sketch, Captain Abney proceeds to describe a number of experiments with light, passing on to the theory of sensitive compounds and the action of light upon them. In the practical division of the book the various processes at present enjoying public favour are treated with sufficient fulness. The chapters on photo-spectroscopy and celestial photography are exceedingly interesting, and we shall take an early occasion to allude to them and other portions of the volume.

As Captain Abney's theoretical and practical skill in photography is so well known and appreciated this treatise will be received with much favour, although not a few English readers will blame the author for his having systematically ignored English weights and measures throughout the whole formulæ in the book, in every case substituting for them the *gramme, cubic centimetre,* and *litre* of our French neighbours. This, to many photographers, will mar the usefulness of the treatise as a work of reference, until they become familiar (as they ought to be) with the French system.

Illustrations of Gabriel Grub. By F. York.

It may be asked—Who is, or was, Gabriel Grub? We reply, on the authority of one of the characters in Dickens's *Pickwick Papers*, that he was a sexton who was stolen by certain goblins. The story is especially adapted for Christmas parties, and Mr. York has very cleverly illustrated the various adventures of the morose and unhappy sexton by photographs from life. They were recently exhibited, as transparencies, by the magic lantern in the large room of the House of the Society of Arts, on the occasion of the "popular" meeting of the South London Photographic Society, when they elicited much applause. Among the pictures, or slides, is a scene in a cavern that is very effective. A dark cloud, which is situated in the farther end of the cavern, is seen to roll away and to disclose a number of domestic scenes depicted with great vividness. Of these cavern effects there are no fewer than six, the method of producing them on the screen being well known to the exhibitors of "dissolving" views. We may state that *Keevil's* lantern, by which the effects were exhibited upon the occasion to which we have alluded, showed to great advantage and proved its suitability for such duplex exhibitions of pictures, as well as for producing the ordinary dissolving effects. The grouping and general composition of these views are excellent, and we commend them to our readers.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
Feb. 4	West Riding of Yorkshire......	Oddfellows' Hall, Bradford.
,, 6	Edinburgh	5, St. Andrew-square.
,, 6	Bristol Amateur	Museum, Queen's-road.
,, 6	Photographers' Benevolent	160A, Aldersgate-street, E.C.
,, 7	South London	John-street, Adelphi.

BERLIN PHOTOGRAPHIC SOCIETY.

This Society met on the 7th December last,—Dr. Vogel occupying the chair.

Herr Schwier, the President of the German Photographic Society, sent a copy of the *Deutschen Photographen Zeitung*, the new organ of that Society, which was laid upon the table, along with Professor Steinhauser's *Treatise on the Mathematical Relation between the Stereoscope and its Pictures*, and a work by Herr José de Rodriguez, Director-in-Chief of the Photographic Section of the Geographical Surveys in Portugal, giving interesting details as to the works carried on under his direction, which are comprised under the heads of "Photolithography," "Photozincography," "Heliogravure," and "Photography."

Some Japanese filter paper was then laid upon the table, and recommended by the President for use in filtering collodion.

Herr Bergemann expressed himself as agreeing perfectly, in consequence of certain experiments, with the previous speaker, but had found that it did not suit for filtering silver baths, and he had not, therefore, seen his way to placing it amongst his stores.

Some of the other members present thought it would be important to get a paper suitable for filtering collodion, even if it did not answer for other purposes, since the filtration of that fluid through cotton wool was a tedious process.

Lichtdrucks by Herren Schober and Baeckmann and by Herr Frisch, were laid upon the table, and Herr Bergemann read the programme of a projected industrial exhibition to be held at Berlin in 1879. The question as to whether the project should be supported by the photographic society gave rise to a lively discussion, and was finally decided affirmatively, the President being requested to place himself in communication with the exhibition committee.

A provincial member sent some silver prints having peculiar matt spots on their surface where the albumen seemed to have disappeared, and he asked if any one could tell him the cause.

Herr Liebmann said he had observed similar flaws in quite freshly-albumenised paper most frequently, especially in the cold season, and when the bath was weak and somewhat acid.

The President said that Mr. Warnerke had experimented with his emulsion—which he credited with greater sensitiveness than dry plates—in his (the President's) studio. There Mr. Warnerke obtained a picture on a plate coated with emulsion, but *not dried*, in about a third of the time required for the exposure of a wet plate. The object was a white plaster figure placed upon a black stand. However, it was only the light plaster that had an action upon the emulsion corresponding to that upon the wet plate; the dark stand, on the contrary, appeared absolutely without action. Thus for dark objects an emulsion appeared less sensitive than a wet plate. Mr. Warnerke used the developer very strong; that is, a saturated solution of carbonate of ammonia, to which was added a proportionately large quantity of bromide of potassium and pyrogallic acid. He (the President) was of opinion that the emulsion, even if it were not equal to wet plates, was, at anyrate, considerably more sensitive than any of those he had as yet tried. The President then laid on the table some of the original photographs, negative and positive, by Professor Draper, by means of which the latter was led to the discovery of oxygen in the sun.

Herr Reichard exhibited a number of negatives in which the well-known rents in the varnish were present in remarkably large numbers. He wished to know the reason of this phenomenon, as well as the means of preventing it. He stated that in all his experience, which extended over many years, he had always been free from varnish rents until now, and that the fault had suddenly made its appearance with a rush in pictures taken scarcely six months since. He had even remarked it in plates taken but a few weeks ago. He also mentioned that the quality of the glass, of the collodion, of the varnish, &c., used was the same as in former years, or, at least, that he always got them from the same sources.

No member present was able to suggest a perfectly satisfactory explanation.

The President thought perhaps the varnish furnished was not always of the same quality, and that it ought to bear the blame. In the preparation of varnish bleached shellac was used, which was often more or less affected by the bleaching agent. Sometimes it was rendered very brittle and imparted that property to the varnish film. He advised the choice of another varnish, and recommended Besler's, which had never shown rents in his hands.

Herr Reichard remarked that for about the last eight days he had used Besler's varnish, and as yet, at least, the plates varnished with it had remained free from rents.

Herr Boll remarked that the glass ought to bear part of the blame. With one and the same varnish he had got rents in the varnish continually when using one kind of glass, while with another sort of glass the same varnish showed no rents.

Herr Reichard said he always used the same sort of glass. He also added that, before varnishing, he coated his plates with dextrine—a proceeding recommended by the varnish commissioners as a very effective preservative againt rents—and that, in spite of all, the rents were there.

Herr Prümm questioned the quality of the dextrine and the concentration of the solution used.

Herr Reichard replied that the dextrine solution he used was not stronger than a proportion of 1 to 16.

Herr Quidde warned him against the use of blue-green plate glass, as with such glass he almost always got rents.

It may be remarked here that the rents in the plates shown by Herr Reichard were broader than usual, without forming the well-known moles' burrows, and that they do not disappear either by rubbing or heating.

The President observed that, in the case of the plates taken in Egypt, those in which the sky was covered with colour rents appeared, but only upon the coloured part of the film, the difference between that part of the plate and the rest being as distinct as if it had been cut off. A dilute solution of gum (1 to 50) streaked over the varnish film and then rubbed half dry with cotton wool proved a very good protection to those plates.

The discussion here ended, and the meeting was adjourned.

VIENNA PHOTOGRAPHIC SOCIETY.

This Society met on the 6th November last. In the absence of Dr. Hornig the chair was occupied by Herr Melingo, who laid upon the table two photochromes sent by M. Vidal, the subjects being metal work.

A communication from Herr Birfelder, of Bern, upon Professor Husnik's paper, was then read, after which,

The Chairman directed attention to a collection of reproductions of old copperplates, by Herr Obernetter, and stated that the works of three competitors for the prizes offered by the Society had been received. One competed for the prize offered for *genre* pictures; the second for that offered for a series of lantern slides to assist instruction in natural history, art, or technical subjects; and the third made a bid for the prize offered for a critical study of the reactions of chromic acid and its salts upon organic substances.—Herren C. Haack and V. Angerer were chosen judges.

A collection of coloured landscapes and animal studies in Japan were laid upon the table by Baron von Stillfried. These pictures were photographs, not very deeply printed upon a special sort of paper, and then worked up in water-colours.

Baron von Stillfried asked whether those pictures could be sold as water-colours, the photograph being a mere outline.

Herr Kramer thought they might, as the public would buy them more readily than as painted-up phothographs.

Herr Luckhardt said truth was always best, and if those were sold as water-colours, and the photographic groundwork were to fade, the imposition would soon come to light.

The Chairman agreed with Herr Kramer's opinion, as the water-colour was the really artistic part of the production.

The Chairman laid on the table a translation, by Dr. J. Schnauss, of Mr. Heighway's *Practical Portrait Photography.*

A discussion followed on the Austrian law of copyright, and the meeting was shortly afterwards adjourned.

FRANKFORT-ON-MAINE PHOTOGRAPHIC SOCIETY.

The first ordinary meeting of this Society for the session was held on the 19th November last,—the newly-elected President, Herr Hartmann, being in the chair. The minutes of the annual general meeting having been read and approved.

Dr. Schleussner made some observations as a mark of respect to the memory of the late Mr. Fox Talbot.

Herr Hartmann took the opportunity of proposing that a collection of articles be made illustrating the progress of photography from its first discovery to the present day.

On the matter being put to the vote, Herr Hartmann was commissioned to carry out the realisation of his own idea.

Dr. Schleussner read a letter from Herr Krüger, the Secretary of the German Photographic Society in New York, expressing the good wishes of that society, and arranging for an interchange of intelligence with the Frankfort society.

Herr Hetzler showed a collection of stereoscopic photographs taken by himself in Australia fifteen years ago. They were taken on dry plates, some of which were supplied by the London Stereoscopic Company, some prepared by an albumen process, and some prepared by Herr Hetzler himself by the Fothergill process. He (Herr Hetzler) then related how each of the various processes had gradually developed, and that glycerine was first used as a preservative, then honey and albumen, and so on, and how useful the dry-plate processes are in countries where every convenience is lacking.

A discussion on the various advantages of the wet and dry processes concluded the proceedings.

The same Society met again on the 3rd December last,—Herr Geldmacher occupying the chair. At this meeting the guest of the evening was Herr Baumann, President of the Cologne Society. After the minutes of the previous meeting had been read,

Dr. Stein spoke at some length in praise of Wilde's dry plates and their suitability for taking microphotographs and physiological photographs. For both purposes he generally employed direct sunlight, when he required but one second's exposure to get a sharp, powerful picture.

Herr Geldmacher laid on the table a collection of microphotographs by Herr Grimm, of Offenburg, and a design for the members' diploma, drawn by Herr Hartmann. The latter was greatly approved of, and it was resolved to have the requisite number of copies printed off the size of a cabinet picture.

Dr. Stein then made some remarks on the effects produced by different coloured lights upon mental disorders—to the effect that, though the physical and chemical action of the spectral colours upon plants had long been known, it was but lately that any specific action upon human beings had been recognised, further than that sunshine cheered and gloom depressed. Two years ago an Italian physician, Dr. Ponza, observed that red light had an enlivening and blue light a depressing influence upon lunatics; so he had three rooms prepared, the window of one being glazed with blue glass, one with violet, and one with red glass. In the red chamber patients with a tendency to melancholy were confined, and in the blue or violet rooms unruly patients, according to their degree of violence. The effect was that, after being in the red room for a few hours, melancholy patients, who for weeks had refused to take proper nourishment, began to eat; while the violent patients soon became quiet when confined in the blue room. Dr. Davies, of Maidstone, is also said to have successfully experimented with blue light upon unruly patients.

Herr Baumann then presented the greetings of the Photographic Society of Cologne, and thanked the members of the Frankfort Society for the kind reception they had accorded him. The meeting was then adjourned.

RHEINISH-WESTPHALIAN PHOTOGRAPHIC SOCIETY.

This Society met on the 16th November last,—Herr Baumann in the chair.

A letter was read from the Secretary of the German Photographic Society of New York, in which he said, amongst other things, that paper albumenised on both sides was not used there because the film which is not sensitised dissolves off. (This paper albumenised on both sides had been recommended as a cure for blisters.) There the usual way of preventing blisters was to wash the prints well and leave them for some time in water acidified with acetic acid, from which they were transferred direct to the toning bath; and as each print was toned it was placed in salt and water until the whole batch was ready to be removed into the fixing bath. The soda solution was usually one to twelve in summer and one to ten in winter. When fixed the prints were placed first in a strong solution of salt and water, then in a weaker, and finally washed up as usual.

To the question—"How does common salt prevent blisters?"

Herr Ehrmann replied that it gave the water the same specific gravity as the soda solution. He (Herr Ehrmann) thought it was important that the water and the *hypo.* solution should be of the same temperature.

The Chairman showed some pictures printed upon paper, prepared by Schleicher and Schüll, of Düren, from old ropes. When sent out of the manufactory this paper contained a small quantity of salt, and when silvered it furnished a faint picture suitable for painting upon.

A lively discussion on the foregoing subjects closed the meeting.

Correspondence.

STEREOSCOPIC TRANSPARENCIES.

To the Editors.

Gentlemen,—With reference to Mr. J. Harmer's communication in The British Journal of Photography of the 25th inst., I can only say I was not aware of that gentleman's existence. I have heard Mr. Breese mention his name, saying at the same time that he was the only man besides himself who knew anything whatever about combination printing for the stereoscope; but he repeatedly gave me to understand that he did not tell Mr. Harmer more than he could help. As Mr. Breese had evidently had some misunderstanding with Mr. Harmer I never pressed Mr. Breese on the subject of Mr. Harmer's connection with him.

I at one time thought seriously of advertising for Mr. Harmer, with a view of making terms with him (if possible) to assist me in publishing stereoscopic transparencies, taking Mr. Breese's negatives as a nucleus to start with, but the idea fell through. Mr. Breese either could not or would not give me any clue to finding Mr. Harmer, and I concluded, as he had not been heard of, that either he had left the country or that he was no longer in existence; for, so enthusiastic have I been with regard to these slides, that I could not bring myself to believe it possible that a man possessing the information necessary to their production would have failed to make use of it in some way—commercially, if so inclined; and, failing that, he would, in the interests of science and art, make the information known for the benefit of others. But Mr. Harmer, no doubt, had his reasons for silence on the subject, and I am quite willing to credit him with the very best intentions.

Judging from a first perusal of Mr. Harmer's letter he evidently has a very intimate and practical knowledge of the subject in hand. I do not purpose dealing with the letter now, as it is probable I may refer to it in my next paper. A good deal of the information I intended to give Mr. Harmer has forestalled me in; but that I do not mind so long as the information gets into the right quarters and results in reviving the interest in stereoscopic work. I neither seek nor do I desire any *kudos* in bringing the subject before the photographic world. I was asked to give a paper, and the subject I chose was, naturally enough, the one I take most interest in, and the one I know most about, as far as photography is concerned.

There are two points I should like to notice in Mr. Harmer's letter before I conclude. He deliberately says that Mr. Oakes's description of Mr. Breese's method of colouring is not correct. I beg to say that it is correct as far as my description goes. I described from memory the slide painted for me by Mr. Breese. I saw him paint it, and the method he adopted in colouring it was as I have described. I am satisfied that Mr. Harmer's account of the way he coloured the original slide is also correct. It is just the way Mr. Breese would go to work, and is very characteristic of him.

The other point I wish to notice is that mentioned in Mr. Harmer's closing paragraph, in which he calls me to account for an expression I used—an expression, as he says, hackneyed in photographic literature. This fact speaks for itself, and proves that it must have had some foundation; but I withdraw it so far as I am concerned. I have no wish to be otherwise than kind and courteous, and I do not know that I had any special meaning in making use of it.

In conclusion: I can only say I am very glad Mr. Harmer has made us acquainted with his existence, and I trust I may look upon him as a powerful ally in reviving the interest in stereoscopic work.—I am, yours, &c. S. H. Ashley Oakes.

16, *Silverwell-street, Bolton, January*, 26, 1878.

[We, too, join with Mr. Oakes in expressing the hope that Mr. Harmer will continue his most interesting account of Mr. Breese's method of working.—Eds.]

IMPROVEMENTS IN CARBON PRINTING.

To the Editors.

Gentlemen,—I greatly regret that in my article in your last Almanac I should have written aught to offend the gentlemen of the Autotype Company, whom I greatly respect.

That article contains two chief propositions, both of which—in spite of the verbal inaccuracy of my quotation, made, as stated, from memory, and, therefore, erroneously put between inverted commas; in spite, also, of the indignant tone of the writer of the letter in the last number of your Journal—I believe to be strictly true, and I still maintain them:—

1. The first proposition is that up to a very recent period the manufacturers of pigment paper were unable to obtain certain tints in permanent colour, and appeared to think the problem unsolvable, as they had stated publicly that a fugitive colour must be employed.

2. That I had succeeded, after a long course of experiment, in rendering such tints perfectly permanent by a process which I had recorded by a patent.

It appears to me that the Autotype Company fully admit the accuracy of the first proposition. When quoting from the sixth edition of their *Manual* they say:—"Up to a very late period the more brilliant tints in the autotype tissues could not be obtained except by the use of cochineal colour."

With regard to the second proposition, I cannot see in what way the Company are prejudiced by it. Do they dispute the priority of my publication of the process, by which this important question has been solved?

I have no doubt that the Company possess many imperfect attempts of mine to solve this problem. If a minute history of the invention be interesting to the public, why not communicate to the journals the substance of our interviews in Paris, in 1876, the particulars of which were subsequently recorded in a written memorandum by Mr. J. R. Sawyer?—I am, yours, &c., J. R. Johnson.

January 29, 1878.

"A TRIAL OF LANTERNS."

To the Editors.

Gentlemen,—In justice to the manufacturers of the "pyro-hydrogen light" I must ask you to kindly insert the following remarks in reference to the trial of lanterns at the last meeting of the Bristol and West of England Amateur Photographic Association, a report of which meeting was given in your issue of January 18th.

From the report, as given, it would appear that the pyro-hydrogen light was inferior to the light of the other two lamps, namely, the sciopticon and Newton's refulgent. This statement, though in one sense correct, is, through the omission of certain important particulars, anything but correct and somewhat misleading.

In the first place, I may say that the sciopticon and also Newton's refulgent lamp were both used in lanterns having for the object-lenses French quarter-plate portrait combinations, having a diameter of about $1\frac{5}{8}$ inch, and were worked *with full aperture.* The pyro-hydrogen light was worked with lenses having a fixed diaphragm of $\frac{3}{4}$ inch. This alone would account for a vast loss of light. In the second place, the pyro. light was used in a lantern to which the jet had not been fitted, and, consequently, the light could not be moved into the correct focus of the condensers, and, also, not being fitted with the requisite adjustment for height, could not be correctly centered, thus placing the light at a manifest disadvantage.

Through an oversight on the part of the optician in omitting to send an adapting tube with the lenses, an additional combination had to be screwed in, in a position where it was not correctly placed. Taking these facts into consideration the only wonder is that the light compared as favourably as it did with the others. Having had the adjustments and necessary alterations made, the light is wonderfully improved, and gives great satisfaction.

I should also add that through some slight disarrangement of the glasses the refulgent lamp was not working at its best, and, though the sciopticon on that occasion gave the better light of the two, the light of the refulgent is certainly more evenly diffused over the disc. My desire to do justice to a clever and really useful invention is my reason for troubling you to insert this communication.—I am, yours, &c.,

Bristol, January 30, 1878. EDWARD BRIGHTMAN.

EXCHANGE COLUMN.

Wanted, a whole-plate camera, in exchange for a musical album.—Address, M. W., 5, Keith-terrace, High-road, Lee, London, S.E.

Ten quires albumenised paper, solar camera, stereo. camera, and changing-box by Meagher will be exchanged for Tench's No. 1 baby lens and paraffine stove.—Address, JAMES ARTHUR, 11, Grove-terrace, Victoria Park, London.

Wanted, a good *carte* camera, with repeating back and rack-and-pinion movement, in exchange for coloured lantern slides (Scripture subjects) by Carpenter and Wesley.—Address, F. SHAW, Willowby-street, New Lenton, Nottingham.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

JAS. B.—Try formula No. 2.

F. A.—We have forwarded the enclosure.

R. O.—No registration in your case is required.

J. R.—We believe the advertisement to be a *bonâ fide* affair, but we are not acquainted with the formula.

T. M. G. D.—When we give the new method of making oxygen a trial we shall communicate the result.

F. G. P.—With respect to the purely legal aspect of the question of Sunday photography we must refer you to a solicitor.

H. A. S.—The article was written by the second on your list. It contains internal evidence of this having been the case.

MORNING (Leeds).—A *brochure* sold at a penny or twopence by a dealer in the provinces will give you all the information required.

W. W.—It is probable that simple filtration, followed by the addition of a *little* acetic acid, will re-establish the good working qualities of the bath.

N. A. C.—Unless made acquainted with some of the details in connection with your method of working we could not offer any suggestion as to the cause of the fog.

INCORRECT EQUATIONS.—Mr. Herbert B. Berkeley directs our attention to a printer's error that occurs in an equation in his article in last number. Instead of "$2\ Ag_3\ Br_2$" *read* "$2\ Ag_2\ Br$."

ONCE GULLED.—Certainly; by calling at our office we shall have the greatest pleasure in showing you carbon prints by the Autotype Company, and also specimens of heliochromy by M. Leon Vidal.

TRAVELLER.—Select a lens that will not distort; do not let it include too wide an angle; place your camera quite level; and make use of a small stop—say a fortieth of the focus of the lens. These are all the conditions required.

J. J. B.—The studio is too short. As this cannot now be rectified you must obtain a *carte* lens much shorter in focus than the one you are at present using. In this way you will be enabled to obtain full-length portraits of your clients.

COLLO.—Your method of roughening the edges of plates is rather too elaborate. Obtain at a warehouse devoted to furnishing materials for the boot and shoe trade a square slab of sandstone prepared for sharpening knives, and use that for removing the sharp edges of the glass plates.

F. BRUCE.—Had you read your letter after finishing it you ought to have been in a position to have deduced this law—a strong solution of nitrate of silver coagulates the albumenous coating of printing paper, whereas much of that albumen is dissolved by a *weak* solution of this salt. Think over this, make one more experiment, and write again.

SIMEON.—To restore the nitrate bath try, first of all, the addition of a few drops (per ounce) of a solution of bicarbonate of soda. If it be still intractable expose it (in a neutral or alkaline condition) to light for a day or two. You may even boil it. Should none of these measures prove remedial apply a strong solution of chloride of sodium to precipitate the silver.

GEO. SMITH.—To remove the cracks in negatives, or rather to prevent them from being seen, take a pledget of cotton wool, charge it with fine lampblack and rub well over the surface of the negative. The following method has been suggested: charge a camel's-hair brush with Prussian blue and run it over the cracks; when dry breathe upon it and wipe off the superfluous colour.

X. Y. Z.—Your best method for making paper negatives is to closely follow the directions given in manuals, especially those published fifteen or twenty years ago, containing an account of the waxed-paper process. To check the development of a collodion plate apply diluted golden syrup containing acetic acid. To keep wet plates good for a few hours prepare them by the glycerine process.

J. HENDERSON.—We willingly agree with your statement that the process possessed much promise, but beyond that we cannot at present go. There is no use, however, in wasting time ruminating over what might have been; the process has been superseded by something so much better that no one, unless he possess "antediluvian" proclivities, would now think of having recourse to it.

G. F. B. S.—Before we can give a description of the *camera lucida* we must know which one is meant. There are three or four very effective methods of forming instruments of this kind, commencing with the prism of Wollaston, which for your purpose we do not think quite the best. Please write more plainly, and describe in a more lucid manner the precise nature of your requirements.

P. R. H.—Depend upon it you will waste far more time in trying to get rid of the reticulation of the film than the collodion is worth. If it arise from the presence of water, this can very easily be eliminated by the sulphuric acid and bell-glass experiment you suggest; but there are so many other causes that we advise you to pour the whole of your collodion into your waste receptacle, and recover the ether by distillation.

"GOLD" (Dartmouth).—When a solution of protosulphate of iron is poured into a solution containing chloride of gold the precious metal is precipitated as a fine powder of a reddish colour. This method is frequently employed when chemically-pure gold is wanted. Although the precipitate is of a dull appearance, it acquires a metallic lustre by friction or heat. To convert this powder into a solid lump nothing more is required than fusing it, having previously added a little borax. If you desire to convert it into chloride of gold it will not be necessary to fuse it, as it will dissolve more readily when in the state of fine division. After washing the precipitate, to ensure the removal of the iron, place it in a test tube of suitable capacity and add, in small quantities at a time, sufficient *aqua regia* to effect its dissolution.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.—The next meeting of this Society will take place on Thursday next, the 7th inst., in the Rooms of the Society of Arts, Adelphi, when a discussion will take place on Mr. Pearsall's paper—*Educational Aid by Photographic Exhibits.*

HONOUR TO A PHOTOGRAPHER.—We are glad to perceive from the *Philadelphia Public Ledger* that Mr. Frederick Gutekunst, of Philadelphia, photographer, has been distinguished as the recipient of the Cross of the Knights of the Austrian Order of Franz-Joseph, conferred by the Emperor of Austria on Mr. Gutekunst, on account of the excellence of his productions in photographic art. Distinctions are well bestowed when made for such reasons as have brought decoration to Mr. Gutekunst.

OBITUARIES.—MM. BECQUEREL AND REGNAULT.—The world of science has lost one of its most distinguished members—M. Antoine Becquerel. M. Becquerel was formerly an officer of the Engineers under Napoleon I., who presented him with the cross of Chevalier of the Legion of Honour in 1812. Fifteen years ago he was promoted to the rank of Commander in the same order. His labours—those upon electro-chemistry among others—gained him in 1874, from the French Academy of Sciences, the half-century members' medal of that learned body. He had also obtained the Copley medal, which England had bestowed on only three French *savants.* M. Becquerel had been professor in the National Museum of Natural History since 1838, and was the clever father of an able son, M. Edmond Becquerel, whose copies of the solar spectra and subjects in natural colours direct from the object—labours dating from 1848 and 1849—will be well remembered, as well as those on exciting and continuating rays, and also on chromic acid compounds.——The illustrious physician and chemist, M. Regnault, died at Auteuil, at the age of sixty-eight years, on the 19th inst. M. Regnault was Engineer-in-Chief of Mines, and was successively Professor of Physic at the College of France and of Chemistry at the Ecole Polytechnique, member of the Academy of Sciences, Director of the Manufactory of Sevres, and President and Honorary President of the Photographic Society of France, to which latter body he had rendered many services. By a singular coincidence M. Regnault departed this life on the day of the anniversary of the battle of Buzenval, in which his son, Henri Regnault, the painter, already celebrated, fell mortally struck by a ball in the Franco-German war.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 927. Vol. XXV.—FEBRUARY 8, 1878.

ON THE DECAY OF STEREOSCOPIC PHOTOGRAPHY.

As Mr. S. H. A. Oakes has announced his intention of publishing the whole of the *modus operandi* of the late Mr. Breese in the production of his justly-celebrated stereoscopic transparencies, and Mr. Harmer has since followed with an instalment of information upon the same subject, it may not be amiss if we say a few words upon some of the causes which have most probably operated to bring about the waning interest in that branch of our art which it is Mr. Oakes's desire to revive, namely, stereoscopic photography.

Mr. Breese's work lay in a special direction; at least those of his productions to which he was mainly indebted for his reputation belong to a distinct branch of photography very little, if at all, worked by anyone else. Though his name is identified with stereoscopic work and with transparencies, it is in the direction of combination printing in connection with the stereoscope that we must look for his speciality, and in which he stood, and to the present day his name remains, alone. It is by popularising this special branch and by placing in the hands of photographers generally the means, hitherto kept secret, by which the various effects are produced that Mr. Oakes hopes to revive the feeling in favour of a description of picture which may be said to have almost disappeared. We remarked, a week or two back, that if anything is calculated to effect that object it is the method Mr. Oakes proposes to adopt; we doubt, however, on second thoughts, whether we were strictly correct in that statement. We fully admit that the production of the class of picture under notice in a popular form and at a reasonable cost would have a great effect upon the non-photographic portion of the community; but how are we to get at the photographers and secure the production?

There is no gainsaying the fact that of late years the stereoscope has declined in popular favour, and the question is—"What is the cause of that decline?" It has been supposed by some to be owing to "the novelty having worn off." On the same grounds we might expect to find photography itself annually narrowing its sphere instead of each succeeding year finding some new application, some fresh votaries. It is true that popular feeling catches eagerly at anything new, to throw it off again as soon as it is found to be worthless; but it is equally true the public are staunch in its support of any novelty which may prove upon a closer acquaintance to deserve it. In what respect, then, has the stereoscope failed to satisfy its patrons—the public generally and photographers particularly? In other words, to what causes are we to ascribe its decline in popularity?

In replying to this question we have to strike an "all round" blow; we hold the stereoscope itself blameless, and lay the onus upon the manufacturers of the instrument, upon the producers of the pictures, and lastly upon the public themselves. The stereoscope, when properly constructed, we look upon not as a mere scientific *toy*, as it is considered by many, but as an instrument capable of numerous applications—scientific, artistic, and educational; and when, from faulty construction, it fails in its application we must lay the failure to the charge of the maker and not of the instrument. Photographers, with a few honourable exceptions, have much to answer for in alienating the popular taste by flooding the market with imperfect, inartistic, and trashy "slides"—got up in a double sense to "sell"—while the public themselves, by accepting, as a standard, "rubbish" against which their better taste must eventually revolt, have voluntarily assumed a large proportion of the blame.

It is scarcely our province to deal with the question as it affects the manufacturers of the instrument, but having laid a charge at their door we are bound to substantiate it. The best-made English stereoscopes are no doubt nearly perfect as regards workmanship; but we require an alteration in the shape and style of the instrument in order that it may be used with ease and comfort. With the form in ordinary use much craning of the neck is necessary in order to secure even a moderately equal illumination of the picture. Another point which has undergone frequent discussion is the correct distance apart of the lenses. This is a matter which varies very greatly with individuals, and to a smaller extent with the distance of the centres of the pictures; but by far the larger number of instruments are constructed as if the eyes of different individuals and the centres of all pictures were placed at an unvarying distance—conditions which, we need scarcely say, do not exist. As an instance of a fortunately less frequent fault in construction we may mention an incident which came under our notice. We possess a cheap folding stereoscope which we find extremely useful and of greater convenience than the more elaborate form when mounting "slides." A non-scientific friend purchased one of the same pattern, which was submitted to us for examination, as it "would not work." This rough description of its powers was certainly correct, and arose, we subsequently found, from a variation of *more than half an inch* in the focus of the two lenses.

If we turn to the shortcomings of photographers we must recognise two distinct classes—commercial and amateur. The influence of the former class has tended to degrade the stereoscope in the eyes of the non-photographic section of the public; while the latter have apparently succeeded in disgusting themselves with their own work, and hence have discarded stereo. work altogether. Looking at the commercial side of the question, we are happily able to say that the evil has almost uprooted itself. The propagators of "trash" by disgusting the public have destroyed their market, and consequently the supply has ceased. In a few shop windows we may still see some of the "old stock" struggling to obtain a sale; but it is chiefly in private collections that we find in all their "ghastly beauty" specimens which raise a feeling of wonder as to how any one could ever have been induced to invest money in such rubbish. Let us hope that, should the stereoscope be reinstated in favour, the public taste may now be sufficiently educated to reject such work should the supply recommence.

We will now turn to the side of the question which more immediately affects the decreased production of stereoscopic pictures by amateurs. It has been urged in explanation of the waning interest in that class of work amongst amateurs that it is owing to a taste for pictures of larger sizes; but this, for various reasons, we cannot believe to be the case. Of late years the tendency has been rather in the opposite direction, and cameras of the "pocket" size have been more in vogue than larger ones. It may be said that the pocket camera is only a roundabout way of obtaining a large picture by subsequent enlargement; but we would ask in how many cases are the original small negatives so utilised? Again: the number of amateurs who confine themselves to large work is comparatively small, while those who occasionally utilise the larger sizes will be found to do the bulk of their work upon a smaller scale—generally one of the "cabinet" (or $7\frac{1}{4} \times 4\frac{1}{2}$ to 8×5) sizes.

It is to the introduction of the latter useful form of camera that we are disposed to ascribe, in a great measure, the falling off in the production of stereoscopic work. This statement may, at first sight, appear somewhat extraordinary when it is considered that these cameras are invariably constructed to give the option of a stereo. or single picture upon the same sized plate; but we shall attempt to show how, in several ways, the new size of plate has tended to the suppression of stereoscopic work. In the first place, it cannot be doubted that the large plates enable us, without difficulty or special care, to turn out stereo. prints of full size without any fear of stained or torn edges, whereas skilful and cleanly manipulation were absolutely necessary with the old $6\frac{3}{4} \times 3\frac{1}{4}$ plate. But, on the other hand, when we consider that the actual portion of the film utilised measures only some 6×3 inches, it is obvious that the new size is not economical; and though probably few amateurs would in a general way make that an obstacle, we can readily believe that under some circumstances it may militate against the production of stereos. Suppose, for instance, a photographer is out for a holiday (be it a day or a month) with one of these cameras and a limited supply of plates: he considers that, *cæteris paribus*, a single negative upon the full-sized plate is of greater value than a stereo., and hence he is reluctant to "waste" a plate on the latter form of negative when he can as easily obtain the more valuable. Of course, with a plentiful supply of plates, or when the choice of subject is limited, this argument would not apply, as the views might then, with advantage, be "duplicated;" but we rather fancy, from our own experience, that the habit of neglecting stereo. work grows upon one. We have known more than one amateur of our acquaintance to go on a photographic tour of some duration, fully "armed" for both stereo. and single work, and to return with a portion of the plates unexposed and not a single stereo. picture taken.

Looking at another phase of the same question: the new size is apt to, and indeed does, lead to the production of stereo. negatives badly composed and altogether unsuited to the purpose for which they are required. Many photographers are in the habit of trusting entirely to the judgment in composing the picture on the focussing-screen, neglecting altogether to consider how much of the subject then depicted will come within the bounds of a stereo. print. In this manner are produced dozens upon dozens of stereo. negatives, technically perfect, perhaps, if only the size of the print were immaterial, but which, when cut down to the inexorable limits of the stereoscope, are found to be wholly ruined as pictures. The use of longer-focussed lenses (six, seven, and even eight inches) than were formerly employed in stereoscopic work tends to increase the liability to error in this direction. Such lenses give undoubtedly a more natural-looking picture in distant landscape work; but the fact must not be lost sight of that, though upon a comparatively large plate the picture obtained may "compose" well, yet when the size of the plate is considerably curtailed, or when the print is cut to stereo. size, the angle of view included is, in the majority of cases, far too small to give a satisfactory pictorial result. We have in our recollection as we write a series of stereo. views of one of our English abbeys, taken upon 8×5 plates, with lenses of six inches focus. As *negatives* they were simply all that could be desired; as *stereo. negatives* utterly useless, except for reduction in the camera. The obvious way out of this difficulty is to mark upon the ground glass the extreme limits of the stereo. prints, and in composing the picture to adhere rigidly to those limits; also to suit the focus of the lens to the subject.

We might bring forward further arguments of the same character, but we have said sufficient to point out an unsuspected cause of the failing interest in the stereoscope. It is tolerably evident that the constant production of unsatisfactory pictures—especially when, as in this case, the cause is not at once plain—will gradually alienate the taste for stereo. work, and the same remark will apply to pictures defective from other causes. Under the latter head we may include want of judgment in the choice of subjects and carelessness in cutting and mounting the prints, all of which have had their share in bringing stereoscopic photography to its present low ebb.

Mr. Oakes has our hearty co-operation in his crusade in favour of the stereoscope; and while we do not anticipate that the bulk of our amateurs will be ready to face the difficulties of combination printing, we have no doubt that he will find some at least to follow him. But we do trust and believe that he will succeed in his object—the revival of an undeservedly-neglected branch of photography.

THE NEW IRON DEVELOPER.

When we last drew attention to the ferrous oxalate developer our experiments with it had been confined to collodion dry plates. Since that period we have been making use of it in connection with gelatino-bromide plates, with the happiest results.

The advantages secured are a lessening of the exposure, and a particular kind of hardening of the film, in virtue of which it appears to stand the roughest treatment without frilling or puckering. These properties have also been found by others, notably so by Dr. Huggins, F.R.S., a letter from whom on this subject we append:—

"In connection with your reference to iron development with dry plates, it may interest your readers to know that as soon as Mr. M. Carey Lea's paper reached this country I made some careful comparisons of the new iron development with the usual alkali method. My experiments were made chiefly with Kennett's gelatine plates.

"After exposure the plate was cut in half with a diamond, one half subjected to the iron development, and the other half developed in the usual way. The result was also in favour of Mr. Lea's method, but very greatly so when the exposure of the plate had been made purposely too short. The pictures obtained by the iron method appeared to me to possess very great delicacy of detail and half-tone.

"A very important advantage of this method arises from the freedom from all risk of fogging the plate; and this property of the iron method is of especial value when it is endeavoured to make up for insufficient exposure by a stronger and more prolonged development.

"The *neutral* oxalate of potash and the oxalate of iron can be obtained at the establishment of Hopkin and Williams. A saturated solution of oxalate of potash is made by means of heat, and into this hot solution the oxalate of iron in powder is dropped until it is no longer dissolved. The solution of the oxalate of iron to be assisted by stirring. This deep-red solution is filtered when cool, and may be used in the concentrated form, or more or less diluted, according to the amount of exposure to which the plate has been subjected."

The frilling of the gelatine film has given rise to a great amount of dissatisfaction with this excellent process. It has now been traced to the state of the water, as regards hardness or softness, with which the plate is subsequently treated, and the knowledge of this will, doubtless, prevent the recurrence of this evil. The new developer, however, seems to be quite inimical to this kind of defect—a point specially noticed by Mr. J. Dudley Radcliffe, a record of whose experiments is as follows:—

"I send you two transparencies developed with the new iron developer. They are both gelatino-bromide plates of my own preparing. No. 1 had three seconds' exposure to a No. 2 fishtail gas flame. It was then soaked in plain water for one minute and the developer poured on. The picture came up faintly in twenty-five seconds, and in fifty-five seconds the development was complete. The plate was now washed, fixed, and again washed. It needed intensifying with acid silver. No. 2 was exposed under the same conditions for two seconds. The developer was kept on for three minutes. This plate was not intensified. I think I ought to mention that these plates would require about the same exposure and would take about as long a time to develope with an alkaline developer. There is a liability for this developer to show drying marks, which there is not with the alkaline method; but, no doubt, further experience in its use may show how to do away with this very serious defect.

"I wish to draw your particular attention to one fact, and that is that those plates did not show the slightest tendency to blister, either during development or during the process of intensification with acid silver. This was the more remarkable inasmuch as they were from a batch which invariably blister under the ordinary alkaline developer.

"The developer was prepared as follows:—A saturated solution of iron oxalate was made in a saturated solution of potash oxalate (neutral) and filtered. No restrainer was necessary. If I found occasion for one I should try gelatine."

As respects the drying marks to which Mr. Radcliffe alludes as being present in two of the negatives he has left with us, it is a matter to which we attach no importance, as it is owing to the developer not being quite washed out of the film. It must be borne in mind that the iron developer is *very* much stronger in regard to the amount of crystallisable matter contained in it than the alkaline pyro. developer, and hence a much more thorough washing is required in order to effect its removal.

The quality of the gelatine negatives produced by the ferrous oxalate developer is so excellent that we think it probable it will, to a large extent, supersede pyrogallic acid for this purpose. We may observe that we are trying some experiments with the developer as applied to *undesiccated gelatine* films and *moist* collodio-bromide plates, and as the result of these we hope in a short time to be able to announce that the greatest degree of sensitiveness hitherto attained will be by this process. The light at present is so bad that we prefer not to speak positively on this subject, but to wait until by a greater number of experiments we shall be able to indicate in more precise terms the value and applications of the ferrous oxalate developer.

We hope to secure the co-operation of some of those able experimentalists whom we are proud to number among our readers, so as to be in a position to have something definite to place at the disposal of practical photographers before the advent of the outdoor season.

WARMING THE STUDIO.

Bearing in mind the old saying that "as the day begins to lengthen so the cold begins to strengthen," warming the studio and *atelier* of the photographer will be considered a most seasonable subject. Various methods of arriving at this much-desired consummation have from time to time been given in the pages of this Journal, and it is now our good fortune to be able to give a brief description of another, which has elicited high encomiums from those who, having tried it, are enabled to speak from personal experience. We allude to the system of heating by means of hot water invented and patented by Mr. James Keith, of Arbroath.

Mr. Keith's invention comprehends a method by which the water to be employed in warming a house is heated with the greatest possible rapidity, and at an expenditure of but little fuel.

The apparatus consists of a new or improved arrangement of boiler and inside heater, with down centre flue, boiler casing, furnace and grate attachments, which the inventor proposes to call "the rapid circulator and fuel economiser."

The boiler, which may be of any desired form, is constructed of either malleable or welded iron or steel, cast iron, or any other metal capable of withstanding the heat. The body and top of the boiler are composed of two shells, between which the water circulates, and connected to the inside shell is a heater or other shell having a flue or pipe carried down through its centre and out at the side of the boiler, by which the flame and smoke pass directly through the centre of the heater. The flames having to turn round and down when at the top of the above flue give an intense heating power, and the draught is very strong and equal, being all drawn to the centre of the heater before descending.

The above heater is properly connected to the inside shell or body of the boiler both at its lower and its upper part, thus causing a constant and rapid circulation in the boiler itself whenever the least heat is applied to it; all parts of the boiler expand, being surrounded or covered with water. The heater has a flat or raised bottom, which is carried down to within a short distance of the top, and covers nearly the whole surface of the fire, thus "frying" over the fire, as it were, and allowing the heat and flames to escape up between the outside edge of it and the sides of the inside shell of the boiler, and after which, passing up between the said heater and the said inside shell, on arriving at the top they turn down through the centre of the heater again (as already described) and pass through the side of the boiler, entering into the space between the outside casing and the outside shell of the boiler, and, after passing once, twice, or more times round the outside and over the top of the boiler, they enter into the funnel or chimney attached to the top plate of the casing. Suitable dampers and soot and cleaning doors are provided at proper places in the funnel, boiler, and casing.

The furnace is, therefore, inside the boiler, in the side of which is the furnace door, the fire being surrounded on all sides by a thin lining of water constantly circulating. The boiler extends to within a few inches of the furnace bar plate, and the space between the bottom of the boiler and top of the bar plate is filled in with a thin lining of fire-bricks moulded to suit to keep life in the fire when it is damped down.

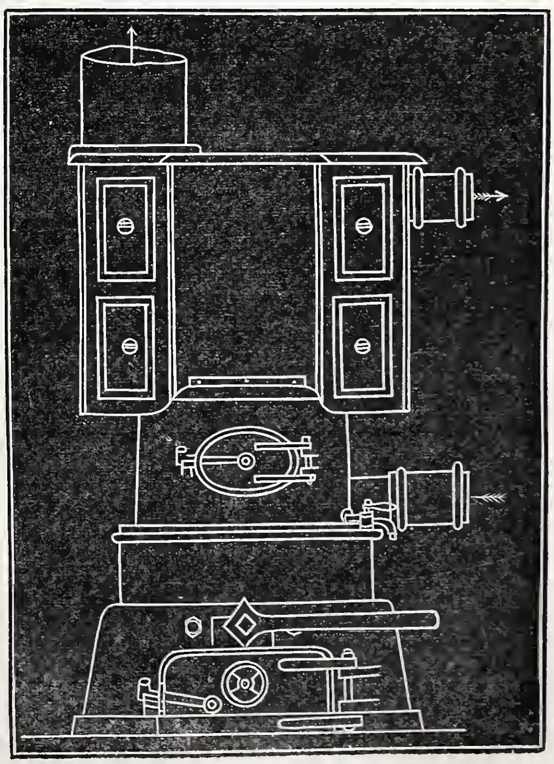
The whole apparatus stands on a metal frame provided with hinged damping grate and ashpan and damper door arrangements complete. No building work whatever is, therefore, required about the boiler, and standing by itself it takes up very little room and is very easily heated up, having no surrounding brickwork to absorb the heat.

The flow or heat-circulating pipe or pipes are led from the very top of the boiler, and the return or cold pipes from the lowest part, and are connected to the boiler by suitable collars or sockets, cast, welded, or bolted on to the outside shell.

All the shells and heater can either be welded together in one piece or rivetted or bolted and jointed properly together, or otherwise connected in separate parts.

The said boiler, either for steam or hot water raising and circulating purposes, owing to its peculiar construction, has more direct and indirect superficial heating surface than other boilers of the same size in use, while its great heating powers, coupled with the minimum consumption of fuel, renders it greatly superior to boilers at present in use for the purposes specified. Instead of the central flue through the heater this flue may be dispensed with, and a central heater hung down from the top or dome of the boiler to give similar effects.

The accompanying diagram affords a view of the exterior of the apparatus, the interior view of which, although also shown in the



specification, we need not here give, contenting ourselves by stating that it is constructed in harmony with the description we have already given. The upper portion is the boiler, through which the heat from the furnace, situated below, travels upwards and downwards, until robbed, or nearly so, of its caloric, the products of combustion escaping through the aperture at the top. The water enters the boiler through the lower of the projecting pipes or apertures on the right-hand side of the apparatus, and is emitted through the upper, suitable pipes being of course connected with these apertures to permit of the water being carried throughout a building.

We have said enough to convey a good general idea of the nature of Mr. Keith's invention; but as regards the manner in which it is practically found to work we are unable to speak from our own observation or experience, and, instead, prefer to give the opinion of Mr. J. Valentine, photographer to the Queen, Dundee, who, we are aware, has had his large new establishment in Perth-road heated by Mr. Keith's system. A portion of these premises consist of two floors, each 80 × 16 feet. To properly heat these rooms during cold weather was found to be no easy matter, and Mr. Valentine has described some of the methods adopted by him to effect the desired end, including an open fire and four of the best stoves he could procure. All these proved inefficient, and he was about to revert to an older and less expensive system previously adopted by him, when he was impressed by an expression contained in a letter on the subject received from a photographic friend, Mr. Marshall Wane, of the Isle of Man, in which that gentleman said he had found Keith's system to be "simply perfection;" so after due inquiry Mr. Valentine adopted it, and reports the results as follows:—

"I have at last got heat to my statisfaction. Not a hitch in its operations since its introduction has taken place. Little attention is required, it being only fed once a day, and at a cost of less than two shillings per week. I use gas coke, although the cheapest coal dross may, with equal advantage, be used. I am now, in the coldest weather, in a comfortable atmosphere, every part of my large premises being uniform in temperature, besides having an abundant supply of hot water for washing. In an hour after the fire is lighted a mild and healthy temperature pervades the whole place. I have said "a mild heat," but a great heat can be secured; only open the damper, give more draft, and shortly afterwards you will feel as if in an oven. The freedom from dust is not a less important consideration; for, except a small quantity of dust which falls into the ash pan, there are no ashes—all are consumed with the smoke, and the ashes that may fall through the grate bars have only to be taken from the ash-pan and placed in the fire with fresh fuel, when they will be burned over again into dust.

"Over the pipes and at the boiler I dry my albumenised silver paper, and from a galvanised hot-water tank, most ingeniously fitted to the higher part of the apparatus, I can draw in my washing troughs an unlimited supply of hot water—so valuable in a printing establishment. This hot-water tank is also so directly arranged and connected to the boiler by separate pipes and stop valves that I can still get the hot water for washing in the summer time without having to heat up any other part of my premises, all the rest of the pipes for heating being shut off in summer.

"As the apparatus requires only to be supplied with fuel once or twice a day, according to cirumstances, it can go on night and day, thus ensuring at all times an equal temperature. At night the fire is simply filled with ashes and fresh fuel, and every inlet and outlet to the fire being closed by suitable appliances attached to the apparatus, the whole is perfectly safe and free from risk of fire. The fire of the boiler, being all water 'jacketed,' or surrounded on the outside wholly by water, the premium for fire insurance is thus reduced to a minimum.

"The piping I have is about three inches in diameter, and of cast iron; but I believe Mr. Keith uses various sizes of pipes to suit the different circumstances under which his system is introduced. He seems to fit up these pipes so as to produce perfect success."

The foregoing account of the performance of this boiler will be read with interest. The saving effected is said to be considerable, while it must be a great comfort to be able to get such an apparatus fitted up without experiencing the necessity for having recourse to the offensive and "messy" services of the bricklayer.

In a private letter Mr. Herbert B. Berkeley suggests the possibility of free silver in a fogging emulsion "combining with, or being taken up by, the silver bromide in such a way that it could not be washed out again." We are not in a position to speak as to the probability of such a change occurring *in emulsion;* but some such combination, whether chemical or only mechanical we cannot say, does appear to take place when silver nitrate and silver bromide react upon one another under certain conditions. If silver nitrate be fused in a porcelain capsule, and freshly-precipitated and dried bromide be added to it, the latter changes colour and dissolves, forming a glassy, transparent mass of a brownish-grey colour. When allowed to cool it assumes the opaque appearance and colour of the bromide. If the temperature be not too high there will be little, if any, evolution of acid fumes; but if the heat employed be much greater than is necessary for the fusion of the nitrate a considerable quantity of nitrous acid fumes are given off, the product in either case being similar in appearance. Now the peculiarity of this product is that, if it be reduced to fine powder and digested in water, it gives but a slight trace of soluble silver salt; but the water may be repeatedly changed without removing the free silver. Treated with hyposulphite of soda it dissolves, leaving a brown-black sediment—apparently hyposulphite of silver. The appearances are such as to justify the belief that, as Mr. Berkeley suggests, the nitrate is taken up by the bromide, without, however, entering into chemical combination. How far such an action is possible under the altered conditions which exist in an emulsion we are unable to say. The writer goes on to suggest that the free silver thus retained by the bromide would be reduced by plain or alkaline pyro. (producing fog), but not by acid pyro. We may remark with regard to this that we have sometimes found an unwashed emulsion which fogged badly with pyro. and alkali give a perfectly clean though feeble image with pyro. and silver; but in the majority of cases the fog appears irrespective of the mode of development. We have never attempted to trace the cause of this difference, but should ascribe it to the presence of perhaps a more than ordinarily strong dose of acid. With a washed emulsion in the fogging state we do not recollect having tried silver development; but it will be interesting to try such an emulsion both before and after the addition of acid, and to note the difference in behaviour.

APPEARANCES *VERSUS* REALITIES.

In one of the very interesting communications upon stereoscopic transparencies which have recently appeared in these columns mention is made about printing-in a moon, with clouds, &c. This so forcibly recals to me some of the vagaries indulged in by painters as well as photographers when the pale orb is in question, that I here make a few notes upon it and cognate subjects.

Photography is always held up as a model of truthfulness, and, in a restricted sense, justly so; but it is only in a restricted degree that I can endorse this character, granting, even, the use of non-distorting lenses and properly-adjusted and managed cameras; and it is this very character of truthfulness that makes photographic deception, whether intentional or not, to be so full and complete. Thus, Mr. Breese's moonlight effects were so wonderfully contrived as to deceive not only the general public, as they did so utterly, but photographic experts also. The pictures appeared to be taken by the light of the moon, but were not so taken.

How often, again, do we hear complaints, and see examples giving just grounds for them, of perspective so exaggerated as to give misleading representations of the proper sizes of objects; while, at the same time, the pictures are quite correct, their fault being an injudicious selection of standpoint and the introduction of objects lying too close to the spectator! That they are correct is easily proved by placing a sheet of transparent glass between oneself and the view, and, keeping the head stationary, marking out leading points and lines of various objects seen beyond; they would coincide to a hair's breadth with the same picture taken in a photographic camera from the same spot. The picture may be made in this manner the exact size of the photographic one by moving the glass to and fro till it is in such a place that any given object drawn upon it so that the drawing covers the object looks as large as it does in the photograph; the rest will then all follow.

This drawing of a picture upon a sheet of glass is the theory upon which the system of perspective, mathematically and exactly treated, is built. Any object of known dimensions, and at a known distance from the glass, can be depicted by the aid of the rules of perspective so as to coincide exactly with the photographic representation; and the different distances of the theoretical plate of glass—"the picture plane"—may be considered as analogous to the various foci of lenses that can be used to photograph with. Hence it follows that, mathematically and truly, a comparatively short-focus lens depicting a very wide angle of view shows us exactly what we do see. Yet we are not aware of it; our senses are deceived by the relative magnitude of objects, and our brain refuses to accept the image presented to it, because it has brought for its mental digestion such an association of ideas as it is not accustomed to.

The same thing exists in everyday life in a remarkable manner. No sooner is an object brought before us for a rigid scrutiny, which ordinarily we see only in a slight and temporary manner, than we perceive such a variety of peculiarities that we never dreamed of before; and if the object be brought before us, not only for close scrutiny, but in an unusual position or in an uncommon conjunction of circumstances, then many of its attributes before unknown were instantly perceived. Take the most usual instance—a face to be photographed. Few faces in existence are quite symmetrical; but, except in gross instances, neither to their owners or their owners' friends is the fact perceptible; and, when the picture comes home, how frequenty is an outcry raised against it on account of that "nose so crooked and those eyes so odd," often taken back at once to the photographer with the complaint repeated to him, and at other times compared with the original, and want of symmetry actually existing for the first time perceived!

Another example I present to my readers:—

S S S S S S S
8 8 8 8 8 8 8

Here are a row of letter S's and of figure eights, taken at random. At a casual inspection the reader might say the letters were symmetrically made—that is, the top and bottom lobes of the figures and letters the same size—though upon a close inspection he would either say that it was doubtful whether any difference existed or he would notice the true relation that exists, the top lobe being the smaller. Let him, however, turn this page upside down and the most cursory glance possible will show him their shapes, and the dissimilarity between the upper and lower halves will strike him with astonishment if he have never tried the experiment before.

Thus, also, with regard to natural objects and their appearances. Everything depends upon their being viewed from an ordinary standpoint. If any position at all unusual be chosen for viewing them from, their appearance undergoes a change from what the mind is accustomed to, and if so depicted an effect of untruth would be presented. Figures are introduced into pictures to give effect—often with ludicrous unreality as to the true size relative to objects about them; and so when they are printed in photographs from a separate negative due regard should be had to appearances as opposed to realities. Thus, if it be desired to place a group of figures at a distance (say) of a hundred yards from the spectator, they would be printed in of appreciable size as to the mind their appearance would require to be done. To test the effect, however, let an observer ascend a high steeple of a church—as high as the distance I have just named. The people below him present such a pigmy aspect that if he were to depict them he would place tiny dots in place of the comparatively large figures in the group I instanced—a difference far greater than would be warranted by the effect of looking at the figures endways, so much do unwonted conditions react upon the judgment.

I may conclude my notes by a further reference to the object that suggested them—the moon. The secret of the moonlight effects of Mr. Breese, in one respect, was found out, and numbers of pictures were produced in imitation—a very conspicuous white moon being frequently added, suggestive of a wafer having been stuck on to the negative, and much sarcastic criticism was spent upon them. The question arose—How large was the moon to be to have a natural effect? To answer this exactly is no easy task. Every one is familiar with the harvest moon, looming large above the horizon—as large, apparently, as two or three ordinary moons rolled into one. I have no doubt that I shall surprise many of my readers when I tell them that this large size of the moon is a purely *mental* effect caused by the real image on the retina being brought close to objects of familiar and known dimensions, *e.g.*, trees, houses, &c. Really the harvest moon occupies the same area of space upon the retina as it does when high up in the heavens. Any doubt on the matter will be at once set at rest by viewing the harvest moon, telescope fashion, through a piece of paper rolled up and held in the hand. At once it appears diminished in size, while when high up in the heavens no diminution in apparent size would be seen through the rolled-up paper.

Still I have not answered the question, and I do not intend to give an entirely definite answer; but, instead, will supply a final means of comparison. Naturally the moon should be represented as large as it appears to be, and how large it does appear to be may be judged by holding up some object in the hand and placing it, as it were, side by side with the moon. I have often asked my friends' opinions, and have received replies unanimous in their great incorrectness, a dinner plate or a crown piece being generally the two extremes of maxima and minima. The truth is that the object which, held up in the hand and compared witht he moon, would appear the same size is neither of these—it is far smaller (a dinner plate would be as large as seven or eight thousand moons); it is a small pea. If a pea be stuck on a pin and held at arm's length it would entirely hide the moon from view!

I think I have shown how deceptive are appearances, and the moral I would draw is:—Before introducing a moon or a figure or any object into a picture think well over all the bearings between appearances and realities, and to aid in doing so I believe the notes I have written will be of some service.

G. Watmough Webster, F.C.S.

A FURTHER IMPROVEMENT IN THE GELATINE PROCESS.

[A communication to the Liverpool Amateur Photographic Association.]

The subject which I propose to bring before you this evening is one, I think, of considerable importance to photographers in the field. The advantage of superseding glass as a vehicle for the sensitive film in favour of something more portable and less frangible cannot be gainsaid. I have already worked out a process whereby the ordinary sheets of gelatine to be purchased in the shops may be made available for this purpose; but, in spite of all the simplification I have been able to effect in the *modus operandi*, the end in view cannot be obtained with the perfection to be desired.

In the first place, the gelatine sheets of commerce are usually full of bubbles and specks; and, in the next place, to obtain complete contact between the gelatine and the surface of its temporary support is a process which, in spite of my own testimony in its favour, I must confess to be, at times, no easy matter. During my recent vacation I set myself to work to discover the ingredient employed by the gelatine makers to enable them to separate the dried sheets from the glass slabs upon which they have been poured. This ingredient had made its presence manifest to me in my previous experiments both by its colour, its taste, and its smell; and I felt that if I could discover its character further it might then be in the power of gelatine workers to make their own sheets for photographic purposes, or even to incorporate this ingredient with a gelatine emulsion, and thus obtain a film which, when dry, might be stripped from its support and form a self-supporting sensitive sheet. My appeals to gelatine makers were of no avail, for I was seeking to unravel one of the mysteries of the Eleusis of trade; books were entirely silent on the subject, and I was, therefore, left to my own resources in the matter.

I will not inflict upon you the wearisome details of my experiments in this direction; suffice it to say that an accidental carelessness in dealing with an emulsion prepared with gelatine containing the substance of my quest gave me the clue, and I found in ox-gall the material I was in search of. I cannot claim to place before you a perfected process; for my leisure time has come to its close while yet the application of the discovery remains in an inchoate condition. Sufficient success, however, has been attained to warrant me in trespassing upon your patience tonight in the hope that other workers may be able to carry the matter to completion.

Ox-gall may be obtained in three forms:—There is, first, the ox-gall proper; then a purified, pasty preparation of it used in medicine, and sold by chemists; and, lastly, a clear, colourless liquid supplied in the shops for the use of artists. I have found that all three kinds—either when employed in the gelatine itself or when used upon glass as a substratum—will effect the desired end, provided that plain gelatine be used; but I have hitherto failed in every effort to employ it thus with an emulsion. The sheets I have here were stripped from glass which had been immersed in ox-gall from the butcher's, and then dried. They proved to be readily removable; but until a harmless and complete deodoriser has been found I cannot recommend the experiment to any one who is not possessed of a strong stomach and very unsusceptible olfactory nerves.

Here are some plates with a dried, plain film of gelatine still adhering to them. In this case the ox-gall is present in the film, and I think I can show you succesfully how readily the sheets leave their support when the point of a knife has been passed round their edges.

My next specimens consist of sheets similar to those I have just stripped from the glass, with the addition of a sensitive coating of emulsion. These also I will remove from the plate and pass round for inspection. I have exposed and developed one of them this morning, which I must show you still in its wet state. The negative is a good one; but, being the first I have exposed prepared by this new process, it has suffered to some extent from the frequent handling and examination it has undergone.

These films were prepared as follows:—Plain gelatine, containing a proportion of ox-gall, was poured upon clean glass, and then, when dry, was sensitised with a film of ordinary emulsion. The advantage of this plan over that to which I have alluded above, and which I have given in detail in The British Journal Photographic Almanac, is considerable. The emulsion will be found to flow easily over the gelatine, and when desiccation is complete the sensitised sheet will easily come away from the glass.

I have not found the second kind of preparation of gall which I have mentioned nearly as effective as the noisome article which the butchers supply; and the prepared alcoholic solution of the artists' colourman is too expensive to be employed largely in the process. But I think that if gelatine workers would only create a demand the manufacturers will supply us with gelatine prepared with ox-gall for this special purpose. It will then be merely necessary to dissolve the required quantity in water, to coat the glass plates with it, and finally to sensitise with the emulsion in the usual way.

The one drawback to the preparation of these films lies in the slowness of the drying process. Some one has recommended dipping the gelatine in alcohol. I tried this recently, but found the alcoholised sheets were quite as slow as the others.

To those who would wish to experimentalise for themselves the following directions will be useful:—Take of fresh ox-gall one ounce; add it to eight ounces of water, soak in this one ounce of common gelatine, apply gentle heat, and filter. Coat the warm plate in the usual way with a thin film, and place it upon a level glass slab. Now pour from the lip of the cup upon the levelled plate about a drachm more of the liquid gelatine, and leave till set, when it may be stored away in the drying cupboard till it is thoroughly dry.

The same process must be repeated with the emulsion, *i.e.*, a supply should be flowed like collodion over the whole surface of a warmed gelatinised plate; the glass must then be placed upon the level slab, and a small quantity of emulsion added. The tip of a glass rod or a clean finger should now be applied to direct the emulsion to each corner and up to the edges of the plate, and it may then be allowed to set and dry in the usual way. The film will come away from the glass by inserting the point of a knife round the edges, and it may be exposed in the camera in front of a thin piece of glass to keep it taut in its place; or, better still, the sheets may be arranged after the fashion of a sketching-block, with a piece of non-actinic paper separating each sheet from the rest, and the whole backed up with a plate of tin or zinc. To develope the sheet: wet it thoroughly, place it in a shallow dish, and apply the usual alkaline developer. Should the negative assume a reddish tinge when fixed, washed, and dried, printing should be accomplished through a piece of blue violet gelatine. I must not omit to mention that the negative should, when the washing is completed, be placed upon a glass plate and left to dry spontaneously.

Throughout the process care must be taken not to raise the temperature of the room or closet in which the drying is effected above 60°, otherwise inevitable cockling and splitting of the film will result. The former evil may, however, be remedied by leaving the cockled sheets in a damp place for a time. They will then become perfectly supple without tackiness of surface, and may be flattened by placing them under a moderate weight.

In conclusion: I may remark that Mr. J. Green, of Dalston, London, is the maker from whom I purchased the sheets I have hitherto employed, and I am not without hope that he and other manufacturers may be induced to prepare for workers in this process a transfer gelatine which could be used as I have suggested above. Possibly also Mr. Kennett or Mr. Mawdsley may be persuaded to try their hands at the production of these portable sensitive gelatines, and supply them to the photographic world for the use of tourists on their travels. H. J. Palmer, M.A.

THE VALUE OF PATENT KNOTTING IN THE STUDIO.

The importance in the studio of the above-named substance can scarcely be over-estimated. It is a glue perfectly insoluble in water, and is equally as strong as cabinet-makers' glue. This is easily proved by joining together by its means two pieces of wood and then breaking the united piece near the joint; for if the joint itself be good it will not break, but the disintegration will take place on one side or the other of it.

When making joints in wood the knotting should be allowed a few hours to dry; but when joining paper or cloth a few minutes will suffice. It is far superior to negative varnish for protecting the dark slide from the action of nitrate of silver, being a stronger body, although similar in manufacture.

Patent knotting is the very thing for making dishes of Bristol boards, &c., so often spoken of; also for protecting iron work from rust. In many cases it will be found to be really "a friend in need."

It should be kept in a bottle, the neck of which should be just the size to fit the binding of a painter's sash tool (brush), and which would answer for a stopper or cork, at the same time keeping the brush always moist and ready for use, although it does not touch the liquid.

The cost of the knotting is about ten shillings per gallon, and I suppose would be about 1s. 6d. per pint. I can assure the readers of the Journal that it only requires a trial to prove its value.

James Harris.

EXPERIMENTS WITH YELLOW CHRYSOÏDINE VARNISH.

[A communication to the Berlin Photographic Society.]

Lately chrysoïdine has been recommended as an ingredient in the preparation of yellow varnish for the covering of negatives and for the yellow windows of the dark room, in the place of dragons' blood, which appears less able to withstand the action of light than the chrysoïdine.

Chrysoïdine is a yellow dye which dissolves easily in alcohol. Forty cubic centimetres of varnish, to which 0·6 of a gramme of chrysoïdine had been added, produced a deep brown colour, and when spread upon glass gave a strong yellowish-red film, darker in colour than ordinary yellow glass. Glass so coated promised, when used for window panes for the dark room, to be useful, as the chrysoïdine solution, examined by the spectroscope, shut out the green and blue rays much more completely than French oiled silk, which is used in the dark room of the photographic *atelier* of the Gewerbeakademie, and gives better results than yellow glass.

Experiment, however, showed that so considerable a quantity of actinic light as still passed through a plate of glass coated on both sides with chrysoïdine varnish, that such a yellow varnished glass being fixed in front of a lens a landscape made a distinct impression through it on the sensitive plate with an exposure of two and a-half minutes. It is also a fact that in clear weather a little actinic light always makes its way through a yellow oiled-silk window, so that fogging can only be avoided by preparing the plate in some of the half-dark corners of the room. Herr Zipser tried a 10×8 sheet of glass varnished on both sides with chrysoïdine as a dark-room window, and, working at a distance of one metre from the window his plates fogged, but at two metres' distance a plate could be prepared without any bad results. In order to test the comparative protective powers of chrysoïdine varnish and oiled silk against actinic light a stereoscopic camera was taken, and, the objectives being unscrewed, the opening left by one lens was covered with French oiled silk and the other with a sheet of glass coated on both sides with chrysoïdine varnish, the camera then placed in front of a window and a wet plate exposed in it. It was then found that when placed opposite a grey sky the double film of chrysoïdine produced fog with an exposure of a minute and a-half, while the much paler-coloured double oiled silk afforded complete protection against the light.

It follows, therefore, that, though chrysoïdine varnish appears darker, and in the spectroscope absorbs green light more powerfully than oiled silk, still the varnish allows a greater quantity of blue—that is, actinic—light to pass through it than the silk. On account of the insensibility of the eye for blue in the spectroscope one does not detect it at all with the eye, though it is easily detected with the aid of the photographic plate. If Herr Bardy used chrysoïdine varnish successfully for a dark-room window, it must have been because he did not coat glass with the varnish but impregnated paper with it, which, less transparent than glass, kept back fifty per cent. of the light.

It is known that a solution of red bichromate of potassium is a powerful absorbent of blue light, and with this substance I have also made several experiments:—A film of one to twelve bichromate of potassium solution was enclosed in a glass vessel with flat parallel sides, one centimetre apart. This film was much paler and yellower in appearance than the double film of chrysoïdine varnish, but it afforded a much better protection than the latter. A plate exposed, fronting the sky, for two and a-half minutes behind the bichromate solution showed not a trace of fogging.

From these facts it is evident that it is by no means the substances which produce the darkest yellowish-red that keep out actinic light best; but, on the contrary, that many paler yellow films give a better protection than the reddish-coloured ones. As a yellow varnish for covering negatives, chrysoïdine varnish is excellently adapted.

H. Vogel, Ph.D.

THE LIQUEFACTION OF GASES.

M. Dumas has thought that the marvellous experiment of the liquefaction of hydrogen by M. Pictet, of Geneva, facilitated in an exact manner the determination of the density of oxygen. It suffices, in fact, to weigh the quantity of liquid obtained by M. Pictet in order to see what is the volume of this same quantity. Now M. Pictet, having obtained the considerable quantity, relatively, of forty-five grammes of liquid oxygen, and this liquid occupying in the tube a space of forty-five cubic centimetres, it is seen at once that the density of the liquefied oxygen is, like that of water, equal to unity. Theory had already established this quantity, but it is now confirmed by experience.

M. Dumas has also given a *résumé* of a second communication from M. Pictet, showing, without the possibility of doubt, that not only has oxygen been liquefied in his apparatus, but also solidified, which is the complete realisation of the prophecy of Lavoisier, the renowned creator of modern chemistry. In fact, the jet of liquefied oxygen issuing from the tube, illuminated by the electric light, has been examined with the polariscope, and it has given indisputable signs of polarisation. Now it is known that for this phenomenon to be produced it is necessary that the light should be reflected from solid isolated particles. In the liquid itself there are in suspension small crystals of oxygen "snow," as crystals of watery "snow" are seen in the middle of those white clouds known to meteorologists under the name of "cirrus."

Doubt is no longer possible that liquid or solid oxygen is really obtainable, it is, therefore, clearly evident that chemists may succeed quite easily in solidifying the atmospheric air now that it has been liquefied; and thus will be realised the curious result of the transformation of a volume of air into a solid block.

The solidified hydrogen was preserved in this state for several minutes by M. Pictet, and produced in falling on the ground the sound of metallic grains. The liquid jet or stream had a steel blue colour.

W. Harrison.

NOTES ON PASSING EVENTS.*

By a Peripatetic Photographer.

What an extraordinary "trial of lanterns" that must have been which took place last month at the meeting of the Bristol and West of England Amateur Photographic Association! To be informed that some of them were exhibited with lenses at open aperture, and others having lenses with apertures very much contracted, is to apprise everyone of the fact that the trial was made under circumstances which would prohibit the results from being placed in comparison. But what is meant by a "trial of *lanterns?*" Is it not, in reality, intended to mean a trial of the illuminating power of the *lamps* in the respective lanterns? Lanterns now differ little, if at all, in their optical parts; and what is, or ought to be, tested is the value of the respective methods of illumination employed, this constituting the chief difference between the lanterns of the various makers. It is true that the external covering, or case, differs in form and construction, according to the maker; but in the Bristol "trials" this feature was, very properly, not attended to, the intensity of the illumination being *the* feature. To test lanterns or, more properly, *lamps* each lantern must be fitted with condensers and objectives of a precisely similar form, and two or three discs from a like number of lanterns thus fitted projected side by side on a screen. A partisan of each form of lantern (there is partisanship even in philosophical apparatus) should be present to see that his special pet is shown at its best, and either the discs or the bare flames should be examined through a piece of deeply-coloured glass. For "rough and ready" photometric purposes I employ several coloured glasses, increasing the number until, when I examine the lights through them, the weaker ones have entirely disappeared. Glasses of the kind used as sunshades for telescope eyepieces, or for sextants, answer this purpose well. I conclude this paragraph by expressing a desire to see a lantern-lamp tournament held, so that we may know which of the various modes of lighting, short of the lime light, gives the most intense illumination. The *lamp* once settled, the question of the optical arrangements would not occupy much time in being determined in an equally satisfactory manner.

* Concluded from page 51.

It has afforded no small amount of amusement to myself and others to see how very conservative the Edinburgh photographers (Dr. Nicol among others) are with regard to the *modus operandi* of Mr. Gray (of that city), who has got hold of, or worked out, a gelatino-bromide process whose merits they proclaim with a flourish of trumpets, but as to divulging its nature they are prudently reticent. We are now informed that they—certain photographers in the north—have "abundant evidence that by it dry plates may be made much more sensitive than the ordinary wet collodion film." Query: has the same thing not been said repeatedly during the past four years of the gelatino-bromide processes of other workers who have displayed less reticence as to their method of preparing this substance? One would, from reading the *dicta* of certain of these writers, almost imagine that the sharp men of the northern capital were not keeping themselves well posted in what has for some years been doing in the world of gelatino-bromide. I here duck my head to avoid the storm which the enunciation of this mild sentiment may evoke; for, however *prudently* they may behave in divulging formulæ tending to advance photography, "nobody can deny" the readiness of our northern brethren to enter the field of strife on a mere whisper that there is a coat tail trailing within range of their visual organs.

The Cleopatra ship containing the famous "needle" is now moored within a hundred feet or so of the Albert embankment of the Thames, opposite St. Thomas's Hospital. The most stupid and careless photographer in the world could not fail to secure an excellent photograph of this famous and quaint little vessel as she lies at anchor, her side always directed to the observer from the embankment.

ON THE CAUSE OF THE SENSITIVENESS OF WARNERKE'S EMULSION.

[A communication to the Berlin Photographic Society.]

With Dr. Vogel's permission I made a number of comparative experiments upon the sensibility of ordinary bromide of silver plates prepared in the bath and Warnerke's emulsion plates. The latter were prepared with an emulsion left behind him by Mr. Warnerke, and the former by sensitising in a bromised collodion (two grammes of bromide of cadmium, thirty grammes of alcohol filtered, and added to three volumes of two per cent. raw collodion), washing and drying. Both sorts of plates were exposed simultaneously, and for an equal length of time, in cloudy weather, in front of a plaster bust standing upon a black stand. The duration of the exposure was not longer than I should have given a wet plate under the same circumstances. Both plates were then treated with Mr. Warnerke's strong developer. The result was that the ordinary bromide of silver bath-prepared plates were scarcely so sensitive as the emulsion plates, but in the black parts of the original they gave more details than the latter. The experiment was several times repeated with the same result. The great sensitiveness of Warnerk'es plates seems, therefore, to depend upon the action of the strong developer.

—— Zipser,

Photographic Atelier of the Royal Industrial Academy, Berlin.

SUGGESTIONS RESPECTING THE SUB-BROMIDE THEORY.

I submit to your consideration the following details of an experiment I should like experimentalists to make, for I think it would throw great light on the worth or correctness of the sub-bromide theory. I would have undertaken it myself were I not compelled to be, for a long period, away from my laboratory.

An emulsion to be formed so compounded as to leave a definite quantity of silver nitrate in excess of that necessary for the transformation of the whole soluble bromide into silver sub-bromide. At first silver bromide is formed, silver nitrate being greatly in excess. If it be correct to say that the silver of the silver nitrate combines with the silver bromide to form silver sub-bromide, the excess of silver nitrate ought to become smaller and smaller in the course of time. Now this may be ascertained by testing the emulsion for free silver, at certain intervals, getting smaller by the transformation of the silver bromide as soon as all the bromide is converted into sub-bromide. This excess will at last prove to be of an uniform value, so, then, as soon as successive tests show or give a constant result the operation is ended. Substracting the final quantity of silver nitrate from the original, we have the quantity which has combined with the soluble bromide, and we may feel satisfied if this theory be fulfilled.

The organic matter of the collodion introduces a slight error in the result. This difficulty may be overcome in different ways:—1. By ascertaining beforehand the quantity of silver nitrate combining with the organic matter in the normal collodion. 2. By making two similar experiments with two collodions containing different quantities of soluble bromide per ounce, sensitised so as to have the same excess of silver in both. Using the same normal collodion, we may say that the same or a similar quantity of organic compounds, combining with the same proportion of silver nitrate, is contained in the two emulsions; so it may be shown that, the quantity of silver combining with the organic matter and the actual excess being the same in the two emulsions, the difference in the quantity of silver nitrate added to the more heavily-salted sample represents the quantity which enters into combination with the bromide. Thus we have the quantity of silver nitrate combining with the difference of the quantities of soluble bromide introduced in the normal collodion. L. O. Sammann.

FOREIGN NOTES AND NEWS.

Two New Journals.—A Wrinkle for Long Exposures.—Applications for Patents.—Dr. J. M. Eder and Capt. Tóth on Chrysoïdine.

The firm of A. Braun and Co., Dornach, have just issued the first number of a new monthly photographic journal, which is to appear simultaneously in French and in German. The French version, which is called *La Lumiére*, has a tricolour title page. The German version raises the number of German journals to eight. The illustration to the specimen number is a photograph of the *Venus de Milo* (in the Louvre).

In the *Photographische Zeitung* Herr von Brauck recommends the following for long exposures:—Dissolve in a bottle and shake—

Distilled water	35	parts.
Alcohol	3	,,
Crystallised citric acid	1	part.
Glycerine	6	parts.
Nitrate of silver	2¼	,,

Pour the filtered solution over the freshly-silvered plate just as it comes out of the bath. Move the plate about, as when coating with collodion, until the greasy marks disappear. Do not use too strong a developer. With plates so prepared one may expose a long time without getting dry spots.

The *Mittheilungen* mentions, amongst other applications for German patents, that of Dr. Liesegang for a peculiar form of camera, and that of Herr Strumper, of Hamburg, for a process for burning-in lichtdruck pictures upon glass and porcelain, &c. Herr Schüler, of Berlin, has obtained a patent for a method of producing a photographic film upon glass, capable of being ground by the sand-blast.

In the *Photographische Correspondenz* Dr. Eder and Capt. Tóth report as follows upon chrysoïdine as a protection against the action of actinic rays:—"As you are aware, chrysoïdine was recommended a short time ago by Rossignol, of Paris, as a colour which transmits no actinic light. The dye, which is difficult of solution in water, but very soluble in ether and alcohol, may be added to a negative varnish with which the dark room window may be coated, or sheets of gelatine may be coloured with it and then placed in front of the window. We found the dye very efficacious, in so far that a sheet of gelatine prepared with it, according to directions given in the *Archiv*, proved a somewhat better protection against the chemical action of light than a pretty dark yellow glass. Red glass of medium density gave a better protection than the chrysoïdine gelatine leaves, and so did a green and a yellow sheet of glass laid one over the other. The experiments as to the transmission of light were made with emulsion plates. Generally it might be said that yellow glass was less of a protection against light than a chrysoïdine film, and that red glass is preferable to either. On account of the agreeable colour, we use in our dark room double sheets of glass—yellow and green—and they are, at least, as effectual a protection as chrysoïdine. Of course the efficacy of the chrysoïdine film varies with the depth of its colour. Still, chrysoïdine is a convenient means, without much trouble, of getting a serviceable dark room; and in emulsion work the coating of the yellow glass with chrysoïdine varnish is a necessity if one do not wish to use double sheets of glass. To decide whether chrysoïdine is absolutely fast, or whether it will bleach in time if left exposed to the light, would require a longer test than we have yet been able to give it; but when we have made further observations on that point we shall communicate them." The same gentlemen have an article of similar purport in the *Archiv;* and Dr. Vogel, in the *Mittheilungen*, gives an account of an independent set of experiments with the same substance. [See page 64.]

In the *Correspondenz* Herren Eder and Tóth have also a report upon Dr. Heid's collodion cotton, which they pronounce excellent for wet collodion, but very unsuitable for use with dry plates.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
Feb. 12	Photo. Soc. Gt. Britain (Annual)	5a, Pall Mall East.
,, 13	Glasgow	172, Buchanan-street.
,, 13	Cheltenham Amateur	Savings' Bank.
,, 14	Manchester	Memorial Hall, Albert-square.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

The monthly meeting of this Association was held on Thursday evening, the 31st ult., at the Free Library William Brown-street,—the Rev. H. J. Palmer, the retiring President, in the chair. The minutes of the annual meeting were read and confirmed.

The Secretary reported that the association *soirée* had been a great success, and that the balance (about £37) had, in the expectation that the *soirée* would be an annual one, been placed in the savings' bank for future use.

Mr. H. A. Wharmby, the new President, then took the chair, and in the course of his address thanked the members for his election. After alluding to the work of the past session he threw out hints as to what might be done in the present one, concluding with wishing that the members might have a happy and prosperous year.

The Rev. H. J. Palmer then read a paper on *A Further Improvement in the Gelatine Process.* [See page 63.] Mr. Palmer, in answering questions on his paper, said that he exposed the films on the front of a glass plate. He also stated that complaints of spots from damp had brought discredit on the gelatino-beer emulsion, but he had just developed some plates that had been stored for a year in a place often filled with steam, and they were absolutely free from fungoid growth.

The President, in moving a vote of thanks to Mr. Palmer, alluded to the general wish for a substitute for glass.

Mr. J. A. Forrest facetiously replied that he thought it would be a long time before the glass-maker's occupation was gone. He remembered that when the waxed-paper process came into use glass was said to be doomed; but, though nothing was more convenient and portable than to pack negatives in a portfolio, glass still kept to the fore.

The Secretary said that after seeing the specimens of photochromes which had been lent to them by Mr. J. T. Taylor, a wish was expressed that some more examples should be shown at the meeting, and in response to a letter M. Leon Vidal had most kindly sent a collection of photochromic prints representing models in the Museum of the Louvre and goldsmiths' work.

The method of producing these was described, and great surprise was expressed at such beautiful results being obtained by mechanical means. The process was admirably adapted for producing illustrations of goldsmiths' and metal work, as by no other means could such work be so exactly and minutely represented.

A hearty vote of thanks was awarded to M. Leon Vidal for giving the members the pleasure of inspecting the beautiful results of a process which M. Vidal had been so successful in bringing to such perfection.

The noted large photograph of the Philadelphia exhibition, which Mr. F. Gutekunst had so successfully printed on one length of paper, was exhibited. It had been lent by Mr. Davis.

Some excellent prints of dead game were shown, taken by Mr. S. G. Payne, of Aylesbury.

Mr. T. Fletcher's lime light without oxygen gas was exhibited. This was sent by Mr. Lewis Hughes.

The President said that he had much pleasure in giving a welcome to those members of the Manchester Photographic Society who had so kindly come down to their meeting. He would ask Mr. Coote, who had brought with him some prints and negatives taken by the favourite process of the Manchester Photographic Society, to show them to the members.

These were excellent examples of the collodio-albumen process, and were examined with interest, the prints—*View on the Llugwy* and *Thorpe Mill*, being much admired.

Mr. W. J. Chadwick then gave a practical illustration of his method of producing oxygen gas with his compact little oxygen generator—a description of which has lately appeared in the photographic journals. He (Mr. Chadwick) also exhibited his registering carrier for the lantern, which ought to be in the possession of every lantern exhibitor, and which is described in The British Journal Photographic Almanac. Mr. Chadwick also showed one of Mr. Woodbury's new travelling cameras, with its several ingenious arrangements.

After examining these and several other interesting objects shown by the members of the Manchester Photographic Society, the meeting was adjourned until the 28th instant.

The members afterwards entertained their Manchester friends to supper at the Angel Hotel, Mr. B. J. Sayce, Dr. Rickard, Mr. W. Keith, and Mr. I. Knott, honorary members, being present.

The Rev. T. B. Banner, M.A., who occupied the chair, said that he had been asked to preside on account of his being the first President of the Association and one of the oldest members; but, as he was suffering from a severe cold and loss of voice, the Secretary had no doubt chosen him for the reason that, on that account, he could not inflict on them a long speech. He was, however, exceedingly pleased to welcome the members of the Manchester Photographic Society, and hoped that they would see more of each other, both at their meetings and, if possible, on excursions together.

Mr. G. T. Lund responded on behalf of the Manchester Photographic Society, saying how much pleasure it would give them to meet oftener, and he hoped that their respective Secretaries would be able to arrange for some meetings in the summer, when they might be able to try results with favourite processes.

PHOTOGRAPHIC SOCIETY OF PHILADELPHIA.

The ordinary monthly meeting of this Society was held on Thursday, the 3rd ult.,—the President, Mr. Ellerslie Wallace, Jun., in the chair.

After the minutes of the previous meeting were read and approved,

Mr. Dixon, on behalf of the room committee, reported that new gas burners had been provided for the room and that the list of members had been corrected. A vote of thanks was tendered to the committee for the improvements.

Messrs. Frank Bacon and C. M. Gilbert were nominated for membership.

Mr. Browne moved that the meetings of the Society should be held semi-monthly during the months of November, December, January, February, March, April, and May.

This being a proposed change in the by-laws the matter was deferred till the February meeting.

On the motion of Dr. Seiler it was resolved that a lantern exhibition be held at the Franklin Institute under the auspices of the Society, and it was moved by Mr. Hewitt, and carried, that the Chairman should appoint a committee to fix the time and place and make other necessary arrangements. Messrs. Hewitt, Browne, and Partridge were appointed the committee.

It was then decided to select the slides for the exhibition from the collection of Mr. Bates, who had kindly offered them to the Society.

The Chairman exhibited a number of novel and interesting pieces of apparatus, including a beautifully-made changing-box for whole-sized plates, by Mr. G. Hare, of London; an exceedingly compact plate rack; and a non-actinic shade made of orange-coloured gelatine, useful for preparing and developing plates by when travelling.

Mr. T. H. McCollin exhibited a number of successful prints from Philadelphia washed emulsion negatives.

Dr. Seiler inquired if any member had used formic acid in the iron developer for wet work, and if any gain in rapidity had resulted from its employment.

Mr. Bell, in reply, said in his hands the addition of formic acid was no improvement.

Mr. Hewitt said that a developer composed of sulphate of copper, pyrogallic acid, and formic acid was the most rapid he had ever used.

Mr. Bell claimed that, for general work, the double sulphate of iron and ammonia made the best developer in use.

The meeting was shortly afterwards adjourned.

PENNSYLVANIA PHOTOGRAPHIC ASSOCIATION.

The usual monthly meeting of this Association was held on Tuesday, the 8th ult., at the rooms of Messrs. Mahan and Keller, Philadelphia,—Mr. H. S. Keller in the chair.

The minutes of the previous meeting were read and confirmed.

The late Secretary passed over the books, papers, &c., to Mr. Thos. J. Mahan, the newly-elected Secretary, who handed them over to the Auditing Committee.

The question-box having been opened, the following was read:—"Will a print from a strong negative last longer than one from a weak negative?"

It was the general opinion that it would, the reduction of the silver being more complete with a strong negative, as it would print deeper and tone heavier. Another question was also read:—"Why does an old bath give better results when nearly worn out than when new?"

All present acknowledged it to be the case, but were unable at that time to give any satisfactory reason, and would like to hear the opinions of others on the subject. The next question read was:—"What is the cause of pinholes in the negative?"

Mr. McCollin stated that he had found, by a series of experiments, that it was often caused by sulphate of silver being formed in the bath, ascertained by traces of sulphur in the iodides; but it might also result from other causes.

Mr. Clemons showed some prints having a rich, warm, purple tone, made with a solution as follows:—

Saturated solution of borax	1 ounce.
Water	6 ounces.
Bicarbonate of soda	30 grains.
Chloride of gold	*Quant. suff.*

The newly-elected President, Mr. J. C. Steinman, was then conducted to the chair by the late President, Mr. H. S. Keller. Upon taking the chair, Mr. Steinman made a few appropriate remarks, which were received with applause by the members.

The officers for the year were then installed in the usual manner as follows:—*President;* J. C. Steinman. *Treasurer:* J. R. Clemons. *Recording Secretary:* Thos. F. Mahan. *Corresponding Secretary:* Thos. H. McCollin.

The meeting was then adjourned.

BERLIN PHOTOGRAPHIC SOCIETY.

A meeting of this Society was held on the 21st December last,—Dr. Vogel in the chair. After a new member had been admitted,

The President announced that he had received a number of programmes of the Berlin Industrial Exhibition, intended to be held in 1879, which he would distribute amongst the members. He further laid upon the table copies of two new periodicals called, respectively, the *Illustrated Patentblatt* and the *Patentblatt.* The latter being the official organ of the patent office, it was resolved that a copy of it should be taken regularly on behalf of the Society.

Herr Zipser, Professor Vogel's assistant in the *atelier* at the Gewerbeakademie, gave an account of his experiments with Warnerke's emulsion plates, from which it appeared that the great sensitiveness of the latter was to be referred to the powerful developer. He (Herr Zipser) exhibited a few plates which supported his view. Herr Zipser also showed a few plates coated with chrysoïdine varnish. This varnish was simply prepared by dissolving chrysoïdine in negative varnish. The plates were a deep reddish yellow, as if covered with four folds of yellow oiled silk, but they still allowed actinic light to pass freely through them, as shown by Herr Zipser's experiments. This was also the case with ordinary yellow glass. The varnish seemed suitable for replacing dragons' blood as a covering for negatives, because the action of daylight, or even of the direct rays of the sun, did not bleach it.

Herr Schaarwächter showed the award he had obtained at the Nürnberg exhibition. It was not a medal in the ordinary acceptation of the word, but rather a metallic memorial tablet enclosed in a frame and ornamented with allegorical designs. In the centre the name of the winner is inscribed, and the surrounding space is gilt. The tablet was generally admired, and many conjectures were made as to how it had been produced.

Dr. Friedlander thought it was a zinc tablet upon which the design had been etched, and that it had been covered with copper and with gold by means of a galvanic battery, the gilding being done after certain parts had been covered with wax.

The President laid upon the table some new specimens of printing in colours, by Herren Albert and Obernetter. Amongst the latter's exhibits attention was principally directed to a landscape in which the blending of the tints of the foreground and the background was very successful. Amongst Herr Albert's productions was a reproduction in two sizes of a landscape painting. The smaller picture made a very favourable impression, but the larger one was not so good. In the latter blue was the prevailing tint, while in the former, from the same original, the prevailing tint was yellow.

It was supposed that this fault might have been caused by the second impression from the negative which was used for the production of the blue lichtdruck having had too short an exposure, so that the blue parts were too thin and consequently printed too dark, or that the negative used for printing the yellow part had had too long an exposure, and thus become too well covered, and so printed too light.

The meeting was shortly afterwards adjourned.

Correspondence.

Heliochromic Proofs by MM. Ducos du Hauron and Vidal.—Papier Torchon.—Photo-Decalque—M. Pellet's Formulæ for Ferro-Prussiate Prints.

The usual monthly meeting of the Photographic Society of France was held on Friday last, the 1st inst. After the voting for a new member had taken place, the correspondence was read, followed by the reading of the extracts from the foreign journals. The Treasurer's report having been presented, M. Peligot, member of the Institute of France, was elected by acclamation President of the Society for the year 1878. The selection of a portion of the committee of administration then took place, which resulted in the election of MM. Bardy, Bayard, Edmond Becquerel (of the Institute), Gauthier-Villars, and Aimé Girard.

M. Berthaud exhibited a new series of photolithographs, which were the reproductions in *facsimile* of old manuscripts, &c., and were much admired.

M. Ducos du Hauron presented some landscapes executed in colours by his system of heliochromy, and which showed considerable progress. He received the well-merited thanks of the Society for his interesting and continuous labours, and for the *Treatise on Heliochromy* which has been published, and which was accompanied by a letter describing, not without some melancholy reminiscences, the difficulties he had met with up to the present time in making his ideas accepted in the practice of the industrial arts, and connected with which there is a great opening for a commercial undertaking to work out for the public benefit this interesting process. Meanwhile, until powerful financiers in England and France carry out the scheme, M. Ducos du Hauron has organised at Agen a small establishment where the process is regularly worked.

M. Vidal presented an admirable album of his artistic treasures of France, which is a magnificent collection absolutely unique in its character and execution, and most magnificently executed by his process of photochromy.

Reports were presented by several members on the excellence of Gilbert's pencils for the retouching of negatives, and Carette's tcha-oma was very favourably spoken of after several experiments made with that material.

MM. Potok and Girond presented some *papier torchon* albumenised (resembling in a certain sense Whatman's rough drawing-paper), which realises the desideratum of several practical photographers, who eagerly sought for an easy means of obtaining beautiful coloured prints. The paper is treated and sensitised the same as ordinary albumenised paper, but must not be printed too vigorously. The toning should be pushed to the black tone. The best fixing agent is sulphocyanide, though the hypo. bath can be used. Occasionally the print on leaving the hypo. bath is yellowish in the light parts and background. When this occurs the proof should be washed in a feeble bath of common salt and water, but cautiously, because the chloride weakens and reduces the image, and even, when strong, sometimes completely destroys it. The print can be mounted on cardboard and passed through a rolling-press if it be desirable to have less roughness on the surface of the paper. The pencils recommended are the *crayons polychromes*—not too soft—and used in strong lines. It suffices to exercise some taste and a proper perception of colour to rapidly obtain portraits or landscapes coloured in the style of pastels. The prints shown at the meeting are the work of M. Potok himself; and it speaks well for the paper, being the first time he has ventured upon the domain of the painter, and the results are good.

M. Potok then exhibited several excellent proofs in black lines upon a white ground, called "*photo-decalque*," the process of Artigue, of Bordeaux, and printed directly without photographic *clichés*—that is, from a drawing in lines, or copies of prints, and very much resembling photolithographic proofs. He said he believed the process would render important service in the industrial arts, and prove useful to draughtsmen. The operations are simple, the impression rapid, and the lines of a beautiful black upon pure white. I am not aware of any means more expeditious and complete for securing *facsimiles*. Ferro-prussiate has already rendered great service, and it can and ought necessarily to render still more; but in the new process in question, introduced before the Society, may be seen this advantage—that the blue is replaced by the black, and that it fulfils all the conditions desirable to attract the attention of the Society, and therefore it is proposed that at the next meeting an experimental demonstration of the process should take place.

M. Henri Pellet said that for the reproduction of industrial designs, plans, &c., to be obtained directly in one operation in blue lines upon white paper, the sensitising liquid was composed of—

Oxalic acid	5 grammes.
Perchloride of iron	10 „
Water	100 c.c.

According to the qualities of the paper and the sensitiveness required the quantity of the liquid is modified. The oxalic acid may be replaced by several other vegetable acids, and if the paper has not sufficient body and sizing he adds gelatine, isinglass, gum dextrine, &c., to the sensitising bath. After the paper has been dried it must be kept in the dark or protected from the action of light, and this appears to be effective for its preservation for an indefinite period of time. The sensitiveness of this paper, called "*cyanofer*," is (M. Pellet said) very great. To reproduce a plan made upon transparent or on tracing paper it sufficed to expose underneath the plan a sheet of the sensitive paper; and in the sun, during summer, it requires an exposure of fifteen to thirty seconds to decompose all the parts not protected by the black lines of the plan. In winter it is necessary to expose from forty to seventy seconds. In the shade, during clear weather, the exposure should last from two to six minutes, and during foggy weather, rain, or snow the operation requires from fifteen to forty minutes. Evidently there exists also differences of light during the same day—that is to say, between morning and evening. In the light the maximum of the iron salt is reduced to the state of protoxide of iron, which is no longer coloured by a dissolution of the yellow prussiate of potass, whilst the parts protected by the lines of the design are coloured. After the exposure to the light the exposed proof is passed into a bath of prussiate of potass of a strength of fifteen to eighteen per cent. Immediately the design appears in blue, and if the exposure has been sufficient the paper can be left a certain time in this developing bath, and the lines are then stronger; if, on the contrary, the exposure has been a little too short, the paper must be left less time in the prussiate bath to avoid the blue points arising from parts of the iron salt not being entirely reduced. The washing is done with plenty of water, and the salt of the protoxide of iron is removed by a bath of eight to ten per cent. of ordinary hydrochloric acid. The ground of the proof whitens, and the lines gain in intensity. If the lines of the plan to be reproduced are made with a very black ink or one charged with yellow, the time of exposure may be prolonged, because there is no danger that the sensitive body under these lines will be attacked. In this case the prussiate development is rather long; but the blue colouration becomes very intense, and when the paper is dry the proof is sometimes more black than blue. After the hydrochloric acid bath, wash and dry. It is preferable, so as to secure a perfect reproduction of a plan, not to colour the original upon the tracing or other paper until after the photographic printing has taken place; in fact, it often arises that the tinting of a plan sometimes causes creases, and if the tints are dark—such as yellow, brown, or red—they are reproduced in blue more or less strongly corresponding to the antiphotogenic character of these colours. If there are slight or feebly-written quotations or figures on the tints they are subject to be more or less masked by the blue colouration. This direct positive process has the advantage of giving very rapidly a reproduction in *facsimile* upon which can be passed with a brush any conventional colours, and upon which any modification necessary can be executed. The process is also sufficiently sensitive to be employed in the evening by exposing the paper to the electric light. The liquid is permanent, so as to produce writing in white upon a blue ground.

The demonstration of M. Pellet was very successful, and was well received by the members. W. Harrison.

Asnières (Seine), Paris.

BROMIDE OF SILVER.

To the Editors.

Gentlemen,—As you state your belief that the "NO_3," supposed to be set free from the Ag NO_3 acting upon Ag Br, combines with organic matter in some way, you appear indirectly to give your adherence to the hypothesis which I have suggested that a pure solution of nitrate of silver in water has no fogging action upon silver bromide; or, to speak more particularly, the silver nitrate does not react on the silver bromide, at least in the way above referred to.

It seems to me possible that the silver nitrate may act by catalysis, or by the influence of its presence, the bromine ejected combining either with organic matter or with alcohol. In this way the sub-bromide might be produced, nitric acid tending to break up the organic bromine compound, with the reproduction of the normal bromide. Either of these hypotheses would account for the absence of a fogging compound in emulsions made with gelatine or with gum-arabic.

It would not be difficult to prove the action (if any) of a solution of pure silver nitrate on pure silver bromide; and the silver nitrate might be tested for quantitatively afterwards.

A somewhat similar experiment might be made upon a carefully-washed collodion emulsion, free from any liability to fog. The silver nitrate, after being allowed to act for some days, might be carefully washed out with distilled water, and then tested for quantitatively. It is needless to add what conclusions would be drawn were either the full quantity recovered, or, on the other hand, only a portion. In this case the organic matter of the collodion causes an element of uncertainty; and for this reason it might be best to use an emulsion which has been prepared with free silver nitrate. In the case of the trial with pure water this cause for uncertainty would, of course, not exist.

I should not "be surprised to hear" that a very small excess of silver nitrate added to an emulsion might be recovered without much, if any, loss—a loss hardly sufficient to lead to the belief that the fogging compound was formed *directly* by the decomposition of that part represented by the loss.

I am aware that I lay myself open to the charge of profuseness in thus bringing forward this bundle of hypotheses; but I feel that, if I do not succeed in hitting the mark with any one of them, others taking up the matter may be more successful. I, for one, should be very glad to have the opinion of others on this subject, which, now that it has again cropped up (as such subjects will, with all the pertinacity of "blisters," periodically) should not be allowed to drop without such a ventilation as may, if possible, effectually "lay" it for ever, leaving as a legacy—*a fact.*

To refer to another point in your leading article. I did not, in the eighth paragraph of my article, intend to convey the idea that "NO_3," as giving $N_2 O_2$, is a remover of fog. In the paragraph referred to I wrote that the "NO_3 would perform a part in the reaction in the way stated by you." By this I meant that it might leave the organic matter and enter into combination with the copper of the sub-bromide of copper, setting free bromine, which would combine with Ag_2 Br, forming 2Ag Br, and with formation of cupric nitrate, $N_2 O_4$ Cu o." You will see that here there can be no $N_2 O_2$ set free, as I understand would be the case with nitric acid acting on a cuprous salt. You have quite misunderstood the drift of this part of my article.

I believe you also do not quite appreciate Captain Abney's meaning where he writes of the difference in the results he has obtained before now with nitric acid and a light-impressed iodide plate from those reported by others. There is no confusion of the "two modes of development," as neither Captain Abney nor anyone else would be able to destroy with nitric acid the power of bringing up a second image by acid silver deposition on a developed plate from which the developed image had been previously removed by nitric acid. If I understand Captain Abney rightly, the supposed sub-iodide of silver forming the latent image is somewhat more difficult to oxidise than is the sub-bromide. It will not, therefore, answer to pour over the undeveloped film *dilute* nitric acid, which destroys the latent image in a bromide film. Strong nitric acid must be used, when, by its action on the pyroxyline, the more energetic oxidiser, N_2O_3, nitric oxide is set free, which oxidises the sub-iodide of silver.

I have ventured this explanation, partly because I should like to ask—What is the effect of an acid silver and pyro. application to an iodide plate from which the latent image has been removed by N_2O_3 (strong nitric acid)? Can an image be brought up by such application in the same way as it can after the developed image has been removed by nitric acid? Or is the power of development no more possible than with a strong alkaline developer? The same query applies to the bromide plate. In other words: must a *visible* image be formed (though dissolved off again by nitric acid) in order that acid silver and pyro. shall bring up an image from what I will call the plain collodion film?

I have a few other remarks to make which, if you allow me, I will leave till another week; meantime, I hope that others will join in the discussion, especially of the methods by which sub-bromide of silver may be formed.—I am, yours, &c., HERBERT B. BERKELEY.

31, *Grove Place, Brompton, S.W., February* 2, 1878.

BALLOON PHOTOGRAPHY.

To the EDITORS.

GENTLEMEN,—I was very much astonished at seeing in your contemporary an article, reprinted from the *Philadelphia Photographer*, from my old friend Dr. Vogel, reporting Mr. Warnerke's progress through Berlin, of which the following is an extract:—

"Mr. Warnerke is on his way to Russia, hoping to introduce his invention in St. Petersburgh for use in the army during the present war. He thinks to make it possible to take instantaneous views of the whole battle-field by means of *a balloon, in which the camera is to be raised up to a certain height, from which, by means of electricity, the lens will be uncovered for a moment*. We shall learn, perhaps, by *his* camera. if the soldiers in Plevna have still provisions or not."

Now, early in last year I patented a method of balloon photography, of which the claim is stated in the following words:—"I claim the combination with a captive balloon of the photographic apparatus actuated by means of electricity, conveyed as required through wires supported by a rope which retains the balloon to the earth, substantially as described and shown." I also placed drawings and directions in the hands of Mr. Warnerke to manufacture the apparatus for me, and having at a late interview been assured that my work was progressing, my astonishment will hardly be wondered at. I, perhaps, felt a little stronger on the subject, considering that Mr. Warnerke had, to a certain extent, built up his reputation on the roller-slide which I invented and described in a paper read at an outdoor meeting of the Manchester Photographic Society, at Bolton Abbey, as far back as eleven years ago—many years before Mr. Warnerke was known in this country. After describing the *modus operandi* I go on to say:—

"For stereoscopic work [my pet at the time] a long glass the right width might be prepared, and equal in length to the width of five or six stereoscopic pictures. This, when taken from the glass, to be mounted in a slide specially constructed on the panoramic principle, having two rollers, one at top and bottom, round one of which the film may be wound, a portion being rolled on to the other after each exposure."

I am under a firm impression that in one of our journals or yearly *résumés* I gave drawings almost similar to the present Warnerke roller-slide; but as I have not found this I will presume that I may be mistaken.

As can be seen from many articles I have written, tissue negatives have long been a favourite subject with me, and, *en passant*, I may say that I think the method described at that time, added to our increased knowledge of emulsions, would possess several advantages, notably for enlarging or copying, which cannot be done from a surface possessing an impression from the irregular surface of paper, no matter how highly rolled.

On seeing the article quoted from the *Philadelphia Photographer* I at once wrote to Dr. Vogel, and also to a friend in St. Petersburg, and while writing the above reprint of the old Manchester paper I have received a telegram from Mr. Warnerke to say that Dr. Vogel's letter was incorrect, which I trust soon to see verified. Without intending any personalities I think the present a good opportunity to reproduce a portion of an article from the same journal as the one that gave rise to this communication:—

"Pillaging in photography, we are sorry to say, is no new thing. Sometimes, however, it is the result of ignorance: it cannot, then, be called 'pillaging,' exactly. But there are times when one person will strive to maintain a claim for an invention which he well knows belongs to somebody else. Such is the case," &c.

The article then goes into personal matters, and concludes as follows:—

"It is not a new thing for an adventurous photographer to take up a process of another and modify it, and then, by sharp practice and sometimes by an advantageous quantity of silver and gold, lay claim to the whole invention. Such conduct should be deprecated wherever met with."

—I am, yours, &c., WALTER B. WOODBURY.

South Norwood, February 1, 1878.

ABNEY'S EMULSION WITH ALBUMEN AND BEER.

To the EDITORS.

GENTLEMEN,—In your very successful ALMANAC for the present year Captain Abney contributes a formula which he highly recommends, and at the same time very encouragingly says:—"Why not make it yourself—the formula is simple?"

Now I happen to belong to that very numerous class of your readers—"an amateur"—otherwise, in all probability, I should not have addressed the following query upon what may turn out to be a very simple matter. However, I will not be ashamed to acknowledge my shortcomings and want of chemical knowledge, and will at once make known my wants.

Now I want to take the gallant Captain's advice—or, rather, suggestion—and "try" to make the emulsion myself.

The quantities quoted are quite intelligible to me until I come to "emulsify with three grains *excess* of silver to the ounce of collodion." Now here I am in a fog. How many grains of silver to the ounce am I to allow before I add this *excess*, for, rightly or wrongly, I take it that the excess of silver referred to means a quantity added as an allowance for waste when the washing takes place?

Also, further on he says:—"Try a plate, and if not satisfactory doctor with chloride of copper." Query: what strength? and under what special circumstances is it used? Am I right in supposing it is intended to doctor an emulsion that gives a *weak* negative, showing lack of vigour, or for pinholes?

I would be ever obliged if you could help a poor fellow out of his difficulties.—I am, yours, &c., "YORKS."

Halifax, February 4, 1878.

[As we have received three letters on this subject we publish the above as a representative one, in the hope that Captain Abney will kindly give the required information.—EDS.]

IMPROVEMENTS IN CARBON PRINTING.

To the EDITORS.

GENTLEMEN,—The "great respect" professed by Mr. J. R. Johnson for the "gentlemen of the Autotype Company" does not prevent him from practically charging them with stating that which is untrue.

In your ALMANAC for 1878 Mr. Johnson quotes the manuals erroneously, with a view to show that up to a recent period the Autotype Company had not solved the problem of producing tissues of certain tints in permanent pigments. To this the editor of the *Manual* replies, by quoting what the *Manuals* actually say, and pointing out that in the sixth edition, published in January, 1877, it is stated that they had "succeeded in employing the active colouring principle of madder," and asserting as a fact that "from the commencement of 1877 all the pigmented papers made by the Autotype Company, with the exception of tissues prepared by agreement to special formulæ, have been made with pigments of undoubted permanency, and certainly not a particle of cochineal colour."

In the face of this Mr. Johnson adheres to his original statement, and in his letter of the 29th January says that it appears to him that the Autotype Company fully admit the accuracy of his first proposition. He is quite welcome to his impressions, of course; we simply state the facts.

About the exceptions to our rule of making all tissues in permanent pigments: feeling that, although we were bound to supply chromotype licensees with tissues made to certain agreed-upon formulæ we ought to make them participators in any advantages we had to offer, we produced two tissues in permanent pigments only, matching very closely the Lambertype colours, and in March, 1877, duly apprised all our chromotype licensees of the fact.

With regard to Mr. Johnson's second proposition, that he cannot see how the Company are prejudiced by his recent patent: it is quite true the Company are not prejudiced by it in any way, for long before Mr. Johnson filed his provisional specification we had for ourselves solved the difficulty of making tissues in permanent pigments.

We are not in the least interested in Mr. Johnson's recent specification, which may become a good and valid patent when he has disclaimed the Wenderoth discoveries; but we decline to allow him to misquote the facts of autotype history without contradiction. We are quite cognisant of the "minute history" of the use of alizarine colours in carbon tissue, and our position with regard to such tissues is this:—

1st. That we have been in the constant practice for more than a year of producing the most brilliant coloured tissues in permanent pigments.

2nd. That for single transfer we have employed nothing but permanent pigments since July, 1876.

3rd. That Mr. Sawyer's memorandum of May 28th, 1876, sent to Mr. Johnson in Paris, gave the basis of the necessary operations for precipitating alizarine lakes in a form suitable for carbon printing, and made a formal and definite claim for having worked out such method to practical purposes.—We are, yours, &c., THE AUTOTYPE COMPANY.

February 6, 1878.

EXCHANGE COLUMN.

Wanted, a whole-plate camera and wide-angle lens by a good maker in exchange for a good studio camera with repeating back, a half-plate camera and lens, and a quarter-plate lens.—Address, W. BOND, Church-lane, New Catton, Norwich.

A pair of stereo. landscape lenses, in sliding mounts, one and a-quarter inch diameter and five inches focus, by Russell Jeffreys, will be exchanged for a studio chair or other furniture.—Address, G. HADLEY, 33, Newland, Lincoln.

A perfectly new photoscope and twelve Frith's transparencies, coloured, will be exchanged for a whole-plate or 10 × 8 camera, bellows body, swing-back, or anything useful in landscape photography. Difference adjusted.—Address, WRIGHT, photographer, Northampton.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

BANBURY.—Exchange note unsuitable in present form. Reconstruct it.

B. B. ALLISON.—Send the camera to the maker, and get him to fit it with a new bellows body.

GEO. S. CORSTON.—See the article on *Artful Dodging*, by Mr. George H. Slight, in our ALMANAC for the present year.

THOS. ALDEN.—We are unable to indicate the name of any optician in this country who makes lenses of the kind specified.

NEMO.—A single achromatic lens will cause the marginal straight lines to be slightly curved, no matter in what position the diaphragm is placed.

J. E. G.—1. The iodide is precipitated, but is not reduced.—2. No.—3. By careful washing the whole of the soluble bromide is removed, and the two films are then alike.—4. It is found by experience that the addition of what we may term "ready-made" bromide and chloride of silver to collodion does not answer so well as when these are formed in the collodion.

T. NWORB.—No. 3 on the list will answer best as a group lens, although it is inferior to the others for taking portraits in a studio. The field of the French lens will be flattened by transferring the diaphragm from its present situation between the lenses and placing it in front of, and close up against, the anterior lens of the combination. If your description be accurate, we see no other method by which the desired effect can be produced.

A. T. M.—1. Give the negative a coating of india-rubber dissolved in benzole, and afterwards apply collodion of a thick and tough quality. When dry, scratch the film all round the margin, place the negative in water, and the film will become detached.—2. See any of the *numerous* articles on mechanical printing which we have published during the past three or four years. In these the proportions often vary a good deal, but we cannot undertake to say which is best.

M. M. C.—A sheet of talc may be employed, instead of glass, for taking negatives upon. No departure from the ordinary routine is required. If you call by appointment at our office we shall be glad to show you a collection of negatives on talc, from which it will be seen that, to employ a hackneyed phrase, it leaves nothing to be desired. *But*—and this is a serious drawback—the difficulty of obtaining perfect sheets of dimensions exceeding quarter-plate is so great that we have given up all hope of ever receiving any. Those which we possess are rather smaller than quarter-plates.

J. W. SYKES.—Our correspondent writes:—"Would the fumes from a paraffine lamp or small paraffine stove act in any way injuriously on the chemicals in the dark room? As an experiment, one day I nailed a piece of sheet iron up in the dark room and put a paraffine lamp under it. In a short time the iron was hot and the air in the room became much warmer. As I have seen gas stoves condemned I was afraid to adopt paraffine as a warming agent, fearing it might vitiate the air. It may appear a simple question to ask, but an answer in the Journal may interest and benefit more of your readers besides myself. If safe, it would be much cheaper and far cleaner than a stove and coal fire, as there is no dust. Besides, as the lamp can be lowered or put out the amount of heat and the cost of consumption can be regulated."——In reply: About five years ago we tested this matter pretty fairly, and the conclusion at which we arrived was that a paraffine lamp might be used with perfect safety for warming the dark room. Let the products of combustion be carried away and it is quite impossible that any harm can accrue to the chemicals.

H. HAMILTON.—This correspondent is about to erect a studio, and wishes for information on the subject. He says:—"I am about having a photographic studio built. The space of ground available is about fifty feet long from east to west, and twenty feet wide, bounded on the south by a wall nine feet in height, and on the north by one of six feet. At the ends east and west there are houses—a tall one at the east, a low one at the west end. I think of building it on the ground, not raising it, and intend having it about 30 × 13 feet. After a good deal of consideration I have decided to have one huge sash about twenty feet long, with a very steep pitch, and believe it would be all that is necessary. It would slope from about twelve feet or more in the centre, or nearer the south wall, to four feet six inches at the eave—no side light. I should be glad of any reader's suggestions as to the modification of these proportions. I may mention that I intend having the panes of glass about three feet by two feet. Now a sash of these dimensions to carry such large panes of glass must be very strong, so I thought of iron as combining the maximum of strength with the minimum of obstruction to light. I should be glad to know where one could be obtained, and the probable cost. There would be nine bars, but no cross-bars. I want to know the best material to cover the opaque part of the roof. I thought of slates. What is the best and cheapest glass? How should the floor be laid? The dark room will be detached. The nine-foot wall will be built in as one side of the studio. The ends will be square. Any information would oblige."

WHITE ROCK.—The stains appear to have been produced by chloride of gold.

G. W. MURRAY.—The form of your studio roof is excellent; there is no restriction to you or anyone else making use of that form, as it was described with a diagram, several years ago in this Journal. It is different from those that have been patented recently.

W. W. W.—It is so purely a matter of taste that we cannot advise you whether to use smooth or grained opal glass. The latter will be most easy to work upon; but it is probable that your clients will prefer the former. The wrapper of the lost ALMANAC, containing your name and address, has been found by the officials of the Post-office.

RECEIVED.—Alex. Henderson, Jno. Ogilvy, Sir Thomas Parkyns, J. Maxwell Jackson, F. Hamblen.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The next meeting, being the annual one, will take place at the Gallery, 5, Pall-mall East, on Tuesday next, the 12th inst., when the election of officers and other business will be transacted.

HERR LIESEGANG'S MANUAL OF THE CARBON PROCESS.—It will be seen that an English translation (by Mr. R. B. Marston) of this important work will shortly be published by Messrs. Sampson Low & Co.—A few pages of advertisements will be received. For particulars see advertisement elsewhere.

PHOTOGRAPHY IN COURT.—At the Bloomsbury County Court, on Monday, the 28th ult., the case of Dickinson *v.* Woolnoth was heard before Mr. Judge Russell. The plaintiff, a photographic operator of Newcastle-upon-Tyne, sued the defendant, a photographic artist, to recover the sum of £10 for an alleged breach of contract. The plaintiff was represented by Mr. Charles Williams, solicitor, who stated that his client entered into negociation with the defendant for the position of operator and manager of his business at Camden Town, and ultimately the plaintiff entered the defendant's service in June of last year, at a weekly salary of £3.—The plaintiff stated that in consequence of the arrangement with the defendant he left Newcastle. On going to the defendant's premises he was told to call the next day, but on doing so he was informed that his services were not required. As he could not get any satisfactory information he had brought the present action. The plaintiff produced his correspondence with the defendant.—The defendant did not deny either the correspondence or the engagement, which, however was conditional on the plaintiff's references proving satisfactory. The plaintiff arrived prematurely, as the reply received from one of the plaintiff's references was of so unsatisfactory a nature that he had written to the plaintiff stating that he could not engage him. The latter, however, had not waited for this communication, and had come to London anticipating that all was right.—The Judge ruled in favour of the defendant, who said that under the circumstances he would not ask for costs.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 928. Vol. XXV.—FEBRUARY 15, 1878.

PRACTICAL EXPERIMENTS IN CONNECTION WITH THE SUB-BROMIDE THEORY.

We last week published suggestions from two independent sources of a method which at first sight appears to offer at once the simplest and most practical means of verifying (or disproving) what has been recently spoken of as the "sub-bromide theory." Though not given in identical terms, the experiments proposed by M. Sammann and Mr. H. B. Berkeley virtually amount to the same thing in the end, the general principle in each case consisting in the preparation of an emulsion with a known excess of silver nitrate; and the point to be determined is whether the free silver is, after a lapse of time, absorbed or taken up by the remaining constituents of the emulsion, or whether it may be subsequently extracted by suitable means without appreciable diminution in quantity.

We have said that at first sight this appears a simple and practical means of testing the theory; but it must be obvious to the most casual observer that, independently of any complications which may be introduced by secondary reactions occurring simultaneously with the supposed formation of silver sub-bromide, so many niceties of manipulation are involved in the exact determination of minute quantities of free silver contained in emulsion, or emulsion residues, that errors may easily arise of sufficient magnitude to vitiate the results of an experiment which, to be of value, must necessarily be accurately performed. We have for some time meditated a somewhat similar line of research, but have been prevented, by press of other matters as well as by some doubt as to its ultimate efficacy, from commencing it; but as the matter has now been mooted in other quarters we propose forthwith to take up the long-delayed task. It is our present intention to give a brief sketch of the course we mean to adopt, in the hope that some of our experimental readers may be induced to undertake a similar line of research, and thus form a sort of check upon our own results.

With regard to the means suggested by M. Sammann and Mr. Berkeley, respectively, we may say a word or two. The first-named gentleman simply directs that an emulsion be formed so as to leave a definite quantity of silver in excess, and we therefore presume that an unwashed emulsion is meant. Mr. Berkeley, on the other hand, proposes to add a definite quantity of silver to an emulsion which has already been washed, and which, in the absence of any fogging propensity, may be supposed to contain only silver bromide, together with the theoretical organic silver compound which is believed to conduce so greatly to the working qualities. Now, in the first case, the difficulty will be to secure the condition which M. Sammann lays down—a definite quantity of silver nitrate in excess. If we had only the soluble bromide to deal with the adjustment of quantity of silver nitrate would be comparatively easy; but it is now generally believed that a portion of the silver combines with the pyroxyline. This portion, though possibly extremely small, varies with different samples of cotton, and hence it becomes necessary to determine the exact amount before we can arrive at the precise quantity of silver actually present in the free or uncombined state. M. Sammann proposes an ingenious solution of this difficulty, based upon the differential results obtained with two emulsions containing varying quantities of soluble bromide and silver nitrate; and if the quantity of silver taken up by the pyroxyline be constant, whatever be the strength of the excess, we can see no reason to doubt the efficacy of the plan. We think, however, on the whole the better course would be to ascertain by careful tests the point of neutrality, and then to add a definite quantity of fresh silver.

Mr. Berkeley's plan of working upon a washed emulsion as a basis does away with this difficulty, as any excess of silver or soluble bromide is thoroughly removed in the washing. There still, however, remains the possibility that the pyroxyline is not in a state of saturation as regards silver; that is to say, that it may still retain the power of absorbing the latter simultaneously with and independently of the formation of sub-bromide. But this is, perhaps, opening up a new question, so we will forbear at present to pursue it further, trusting to the result of our experiments to throw some light upon it. The method we propose to adopt will consist in the preparation of an emulsion which, in its first stage, will be subjected to the action of free silver for a sufficient length of time to allow the formation of the organic compound. No acid will be employed, freedom from fog being ensured by the use of zinc bromide for the subsequent neutralisation. After the lapse of a sufficient time the emulsion will be neutralised by the cautious addition, drop by drop, of an alcoholic solution of bromide of zinc, after each such addition pouring a drop or two upon a sheet of glass and testing with bichromate of potash. As a final test one drachm of the emulsion may be precipitated in a small quantity of distilled water, boiled, filtered, divided into two portions and carefully tested for both silver and soluble bromide. By carefully following this course the error, if any, may be so far reduced as to be of very little moment.

Having in this manner obtained an emulsion in a neutral state as regards silver and bromide, it must be tested photographically; if it show any tendency to fog, as it most probably will, it must be allowed to rest until it becomes clear. Up to this point we may work upon any convenient quantity of material, and any smaller quantities used for testing purposes produce no effect upon the result. But before proceeding further we have to measure out accurately a definite quantity, to which we add a known weight of silver nitrate. If we accept as correct the formula Ag_2 Br for sub-bromide of silver, it will be evident that to convert the whole of the bromide into sub-bromide (if that be possible) a quantity of silver nitrate equal to that which has already been used in sensitising the emulsion will be necessary. But it is neither necessary nor, we think, expedient to use so large an excess, while if the quantity be too small the result will be more likely to suffer from accidental errors; perhaps a medium of four or five grains to each ounce will be found to answer all purposes.

Let us proceed then to measure out as accurately as possible (say) three ounces and a-half of the neutral emulsion, and to this add sixteen grains of silver nitrate dissolved in three drachms of hot alcohol in a test tube or flask, rinse out the flask with another drachm of alcohol, and this will make up the bulk of emulsion to four ounces, with four grains of free silver to each ounce. After a thorough shaking it may be carefully divided into two equal portions—one to be kept for the final analysis, the other to supply the material for a series of periodical tests. As a simultaneous experiment we intend also treating a washed emulsion with a similar excess of silver; in this case there need be no special precautions taken in the preparation of the emulsion, the only care being to ensure its freedom from fog before the addition of the second dose of silver.

As regards the method of testing, we think it will prove more convenient to apply the intermediate tests to small measured quantities of the emulsion itself in preference to extracting the free silver and determining its quantity separately. For this purpose take one drachm, or other convenient quantity, and add to it one drop of a strong solution of bichromate of potash, which will give a reddish-brown colouration to the whole; now proceed to add, drop by drop, a solution of known strength of soluble bromide in alcohol (shaking between each addition) until the emulsion resumes its normal colour. The quantity of bromide used will give the amount of uncombined silver, and by comparing the results of successive trials upon equal quantities of emulsion it will be easy to detect any variation in the free silver caused by absorption. The alkalimeter described a few weeks ago will be found very convenient for making these trials; but, failing that, an ordinary dropping pipette may be made to answer the purpose if certain precautions be observed.

Let a tube be chosen capable of delivering tolerably large drops when water is used; we say this because a pipette which delivers small drops of *water* will deliver them very much smaller when *alcohol* is used, a tube recently tried giving between seventy and eighty drops of water to the drachm, and over three hundred of saturated alcoholic solution of bromide of cadmium. Having selected a tube, ascertain how many drops it delivers to the drachm, *using the actual solution to be employed for testing*. This point once known will not be found to vary to any appreciable extent so long as the same solution is used.

The ultimate analysis, for obvious reasons, will be better performed by extraction of the silver from the measured bulk of emulsion. We do not, however, advise that this should be done by precipitation, but rather by pouring out and drying the emulsion in a dish or upon a plate of glass. When "set" thoroughly the pellicle may be cut up small and boiled in successive changes of distilled water until exhausted of all soluble matter, when the quantity of free nitrate may be readily determined by the alkalimeter. To complete the analysis the quantities of silver and of bromine in the remaining pellicle may be determined, and we should then be in possession of sufficient information to enable us to decide at least the question of sub-bromide.

In conclusion: we repeat our hope that some of our readers will undertake this course of experiment. It will necessarily extend over some little time, for which reason we have penned these notes with a view of enabling our co-workers to tread the same ground as ourselves. In addition to the points we have noticed it would be interesting to look for free nitric (or other) acid in the kept emulsion, as well as for free bromine. For the present we leave the matter in the hands of our fellow-experimentalists.

ON THE TRIMMING AND CUTTING OF ALBUMENISED PAPER.

How to cut up a sheet of albumenised paper economically—so as to avoid waste, and, in consequence, obtain from it the largest number of prints—is a subject which has occupied the serious attention of every photographer. The pages of this Journal and the ALMANAC contain suggestions by several writers as to the best method of obtaining the most considerable number of *cartes* from a sheet, and to such economical perfection has this special department arrived that forty-eight *cartes* may be obtained from a sheet of the usual dimensions. There are, however, other "sizes" used in photography besides *cartes*, and in the course of this article we propose to explain one of the most ingenious and convenient methods of cutting up a sheet of sensitive paper into any of the sizes usually employed that we have ever yet seen or heard described. But previous to doing so we have a few words to say upon cutting-boards.

Some mounters employ as a board upon which to cut and trim their prints a hard wooden slab, planed smooth; some, on the other hand, prefer a large plate of zinc; whilst others, again, exhibit a preference for a glass plate. This is one of those matters upon which one cannot theorise, but upon which an experienced and skilful manipulator may speak with the certainty of being listened to with becoming deference.

At the last meeting of the South London Photographic Society, Mr. W. M. Ayres, one of the most experienced of silver printers, exhibited a block of wood that he has had in use for the above purpose for several years, and which has yet shown no signs of roughness or abrasion on the surface. It measures twenty-nine inches by twenty-one inches, being about two and a-half inches in thickness. It is formed of lime tree—a wood having a close and firm texture. From his acquaintance with the properties of wood, Mr. Ayres was led to adopt the end-grain of the lime tree, for the following reason:—It is known that if the knife be frequently passed in cross directions over the surface of wood, the grain of which runs parallel with the surface, the small interstices formed by the knife passing in all directions would break out, leaving the surface uneven. This will not be the case if the wood be "end-grained;" that is, the grain standing at a right angle to the surface presented to the knife. Practice affirmed the correctness of his surmise, for he finds that, no matter how much marked by the knife the surface of the block may be, all that is necessary to completely efface these markings is to pass a wet sponge over the surface at night, by doing which it is found to have regained its original smoothness in the morning, every insterstice having been closed. For this reason a cutting-block constructed according to this principle can be most strongly recommended.

But the cutting-block is only a part of the system. Its great feature lies in the method of cutting the sensitised sheets in such a manner as to avoid any waste, no matter what the dimensions of the pictures may be, it being, of course, understood that such dimensions are those in common use.

A series of folding rules or gauges are provided, each of which, when extended, corresponds with the length or the breadth of the sheet of paper. Some of these are divided into two, some into three, and others into four parts, all loosely hinged together. They are composed of zinc, covered with leather on both sides so as to prevent the surface of the paper from sustaining such injury as would arise were metal alone employed. On each divisional piece is legibly marked its size, such as "6½ inches," "12 inches," "3¼ inches," and soforth, the aggregation of which shall equal the dimensions of the sheet. Each of these folding rules has its counterpart, because one is required for the length and the other for the breadth of the sheet, and these pairs are covered with leather of the same colour, so that when working in the dim light of the darkened room no trouble is experienced in selecting the pair required.

The method of using these gauges is as follows:—Supposing that 10 × 8 prints are required, the pair of rules or gauges, which are of (say) a red colour, and which have been divided with special reference to such dimensions of print, are selected. Four weights are now placed upon the sheet, and the shorter of these red rules is placed across the end of the sheet, and folded back so as to permit a pencil mark being made at the end of the piece pressed against the paper. The folding piece is then laid flat down, and a second mark made at its end if there be still a third piece, and so on until a pencil mark is made on the paper to correspond with the length of each division of the jointed gauge, which is then removed to the other end of the sheet, a similar course being then adopted. When this is done the longer of the two red guages is laid along the margin of the sheet lengthwise, and the various lengths of *its* divisional parts are marked off as before. When the four margins have been thus marked—which does not occupy many seconds to effect—the paper is cut by means of a knife guided by a flat ebony ruler.

It will not for a moment be imagined that a sheet will be cut up into squares all of the precise dimensions wanted; but what will be secured is that the greatest number of pieces of these dimensions can be cut out of the sheet, leaving in the form of waste different sizes useful for other purposes, such as are required for *cartes*, cabinets, or stereoscopic pictures.

A GROWING GRIEVANCE.

Our transatlantic brethren, at their annual congresses and on other occasions, manage to ventilate very freely their professional difficulties as between their sitters and themselves, without interfering in the slightest degree with those interesting technical discussions in various directions which we have from time to time reported. This practice, which has many advantages, prevails also on the continent, as the reports we give of all the important societies will show.

Various rates of charges from one end of the United States to the other, reception-room arrangements, salaries of operators, disagreements between the principal and his clients, and the styles of picture most in favour in different localities—all are fully and freely described and discussed in an amicable manner or otherwise, at the same time with troubles with the bath, difficulties with varnishes, and all the usual ills that photographers are heir to. But in England nothing of the sort is attempted, and practically the photographic press is the only medium for such discussion or for bringing before the body of professional workers points of this nature, all-important as they are.

It cannot be forgotten that the conducting of a professional photographer's business has necessarily a commercial aspect. Though we give way to none in our anxiety to uphold and improve the status of photographers in general, we must state that we consider a discussion of such points, under proper limitations, might, with advantage and without loss of dignity, be periodically initiated under the auspices of some of the leading societies.

Every person has his own mode of conducting his business, and the system which in one place proves to be successful might in another be calculated to drive every sitter away. The rules of a studio in May Fair could not safely be carried out among a population of miners; and though a successful photographic artist from the New Cut would be likely to create a sensation if he removed his establishment to Bond-street, it would not be a pecuniarily successful one. But, at the same time, if a sufficient number of leading men of any class were to interest themselves in such matters of prominent interest it might lead to concerted action of some sort which would prove of mutual benefit. It is for such purpose we allude to the subject, and our correspondence columns will be freely open to any who may desire to bring attention to bear upon any special point.

We have been led to make these remarks by the unusually loud complaints made of late of the frequency with which sitters have asked for re-sittings, apparently upon the most trivial grounds.

This is one of the most important questions possible for a professional portrait photographer with a large connection. There are still, of course, a select few who can dictate their own terms to their clients; but to the body of photographers generally this is not permissible, and some concessions have to be made. The question is—To what extent must they go? We well remember being told, in the palmy days of the *carte* mania, of a well-known artist who never sent proofs or specimen pictures out, and never took an order for a less number than fifty *cartes*, but who on one occasion, through the urgency of a lady's entreaty, so far broke through his rules as to send her one *carte* for a special purpose before the whole number was done. When it arrived it was so little liked that a message was sent to say so, and that the lady would sit again. The autocratic reply was—"I am quite satisfied with the picture, and will not trouble you to sit again."

We suppose that very few could carry out a system of such complete independence as this at the present day. There is, however, a limit to all things, and we think the number would be equally few who would be so patient as the long-suffering American photographer who, as recorded some months ago in these columns, took a lady's portrait twenty times before she was satisfied. A thorough display of the opinions and practice of leading metropolitan and provincial photographers might be expected to lead to the adoption of a more uniform system throughout the country. The topic will, of course, be interwoven with various allied subjects, such as the thorough finishing and retouching of proofs before sending as against the method of sending out plain, untouched prints to select from. Of this side issue we may quote a typical example which occurred only a week or two ago. Portraits of a fair, but exacting, lady sitter were taken in eight different styles for cabinet pictures, and rough proofs were sent to her. She did not like any, but selected three, of each of which she would have two!

This brings us face to face with the query—What is the cause of the discontent with pictures so frequently manifested of late? Is it that sitters are more exacting? or is it that there is some common existing cause? The latter is, without doubt, the case. For some time past the growing tendency of ladies' attire has been to simplicity even to severity as regards decorative treatment. The more usual dress of a lady now is one of very plain make, with little or no ornamental attachments in the body, and without any drapery about the arms to form flowing folds to break up monotonous patches; while the adornments oftenest made use of are dense masses of lace, forming conspicuous spots at the neck and wrists. Add to this that the hair is commonly treated as though the photographer were a phrenologist and desired to make an investigation of the sitter's bumps with the least amount of labour, the beautiful tresses being brushed tight and plain, and the head showing in a print or seven-eighths' view of the face an exact contour of the skull. Sitters who have been taken on previous occasions with a moderate amount of ornament (by which term we are by no means to be understood as alluding to jewellery) are astonished that the photographer has taken them so badly. "Not nearly so nice, Mr. Camera, as the picture you took of me a year or two ago"—a picture which Mr. Camera will recollect as having an artistic arrangement of hair, and with a dress amenable to a little artistic manipulation.

This, we are assured, is the cause of the growing evil, and, with the hope that it may be of some use to call attention to it, we have addressed the photographic public, again stating that we shall willingly print in our correspondence columns any not over-lengthy or diffuse communications upon some way of meeting this growing grievance.

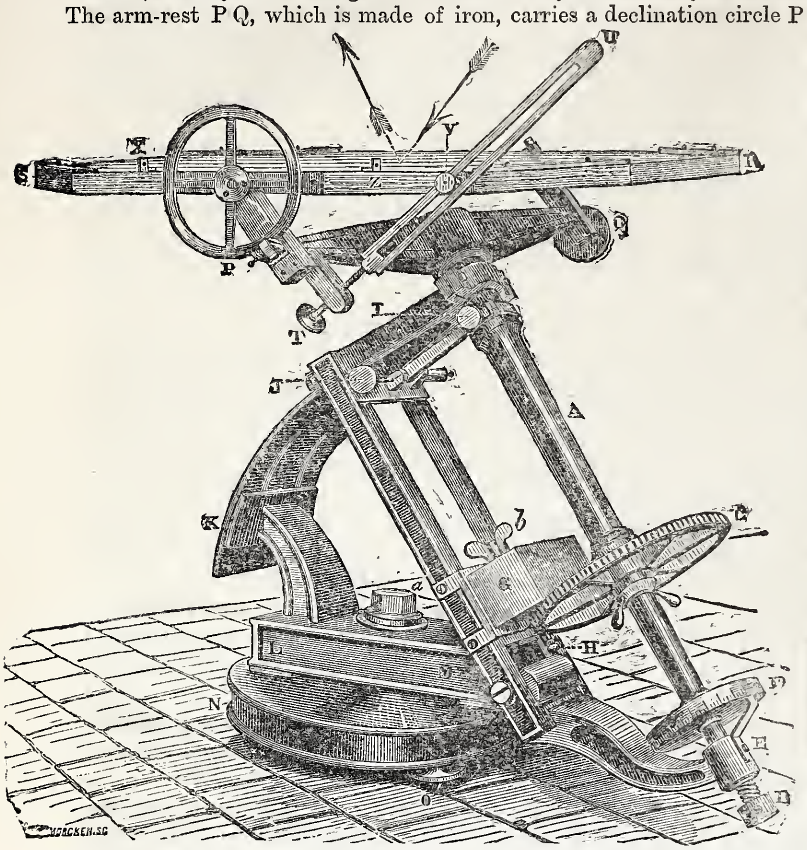
THE HELIOSTAT.

From our report of the meeting of the Photographic Society o Great Britain, held on Tuesday evening last, it will be seen that an important feature in the proceedings of the evening was the exhibition of a heliostat by Mr. Viles, who described its various parts and actions.

As much interest was shown in this instrument we annex a drawing and description of it, for which, we need scarcely say, we are indebted to our own Almanac for the present year. No apology is needed for transferring to the pages of the Journal a description of an instrument brought prominently before the leading photographic society within the present week, and which is destined to become of great importance:—

"The heliostat now to be described by means of the accompanying diagram is believed to possess all the advantages without the disadvantages of any other, inasmuch as it works with a smooth motion and can be made use of in midwinter when the sun is at its lowest equally as well as in midsummer, and also in any part of the world where the sun is visible.

"A circular cast-iron table N is supported on three screws O, and has a centre screw *a* capable of allowing the piece L M to turn. A spirit-level serves to aid in the levelling of the table. The support J K L M is of iron. The arc J K—necessary for the adjustment for latitude—is movable, but is fixed for the latitude for which the instrument is required, and when once fixed must never again be disturbed. To this piece is fixed the rest in which the axis A turns. This axis is attached at its upper end to the arms P Q, and rests at its lower end upon screw B. The wheel C is divided into 360 teeth, and is rotated by a pinion H projecting from the clock G, which is wound up by the handle *b*. Near the lower end of the axis is the hour circle D, divided into hours (and minutes) from six in the morning to six in the evening, the index E serving to indicate the time on it. The collar I works in a groove cut in the polar axis, and by fastening or setting free the screw there shown it is either loosened from or fixed to the axis. Attached to the collar is a lever which, by means of a spring, presses towards a screw J, and by the turning of it a delicate adjustment may be made. The arm-rest P Q, which is made of iron, carries a declination circle P



and an adjusting screw T U. S R is a mirror of silvered glass and of an octagonal shape. It is supported upon pivots, the imaginary axes of which pass through the plane of the mirror and at right angles to the index X Z and to the axis. By means of the screw V the mirror, when once adjusted, is clamped to the apparatus."

Particulars as to its method of action and uses are given in the ALMANAC, to which our readers are referred.

ALBUMEN AND BEER PROCESS.—ACTION OF BROMIDE ON SILVER NITRATE.

I MUST ask the pardon of your three correspondents for the lack of intelligibility in my communication which appears in THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC. I am aware that my thoughts frequently outrun my pen, and that sometimes I have the misfortune to leave out "a something" which may be necessary for the easy understanding of what I may wish to communicate, though as a rule my meaning may be inferred. I may at once say that this defect on my part often entails considerable labour on me—a labour, however, which I do not grudge—as at times I have as many as five or six letters at a time to answer regarding the meaning of expressions in which my words have been twisted in almost every conceivable manner except the right one.

Your correspondent "Yorks"—hailing, as he apparently does, from a county which is proverbially noted for its cuteness in certain dealings which are not photographic—however, has asked two pertinent questions, one of which, when answered, will save him a small amount of calculation; whilst the reply to the other will, I am afraid, not put him in a way to avoid exercising a little patience or obviate the necessity of a little experiment.

The first query is—"How many grains of silver am I to allow before I add this excess?" &c.

The combining weight of zinc is 65·2,
" " Br " 80,

and the chemical formula for zinc bromine is $Zn\ Br_2$; hence its combining weight is 225·2.

The combining weight of silver is 108,
" " nitrogen is 14,
" " oxygen is 16,

and as the formula for silver nitrate is $Ag\ NO_3$, its combining weight is 170.

Now the formula for silver bromide is $Ag\ Br$, whereas that for zinc bromide is $Zn\ Br_2$; hence we must double the combining weight of silver to arrive at the quantity of $Zn\ Br_2$ necessary to form silver bromide, so that all the bromine may be utilised. By a simple rule-of-three sum we arrive at this amount:—

$$225{\cdot}2 : 340 :: 20 : x.$$

This gives x, or the amount of silver nitrate required = 30·2 grains. The excess of three grains to the ounce of collodion will give us thirty-three grains as about the amount of silver to add to the bromised collodion.

Now, as to the second query: so much has been written on the subject that I imagine I need not be very explicit on this point. Dissolve ten grains of chloride of copper, or three or four grains of iodine, in one ounce of alcohol, and add it drop by drop till the emulsion gives a perfectly clean picture. This, alas! can only be arrived at by trial and the exercise of patience. I may as well say that, as a rule, no doctoring will be required if the organified pyroxyline be not employed. The addition of copper chloride, or iodine, is not made to convert an emulsion which gives, by alkaline development, a thin image into one giving a dense image. The density is obtained by using the ordinary intensifier, as indicated in the article.

I now wish to revert to the articles which have lately appeared in this Journal, written by the Editors and Mr. H. B. Berkeley, particularly as to the disposal of a certain NO_3, liberated by the action of bromine on silver nitrate. It is very necessary to distinguish between two cases—one when bromine acts on *dry* nitrate of silver, and the other when it acts on it moist or in solution.

Some years ago (I forget the date) Mr. Spiller proved by analysis that silver bromide, when exposed to light beneath a solution of silver nitrate, caused the formation of pure silver bromide with the liberation of hypobromous acid, which may be expressed thus:—

$$Ag\,NO_3 + H_2O + 2\,Ag_2\,Br_2 = 2\,Ag_2\,Br + Ag\,Br + H\,NO_3 + H\,Br\,O.$$

In other words, where the disengagement of bromine was slow we may take it that this reaction would result. I would here remark that silver bromide, if brought in contact with hypobromous acid, decomposes it according to Roscoe. When the bromine is added rapidly to the solution of silver nitrate—such as liquid bromine being added at once—a certain amount of bromate of silver might be formed. The formation may be indicated in this way:—

$$6\,Br + 6\,Ag\,NO_3 + 3\,H_2\,O = 5\,Ag\,Br + Ag\,Br\,O_3 + 6\,H\,NO_3.$$

Now, in reference to the action of bromine on dried silver nitrate, the above reaction holds good. For experiment I powdered perfectly dried silver nitrate, immersed it in pure bromine, and left it twenty-four hours. When freed from bromine, which it soon was, by the volatilising of the liquid, the residue was analysed, with the result that both bromide and bromate of silver were formed in about the proportions indicated. One point in the experiment caused me considerable surprise, which was to find that there remained a very large quantity of silver nitrate unacted upon at all. Doubtless free particles of the powder, though fine, had their surfaces merely converted into the new compound.

Mr. Berkeley, in your last number, has rightly explained my meaning of the action of strong nitric acid on the iodide film; and in reply to his query I state that the *undeveloped* image, of the nature called "latent," is destroyed by the action of strong nitric acid in the film of iodide embedded in the organic matter called "collodion." The image refuses to develope by the action of acid pyro. and silver. The same applies to the bromide film. One further experiment I leave for your consideration. If a glass be silvered by Martin's method, and be immersed in bromine water, it will be found that we get at first, and till considerable time has elapsed, a dark-coloured compound, which reduces almost immediately to metallic silver by the action of the alkaline developer, and on which no image can be traced if the plate be exposed beneath a negative. Further: if the action be comtinued so that the silver is converted into yellow bromide, this action of the developer does not obtain. From what I can judge of at present the whole of the silver is first converted into the sub-salt, and then subsequently into the fully saturated salt, If this be the case we have a further proof that the bromine has a much greater affinity for metallic silver than has the second atom for the sub-bromide.

W. DE W. ABNEY,
Capt. R.E.

LANTERN LIGHTS, OXYGEN GAS MAKING, &c.

MUCH of my lantern practice has been connected with engagements at private parties, and my aim has been to provide as good and safe a light as possible.

Until lately I have been using the ordinary oil light, and that has been attended with a great deal of trouble and dirt; for, unless the lamps are thoroughly cleaned after using, the light is very poor. I next tried a Silber lamp of the best construction; it is far less troublesome and causes less expense, but gives no better light than the best oil lamp.

On the recommendation of Mr. F. York I tried one of the new refulgent lamps, and, after having, by a little practice, got into the best way of working the instrument, it has proved highly satisfactory. It gives a light superior to the Silber lamp, and gives a far better illumination of the disc. The wicks should be turned up slowly, and then the light will be steady; but if turned up full at first the result will be very unsatisfactory.

In making oxygen I have tried sand and various other substances, but am obliged to go back to the oxide of manganese. This, when I get a few pounds, I put into an old, thick, iron retort, and give it a good roasting. When cold I reduce it to powder, and then try it with a little chlorate of potash. The chlorate I put on a thick board of hard wood, and reduce it to powder by rolling a large bottle backward and forward over it, and this soon reduces it to powder. I find thirteen ounces of chlorate and three ounces of manganese enough to fill a small bag 24 × 18 inches, eighteen inches rise. This will hold a little more than three cubic feet, and last one hour and a-half with a jet that I have made and have lately been using with great satisfaction. The powdered chlorate and manganese are well mixed with a bone paper-knife and then put into the retort. The wash bottle is a large, round, wide-mouthed bottle, with two pieces of lead tubing passed through the cork and sealed over with melted wax and shellac. The bag is filled in about fifteen or twenty minutes, and I think it best not to put it over too strong a fire. I have been so often bothered in making connections with the usual gas, having sometimes to use forty or fifty feet of tubing, that I have entirely taken to using a spirit jet of novel construction. Three feet of gas will supply a good light for nearly two hours, and which gives a clear ten-feet picture with very little trouble. I must describe this jet in my next communication.

THOMAS GULLIVER.

OXIDATION OF THE LATENT IMAGE.

I SEE that M. Sammann has proposed a similar experiment to that suggested by me in your last number. Curiously enough, like myself, he is unable at present to practically test the correctness of any views he may be inclined to entertain. In neither case, however, is this from want of the *will* to do so.

I mentioned in my last communication that I had a few additional remarks to make; with your permission I now send them for insertion.

I think that an account of the following simple experiment may be interesting to some at the present time, as, though the fact is not unknown to many, there may be some misapprehension as to the mode of chemical action. I therefore state the experiment in order to show how nitric acid and a bromide of a monad metal probably react upon silver sub-bromide.

Silver chloride was precipitated and washed, and then exposed to light until it became violet coloured; then again washed and treated in the dark with dilute nitric acid and also with strong nitric acid. After many hours no silver nitrate could be detected on testing. Some ammonic chloride was then added, and the violet chloride gradually returned to the white state. This proves that silver cannot be dissolved out of a sub-haloid of silver by nitric acid—at least at the ordinary temperature. (The experiment also seems to render it unlikely that this action of light is to liberate free silver, as has been lately proposed by M. Lernontoff in a foreign journal). It appears that there are two entirely separate reactions—(*not* thus: $2\,Ag_2\,Cl + 2\,Am\,Cl + 2\,NO_2\,Ho = 4\,Ag\,Cl + 2\,NO_2\,Am\,o + H_2$) —the second depending upon the first, and going on together with it:—

$$\begin{cases} 4\,Ag_2\,Cl + 6\,NO_2\,Ho = 4\,Ag\,Cl + 4\,NO_2\,Ag\,o + N_2\,O_3 + 3\,O\,H_2, \\ NO_2\,Ag\,o + Am\,Cl = Ag\,Cl + NO_2\,Am\,o. \end{cases}$$

This experiment suggests some doubt as to the action of nitric acid on the latent image (supposed to be sub-bromide) in the bromide plate. Captain Abney states that half the silver of $Ag_2\,Br$ is oxidised by the nitric acid. Now, whether this oxidation be the formation of $Ag_2\,O$, or—what would seem inevitable, were $Ag_2\,O$ formed—of silver nitrate

$$(Ag_2\,O + 2\,NO_2\,Ho = 2\,NO_2\,Ag\,o + OH_2),$$

how can we reconcile any such action with the inactivity of nitric acid upon the sub-chloride in the above experiment? Again: granting the possibility of such action, why should not nitric acid act upon the sub-bromide in *emulsion* as well as upon the sub-bromide (?) in the exposed plate? For though the silver nitrate—which it seems to me must be formed, even if $Ag_2\,O$ be first formed—may be washed out of the film in rinsing, the silver nitrate might be equally well washed out of the film after coating a plate with emulsion which had been treated with nitric acid. It may, perhaps, be said that the quantity of nitric acid generally added to emulsion is not sufficiently powerful to form the nitrate. But there seems some doubt whether it is possible in any way to oxidise, or otherwise change, this sub-bromide with nitric acid alone; and as the latent image in silver bromide is undoubtedly destroyed by dilute nitric acid (I take this to be settled by Captain Abney), there appears to be good reason for doubting whether the latent image be composed of sub-bromide at all. I think the following experiment would throw some light upon this part of the subject:—Expose under a negative, or in the camera, a bromide plate until a slightly visible image is perceptible; then treat with dilute nitric acid and await the result. If the visible image were destroyed, or, on the other hand, rendered unavailable for the subsequent reduction of the image by the alkaline developer, the theory that the latent image is composed of sub-bromide would be supported, and that the sub-bromide can be oxidised in some way by nitric acid. If, however, the visible image remained unaltered in its properties, the fact would be shown that the actinic rays have two distinct actions upon the sensitive film.

There is another experiment in connection with the presumed oxidation of the latent image by various oxidisers which it appears to me would be worth trying. It is to expose a bromide plate under a negative, taking means that the plate may be replaced in the same position under the negative any number of times desired. The plate would then be acted upon by an oxidiser, washed, organified, exposed under the negative again, and then washed and "oxidised," the same operation being repeated any number of times. After a certain number of these operations it would seem that a brown image of $Ag_2\,O$ would gradually make its appearance; that is, if every two molecules of $Ag_2\,Br$ form one of $Ag_2\,O$ by oxidation. The image should then be insoluble in hyposulphite of soda, and would form very good practical evidence of the oxidation theory.

It would also be well to try the action of an oxidiser, such as potassic permanganate, upon the visible image produced by the prolonged action of light. If the action is as has been proposed by Captain Abney, the image should be no longer soluble in hyposulphite of soda. It is possible that the oxidiser may have no effect upon this visible image, when there would be additional evidence that the actinic rays have two distinct modes of action.

It occurred to me some time ago that there is an action which does not take place in practice, but which theory would seem to indicate should take place. If the primary action of light is to change $2\,Ag\,Br$ into $Ag_2\,Br$ and Br, how is it that we do not find, when testing volumetrically (say) for the combining equivalent of a sample of bromide, that a quantity of silver nitrate exceeding the theoretical equivalent is necessary to destroy all traces of soluble bromide, the testing being performed in the ordinary light of the laboratory? I do not think that more silver nitrate would be found to be converted than when the precipitation is effected in the dark room. It may be said that the silver sub-bromide is not easily formed in the absence of organic matter; this forms a difficulty, as, if any organic matter be added, the bromine ejected may combine with it, and thus get out of the reach of the silver nitrate. In order to do away as much as possible with the restraining influence of soluble bromide the bromide might be precipitated with silver nitrate in excess throughout, when, I believe, the result would be the same. The following reactions ought, apparently, to take place according to the sub-bromide theory of the action of light:—

$$4\,Ag\,Br = 2\,Ag_2\,Br + Br_2;$$

the nascent bromine should, I believe, combine with the hydrogen of water—

$$2\,Br_2 + 2\,O\,H_2 = 4\,H\,Br + O_2;$$

the hydrobromic acid thus formed would react upon the silver nitrate—

$$H\,Br + NO_2\,Ag\,o = Ag\,Br + NO_2\,Ho.$$

In this way a mixture of $Ag\,Br$ and $Ag_2\,Br$ should be formed, and consequently more silver nitrate than the quantity necessary in the dark would be required. But we do not appear to find any inconvenience when operating in ordinary light; it would, therefore, seem either that $Ag\,Br$ is not affected at all by the action of light in this case, or that it is affected in a different manner than by the ejection of bromine, with formation of $Ag_2\,Br$.

I hope that those of your readers who are interested in this subject will find the above remarks worthy of their consideration.

I should have preferred to have given an account of experiments rather than to have suggested them; and it is not with the wish that "*others* may try" that these suggestions have been given.

HERBERT B. BERKELEY.

PHOTOLITHOGRAPHY AND PROFESSOR HUSNIK'S PAPER.

[A communication to the Vienna Photographic Society.]

THOUGH the directions for use given by Professor Husnik may be sufficient for photographic purposes, still there are doubtless many of my colleagues to whom an account of the observations I have made during my last half-year's experience in practical photolithography will be useful.

If in photography it is most important to start with a good negative, it is doubly so in photolithography. And he who is not in a position to produce a perfectly clear, properly-exposed, and, in every part, equally-developed and covered negative need not waste his time on photolithographic experiments. A negative which in the ordinary silver process furnishes prints passable enough is generally scarcely sufficient for a proof upon stone. The difficulty is to produce a negative which shall be equally strongly covered in all its parts, yet in which all the lines, even the finest, shall be left perfectly clear.

If the negative can be taken in sunlight, and if all the chemicals are in good working order, one can in most cases get sufficiently-covered negatives without having recourse to sulphide of ammonia or similar aids. I give the preference to a negative not too strongly covered, if it be only perfectly clear, since by the treatment with lead and sulphide of ammonium the finest lines are apt to be somewhat covered over if the exposure be long enough for the thick lines. If, on the other hand, the exposure be too short, then the drawing in the blackest parts will be too coarse. The greatest advantage of using Professor Husnik's paper is, in my opinion, that with it absolutely opaque negatives are not necessary, as with other processes.

Though sunlight is not to be had for the taking of the negative, it is still advisable to take it in the open air, because in ordinary portrait studios it is often quite impossible to light a large, flat surface perfectly equally. As a rule, I coat the plate twice with collodion, letting it run off the plate the second time in the opposite direction to what it did the first time. Thus I ensure an equal film. For this purpose I dilute the alcohol beforehand with ether. If the collodion should be too rich in alcohol in proportion to the ether the film will dry unequally, and the necessary covering will not be produced. Since, as a rule, only one impression is required, I always omit to varnish the negatives, because they lose a little of their intensity with most kinds of varnish. Meantime, a coating with a solution of gum arabic is a sufficient protection against injury. Spots or holes in the negative do no harm, as they may easily be mended with indian ink as long as the drawing is preserved; but it is always advisable to go over the negative, very carefully spotting out all such flaws, as they are not nearly so easily removed from the stone.

The printing upon the transfer paper differs in no way from silver printing, except that a few precautionary rules must be obeyed. The paper should be freshly prepared—that is, sensitised. Even after twenty-four hours it is much more difficult to wash off the transfer colour from the unexposed parts; one has to rub harder, and thus run the risk of injuring the drawing itself. The development can scarcely be overdone, since small particles of the colouring matter lodge easily between the lines, where they are apt to be overlooked, but which make themselves very disagreeably evident on the stone after inking, and are then very troublesome to remove. Lithographers are not yet very well up in this new art, so one must not throw too many difficulties in their way.

It is in inking the paper, after exposure in the printing-frame, that most beginners err by putting on too much ink. If the lines of the drawing do not lie close together, this is of less consequence; but, on the contrary, in drawings where the lines are very close, the colour is squeezed out by the pressure which transfers the prints to the stone, and the impression has a smeared appearance. With the help of a magnifying glass this fault may be recognised on examining the stone. In such a case recourse should not be had to retouching, but after drying the print it may be inked and developed over again. I have in this way got three proofs upon stone, which were equally good, from the same paper and picture. It is very important to get the proper degree of moisture for the transfer to stone. If the paper be too wet, then the stone sucks up the moisture and does not take on the ink well. I therefore allow it to become almost dry, and then lay the sheets for half-an-hour between two damp sheets of blotting-paper. The transfer requires a good deal of care. Usually I draw the stone and paper about ten times through the press. Each time a fresh sheet is laid on and the roller reversed. It is also important, after the transfer and inking, to let the stone lie for some time amongst gum. I usually transfer in the evening and let the stone remain in the gum over night.

Photolithography cannot be employed for everything. In the first place a good original is required. Weak, grey, and smeared drawings can never give good pictures. Blue lines do no harm. Reductions of good drawings cannot be produced of equal beauty in any other way for the same cost and at the same price. I once got a composition from an artist which had formerly been drawn upon stone, and after a whole edition had been pulled it was ground off. A new edition was called for, and the artist could not make up his mind to draw the picture again. It was a beautiful summer day. At noon I fixed up the picture and took two negatives—one the same size as the original, and the other reduced to half the size. In the evening both were transferred to stone, and next morning they were printed. The painter (a friend of mine, but an enemy to photography) was then, for the first time, made aware *that at a pinch photography could take the place of art.*

J. BIRFELDER.

EDUCATIONAL USES OF PHOTOGRAPHY.

[A communication to the South London Photographic Society.]

MR. PEARSALL's paper on *Educational Aid by Photographic Exhibits* was so full of suggestive matter that it would be difficult for one person to study all the points touched upon so as to make observations upon the same.

I, therefore, propose to say a few words respecting the usefulness of photography in one or two educational points of view, and more especially in respect to its aid to the art student in drawing; and I speak practically upon this part of the subject, having studied as an artist in the Royal Academy, and also from having taught drawing in schools in earlier days.

Now, it must never be forgotten that the intention of drawing by hand is not only the correct representation of the object, but also to cultivate an individuality in the style or manner of producing such representation.

In learning to draw, the young student has first to perceive the difference between lines opposing each other and afterwards those closely approximating, and to practise the hand in its endeavours to imitate such differences; hence the first models or outlines must not only be very distinct, but the differences between two or more lines must be strongly marked.

With regard to the correct representation of any object, of course all artists must admit that no drawing by hand can equal the absolute imitation which photography gives, both in contour and shading of surfaces, and it is just because these outlines are so exquisitely beautiful in the softness or, rather, total absence of outline and submergence of one part into another that causes photographic representations to be very difficult to the young student in drawing to copy or imitate.

It will then, I think, be evident that the necessity plainly arises for some skilful and cultivated hand to prepare the early studies, as he can firmly define all outline, and the student is not perplexed, but sees at a glance what he has to do; or, rather, as drawing is, after all, nothing but the outcome of memory, which the hand is taught to obey and reproduce, so the forms which impinge upon the mind through the eyes should be well defined, and thus simplify the work which the hand is educated to perform.

The same remarks apply to shading, as it would be utterly impossible to imitate the continuous deepening of tone which nature reveals through the agency of photography. It also, in this case, becomes necessary to form or invent a manner or style of producing an imitative result by some distinctly-defined shading, which either is individual or general. Hence I arrive at the conclusion that photographs of natural objects are not the right things to place before a beginner in drawing. But as soon as the power to represent visible objects by what are really *artificial* signs has been attained, then photography would be useful as standing in the place of the originals.

But it is quite another thing to recommend the multiplication of a good drawing copy by means of photography. In this case every variation in touch—even the gradual wearing away of the pencil or crayon—becomes evident; and the expression, or what is called the "feeling," of the artist can be seen, as also the possible repetition of lines, by which he arrived at his final outline. In this way photography can do splendid service as an educational aid. I cannot but think that there is a future for photography in supplying such an evident want. The difficulty to be overcome will be in producing at a commercial price the number of copies. However, in view of the immense strides which mechanical printing through the agency of photography has recently taken, the means may very soon exist by which artistically-arranged and technically-adapted natural existing objects may be multiplied and brought out as useful and necessary aids to educational study.

Mr. Pearsall says:—"Lithographic copies are given to be copied with the lead pencil." I quite agree with him that this is wrong, and equally errs, although on the opposite side, with photographs from objects, because the mode of production being different how can the imitative results be equal?

Again: it is stated—"That photography would aid in correctly training the faculties of observation." Here every one who gives a thought to the matter will agree with such statement, more especially in botanical studies, where photography renders the minutest form and development of parts with such marvellous fidelity. But here comes in the point of view I have taken with respect to drawing. All these photographs should be produced under certain conditions of representation which would show them as distinct and separate from surrounding objects, so that the individuality of the object should be taken in at a glance.

As an aid to botanical studies, where stems, leaves, blossoms, and flowers can be so beautifully shown, we have had strong evidence of the capabilities of photography in the many really exquisite examples recently seen at the photographic exhibition, but which, for the purpose of being useful for educational purposes, would require to be treated both from their own perfectly natural positions and also from some more conventional way of representation, for the purpose of classification and distinctness of form.

Then, take photographs of surgical cases as an educational aid to the medical student. Here difficulties arise in the matter of colour, which becomes so great a help in the diagnosis of disease. I recollect, many years since, when, as a young artist, being engaged to attend at the Ophthalmic Hospital to make drawings of diseased eyes, I was much surprised to have eyes put before me which to all appearance were perfectly correct, but which, upon closer inspection, proved to have some very small irregularity in the colour of the pupil. This necessitated much care and skill to make evident on paper. Here photography would have been comparatively useless; but, where conformation or abnormal form is all that is required, photography must be invaluable, as all the parts being taken at the same time their relative size and position become correctly represented.

Photography, then, I consider, becomes applicable as an educational aid, and especially in its relation to drawing, when facts have to be recorded and the *objective* side of knowledge is in operation; and it is because those photographic facts are so purely objective that therein lies their great power and usefulness. But the very moment that the *subjective* side of knowledge is cultivated—where expression and the consequent development of individuality becomes a necessity—then photographic records must give way to those produced by the human hand, which, being guided by the mind, becomes imbued with a vital meaning; in other words, give evidence of the wide gulf which must ever separate matter from mind.

At the same time there remains much good and true work which photography can do, and the only thing at the moment to be brought about by such discussions as these is to define the proper and legitimate road along which our art-science, by steadily pursuing its way, will ultimately arrive at a position where its utility will be recognised, and its work accepted as helping forward the progress of education.

EDWIN COCKING.

Meetings of Societies.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

THE annual meeting of this Society was held on Tuesday last, the 12th instant,—Mr. James Glaisher, F.R.S., President, in the chair.

Mr. Frank Bishop having been elected a member, the reports of the Treasurer and the Council were read and adopted. These will probably appear in our next issue.

Votes of thanks to the Secretary, the Treasurer, and the Auditors (Mr. R. Murray and Mr. F. Beasley) were then awarded.

It was proposed, and unanimously adopted, that the service medal of the Society be awarded to Mr. Henry White, a former treasurer, as an acknowledgment of the valuable services rendered by him in that capacity.

The CHAIRMAN said that the Council had unanimously decided that the progress medal of the Society should be awarded to Captain Abney, on account of the originality and value of the scientific researches in photography made by him and submitted to the Society.

This announcement elicited much applause.

Captain ABNEY thanked the members for the honour they had done him, but begged respectfully to decline the medal for the reason that, if they remembered, the proposal to make an annual award of a medal for progress was made by himself, and owing to this he did not consider it was fitting that he should be the first to be thus honoured.

The members, however, would not receive Captain Abney's declinature of the medal, which he was eventually compelled to accept.

Captain ABNEY proposed that the sum of seven pounds be set aside for two prizes—respectively of five and two pounds—to be offered in connection with the technical examinations conducted by the Society of Arts. This would enable them to include photography in its scientific and practical bearings in the branches of technical education. For an examination as to the competency of photographic students every facility existed.

Mr. FRANCIS BEDFORD seconded the motion, which was agreed to.

Captain Abney exhibited a large transparency of the sun, executed by M. Jansen.

Mr. W. S. BIRD, on behalf of the scrutineers of the ballot, announced that Mr. Francis Bedford had been elected to fill the vacancy among the Vice-Presidents caused by the retirement in rotation of one of that body, and that the seven vacancies created in a similar manner in the Council would be filled by Messrs. Blanchard, Dallmeyer, Davis, England, Fry, Mawdsley, and Pritchard.

Mr. E. Viles then exhibited a heliostat and explained its application to such photographic purposes as the production of solar enlargements, whether of a microscopic kind or large carbon pictures. He also exhibited and explained the action of the solar microscope employed by him in obtaining the negatives from which were printed the pictures for which he was awarded a medal at the recent exhibition. The heliostat exhibited by Mr. Viles has been described, with a drawing, at pages 31 and 32 of our ALMANAC for the present year, and which we reproduce in our current number.

Two other heliostats—one of them possessing great simplicity of construction—were exhibited by Captain Abney. Concerning these we shall have more to say hereafter.

The CHAIRMAN proposed the thanks of the Society to Mr. Viles.

A large collection of the most recent works in *photochromie*, by M. Leon Vidal, were exhibited and examined with much interest.

The CHAIRMAN tendered the thanks of the Society to Mr. J. T. Taylor, who had been the means of such a collection being brought before the members, and to Mr. Hore, who had kindly attended to exhibit these specimens.

A vote of thanks to the Chairman for his services as President during the present year, proposed by Mr. Bird and carried by acclamation, brought the proceedings to a close.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting of this Society was held on Thursday, the 7th inst.,—the Rev. F. F. Statham, M.A., F.G.S., President, in the chair.

With a view to opening a discussion on Mr. Pearsall's paper on *Educational Aid by Photographic Exhibits*, Mr. E. Cocking, Secretary, read a paper on the same subject. [See page 76.]

The CHAIRMAN spoke of the great advantage of photography as a means of multiplying works of art which could not otherwise be multiplied except by a great loss of time. The conventionalism that existed in modes of treating subjects, such as trees, by artists militated against the employment of photographs from nature as copies for young artists; but, if such photographs were employed as studies, there was no doubt that a better and more accurate system would be brought about. It was only by degrees the conventional method alluded to had been adopted, and by a more extended use of photography in copying from nature a closer approximation to nature would be attained in our works of art than is now the case.

After a few remarks by Mr. Cocking, and no other member speaking on the subject,

Mr. PEARSALL, in reply, said that he was gratified by the interest that had been taken in the communication he had made, as shadowing out the advantages to education by photography, by the discussion and papers there and elsewhere, and he thought he could discern in several quarters the entertainment of the question. He had but little to reply to in the shape of answering objections; but he might explain that he did not wish in any way to reflect upon the education of artists or on high art. What he had contended for was to place drawing upon a footing to be taught like writing, and, as these forms were to represent language and ideas, that drawing should be able to express forms of nature and facts of daily life by ready symbols or pictorial means. He pointed out the practice deemed necessary to acquire music, where the vast volumes of noise and amount of error vanished in daily practice, and the early copybooks were thrown aside; but, with drawing, to attain the proper practice and to correct errors, the amount of wasted material was so great that the child was too early allowed to draw, and thus the errors were made painfully permanent. All parties were dissatisfied, and few pupils acquired power to draw when alone, and very few persons were found to retain sufficient power to draw in after years. What he asked for was the simple means of drawing lines to be used to express forms, and shading to give the solidity that could not be given by mere outline. Photography would furnish subjects for copies of unexpected and beauteous novelty, and thus students, children, and teachers would be interested and rewarded. Still, if it were necessary to defend the employment of enlarged photographs in place of casts and statues, he thought that such copies had advantages. Taken for the million—from the best subjects of study or life, in the best lights, and selected with critical care by a professional artist—they would not at least present the repellent aspects of too many pieces of sculpture. Horses flying along, yet permanently and necessarily supported by a trunk of a tree, or impaled upon bars of iron! It did require an imagination and time that ordinary students did not possess to overcome the violent aspects of many of these works of art—too many loaded with dust and a complexion of polished dirt seen nowhere else, and the parts recessed instead of deep shadows showed velvet, dusty aspects, or even absolute whiteness. He named the clever painting of a *Tomb in the Church of St. Roch, Paris*, where the visitor was called upon to admire how effectively the painter had imitated the dust and dirt of ages upon the portions receiving the lights. Having been induced to look at the state of photography in its many pleasing aspects as a new power to civilisation, he found the capabilities to aid education so many and so strong that he might be permitted to add the weight of one of their leading scientific men—that while for language and ideas we had classic models, and for music mathematics and geometry, we had logical rules for training. In the mechanical arts tools and machines and materials could be properly applied, yet for natural and experimental philosophy, as required at the present day, they had no recognised means to test the fitness of a youth for science. It was believed that of all the means that could be employed to teach, the art of photography was the best; for, if the young student had not the habit to be interested with the experimental training to produce such true and valued transcripts of nature as could so readily be obtained, it might safely be inferred that he was not well fitted for delicate manipulations to obtain true results. Photography might thus afford the means to show how much confidence the student had in himself, and it enabled his friends to form an estimate of the confidence to be placed in him and the results he might obtain. Taking a wider view, he ventured to think photographers had reason, in these dull times, to be satisfied with the position of photography, aided, as they were, by the noble army of enthusiasts and amateurs to encounter all expenses and difficulties, to obtain results, to develope truths, and to advance good practice. He thanked them for the marked attention with which they had been pleased to honour him.

A vote of thanks was tendered to Mr Cocking and Mr. Pearsall.

A fine and large photograph of the celebrated group, *The Laocoon*, was exhibited by Messrs. Mansell and Co.

A large collection of choice photochromes by M. Leon Vidal, of Paris, was submitted for examination by Mr. Hore.

Mr. R. Kennett, alluding to a statement that had somewhere been made relative to the improbability of dry plates being ever used in the studio, exhibited a number of negatives of portraits which effectually contravened such a statement. He also exhibited a variety of negatives of groups and landscapes of excellent quality. These were all taken on dry gelatine plates.

Mr. Pearsall exhibited two diffraction gratings—one of which had been ruled by a diamond point, the other being a photograph. They contained four thousand lines to the inch.

Mr. Bolas directed attention to the recent patent of Mr. J. R. Johnson, and exhibited a transfer from a negative obtained by following the directions given therein. The negative was a copy of Captain Waterhouse's article in The British Journal Photographic Almanac, and a curious thing about it was that the negative, which had been strongly intensified, was split into two pellicular halves, one half remaining attached to the glass plate, the other being removed on the gelatine. Both possessed printing intensity. [This curious negative may be seen at our office.]

Mr. W. M. Ayres showed a large block of end-grain wood suitable for trimming prints upon. A brief description of this will be found in another page.

Messrs. Wratten and Wainwright exhibited a collection of prints obtained from washed emulsion negatives. These comprised groups, landscapes, and architectural views.

After votes of thanks to the various gentlemen who had made exhibits the proceedings terminated.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

The annual general meeting of this Association was held on Wednesday, the 6th inst., at 160a, Aldersgate-street, E.C.

The minutes having been read and confirmed, the balance sheet was placed before the meeting. After being examined by the members the following resolution was carried, having been proposed by Mr. O'Connor and seconded by Mr. Howard:—"That the balance sheet be taken as read."

The reports of the Secretary and Board of Management were next submitted to the meeting, and it was proposed by Mr. Ralph and seconded by Mr. Evans—"That the Secretary's report and the report of the Board of Management be passed." Carried unanimously.

Annexed are the two reports:—

Secretary's Report.

Gentlemen,—You will hear the report of the Board of Management. I wish, however, before that is read to make a few remarks on the condition and prospects of the Association financially, as regards its past, present, and future state.

In the year 1876 the actual receipts were £39 15s. 1d., and the expenditure £58 1s. 5d., thus reducing the balance in hand from £68 16s. to £50 9s. 8d. For the year 1877 the receipts, though less than those of 1876, show an improvement in the most vital part, viz., subscriptions from ordinary members. The actual receipts were £35 13s. 4d., and expenditure £38 9s. 2d., the latter exceeding the former by £3 5s. 10d. as compared with last year's difference of £18 6s. 4d.

As to the prospects for 1878, I can safely assert that the expenditure, as far as working expenses are concerned, will be considerably reduced. The rent, which for last year reached the sum of £7 18s., will this year be only £3. This is not the only advantage attached to the removal of the offices of the Association, as all must admit who have visited the former and present offices. Another point upon which I wish to remark are the expenses incurred for printing during the year 1877. Several alterations in the rules having been made at the last annual meeting, a new edition was printed. That would, of course, be a heavy item, but one not necessary this year, and consequently there will be a reduction of expenditure in that direction also. Copies of the rules can now be obtained at sixpence each, and I should strongly advise those gentlemen not possessing one to obtain the rules immediately, and to further the interests of the Association by circulating them amongst their friends, who probably by that means would become members.

In conclusion: I trust to be able at the next annual meeting to show an improvement in all points. I would impress it upon you that the expenses would be but slightly increased should the Association become of twenty times its present strength. H. Harland, Secretary.

Report of the Board of Management.

The Board of Management tender their thanks to those gentlemen who have kindly contributed to the funds during the year, and trust by a continuance of that support to be enabled to further develope the benefits of the Association.

Since the formation of the Association the sum of fifty pounds has been granted for relief, in amounts varying from £7 10s. downwards, to meet the requirements of the applicants, due precaution having first been exercised. The Board of Management feel confident that the manner in which each case has been considered and finally dealt with will meet with the approval of all members.

The number of applicants for relief during last year (1877) being somewhat less than previously is attributable to the fact that, by means of the Employment Register, its members have been engaged, thereby rendering such application unnecessary. This fact should recommend itself to photographers generally; and, taking into consideration the small sum requisite for membership, and the knowledge that if one does not require assistance he is at least helping his poorer brethren who do, the Board would, therefore, urge all members of the profession to join the Association, feeling confident that it is only the want of being more generally known that prevents its strength being considerably augmented.

The subscription to the Association for an ordinary member is three shillings quarterly, or five shillings and sixpence half-yearly, or ten shillings and sixpence yearly. The advantages offered are—substantial relief when a member needs it; railway fares to enable a member to reach a situation at a distance; a list also being kept of vacancies at the office. Applications sent to the Board receive prompt attention.

The Board of Management, in bringing its term of office to a close, would urge upon the members the necessity of their active co-operation in the future, and would request them to make known as widely as possible the purposes for which the Association has been formed, and to forward to their utmost the interests of this Association.

There is still one of the objects of the Association that has not yet been developed, viz., granting annual pensions to aged members or their widows. To carry out this object the Board is anxious to form an *invested fund*, and respectfully solicits donations and subscriptions, which will be thankfully received by the Hon. Treasurer, H. Baden Pritchard, Esq.

W. M. Ashman, Chairman.

A letter from Mr. Bassano, of Old Bond-street, was read to the meeting, in reference to his proposal to hold an exhibition at the above address, all surplus profit from the exhibition to be handed to the Photographers' Benevolent Association.

The Secretary was instructed to thank Mr. Bassano in the name of the Association

Robert Millard was struck off the list of members for unsatisfactory conduct.

Messrs. Windridge and Foxlee were elected as ordinary members of the Association.

The election of officers for the ensuing year then took place, with the following results:—*Vice-Presidents:* Rev. F. F. Statham, M.A., F.G.S., and J. H. Dallmeyer, Esq., F.R.A.S.—*Trustees:* Colonel Stuart Wortley and Captain W. de W. Abney, R.E., F.R.S.—*Treasurer:* H. Baden Pritchard, Esq., F.C.S.—*Auditors:* G. Taylor, Esq., and L. Sisman, Esq.—*Board of Management:* Mr. W. S. Bird *(Chairman)*, Mr. W. M. Ashman *(Vice-Chairman)*, Messrs. H. J. Burton, T. Bolas, J. D. Fage, T. S. Hicks, J. A. B. Hall, E. D. Lavender, O'Connor, D. Rheinlander, J. Rolph, and H. J. Thorne.—*Secretary:* H. Harland.—*Travelling Agent:* Mr. Ramm.

The proceedings of the evening were brought to a close by Mr. Fage proposing a vote of thanks to Mr. Ashman, the Chairman, which was passed unanimously.

The meeting was then adjourned till March 6th, at 8 p.m. To that and other meetings the Board earnestly invite all photographic friends.

BALANCE SHEET FOR YEAR ENDING DECEMBER 31, 1877.

EDINBURGH PHOTOGRAPHIC SOCIETY.

THE fourth ordinary meeting of this Society was held in 5, St. Andrew's-square, on the evening of Wednesday, the 6th inst.,—Mr. J. Lessels, President, in the chair.

The minutes of the previous meeting having been read and approved, Mr. W. W. Halliburton was unanimously elected an ordinary member of the Society.

Mr. W. GILMOUR then gave an address on some properties of glass, of which the following is a summary:—After an apology for not having something more immediately bearing upon photography to bring before the meeting, he (Mr. Gilmour) stated that he intended to take them to a closely-allied subject, and would make all his remarks *On Some Properties of Glass* correllate as much as possible around lenses. A lens in its simplest definition, it was explained, was a glass so prepared that the rays of light passing through it were refracted. All simple lenses, however, did more than refract the light passing through them, for they also dispersed it, owing to the unequal refrangibilities of the different rays which formed ordinary white light. This property of refraction and dispersion was shown by means of a ray of light from an oxyhydrogen jet, the amount of refraction being determined by the distance the ray of light was bent out of its straight course, whilst the dispersion was determined from the length of the band of colour produced by the accompanying decomposition of light. Newton, who first discovered the compound nature of light, held that refraction and dispersion were both reciprocal and proportional; that is, there could not be refraction without dispersion, nor could there be dispersion without colour, and, further, the dispersion was in a corresponding ratio to the refraction. The apparent truth of this theory was shown by the refraction and dispersion produced by transmitting light through different media—such as glass, water, bisulphide of carbon, &c.—by means of which it was shown that where a ray of light was much refracted the dispersion was correspondingly great, and *vice versâ*. Nearly half-a-century later, however, another philosopher discovered that by combining substances of unequal refractive and dispersive powers the dispersion might be got rid of, leaving still a considerable amount of refraction; and, referring to the very interesting donation which had recently been made to the Society in the shape of a lens achromatised by means of water, he (Mr. Gilmour) stated that he had referred to the principle of achromatism merely to show the achromatic action of the water. This was done by a very interesting and beautiful experiment, in which the decomposing action of the lens was first shown, then the achromatic action of the water, and, lastly, the residue of refraction after the lens was properly achromatised. Referring next to the refractive action of all transparent substances, it was stated that they might all be classified into two divisions, namely, those that were single refractors and those that were double refractors. The single refractors required no explanation, but the double refractors were illustrated by passing the light through a crystal of sulphate of lime, and double refraction itself explained and illustrated in various ways. This was done for the purpose of explaining the remarkable property of glass whereby it might be resolved either into the division of single or double refracting substances. A perfectly homogeneous plate of glass, for example, was shown by several experiments to be capable of being converted into a double refracting plate, this being done by pressure, heat, &c. The process of annealing glass was next referrred to, and illustrated by several very interesting and beautiful experiments, and the whole of the remarks on double refraction were briefly summarised in their practical bearing on, and application to, lenses as stated at the commencement.

The address was illustrated throughout by very numerous experiments—some, in which the polariscope was introduced, relating to the formation of crystals and to various kinds of glass, both annealed and unannealed, being of a most interesting and beautiful nature. It was shown that light passed through crystalline bodies much more readily when directed vertically to the plane of cleavage, due to the molecules all lying in one direction. When a ray of polarised light was passed through a piece of annealed glass the screen exhibited a white light, but by causing a screw to press on the edge of the piece of glass the light suddenly became beautifully coloured in consequence of disturbing the equality of its density. The coloured rays had a common axis which formed the centre of a black cross, the latter indicating where the light was intercepted. Where a piece of unequally-cooled glass was examined a similar effect was seen, but each piece had its own distinctive form and structure. Thus a circular plate of glass had one axis, from which, as a centre, coloured circles were described; an oval plate, on the contrary, had two axes, around which there were the coloured rings severally described with mathematical precision.

In answer to Mr. Pringle, Mr. GILMOUR said he believed the visual and chemical foci of a lens might be modified if it were screwed too tightly or unequally in its setting.

Dr. THOMPSON directed attention to the advisability of allowing sufficient room for the expansion of the lens by heat, so that the brass cell might not derange its quality. He also referred to the iridescent glass of Herculaneum, Pompeii, and Carthage, the peculiar property of which, he believed, was due to oxidation.

An interesting conversation then ensued on the change in colour some kinds of glass underwent when exposed to light. One very notable example of this was to be seen in the large plate glass window of a hosier's shop in Princes-street, which, from being at one time colourless, was now so deeply coloured that all white articles seen through it appeared of a deep rosy lavender colour.

Several members had noticed that the glass most free from colour when new was the soonest deteriorated when exposed to light.

Mr. M. G. DOBIE proposed that a presentation print be given to each member of the Society, and desired that it should be of a very high-class character, worthy of such a large and prosperous Society.

Mr. A. MATHIESON proposed that the print be mounted with an appropriate title, &c., so that it might not only represent the most advanced state of the art, but be finished in the best manner possible, as is usual with first-class presentation prints, and be issued ready for framing.

Both these propositions were carried unanimously, and the matter was referred to a committee to make choice of a subject, and to carry out the wishes of the Society.

Votes of thanks to Mr. Gilmour, for his interesting and instructive lecture, and to the Chairman, terminated the meeting.

VIENNA PHOTOGRAPHIC SOCIETY.

THE usual meeting of this Society was held on the 11th December last,—Dr. Hornig in the chair.

The minutes of the previous meeting having been read and approved, and some business of no general interest having been transacted,

The CHAIRMAN intimated that it had been thought advisable to add to the numbers of the committee appointed to adjudge the Voigtländer prizes.

The additional names were those of Dr. Bauer, Professor Husnik, and Herren Leipold, Martin, and Scamoni, who may be regarded as experts, and were principally required to decide upon the *Treatise on the Reactions of Chromates upon Substances of Organic Origin.* The final award was postponed to allow all the members of the jury to read the treatise.

The CHAIRMAN also announced the arrival of another competing work after the time fixed for receiving such; but after some discussion it was agreed to admit the belated work, as the judges had extended their time for deliberation.

Several bottlesful of a new preparation of Professor Husnik's for producing copy-negatives by a dusting-on process were laid upon the table, and any member inclined to experiment was invited to take a bottle with him and to report on the results obtained. Professor Husnik had also sent a number of negatives produced by his process, and an essay on *Lichtdruck in Natural Colours*, which was read by the Chairman.

Several copies of a pamphlet, by Professor Steinhauser, on the mathematical proportion between the stereoscope and stereoscopic pictures, were also distributed. Dr. Eder had undertaken to make a report on the subject, but was prevented by illness. A communication was also read from Herr Brandt, of Bayreuth, in which he described his experiments in direct printing from glass negatives.

A number of other objects were exhibited and commented on, but nothing of general interest, and the meeting was shortly after adjourned.

AN extraordinary meeting of the same Society was held on the 29th December, in order to give Baron Stillfried an opportunity of exhibiting a Warnerke travelling apparatus, which was examined with great attention.

Dr. EDER then said that Professor Steinhauser based his calculations, on on the one hand, on the mathematical connection between stereoscopes and pictures on the focus and distance of the lenses by which the picture was taken, and, on the other hand, on the focus and distance of the lenses of the stereoscope and the height of the box. Thus Dr. Steinhauser showed that to give a perfect idea of the original object stereoscopic pictures must conform to the following conditions:—1. All the pictures should be taken by lenses of the same focus (say fifteen centimetres).—2. All half-stereoscopic pictures should be the same breadth (say seventy-five millimetres).—3. Whenever possible the focussing point of the lens should be taken at the same distance (about eighty millimetres). When this is not practicable on account of the greater distance, the distance should always be given.—4. The distance of the principal point of the object should be approximately ascertained and given.—5. When the union is not got by the objectives their focus should be given.

Herr ZAPPÉ thought that for distant objects the lenses should be focussed to suit the eyes.

With regard to the controversy on the power of boiled water to absorb air-bubbles,

Dr. EDER said he had never denied that boiled water might be useful in removing air-bubbles from blistered paper, but only that that was wholly due to the great absorbing power of water for air; and in support of his opinion he mentioned the following experiment, which anyone interested in the subject might easily repeat for himself:—Take a watch-glass and tilt it backwards, convex side up, so as to enclose some air upon a vessel containing boiled water; and at the same time place in the same water a piece of blistery paper, according to Baron Szetter's directions. In this last case the air-bubbles will be pretty quickly absorbed, while in the first case a bubble of one cubic cent. would not be absorbed by a litre of water in twelve hours, much less in ten minutes.

Dr. EDER then showed a sample of chrysoïdine and of paper and gelatine coloured with it, remarking that experience only would show whether chrysoïdine would bleach with long exposure to the light.

Several other objects were exhibited, and shortly after the meeting was adjourned.

Correspondence.

M. LAMY'S SUBSTITUTE OF OX-GALL FOR COLLODION AS A TEMPORARY SUPPORT IN THE CARBON PROCESS.—M. DARLOT'S NEW RAPID HEMISPHERIC LENS.—M. BERTHOLET'S DISCOVERY OF PERSULPHURIC ACID.—NEW PHYSICAL OBSERVATORY FOR FRANCE.—AN *OUTRÉ* DEVELOPMENT OF PHOTOGRAPHY.

AT the December meeting of the Photographic Society of France M. E. Lamy communicated the result of his researches for substitutes for collodion in the preparation of glass plates as the temporary support in the carbon process. Amongst the substances he then indicated to form the necessary coating, the last-mentioned, namely, ox-gall, has not since that date, even with new samples, given him invariably good results. The ox-gall he used in December was an old one and smelt very badly, and as long as this lasted it gave him entire satisfaction; but from the moment it was all used, and that he was obliged to replace it with another sample he was unsuccessful. The new gall was fresh and without smell. He then procured a third one, smelling badly; but even with that the result was still not as satisfactory as was desired, for the images creased during the development in the warm water. This irregularity of action was not astonishing, after all, when he found that some samples of ox-gall were acid and others alkaline, and that they were, besides, more or less charged with fatty and albuminous matters. He overcame the difficulty, however, in the end, and he now succeeds regularly in the preparation of the coating for the temporary support with ox-gall.

In ox-gall of about 500 cubic centimetres its two principal component parts are separated by the reaction of 30 c.c. of glacial acetic acid, or by 100 c.c. of strong vinegar, causing a yellow precipitate of acid fatty matter, which is separated by filtration through paper. This filtration is slow, but when it is terminated the filter paper and the filtrate matter is taken from the funnel, placed in a vessel, washed with distilled water, and the whole poured into a new filter paper. He is obliged to proceed in this way, for the washing of the precipitation cannot be either quickly or effectually done by filtration alone, as the first filter paper soon gets clogged up. The deposed fatty matter, after being several times refiltered, is filtered once more—this time with 250 c.c. of liquid ammonia at 22°. All the matter is dissolved, and if the ammoniacal solution be first slightly warmed on the hot sand bath the dissolution is more rapidly effected.

Dissolve in another receptacle one gramme of alum in 250 c.c. of distilled water, which is then added to the ammoniacal solution. The mixture is slightly cloudy, but this disappears by agitation; and thus prepared the solution is ready for use.

When fresh ox-gall is used, and consequently without a bad smell, the precipitation caused by the acetic acid is of a yellow lemon colour, and not very abundant; the filtered liquid is of a fine green. A fresh addition of acetic acid does not cause any additional precipitation; but if the ox-gall has been left to age until it smells strongly, the precipitation obtained is of a greenish-yellow colour and very abundant, and a little acetic acid may be added to the filtered liquid until it is no longer cloudy. When this state is attained the filtered liquid is no longer green, but clear, or slightly yellow. Therefore, to succeed uniformly in the operation, it is desirable to treat the ox-gall in a state of decomposition with acetic acid, so as to remove all the fatty acid matter that it contains.

Before applying the solution on the glass plate it should be filtered, and may be used either in a horizontal tray, as before described at page 605 of the last volume of THE BRITISH JOURNAL OF PHOTOGRAPHY; or, if the operator prefer to pour on the solution like collodion, it will be necessary, in preparing the solution, to reduce by 125 c.c. the water in which the alum is dissolved, and to add instead, when the mixture is made and otherwise ready, 125 c.c. of pure wood spirit or spirits of wine at 36°

The glass plates, when covered, should be dried upon a grooved drying-stand, which may be placed before a fire until desiccation takes place, and without any other preparation the substratum from the moment it is dry is insoluble either in cold or warm water. In this manner any number of glass plates may be prepared in advance, and, when dry, kept, until required for use, in grooved plate-boxes, being thus protected from dust.

This substratum has the remarkable property of holding by adherence under water the exposed bichromated carbon paper, and of retaining the image during the whole time of development with warm or even boiling water; and after the application of the transfer paper and desiccation the separation of the image from the glass is always easy and complete.

M. Lamy still finds the best mode of developing to be as follows:—Take one of the coated glass plates and place in horizontally upon levelling screws; pour upon it a slight stream of water, so that it covers the whole and remains as a pool thereon. The exposed carbon paper is softened in a water tray, and the moment it becomes flat is to be applied, carbon side downwards, upon the pool of water upon the plate; the upper corners of the glass plate and the carbon paper being now pressed together between the fore-fingers and the thumbs, are then raised vertically, the water runs off, and the paper becomes attached to the coating upon the glass without any air-bubbles intervening. Then slightly squeegee and place the glass with the image underneath upon a flat surface, interposing two thicknesses of blotting-paper; after the lapse of fifteen minutes the development may be proceeded with.

The prepared coating as above described will not serve to retain indefinitely the carbon image of portraits or views which are destined to rest upon glass as a permanent support. It is to be feared that the pellicular image would detach itself sooner or later; consequently, for stereoscopic views, lantern slides, transparencies, and windows, the solution must be modified as follows:—The preceding solution, 500 c.c.; solution of well-beaten albumen, one egg in 100 c.c. of water (allowed to settle and decanted).

Up to the present moment M. Lamy has not had leisure to dry the precipitated fatty matter of ox-gall, so as to establish by weight a more precise formula.

M. Darlot has manufactured what he calls a new rapid hemispheric lens, eighty-one millemetres, or three and three-sixteenths of an inch, in diameter, for portraits and landscapes, which, having a much greater depth of focus. replaces the old six inches lens. The tubes by a revolving motion cause the anterior and posterior lens to approach each other when the operator wishes to obtain a bust, and separates them apart when a full-length portrait is to be produced. For landscapes the same lens covers without the least distortion a plate of $28\frac{5}{8} \times 19\frac{1}{4}$ inches.

A New Acid: Persulphuric Acid.—Persons familiarised with chemical nomenclature know that sulphuric acid is a composition of sulphur the most rich in oxygen gas. Its formula is expressed by $S\,O_3$ one equivalent of sulphur for three of oxygen. M. Berthelot has made known to the Academy of Sciences that he has found a compound of sulphur more rich still in oxygen—an acid which he calls "persulpuric acid," of which the formula is S_2 O7, which is two equivalents of sulphur so seven of oxygen. M. Berthelot has obtained this new acid in submitting sulphurous acid to the influence of an electric emanation.

It is announced that M. Bardoux, Minister of Public Instruction, has the intention of shortly presenting to the Chamber a project of law relative to the establishment, in the old palace of Meudon, of a physical observatory, where will be erected a telescope of very great power. M. Janssen, the director of the present observatory, who is now obliged to camp in wooden barracks and under tents, will take possession of the chateau when newly restored. The projected restoration is very ingenious. The two wings of the first story, which were nearly destroyed during the troubles of 1870-71, will be taken down, whilst the *façade* of the middle part will be retained, so that at an expense of £6,800 only will be restored the outside architectural character of this fine monument, whilst the interior will be appropriated to the requirements of the new observatory. The grand telescope, the objective or lens of which will be from $25\frac{1}{2}$ to $26\frac{3}{8}$ inches in diameter, will, it is said, cost £10,000.

One of my friends, just returned from a tour, informs me of the mania of some of the inhabitants of a small town and its environs, not fifty miles from Paris, where a new photographer has recently installed himself, and to attract attention has placed in his glass-case exposed outside his place of business, so as to tickle the palate of the curious, a model portrait *carte* of a gentleman decapitated, and suspended from one of his hands by the hair of his head is seen what should be the seat of his intelligence—his "face divine." This model appears to have brought fortune to the adept in the black art! No fewer than six hundred persons have had the questionable taste to have their portrait taken after this model, a series of changes being rung, such as the husband holding the head of his better half, and the better half shaking with evident delight the head of her lord and master! O! married woman thou hast much to answer for! The *modus operandi* is facilitated by the use of the camera described by me in the pages of this Journal some thirteen years ago, and which has two interior half-shutters, each opening from the middle vertically on pivots between the lens and the sensitive plate. During the exposure one half-shutter conceals half the glass, while the other half is open for the impression of one of the poses, the shadow of the alternate shutters concealing the joint between the two pictures. The most amusing *carte* I have yet seen is a side full-length double view of the same person standing up or sitting down on one side of the picture, showing by facial contortions his sufferings, from the head-rest being clumsily applied by the selfsame individual, who, occupying the remaining half of the *carte*, laughs at his counterpart's pain, caused by his unskilfulness. W. Harrison.

Asnierès (Seine), Paris.

THE GELATINE PROCESS.

To the Editors.

Gentlemen,—Since writing my paper on a new application of gelatine to photographic purposes, I have had sufficient further opportunity for testing the matter to enable me to cancel what I have there said as to the incompleteness of the process, and to assure gelatine workers of its entire success. I have further ascertained that, although the several samples of ox-gall which I had used in the experiments upon which my paper was based were deserving of the epithet of "noisome," the liquid itself, when really fresh, is entirely free from objectionable odour.

My butcher assured me he was supplying me with gall from a newly-killed ox; whereas he was, in fact, favouring me with specimens in an advanced stage of decomposition. Thus, then, this objection to the process vanishes, and there is no need for photographers to depend upon manufacturers for their supply of transfer gelatine. We can make it for ourselves cheaply and effectively, and without the unutterable annoyance to which I myself was subject in my preliminary experiments.

I think it will prove advantageous to diminish the quantity of gall, and to use a few grains of chrome alum with each ounce of gelatine. This will prevent undue expansion of the film, and tend to reduce the yellowness of the resulting negative. I believe, too, that the use of chrome alum, or of bichromate of potash, will enable those who prefer collodio-bromide emulsion processes to employ these home-made sheets with success.

I wish, however, to point out a few of the advantages of the use of sensitive gelatines, and thus to stimulate those who are preparing for the coming season to make a trial of my latest improvement in the gelatine process.

In the first place, nothing can be more simple than the mode of procedure from beginning to end. There can be no such thing as failure to those who have learnt to coat a plate with collodion, can make a gelatine emulsion or dissolve Kennett's pellicle, and are willing to follow the directions I have given. The only difficulty I have met with is readily avoided by the use of a suitable cup for the gelatine. The best vessel that I have used for the purpose is the cup of a child's food-warmer. The lip of this and the slope of the sides enable the operator to pour the gelatine in close proximity to the plate, and thus bubbles are avoided. It is necessary, however, to examine the plate carefully before the film has set; and then if the presence of a bubble be detected it may be at once removed with the point of a knife. I have found that the addition of a few grains of sugar per ounce greatly facilitates and hastens the drying.

In the next place, a gross of quarter-plate sensitive films can be carried with ease in the coat pocket; and I find that the weight of two dozen of them is about equal to that of one glass plate of the same size and of medium thickness. Here is an unmistakable advantage to a photographic tourist, and one which cannot fail to be appreciated by those who have to climb an Alpine pass or peak, and desire to be independent of guides and porters.

And then, further, my gelatines differ from other forms of sensitive tissue—not only in the fact that the process of making them is so simple that the merest tyro may make them for himself, but also that they are rigid. This quality gives the tourist photographer a yet further advantage in that he will be able, if he please, to abolish very much of the heavy timber of his camera and double dark slide of wood, and adopt, instead of the latter, a simple pasteboard slide.

I am employing some of my leisure time in devising a form of cardboard dark slide to carry my new films, which, in combination with Mr. Woodbury's scenograph, will reduce the *impedimenta* of the photographic tourist to the very minimum of bulk and weight.—I am, yours, &c.,

Wallasey, February 11, 1878. H. J. Palmer, M.A.

BALLOON PHOTOGRAPHY.

To the Editors.

Gentlemen,—Since writing my communication last week, under the head of *Balloon Photography*, I have received letters from Mr. Warnerke and also from a friend in St. Petersburgh, to whom I had written on the subject. Both these communications tend entirely to exonerate Mr. Warnerke from the imputation which anyone would have gathered from the letter of Dr. Vogel, which had already appeared in several journals, and which must have been the result of some misunderstanding on his part.—I am, yours, &c., Walter B. Woodbury.

Manor House, South Norwood, February 11, 1878.

THE FERROUS OXALATE DEVELOPER.

To the Editors.

Gentlemen,—We have much pleasure in giving our testimony to the value of the ferrous oxalate developer for dry plates, given to the world through your columns by Mr. W. Willis, Jun.

Being very rapid and energetic in its action when employed at full strength, we deem it well to caution those who employ it for the first time to wash the plate with more than usual care after moistening with methylated spirit, or markings and uneven development will be the result. According to our comparative trials with it up to the present time its power is greater than that of carbonate of ammonia in saturated solution or of liquor ammonia of *usable* strength; and one of its best features is almost a total absence of any tendency to cause fog.

We have just received from Mr. William Cobb, of Woolwich, prints from negatives taken professionally in the studio with our "B" washed emulsion developed with ferrous oxalate, and which were better exposed than wet plates which had the same time given them. The quality, you will observe from the enclosed, is all that can be desired.

We hope the new developer will have a fair trial from all who take an interest in dry-plate photography.—We are, yours, &c.,

February 11, 1878. Wratten and Wainwright.

IMPROVEMENTS IN CARBON PRINTING.

To the Editors.

Gentlemen,—Permit me, thrfugh your columns, to assure the gentlemen of the Autotype Company that they have as completely misunderstood the spirit and tenor of my last letter as they have those of my article in your Almanac. In neither is there a word to disparage themselves, their accuracy of statement, or their productions. Their error arises from the misconception of the somewhat dubious term "recent period," which they persist as understanding to mean "present time." A simple perusal of my article will prove that this was not my meaning, inasmuch as I give authority for my statement by quoting, or endeavouring to quote, the fifth edition of their *Manual*, and the authority cannot extend beyond the time at which the words quoted were written.

Permit me again, in spite of the repetition, to state in more precise terms the only propositions affecting the Company in that article, and my object in writing it. We are all emulous of doing our best to render the autotype process more perfect and practicable.

Having seen weekly announcements of the Autotype Company's progress in permanent tissue-making I was desirous of putting on record the result of my own labours during the past year in the same direction; hence the article which has given such unreasonable offence. I said, or would have said had the *Manual* quoted been before me:—

1. Up to a recent period, certain desirable colours could not be obtained in pigment paper without the use of cochineal—a more or less fugitive colour. This is admitted and recorded in one of the later editions of the *Manual* of the autotype process, 5th edit., p. 82.

2. I have succeeded in solving this problem by the use of alizarine combined with alumina and some other base not affecting the solubility of gelatine.

Where is the offence? The only possible way in which the Company can be affected by my claims is that the process which I have patented should have proved to be identical with that which they employ; in which case I should still have claimed priority, inasmuch as a secret use of any process is not received in evidence either in a court of law on a question of patent right, or in a court of honour as a question of priority of discovery or invention, prior publication being universally received as the test of priority of discovery.

But this point has been set at rest by the editor of the *Manual*, who states that my patent may be good when I have disclaimed Wenderoth's process; our processes are, therefore, not identical.

Trusting that the explanations I have given will be satisfactory to all aggrieved—I am, yours, &c., J. R. Johnson.

February 12, 1878.

Photography in Court.—*Photographers and Celebrities: The London Stereoscopic and Photographic Company* v. *Stanton.*—This case was heard on Friday last, the 8th inst., at the City of London Court, before Mr. Commissioner Kerr. It was a claim for £5 for work done. The defendant pleaded never indebted. Mr. Weatherfield appeared for the plaintiffs, and called Charles Hunt, in the service of the complainants, who stated that the defendant ordered 187 photographs of himself in professional costume, as the champion bicyclist. The photographs were duly delivered, and afterwards witness applied to the defendant for payment, who promised to call at the complainant's office in Cheapside and pay for them. At the same time he said he had only received 150, and the value of that number was now claimed. Stanton, who appeared in person, denied giving the order. He said Mr. Walker, the agent of the company at the Alexandra Palace, called on him, and asked him to sit for his photograph. He complied with the request, and sat in seven different positions, the understanding being that he was to have a monetary advantage therefrom.—The Commissioner: In what way are you a celebrity? Stanton: I am the champion bicyclist, your honour.—The Commissioner: You say you were called on to sit for your photograph as a bicyclist? Stanton: Yes, your honour. They came after me several times, and it was understood that I was to have something for my sitting.—Mr. Weatherfield said it was usual for the company to give celebrities a dozen *cartes* for themselves. In this case the defendant had been allowed thirty-seven.—Stanton: Do you think I was going to let the company sell my photograph all over the world for a paltry gift of thirty-seven to me? What is the worth of such a number to me? (Laughter).—The Commissioner said there was a flat contradiction on both sides, and it was a case that he thought a jury had better decide. He should adjourn it for that purpose to a future day.—Stanton said he was under articles to ride his 1,000 miles race, and asked that in consequence the case should not come on before March 2nd.—The learned Commissioner complied with the request, and ordered the case to be adjourned till some day after that date.——*Assaulting a Wife.*—Henry Poole, a photographer, of 775, Commercial-road, was brought before Mr. De Rutzen, at the Thames police court, on Wednesday, the 6th inst., charged with committing a violent and unprovoked assault on Mary Poole, his wife.—Mr. W. Moore, the prosecuting officer of the Associate Institute for Improving and Enforcing the Law for the Protection of Women, watched the case; Mr. May, solicitor, appeared for the prisoner.—The complainant, who had a severe cut on the side of her nose, proved that defendant struck her a violent blow on the side of her nose, and rendered her nearly insensible. She lost a great deal of blood, and could not stop the bleeding for two hours. Defendant was sentenced to two months' hard labour.

EXCHANGE COLUMN.

No charge is made for inserting these announcements; but in no case do we insert any article merely *offered for sale*, that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a *nom de plume* be thought desirable), otherwise the notice will not appear.

For exchange, a pair of dissolving-view lanterns, with oil lamps and three-inch condensers, in neat box. What offers? Want a small portable camera and stand for dry plates.—Address, F. M. S., 30A, Flowergate, Whitby.

Portable glass-house, 22 × 10 feet, and tent, 11 × 18 feet, covered with unbleached calico, offered in exchange for bellows camera and doublet lens; also, glass-house on wheels.—Address, F. Hamblen, Dobwalls, Liskeard, Cornwall.

Landscape background, by Claudet and Houghton, 8 × 7 feet, cost 37s. 6d., never been used; How's tent and tripod stand, in good condition, but stained, cost £6; in exchange for useful studio accessories. Photographs exchanged.—Address, Geo. Avery, Tonbridge.

$7\frac{1}{4} \times 4\frac{1}{2}$ landscape camera with swing back, wet slide, and changing box; changing box for stereo. size, Smartt's dark tent, opal printing-frame, magic lantern by Dancer, Malden dissolving tap, Fletcher's aspirator, Fletcher's large-size foot blower, Gore's gas furnace, pair lantern objectives (portrait combinations), and lead hydrogen generator. All or any of the above apparatus will be exchanged for scientific apparatus, &c.—Address, W. J. Chadwick, Moss Side, Manchester.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

Lieut. Lysaght.—Thanks. In our next.

J. Cowell.—Received. Thanks. In our next.

Newnham.—The gentleman you name is not now a manufacturer of photographic lenses.

B. L. L.—By a ten-per-cent bath is meant one containing one part of silver to ten parts of water.

T. S.—Unless a special agreement has been made to the contrary the negatives must be held to be your own property.

Historicus.—You are mistaken; we have invariably recognised the right of inventors to secure their inventions by patent.

XYZ.—The process must be looked upon with great suspicion. Its results are not at all permanent—a fact of which we have had but too good proof.

Old Reader.—If your architect will put himself to a little trouble in studying the light required for a studio he will soon be able to set matters right.

Alpha.—By using a much weaker solution of tannin softer effects will be obtained. Try a solution containing not more than six or eight grains to the ounce.

Boomerang.—Try the effect of making the toning bath with six grains of sulphocyanide of ammonium to one grain of chloride of gold. This quantity will suffice for four or five ounces of water.

T. C.—A "drop" is a very unsatisfactory degree of measurement, for drops vary according to the nature of the liquid. The terms *minim* and *drachm* are definite and satisfactory, and ought to be employed by you.

Veritas.—We shall look into the matter. It is a question upon which, from the practitioner's point of view, we are not likely to be much enlightened by appealing to practical operators, as we are not aware of any who now employ the process.

W. E. C.—This correspondent asks if any reader of this Journal will inform him what is the *best* book on landscape photography that has been published. For our own part we are not aware of any book that is specially devoted to that subject.

J. Wilson.—Seeing there are so many methods by which opalotypes can be produced, it is quite impossible for us to answer your question—"How are opalotypes made?" To give a general answer: they are made by means of wet collodion, dry collodion, silver printing, and carbon printing.

Jas. Scott.—Try the method, described in our Almanac for the present year, of first producing a large transparency the demensions of the desired enlargement, working upon it with a pencil, and from it obtaining, by superposition, a negative to be employed in printing the enlargements direct.

Chemicus.—It is probable that the phantom image that has appeared on your plate is owing to your having made use of an old plate from which the former picture had not been thoroughly removed. By cleaning the glass thoroughly and making use of a substratum you will no more be troubled with such ghostly figures.

Bristoliensis.—While a French-made camera will answer the purpose, it will not give such an amount of satisfaction as one of English manufacture; and for this reason we cannot advise you to make the contemplated purchase. There are several branches of manufacture in which the French greatly excel, but we cannot in that category include either cameras or lenses. In these our English makers stand unrivalled.

A. Bennett.—Your proposed plan is good. As it stands at present the feet of a standing figure might be rather imperfectly illuminated, but this can easily be obviated by making use of a small platform about twelve inches in height. Twenty-one ounce glass will be quite strong enough. Common Belgian sheet will answer well, and is moderate in price.

T. Nicholls.—Mr. Breese was a photographer—half amateur, half professional—in Birmingham for a considerable period, but a few years before his death he removed to Sydenham, near London. As you will see from what has been published with respect to his photographic works during the past three or four weeks, his *spécialité* lay in stereoscopic transparencies.

Pyro.—The work is most excellent considering the short time which has elapsed since you first commenced to practice photography; but you have much to learn yet ere you become qualified to take portraits professionally. We advise you to pay a premium to some photographer in good practice, and secure the advantage of a few months' constant employment in the studio.

L. S. D.—It is quite true that the focus of a lens is an uncertain quantity, as it depends upon the distance at which the object to be depicted is situated from the lens. When "focus" is spoken of the object is understood to be at a great distance—as the sun, for example. But it would needlessly encumber our phraseology if this were to be explained every time one spoke of the focus of a lens; hence the *solar* focus is always understood. When the object to be reproduced is situated within a short distance—say a few feet—of the lens, the relation of the object to the lens, on the one hand, and the lens to the ground glass, on the other, is known as the conjugate focus.

A Member wishes to be informed by what kind of objective Mr. Viles took the large microphotographs with respect to which he made some observations at the meeting of the Photographic Society of Great Britain on Tuesday evening last. We reply: Mr. Viles, as was stated in his paper read at the January meeting, makes use of the ordinary microscopic objective, the chemical focus of which is previously made to coincide with its visual focus by means of a double-convex lens of low power (a spectacle glass being usually employed for this purpose) placed at the posterior end of the objeetive. The precise strength of glass required for this special purpose can only be ascertained by experiment, as the same corrector will not necessarily answer for two objectives of precisely similar focus. If you have access to former issues of The British Journal Photographic Almanac you will find articles devoted to this special subject.

LONDON GAZETTE, *Tuesday, February* 12, 1878.

Public Examination.

February 25.—E. Williams and W. Singer Suoden, Exeter, photographers.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician.

For the Week ending February 13, 1878.

These Observations are Taken at 8.30 a.m.

JOURNAL OF PHOTOGRAPHY.

No. 929. Vol. XXV.—FEBRUARY 22, 1878.

ON THE ACTION OF OXIDISING AGENTS UPON THE UNDEVELOPED IMAGE.

In the course of our experiments with the various agents mentioned by Captain Abney as capable of destroying the latent (or undeveloped) image upon bromide of silver films we have partly gone over the ground suggested last week by Mr. Herbert B. Berkeley, inasmuch as we have examined the action of those substances upon the *visible* image produced by prolonged exposure to light. The general result tends to prove that the difference between the visible and invisible images is merely one of degree, and not, as it has been supposed by some, the issue of distinct reactions; but, though the various agents act uniformly in destroying the latent image, we have found so wide a difference in their behaviour in other respects as to raise a doubt in our mind as to whether the effect is identical in each case; that is to say, whether the removal of the image is really performed by virtue of the power of oxidation.

Before proceeding further we may allude to something we have already written (*ante*, page 47) with regard to the action of potassic bichromate. It will be remembered that we sought to utilise that salt as a fog-remover in an emulsion containing free silver, but that it rendered the latter absolutely insensitive, notwithstanding that when applied to an unexposed film it exhibited no such desensitising effect if washed off previous to exposure. In searching for the explanation of this anomaly we have, we believe, succeeded in tracing it to an unsuspected source—the employment of cadmium bromide in the decomposition of the chromate of silver. This would result in the formation *in the emulsion* of insoluble chromate of cadmium, which is the cause of the loss of sensitiveness. Solutions of bichromate of potash and bromide of cadmium may be mixed without suffering decomposition; but if oxide of cadmium be treated with solution of potassic bichromate an equivalent of chromic acid goes to the cadmium, forming a yellow precipitate of chromate of that metal, and leaving chromate of potash in solution.

If, now, we add a few drops of the bichromate solution to an emulsion containing excess of cadmium bromide no decomposition ensues, and all traces of the bichromate may be removed by washing; but if we add sufficient silver nitrate to decompose the free bromide and leave a slight excess we shall have chromate of silver formed. If the latter be now decomposed by cadmium bromide the chromic acid goes to the cadmium, and we thus obtain an emulsion indistinguishable as regards colour and general appearance from an ordinary one, but containing chromic acid in an insoluble form, and, therefore, incapable of removal by washing. The *rationale* of the desensitising action of this substance in emulsion is not very clear; but we may suggest that two atoms of bromine liberated by the action of light from four atoms of silver bromide (assuming the sub-bromide theory of the formation of the latent image) combine with the cadmium, setting free the chromic acid and oxygen. The latter then seizes the two loose atoms of silver of the sub-bromide, forming oxide of silver, which in turn is decomposed by the chromic acid with formation of silver chromate, the chromic acid eventually going back to the cadmium by direct decomposition, thus:—

$$\begin{aligned} 2\,Ag_2\,Br \times 2\,Br \times Cd\,Cr\,O_4 &= 2\,Ag_2\,Br + Cd\,Br_2 + Cr\,O_3 + O. \\ &= 2\,Ag\,Br + Ag_2\,O + Cd\,Br_2 + Cr\,O_3. \\ &= 2\,Ag\,Br + Ag_2\,Cr\,O_4 + Cd\,Br_2. \\ &= 4\,Ag\,Br + Cd\,Cr\,O_4. \end{aligned}$$

That free bromine is capable of decomposing cadmium chromate we have satisfied ourselves by experiment; but such calculations as the above still leave open the question as to why the liberated bromine should show greater activity in combining with foreign matter than with the loose atom of silver of the compound from which it has been ejected. This, indeed, forms the chief obstacle in the way of our complete acceptance of the sub-bromide theory, and we can only assume that the foreign matter acts by a species of catalysis. It will be noticed in the above equation—and the same may be said if the potassium bichromate be substituted for the cadmium salt—that the chromic salt suffers no permanent change; and this fact, if taken in connection with other circumstances and with the behaviour of potassic permanganate, tends rather to support the sub-bromide theory than otherwise.

Recognising the possibility that the latent image and the visible impression produced by prolonged exposure to light might be caused by different reactions, and taking it as an accepted fact that the colouration produced in the latter case arises from the formation of sub-bromide, we undertook the examination of the various changes brought about by oxidising agents upon emulsions and films thoroughly reduced by exposure. Our first experiments were made with an emulsion in which the reducing action of light had been carried to the fullest possible extent. It was precipitated in the presence of a slight excess of soluble bromide, washed, and dried, the resulting powder brought to a state of extreme fineness and exposed to full daylight for several hours, precautions being taken to bring every portion of it under the light's action. When uniformly darkened to a dull slate colour it was re-emulsified, when, as the normal yellow colour partially returned, the emulsion was again exposed to light until, upon thorough shaking, no alteration in its appearance was noticeable.

It is well known that when an ordinary emulsion is exposed to daylight for a sufficient length of time to discolour it a vigorous shaking almost entirely removes the discolouration; and, except in the presence of excess of silver, it is almost impossible to produce a permanent reduction throughout the whole body of the emulsion. The outer portions only appear to be reduced, and when shaken up again it would appear that the ejected bromine rapidly recombines with the loose atom of silver, removing the discolouration. In the case of the emulsion we have spoken of above it may be remarked that a comparatively brief exposure sufficed to produce the maximum of discolouration, and, that point attained, there seemed to be no tendency to go back to the normal shade. We mention this because it may possibly explain the discrepancies between the behaviour of the emulsion and the exposed films of which we have to speak; in point of fact it appears more than probable that, during the several hours' exposure to light which the dried emulsion underwent, the bromine was not only *disengaged* but actually dissipated, and thus the final emulsion, being deficient in bromine, was incapable of resuming its original state under the action of the various oxidising agents. Contemporaneously with the preparation of this emulsion we exposed another containing free silver until it ceased to change colour upon shaking. In this case the change was rapid, occupying only about a couple of hours.

Each of these emulsions was then divided into two parts, which were treated respectively with potassic bichromate and potassic permanganate in saturated solution. Ten drops of each solution in one ounce of emulsion (dropped from a glass rod) were added—as large a quantity as the emulsion would conveniently bear. In the case of the first-named, or neutral emulsion, no immediate change was evident with either reagent; but the other produced with potassic bichromate the deep red colouration of chromate of silver, and with the permanganate a dirty brown. A solution of bromide of ammonium in weak alcohol was then added to the emulsion containing chromate of silver until the red colour was removed, and an equal number of drops were also added to the permanganate sample. Here the first difference was noticed. The portion treated with bichromate assumed, after the neutralisation with bromide, the ordinary slaty colour produced by exposure to light, while the other exhibited a yellowish-drab shade; beyond this there was no further change apparent for several days.

After standing more than a week the two portions of neutral emulsion were quite unchanged in colour. We then added to each two grains of ammonium bromide in crystals, shaking well until solution was effected; still no change occurred, but after standing undisturbed for about an hour a distinct difference was noticeable in the colour of the two samples, the bichromated one having become lighter. After three or four days the maximum change appeared to have taken place, and the colour became stationary, the portion treated with bichromate exhibiting a yellow colour—not the pure shade of an ordinary emulsion, but a greyish-buff tinge—the other a yellowish brown. The two remaining samples, after standing about a week, deposited the whole of the suspended matter, the clear liquid in the case of bichromate being steel-blue, and in that of permanganate rich brown. The deposit in the one case was of a dirty green shade, in the other yellowish or drab, and when shaken up the same colours remained.

It is needless to say that none of the four samples are in workable condition, nor do they offer any probability of ever being so; the action of the oxidising agents upon the organic matter of the collodion appears to mask any other effects, while the severity of the mode of preparation would seem to be too great. The green colour mentioned in connection with one of the samples would point to the formation of one of the oxides of chromium, while the yellowish-brown colouration exhibited by both the samples treated with potassic permanganate arises no doubt from oxide of manganese, and probably sub-iodide of silver.

The emulsion experiments having for our purpose proved fruitless we next turned our attention to films thoroughly reduced by exposure to light. In addition to the two oxidisers already spoken of we employed dilute nitric acid also (equal parts of acid and water). The plates, after exposure to bright daylight for five minutes, were immersed in the different solutions; but by this method we found it difficult to judge, in the yellow light of the developing room, whether any change had taken place, except in the case of nitric acid, which had produced a distinct alteration in colour. We next placed an exposed plate upon a levelling-stand and dropped upon it a few drops of each of the reagents, so as to form three small pools in close proximity for convenience of comparison. The oxidisers were left to act for five minutes; the plate was then inclined and the solutions allowed to run off, and a stream of water from the tap directed upon the film in such a manner as to wash off the surplus without allowing the different agents to commingle. After allowing the plate to soak for two or three minutes, in order to remove any traces of the bichromate and permanganate, the film was examined. By reflected light the portions which had been acted upon by the oxidisers were plainly visible. Nitric acid had apparently *almost* removed the discolouration, the other two had produced a change; but whether it was a partial removal of the sub-bromide or an alteration in the colour of the film it was impossible to tell. By transmitted light, however, the mark left by the permanganate appeared considerably denser than the remaining portions of the plate, while the bichromate had left a faint trace of the same description. After treating the film with hyposulphite of soda the permanganate stain remained distinctly visible as a greyish-brown deposit, the rest of the plate being quite clear.

Now, here was very strong evidence not only of oxidation of some sort, but of a very distinct difference in the action of potassic permanganate as compared with the other reagents. In order to test whether the oxidation was performed solely at the expense of the sub-bromide we treated an *unexposed* film with bichromate and permanganate. After a thorough washing a distinct brown stain remained from the latter, but no trace appeared of the action of the bichromate. The permanganate stain remained after treatment with hypo., but not so well marked as upon the exposed plate. We next treated a *plain* collodion film with permanganate, and the result was a faint transparent brownish stain entirely different from that produced upon a film containing silver bromide. It would appear from this that the permanganate acts not only upon the sub-bromide but also upon the pyroxyline and *the organic silver compound* contained in the emulsion; the bichromate is apparently free from the two latter actions.

From this action of the permanganate upon an unexposed film it appeared not improbable that it should exert an important influence upon the sensitiveness of the film so treated. Accordingly we prepared a plate, washed it, flooded it with permanganate, again washed thoroughly, and dried without organifier. Exposed under a transparency it gave *not the slightest trace of an image.* Another plate was prepared, one end being treated with bichromate and the other with permanganate, the middle portion remaining untouched. Exposed for half as long again as we judged necessary for the centre of the plate, that portion and the bichromated end showed not the slightest difference in result, while the permanganate end remained blank. The development was continued until the picture became almost buried; but the only result upon the part of the film treated with permanganate was a uniform reduction (or fog) without a trace of an image.

It only remains to be said that these experiments were performed with saturated solutions; when the strength was considerably reduced the effects produced were similar but less marked. As a destroyer of the latent image the permanganate is much more powerful than the bichromate, and must, therefore, be used more sparingly.

We may observe, in conclusion, that these results do not in any way clash with those of Captain Abney, as that gentleman employed very weak solutions while we have worked with strong ones. The deductions we arrive at are that the action of potassic permanganate differs entirely from that of nitric acid or potassic bichromate. The two latter, we think, oxidise *temporarily* the loose atom of silver of the sub-bromide, and bring it within the influence of another power, while in the case of permanganate simultaneously with the action upon the sub-bromide occurs another—the oxidation of the organic constituents of the film. It seems to us that any agent which produces a permanent alteration in the composition of the sensitive film is unsuitable for use as a fog-remover.

THE PROGRESS OF PHOTOCHROMIE.

It is always interesting to note the progressive development of a process—to observe its gradual growth from inception to completion, if indeed it be safe to apply such a term to anything in connection with photography. This is in a peculiar degree the case with the photochromic process of M. Leon Vidal, which we have watched with friendly interest ever since a few crude specimens of the then undeveloped process were placed in our hands several years ago for the purpose of being exhibited at the Bradford meeting of the British Association. These specimens consisted of a number of transparent pellicles each containing a small portion, in one colour, of a picture, or, more correctly, all the portions of the picture that had to be produced in one colour. On one pellicle were all the reds, upon another the blues, and so with the yellows, the flesh tints, and soforth. The finished picture was composed of these pellicles set off in rotation upon white paper.

This method of building up a picture in colours was exceedingly troublesome and necessarily expensive; and it was felt by many that the ingenuity demanded far exceeded the chances of the process being matured into a practical industry. Since that time, however, M. Vidal has effected a complete change in his method of producing photochromes, and their manufacture, if such a term be applicable to works of art, is now being proceeded with commercially.

Having being apprised by M. Vidal that he had established an agency at 33, Southampton street, Strand, we lost no time in calling upon M. Vidal's representative, Mr. Hore, who has on exhibition at the address indicated a collection of photochromes so choice as to elicit expressions of unqualified admiration from all who have seen them.

If we correctly apprehend the method by which these pictures are now produced, it is as follows:—As many negatives are taken as there are colours in the subject to be reproduced in photochromie. From each negative is stopped out, by means of opaque varnish, every part except that which is required to be a certain colour, such as neutral, green, red, blue, or yellow, each negative representing only one of these or other colours. Lichtdruck plates are now prepared, one from each of such negatives; and as each plate is capable of printing its own special colour with all the delicate gradations of tone, from the faintest manifestation to the most intense rendering, very charming and natural effects may be obtained. The picture which is being printed receives an impression, in turn, from each of these collographic-printing surfaces, and when it has passed the last of these every portion of the subject will have been impressed.

Chromolithography is naturally suggested by this mode of proceeding; but this kind of photochromie differs from chromolithography, inasmuch as, while the former possesses all the advantage secured by correctness of registration of the colours, and the production of secondary and tertiary tints by the overlapping of those represented by special negatives, it possesses the further and immense advantage that each tint possesses in itself the smoothness and graduation of a silver photograph. The technical smoothness of photographic monotone is here *plus* colour; and these colours may be of any degree of brightness or sombreness thought desirable. The truthfulness and fidelity is that of a photograph, while the brilliancy of colour and permanence are those associated with the printing inks made use of by the chromolithographic printer.

In the representation of articles in steel, silver, and gold the Vidal polychromes are marvellous. How are they produced? Our opinion is that in this department of photochromatic practice will be found at once the most effective and the simplest application of the new art. Suppose such an article as a shield, a helmet, or other piece of *repoussé* work in steel, is the subject to be represented: the ground upon which it is to be printed must be either silvered or tinned by methods known to workers in bronze powders. Upon this the design is printed, collographically, in monotone, the background obliterated by opaque ink, and the thing is at once done. An imprint of a transparent yellow or "aurine" colour upon this converts any desired portions of it into gold or brass, as the case may be.

By stating that such effects may be produced easily we are so far from detracting from the merits of the process that we thus bestow upon it the highest commendation in our power. In order to demonstrate how very successfully the process is carried out we may refer to the shield of Henri II., in steel, and to the casque of the same monarch, which bear examination through a magnifying-glass without dispelling the charm of the first impression. The royal sceptre of Charlemagne is in gold, and contains a fine display of precious stones, for the representation of which M. Vidal's system of polychromie seems to offer peculiar advantages.

Examples of this class of work have already been exhibited at meetings of both the London photographic societies; and we are assured by the agents of the society under whose auspices they are published in this country that they will have pleasure in exhibiting them to all who choose to call for that purpose at the address given in a previous portion of this article. Societies in provincial cities and towns are already aware that every facility is afforded to them for examining these the latest novelties in the art-department of photography.

RECTIFYING THE BATH.

We have lately, in treating upon the use of the double bath for dipping plates, stated that it is quite possible to work a bath down till it is almost all used without any necessity for tampering with it in any way, either strengthening or sunning, except an occasional pouring in a large dish to get rid of alcohol and ether. We still adhere to this principle of practice; yet, of course, we know that through accident, carelessness, long disuse, and a variety of causes, it is quite possible for the bath to get disordered and require rectification in some manner. To accomplish this—which means, in effect, to get rid of some obnoxious substance—there are three courses open:—First, to dissipate easily volatile matter by means of spontaneous evaporation; secondly, by means of boiling to rid the silver of a portion of the water and most of the alcohol and ether; and, finally, by means of sunning to precipitate nearly all foreign matter, volatile or solid, by precipitation.

In nine cases out of ten where boiling and sunning are resorted to we are assured that simple laying aside for a day or two in a clean shallow dish will answer all purposes, due precautions being taken to prevent the access of dust. When a bath streaks and stains the plate in the direction of the dipping or the draining the irregular marbled appearance does not necessarily signify that the bath is chemically wrong; it merely indicates that, through what might be termed the "mechanical action" set up through the fluids of different densities—the ether and the ether-saturated bath—not thoroughly mixing, and also through the surface tension being too rapidly and irregularly altered, the deposit of silver takes place unevenly when the mixing is incomplete, or when, through evaporation, the surface tension is brought to an abnormally unequal state. A plate prepared in an old bath, placed in the dark slide for a minute, and then developed after a moment's exposure to the open window of the dark room, will show streaks, stains, and mottling, but rarely fog; yet, if developed immediately upon removal from the bath after a similar exposure to light, it would be almost, if not quite, as clean as a plate prepared in a new bath. A bath so out of order we should term "mechanically deranged"—a state quite different from that which will not allow of a picture being taken under any circumstance without both fog and stains. Such a bath we should term "chemically wrong," and unless the exact cause were known sunning would be the treatment for it.

We have found that by leaving a bath for two days for spontaneous evaporation, in a dish large enough to admit of the solution being no greater depth than half or three-quarters of an inch, nearly the whole of the ether and alcohol will be removed—quite as much as is necessary for all practical purposes. A good portion of the water, also, will have been dissipated into the air, so that it will be quite necessary to ascertain the strength, and make up with water before using. The old method was, after calculating the amount of water required, to put it into a separate vessel and add a portion of the bath to it, and then, after filtering the precipitated iodide, to mix the two solutions together. For those who do not care to try the nitrate of baryta plan this mode of treatment is still to be recommended, there being no doubt that the precipitation of a portion of the iodide in this manner usually gets rid for a while of a tendency to pinholes, though there have often been cases where complaints have been made to us that this treatment has not succeeded.

It is to be noted that a double filter is always necessary in filtering a solution containing precipitated iodide of silver, the particles being so fine that they pass through paper of the closest texture. Even after filtration we have often found that it has been needful to add a few crystals of silver to entirely remove the opalescence.

The second mode of treatment is more troublesome, entailing the use of an expensive evaporating dish and careful attention during the process lest the evaporation proceed too far and the dish should get broken, as it is liable to do, if the bath boil till dry, unless the heat be carefully regulated. The only advantages of the boiling method are the more speedy removal of the ether and alcohol, though even after an hour's boiling they are not entirely removed. The tenacity with which volatile liquids dissolved in water cling, as it were, to it is most remarkable.

In our own experience with boiled baths we have usually found that they give hard pictures, even with a maximum of exposure, and that they also generally work slowly. We, therefore, when we have boiled a bath, have generally proceeded to sun it without any trial of its qualities. We made a series of experiments some time ago upon baths so treated, and then dialysed into pure water. We obtained not the slightest benefit by the process, much to our disappointment; for we had formed the theory that the substances giving the hard and foggy quality to the bath were likely to be among the colloids—a theory which was further rendered probable by the appearance of the liquid in the dialyser, which, when filtered, was of a deep straw colour; but, as we have already said, no benefit accrued from the use of the method.

Finally: there is the sunning, which we think is only necessary in a limited number of cases. It has been so often described that little can be added to our knowledge of the process. We may, however, remark that the end to be attained is brought about most quickly by rendering the bath decidedly alkaline by means of ammonia. We have not found it sufficient simply to neutralise, the clearing then being slow and less complete; five drops of ammonia beyond the point of neutralisation is the quantity we have usually added to half-a-gallon (or a Winchester quart) of solution when making use of the sunning process. When the light is good and the sun well out a few days will see the solution quite clear, with a thick black deposit at the bottom, no further exposure to light causing any alteration in the appearance of the liquid. The bath, then, being alkaline has to be brought to a working degree of acidity, and this has to be done *after* filtration.

With a quantity not larger even than a Winchester quart this is a very tedious process, as a thorough shaking, followed by a few minutes' rest, has to be given between each addition of acid, and testing with litmus paper, to ensure its thorough distribution. The plan we have found to save a considerable loss of time has been to keep two separate bottles of diluted nitric acid and ammonia, of such a strength that equal quantities of each exactly neutralise one another. All that is required after sunning and filtering is merely to put in as much acid solution as there was added before sunning of the ammonia solution. The amount of ammonia absorbed during the precipitation is very slight, one extra drop of acid being more than its equivalent, so that the acid solution required should be diminished to that extent.

Failing the adoption of this method, it will be found easier to take only a part of the bath—say one-fifth—and neutralise it, which will be done far more readily than if the whole quantity were so treated; the acid required to neutralise this portion being multiplied by four, gives the quantity needed for the remainder of the half-gallon.

SILVERING GLASS SURFACES.

The growing importance of reflecting surfaces for optical purposes renders it desirable that we should keep our readers well informed as to every development of the art of silvering glass. Mirrors silvered on their outer surface are, we need scarcely observe, now being extensively employed in the production of reversed negatives for various purposes in photography, the reversing prism having in most instances been superseded by the surface of silvered glass.

The method we have employed for several years is one with which (thanks to the lucid directions given by Mr. H. J. Burton in our Almanac for 1873) we have never experienced a failure. Further modifications—all tending to impart a greater degree of simplicity and certainty to the process—having been discovered by Mr. Burton, he embodied these in a second article on the subject in our Almanac for 1876. From that article we give the following extract, showing the manner of preparing and using the various solutions:—

Solution 1.—

Nitrate of silver	25 grains.
Distilled water	1 ounce.

Solution 2.—

Potash (pure)	25 grains.
Distilled water	1 ounce.

Solution A.—

Solution 1 } Solution 2 }	equal parts.
Ammonia	to *just* dissolve the precipitate.
Solution 1	to just cause a discolouration.

Solution B.—

Loaf sugar	2700 grains.
Distilled water	20 ounces.
Nitric acid	2 drachms.
Alcohol (strong)	10 ounces.
Distilled water—to make	80 ,,

For Use.—

Solution A	1 ounce.
Solution B	1 drachm.

"In preparing solution A do not be deceived at the time of adding the ammonia, as a little of the precipitate will not dissolve. If the liquid be clear sufficient has been added.

"*Precautions to be Observed in Carrying out the Process.*—Keep the solutions and dishes always in a warm room, or the deposit will be thin and black, instead of stout and bright. Dust the mirror after cleaning, and also the dish before pouring in the solution, or there will be a quantity of pinholes. Well mix the solutions before using, or the surface of the mirror may be mottled. Remove the mirror from the dish as soon as all the silver is deposited, or a bleaching action will commence. It may be known when the silver is all down by gently removing a little of the scum from off the surface of the liquid with a piece of paper and observing if the solution be clear; if so, the deposition has ended. Upon its removal from the dish the mirror must be well washed and dried off quickly upon blotting-paper, and finally warmed to about the same temperature as a negative that is about to be varnished with spirit varnish; and while still warm it should be polished. A little care is necessary when the polishing is commenced, and three soft and dry wash-leather pads should be made, kept separate, and marked Nos. 1, 2, and 3. No. 2 can be charged with the finest rouge, and beaten out again; the other two require no further treatment. Gently pass pad No. 1 in circular strokes over the newly-silvered mirror for five minutes, then pad No. 2, till properly polished, and finish off with pad No. 3. Keep the pads in tin boxes, and quite dry.

"While a mirror is in use it requires to be frequently polished—say twice a week. Never let it get tarnished. Use the pads in the order as given above, and do not forget to warm the mirror before using the pads. Keep the mirror covered up when not in actual use."

As respects the keeping properties of these solutions Mr. Burton finds that A is subject to a slow decomposition, the silver being deposited upon the sides and bottom of the bottle. On this account he prefers keeping the potash and the silver in two separate solutions. With regard to the other he says:—

"Solution B, on the contrary, certainly improves by keeping. I am using some that is seven months old, and it works admirably. In using grape sugar as the reducing agent I have succeeded very well; but it is not so certain as my solution B, nor does it keep so well in solution.

At the last meeting of the Photographic Society of Great Britain Captain Abney referred to a process of silvering he had employed with great success, by which, using the most ordinary care, he said it was impossible not to succeed. From Captain Abney's description of his method of working, given in the last number of the *Journal of the Photographic Society*, we make the annexed extract:—

"The following is the formula given by Martin:—

No. 1.—	Silver nitrate	17·5 grains.
	Water (distilled)	1 ounce.
No. 2.—	Ammonium nitrate	26·25 grains.
	Water (distilled)	1 ounce.
No. 3.—	Caustic potash free from Cl and CO_2	4·4 grains.
	Water (distilled)	1 ounce.

No. 4.—Dissolve 44 grains of sugar in 10 ounces of distilled water, add 5·3 grains of tartaric acid, and boil for 10 minutes. Next add 2 ounces of alcohol, and add sufficient water to make up to 20 ounces if the silvering is to be done in winter, or to more if it is to be done in summer.

"The effect of tartaric acid in the sugar is to produce inverted sugar, which reduces the silver from the mixed solutions.

"In my own practice I use about 31 grains of ammonium nitrate, instead of 26·25 grains, the crystals being dried beforehand.

"The plate is cleaned with concentrated nitric acid, by the aid of cotton wool, perfectly free from all extraneous matter. It is then washed in distilled water and dried. Equal parts of No. 3 and alcohol are next applied, and whilst still wet the plate is placed in distilled water, and all the alkali rubbed off by a badger-hair brush. The plate is finally placed face downwards in distilled water, resting on a couple of *clean* strips of glass.

"To prepare the silvering solution, equal parts of Nos. 1 and 2 are mixed in one measure, and the same quantities of 3 and 4 in another. The mixture in the second measure is poured into the first measure, and after thoroughly stirring the whole is transferred into a dish. The quantity should be so arranged that the solution just covers the bottom surface of the plate to be silvered when resting upon wedges (wooden ones covered with india-rubber solution will answer) about a quarter of an inch in height. The solution being poured in, the plate is placed in silver. If the mixture become blackly turbid at once it is probable there is not enough of No. 2 present, whilst if it remain clear for two or three minutes there is probably an excess. When the solution turns inky black the silvering commences, and the dish should then be rocked slightly for about five or ten minutes, when, if correctly made up, the solution should become clear and flakes of silver float up to the top. The glass will now be covered with a coating of silver, and it should appear perfectly bright if the chemicals are *pure*, and if the plate has not been left too long in the solution. The deposit should be very nearly opaque; any light passing through should be of a deep indigo colour. There is often a little bloom on the surface, which, when the surface is dried, can be removed by a tuft of cotton wool. A surface which is slightly matt can be polished by a pad of *fine* chamois leather and a little jewellers' rouge. The pad should be warmed and the polishing done with a light hand. A green tint in the deposit indicates defective cleaning of the plate, whilst a purple tint indicates something wrong in the solutions."

Comparing these two sets of formulæ it will be seen that they differ very slightly, and mainly as respects the proportions employed. As we have said we, and others, have succeeded admirably with Mr. Burton's formulæ, and Captain Abney says of the other that failure with it is wellnigh impossible. Here the process of silvering glass rests at present.

It has been recently proposed to utilise salicylic acid in connection with ferrous sulphate for the purposes of development, or, more properly speaking, for the intensification of images already developed by other means. For this purpose the salicylic acid, which is but feebly soluble in cold water, is mixed (in saturated solution) with the ordinary iron developer, and with the addition of a few drops of solution of silver nitrate is applied in the usual manner. The salicylic acid, though possessing to a slight extent reducing powers, is said to retard the precipitation of the silver from the solution, and in this manner enables the iron solution to be used for a considerable time without becoming muddy. The new intensifier is also credited with the power of producing a much finer deposit than the ordinary iron solution, and hence an image of better quality. We have tried the substance in question in a variety of ways, but regret to say we can find nothing to recommend it in preference to pyro., or even to bring it into competition with the old form of intensifier. We have used it with ferrous sulphate alone and in combination with acetic and citric acids. Even in the absence of restraining acid the tendency of the solution to become muddy is very slight, but the intensification is, under these circumstances, not satisfactory. An explanation of the restraining action of salicylic acid may be found in the fact that decomposition occurs upon its addition to the solution of ferrous sulphate, as is proved by the production of a beautiful purple colour. If this colour be due to the formation of a salicitate of iron it is evident that sulphuric acid will be set free, which would sufficiently account for the anomaly of a reducing agent apparently acting as a restrainer. As a developer we find that the new solution possesses little power, a very long exposure sufficing only to produce a feeble impression.

SPOTS IN EMULSION PLATES.—INFLUENCE OF SILVER IODIDE IN EMULSIONS.

In looking over the interesting pages of your Almanac, which reached me a few days since, I was particularly attracted by some remarks of Mr. Henry Cooper, who touched upon the same subject that I had happened to take up in a short article contributed, viz., *Spots on Emulsion Plates*. I agree with him entirely in believing that in plates made with a preservative the preservative tends to diminish danger from spots and to limit their action. Once before in these columns I made this comparison with paper: a drop spreads rapidly and widely on unsized paper, whereas on sized paper its action is much slower and more limited. *Gum* has always been found valuable in preservatives, and is incidentally present in all plates made with ale or beer. It heightens sensitiveness, and also gives a sort of glazing to the film, which certainly has its value.

Of course in washed emulsions, if we are to avoid an additional operation, we must employ substances dissolved in the collodion, as Mr. Cooper suggests. Gum unfortunately does not dissolve in alcohol, and the gum resins that do dissolve are insoluble in water, and convert the collodion into a sort of varnish, into which water will not easily penetrate. *Tannin*, of which Mr. Cooper speaks, has the advantage of solubility in both alcohol and water, and when dried rapidly, as in the case of a thin film on a plate, forms a sort of varnish which, of course, dissolves in water. *Gallic acid* acts very curiously on sensitive films. It is well known that gallic acid easily reduces silver, and therefore one would be apt to expect, *à priori*, that applied to a film it would increase sensitiveness and diminish both cleanness and keeping properties. The exact opposite of this is the truth. It was known, even in the early days of photography, that a final wash of gallic acid increased the brightness of the image and the keeping properties of the plate.

I have myself made many experiments in this direction, and can say with certainty that gallic acid considerably diminishes sensitiveness and tends to give a clear, brilliant plate, easily managed in every respect from first to last, but requiring an exposure of one half longer at least. In fact, its properties seem to partake more of those of its acid character than of its reducing nature. Tannin (gallo-tannic acid), I think, acts much in the same way, though I cannot speak so much from direct experiment.

Notwithstanding these properties of gallic acid, it must not be brought into contact with free silver nitrate. For example: if potassium bromide is dissolved in water and gallic acid dissolved in the solution, and then solution of silver nitrate added in excess, the mixture soon darkens from reduction, unless very heavily dosed with acetic acid. Even then it soon changes if the excess of silver solution has been considerable.

Undoubtedly the great foe to dry-plate work is *dust*. It is commonly said that sodium chloride is so universally diffused in the atmosphere that almost any flame viewed by the spectroscope will show the characteristic D lines. How much more, then, may we not expect to find substances diffused in the air of a work-room which are in continual use in it—especially sodium hyposulphite? Silver nitrate claims a certain amount of care, because it is comparatively expensive; but hyposulphite costs next to nothing, and if, in weighing, a few crystals are spilled on the floor they are not worth picking up. They are presently ground in by the feet; the fine dust is scattered by movements, rises and settles again on shelves, amongst cloths, on garments, &c. Perhaps a spot on today's plate comes from hyposulphite spilled on the floor years ago, which previously rose in dust and settled on shelves, until disturbed by some unusual movement. What is then to be done? To wash the floor frequently and wipe off shelves, but not shortly before making plates; to avoid spilling hyposulphite as carefully as if it were gold chloride; and to take particular precaution with the plates themselves.

I sent to this Journal some years ago the observation that the ordinary wide camel's-hair or beaver brush will not satisfactorily remove dust from a plate—a fact that everyone may verify for himself. Suppose a dry-plate worker to take out a dozen clean glasses, dust them off carefully with such a brush, stand them in a row on a rack, edge them all with rubber, and then proceed to coat them. What will be the result? The brush will not have removed all the dust, but, unless the air be very humid, it will electrify the surface of the glass, so that that surface will attract every mote in the atmosphere that is near enough, and there will be plenty of time for this between the brushing and the coating. The resulting plates will probably yield a succession of disappointments.

Suppose, now, that the photographer takes his clean glass and edges a few plates, as the first operation. As soon as the first one edged has dried sufficiently not to smear, he takes a stiff bristle brush, such as is used by house painters (one-inch diameter is a good size), and goes over the plate—not lightly and gently, but roughly, and as if he knew that the dust would stay if it could. Then *immediately* after he coats the plate, and sets it instantly in a drying-box. For this purpose the box need have no special drying appliances, such as sulphuric acid or hot air; the object is simply to avoid dust, and a wooden box containing a rack is sufficient. Perhaps, also, we might take a hint from Professor Tyndall's observations on atmospheric particles, and moisten the edges of the box with glycerine. This latter idea I have not given actual trial to, though it seems it would be certainly useful; but in the matter of brushing I speak from multiplied experiences. In fact, anyone may convince himself by taking a clean plate on which dust has been allowed to settle and trying to clean it with a camel's-hair brush. If this be done by a well-lighted window it will easily be observed how insufficient the ordinary brushing is, and how often the brush may sometimes pass over a particle without removing it.

In the vexatious experience narrated by Mr. Cooper it is quite possible that the obnoxious dust may have settled before coating as well as after. Sodium hyposulphite is quite insoluble in collodion. A speck of hyposulphite dust would therefore remain undissolved by the coating operation. If the plate were to be used immediately, and liberally wetted before developing, the injurious action would be less than if the speck were gradually dissolved and moisture absorbed by the film out of a damp atmosphere.

I have found a very useful precaution to be that of brushing off the film with a broad, soft brush immediately before development. I do not offer this as anything new; doubtless others practise it, but I do not recollect to have seen it in print.

In looking over the Almanac I was glad to see that several contributors recognised the fact which I believe I first noticed—that the sensitiveness of an emulsion, whether washed or unwashed, is *increased by the presence of silver iodide.* This was strongly controverted when I first asserted it, and I observe that one of your contributors mentions the increased clearness and sensitiveness as a new observation. It was also affirmed by some that silver iodide could not be emulsified. Under certain circumstances silver iodide remains suspended longer than any other of the silver haloids. I have at this moment in my laboratory a precipitating jar in which a quantity of silver iodide was precipitated a week ago, using aqueous solutions. During all that time it has remained suspended, and now it is only the upper half inch of the liquid that has become clear. This case differs from that of most emulsion work, in that there was an excess of alkaline iodide present. But it is also to be remembered that a precipitate settles far more easily out of water than out of viscid liquids, like collodion. It is certainly true that when the operation is conducted in the manner which I recommended there is *not the slightest* difficulty in obtaining an emulsion. In all my experiments and plate-making I never met with a single failure in this respect. It is true that on first mixing it may happen that the whole of the silver haloid may drop to the bottom, leaving the liquid clear above it, and the precipitated material may have a coarse, crystalline look. This seems very discouraging, and perhaps the preparation is thrown away as a failure; but a shaking for a single minute will totally change this state of affairs. The crystalline precipitate breaks up into a state of the finest division, emulsifies and remains suspended, and gives a film of the finest possible grain. M. Carey Lea.

UPON THE DETERMINATION, BY PHOTOGRAPHIC MEANS, OF MINUTE PORTIONS OF TIME.*

The method for determining time by photographic curve pictures, which I described in a previous number of this Journal, had a want, on account of its being necessary to use a Hipp's chronoscope, which, as I remarked at the time, could only be supplied by the activity of the observer. This want was caused by the indispensableness of differential calculus, or, rather, of the computation of the minute errors introduced by the mechanism of the apparatus into the deduction. I therefore set myself the task of finding out a method which, at the same instant as the curve was photographed, would show on the same plate the time that had been required to produce the photograph.

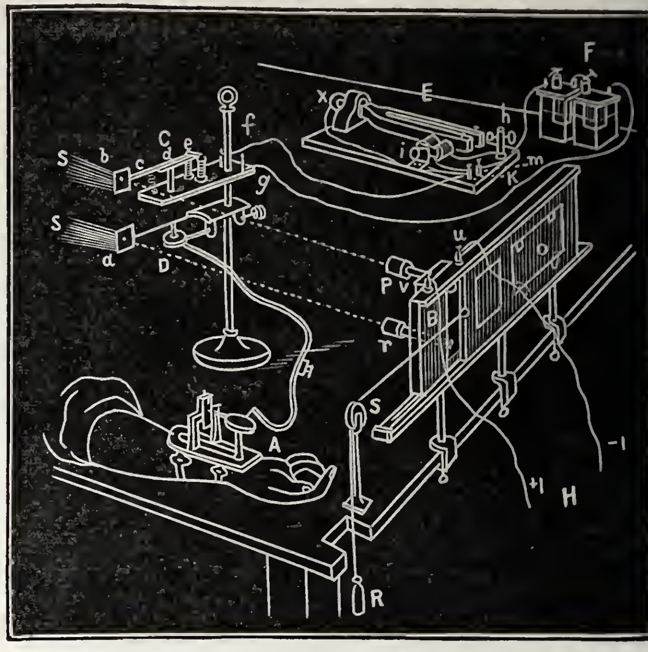
As readers of my former publications will remember, I have photographed sound curves, as well as the minute movements of the pulse and of breathing, both directly from the body and at a distance, where the physical movement was exactly reproduced and photographed. I made use, for transmission, of an electric current, or of thin columns of air enclosed in rubber tubes, according to the peculiarities of the movement transmitted.

It then occurred to me that I should obtain the exact curve calculation aimed at if I were to photograph a curve movement of known size or duration at the same moment, on the same plate, and directly above the curve with which I was still unacquainted, and whose duration was unknown. For this purpose I used a Marey's tuning-fork. The way in which this is done can only be made clear, to those who have not seen my instruments, by means of an illustration, on which account I give the following diagram with accompanying explanation:—

I assume, for example, that the pulse of the arm A is to be photographically drawn, and that one wishes to know exactly the duration not only of each separate beat of the pulse, but that its subdivisions are to be taken into consideration also. According to my previous experiments each individual pulse-beat consists of three or four smaller beats, which can only be graphically reproduced with absolute exactitude by means of the sensitiveness of the photographic sphygmograph.

The movement of the pulse is communicated by means of the apparatus A (which I described in my work upon *Light)* to the apparatus D, by which means the pierced sheet of mica *a* exactly reproduces the movement of the distant pulse A. Upon the same stand as the pulse-

FIG. 1.



Photographic Electric Pitch-fork Apparatus for the Determination of Time.

transmitting apparatus D a small electro-magnet C may be seen with a lever movement. To this lever *c* a pierced sheet of mica *b* is fixed. This small apparatus corresponds to the small electro-magnet (described in an article on the photography of sound), by the help of which the vibrations of a note sung by a human voice or struck by a pitch-fork were photographed. The electro-magnetic apparatus C is placed in connection, by means of conducting wires, on the one hand with the battery F, and on the other hand with the large pitch-fork E, which gives ten vibrations in the second—a sufficient number for the purpose for which it is used, viz., the determination of the time of the pulse vibrations.

Through this pitch-fork the whole electric current passes, entering at *m* and coming out at *k*. At *h* is a peg which lightly touches the fork, and by whose contact the current enters. When the fork vibrates then the electric current is broken. This break in the current is carried on the length of the little magnet *e* at C. At each swing of the pitch-fork the electric current is opened and closed.

Thus the electro-magnet *e* alternately attracts the lever *c d* at C towards itself and releases it again; and thus, if the pitch-fork give ten beats in a second, in the same time the sheet of mica will make ten small up-and-down movements, which may be photographed in the form of a curve, on the principle already described several times by me. The photographic manipulation is the same as that described in the previous article on this subject,* only that, instead of one lens, two lenses must now be fixed to the dark slide B, one above the other, at *p* and *r*. Both curves—that of the pulse which is photographed by means of the pierced mica *a*, and that of the time produced by the mica leaf *b*—are thrown upon the same plate, which is drawn along in the dark slide *o* before both lenses at once by the weight R, which runs over rollers. The current belonging to the pitch-fork leaves the carbon pole of the battery F, passing towards *m*, and from thence through the electro-magnet *i*, which keeps the fork in perpetual motion, to the peg *h*, and from that again through the fork itself, and then by the wire × to the spring screw *k*. From *k* it goes to *f*, then through the electro-magnet *e* to *g*, and from *g* back to the battery F. The shutters of both lenses are opened and shut, automatically, by the electric method described in the previous article, two conducting wires, × 1 and — 1, from a battery, supposed to be placed at H, communicating the galvanic stream coming from H to the closing arrangement of the lenses by the spring screws *v* and *u*.

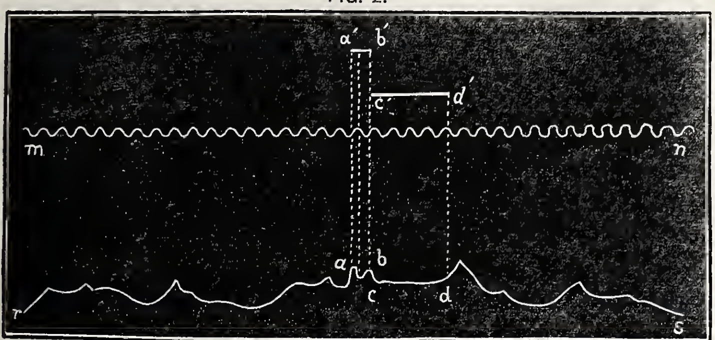
Fig. 2 is the *facsimile* of the image of the pulse-beat as taken photographically in the above manner. The upper curve represents the time; the under one is the photograph of the pulse-beat. Each little point on the upper curve represents one-tenth of a second, since by the movement of the pitch-fork this fraction is irrefutably indicated.

* Continued from page 475 of The British Journal of Photography, vol. xxiv.

*See The British Journal of Photography for October 5, 1877.

In *fig.* 1 the two lenses are represented as placed at some distance apart, in order to make the picture more easily understood. In reality, however, the lenses *p* and *r* are placed directly one above the other; and there is a contrivance for bringing them nearer to or moving them farther from each other.

FIG. 2.



Tuning-fork curve of ten vibrations per second and the pulse curve of a person suffering from disease of the heart.

When one wishes to know how many seconds the part of the curve from *r* (*fig.* 2) to *s* has required, all that has to be done is to count the hooks in the upper curve, and to divide the result by ten. If, however, one wishes to know what length of time an individual movement or pulsation has occupied, a line must be set off running parallel to the length of the curves, and from it perpendicular lines must be dropped, cutting the curves at regular distances, as shown by the dotted lines *a*, *b* and *d* (*fig.* 2). The little elevations marked off by the perpendicular lines show how we may ascertain quite sufficiently the exact duration of each movement. In the case before us from *a* to *b* represents one-tenth of a second, and from *c* to *d* four-tenths or two-fifths of a second. In the same way the duration of all the other teeth or jagged points of a pulsation may be measured with regard to time—a circumstance of considerable interest, and of special scientific value in the case of the pulse-curves of sick persons. The pulsations represented in *fig.* 2 are those of a woman suffering from disease of the heart; and, if they be compared with the photographed pulse-curves which appeared in the May number of the *Photographische Correspondenz* for 1874, it will at once appear how irregular they are.

Of course this is not the proper place for going more minutely into the details of the specially medical importance of the picture obtained, as in a photographic journal only the photographic technicalities of the subject can be suitably touched upon; but I may just say, in passing, that the diseased pulse in question goes at the rate of ninety beats in the minute, or one and a-half beat to the second, and that, as the diagram shows, in consequence of its irregularity the various beats occupy a varying portion of time. From the diagram one can see that after the trembling movements of the pulse between *a b* there is a pause, caused by a spasmodic contraction of the heart, and indicated by the line from *c* to *d* being continued in a horizontal direction. This time, during which the heart stands still, measured by the upper curve between *c* and *d*, is shown to be two-fifths of a second, and by the same method the time of the tremulous movement which precedes the contraction of the heart is shown to occupy (from *a′* to *b′*) but about one-tenth of a second. One would proceed in exactly the same manner in photographing the curves of sound waves or any of the other curve photographs already given by me; only it would then be necessary to replace the tuning-fork, which gives ten vibrations in a second, by one that would give 50, 100, 200, or even 500 vibrations in a second. There would then be upon the photographic plate, above the image of the curve of the sound whose number of vibrations was still unknown, a photograph of the curve of the vibrations of the tuning-fork, the number of whose beats in a given time was known. Let lines be then drawn so as to cut both the photographed curves, and the comparison between the known curve with the number of curve hooks of the unknown curve is at onee obtained, and at the same time it is seen how often a sound sung into an apparatus, like that described in the May number of last year, has vibrated in a second, and, what is more, it can be seen what note has been sung.

I hope that professional men, especially physiologists and natural philosophers, will adopt the methods described, and make use of them in their physiological and acoustic experiments. S. Th. Stein, *Dr.* —*Photographische Correspondenz.*

ON THINGS IN GENERAL.

I do not think that there would be many persons among those taking up a few numbers of the current photographic periodicals who would be inclined to class photography among the exact sciences. I was never more struck with its aspect in this respect than I have been of late. The old story of King James II. and his philosophers was forcibly recalled to my mind. He asked his assembled wise men, on one occasion, how it was that, if he took a globe brimming full of water and placed a gold fish in it, it would not cause the water to run over. A variety of profound explanations were offered, till, at last, one wiser than the rest replied, "Please, your Majesty, I doubt the fact." How often could this remark have been applied of late to some "facts" published under photographic auspices!

At a meeting of the Pennsylvania Photographic Association a query from the question-box was—"Why does an old bath give better results when nearly worn out than when renewed?" The assumption contained in the question was, strange to say, endorsed by all, though my experience of photographic text-books is that they say, when superexcellence of every kind is wanted—rapidity, cleanliness, and good keeping quality—a new bath should be made. Therefore, to this Association I should say, "Please, your Majesty, I doubt the fact."

I read also the other day an account of a very wonderful photographer who, having had brought to him to copy a portrait of a gentleman who was "wanted," told the police authorities, much to their surprise, that he was able to say from the appearance of the picture that it portrayed a red-haired man with sandy whiskers! This amount of penetration and insight is far beyond any experience of mine—so much so that I cannot but say, "Please, your Majesty, I doubt the fact."

Cartes de visite are retailed at one shilling each, and supplied to the factors certainly at not *more* than half that price; hence, when seeing intimated, as I saw the other day, that the sale of 100,000 portraits brought in a profit of three or four thousand pounds, and when I calculate that 100,000 sixpences is only two thousand five hundred pounds, the odd hundreds of which must be at least knocked off to allow for material and working expenses, I again say, "Please, your Majesty, I doubt the fact."

So also I should reply if I were told to expect a hearty response to the offer of a well-known photographer to hold an exhibition of other photographers' work, and that an augmentation of their balance would accrue to that deserving society, the Photographers' Benevolent Association. So, again, when a gentleman from Amsterdam makes a suggestion that Messrs. Wratten and Wainwright's method of extracting soluble salts from bromide of silver gelatine by means of alcohol might also be efficient when applied to prints partly washed out, and further suggests the recuperation of the alcohol by distillation, "which could easily be done in large establishments," and read, in reply to him, that gelatine is very permeable whilst paper prints are not; and, finally, when I read further in reply that "experiment alone can determine the value of the ingenious," I gasp out, after recovering from my astonishment in presence of the non-solubility of hypo. in alcohol, "Please, your Majesty, I doubt all these facts."

A course of study of The British Journal of Photography, in whose pages I read many years ago that hyposulphite of soda was an incorrect term when applied to the salt known to photographers under that name, would seem to be a very excellent study to some gentlemen whose acquaintance with the properties of this salt seems as complete as the freshness of their knowledge as to its nomenclature. I should be rather ashamed of our Editors if they deemed a leading article necessary today to call attention to the name.

There was interesting matter enough in Mr. Pearsall's and Mr. Cocking's papers, read at the South London Photographic Society, but I take exception, in a friendly way, to one or two points. Where, for instance, I wonder, except at the select drawing-classes at Minerva House, are lithographed drawing copies given to be copied in pencil? In fact, except for training the hand in outline drawing, where lithographed lines do as well as pencil, when is blacklead pencil used at all? I thought the old "shaded drawings" had vanished before the superior curriculum inaugurated by the South Kensington authorities. Mr. Cocking, too, spoke of minute variations of colour in the pupil of the eye, which is difficult to understand, seeing that the pupil is merely an abstract phenomenon and not a material substance. I feel bound to protest also against the assumption that photographs of foliage, for instance, give better transcripts of nature—truer, and more natural-looking—than the creations of the brush. In fact, I must flatly contradict it. Let any one who has the opportunity turn into the Grosvenor Gallery, now open, and look at some of the works of David Cox and Constable, and then ask himself which are the most suggestive of natural foliage—those wonderful paintings or the finest photographs extant, such as those of the noble trees in Windsor Park, that have been so much admired. I have not a doubt what the reply of a thoughtful judge would be—"the photographs fail in representing masses of tree foliage, except in a few instances."

Two men who may be considered as occupying the very foremost place among those who have benefited photography by their discoveries are Mr. Woodbury and Mr. Warnerke; hence when I saw the very severe letter of the former gentleman, I felt greatly surprised. I must say that Mr. Warnerke has not to any extent, to my mind, built up his reputation on the roller slide invented by the former gentleman. After receiving the telegram sent by the latter gentleman I cannot conceive how Mr. Woodbury could feel justified in casting the overt imputations of piracy that his letter conveys. The explanation given by Mr. Warnerke seems complete and sufficient. As a unit among the large body of photographers, my opinion of the great inventor of the Woodbury-type process would be greatly increased if he could withdraw more generously the imputations he has made. We cannot afford that investigators like these two gentlemen should have the foils in hand; they are too useful to us. Free Lance.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
Feb. 28	Liverpool Amateur	Free Library, William Brown-st
„ 28	Oldham	Hare and Hounds, Yorkshire-st.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

At a meeting of this Society, held on Tuesday, the 12th inst., the Secretary read the following

REPORT OF THE COUNCIL.

The Council of the Photographic Society of Great Britain, in presenting their report for the year ending 1877, will, as is customary, pass in brief review the work done during the session, and briefly glance at any special progress that has been made in the art or science of photography during that year.

In regard to the business of the meetings: it will be in the memory of the Society that, at the close of the year 1876, a trial was made of introducing some particular subject, and discussing it in its various bearings, and in the last report presented to the Society this practice was hopefully referred to. During the past year the experiment has been repeated with a certain measure of success, though on one or two occasions the members of the Society who were most conversant with the particular subject before the meeting could not be induced to join in it. This is much to be regretted in the interests of the Society, and it is hoped that if such members feel any delicacy in addressing the meeting that they may be induced to communicate their experiences to the Society's *Journal*, or to prepare beforehand (as was occasionally the case with some members) a short note giving details which would bear upon the subject under discussion.

Perhaps the subject which was more fully discussed than any other was the silver bath; and the Council are certain that new light was thrown on some of the phenomena met with in general practice, but that even then there still was a wide field for open discussion.

In referring to the list of papers read before the Society, it is a matter of regret to the Council that so few names appear as contributors. With two or three exceptions the communications have been made by gentlemen who are in the constant habit of contributing. It would greatly conduce to the welfare of the Society if, in addition to these gentlemen, other members of the Society would come forward and communicate their experiences. It rarely happens that any photographer does not meet with some phenomenon which may require explanation or elucidation, and if any member would make a note of his difficulties, and allow the Society to discuss them, much valuable information might thus be brought before it. Photography is essentially an experimental science, and progress towards the attainment of perfection can only be ensured by noting every phenomenon which is different to that usually encountered. If, then, members would give the benefit of their note-books to the Society a much more rapid advance in the required direction would be made. The Council earnestly beg that the above suggestions may be taken into consideration in order that the Photographic Society of Great Britain may still exist "for the promotion of photography." Still, as regards the progress in the theory of photography, there is much to be satisfied with. Many of the papers have been essentially on the results of research into some of the many unsolved problems still remaining; and it may be pointed out that it is only by maintaining a high standard of *general* papers that the results of researches in photography of any value can be hoped to be communicated to the Photographic Society, since there are so many societies which have acquired a certain prestige, and which are ready to receive the photographic contribution with the greatest advantage to the authors.

The Council have also pleasure in calling attention to the favourable position which the Society's *Journal* now occupies. After a careful consideration, the editor was not limited as to the space which it should occupy, and in consequence it will be found that the last volume occupied seventy pages of printed matter against fifty-five pages of the year before, the increase being made in the last half of last year's volume. It is hoped that the additional matter to be found in its columns will prove of value, though it does not absolutely belong to the transactions of the Society.

The meetings of the Society have been more largely attended this year than last, and from this fact it may be presumed that its proceedings have been of more interest to the members at large.

The following papers have been read during the year, viz.:—

1. *Photography from a Holiday-Maker's Point of View.* By H. Baden Pritchard, F.C.S.
2. *The Nitrate Bath: its Defects and Restoration.* By John Spiller, F.C.S.
3. *A Note on the Silver Bath.* By Colonel H. Stuart Wortley.
4. *Remarks on the Silver Bath.* By F. York.
5. *On a Neglected Method of Intensification.* By Capt. Abney, R.E., F.R.S.
6. *Further Note on Alkaline Development.* By Capt. Abney, R.E., F.R.S.
7. *On the Continuing Action of Light on Sensitive Carbon Tissue.* By J. R. Sawyer.
8. *On Emulsions.* By Herbert B. Berkeley.
9. *Note on the Silver Bath Discussion.* By R. W. Thomas, F.C.S.
10. *On Fog-Producing Emulsions and their Rectifications.* By Capt. Abney, R.E., F.R.S.
11. *On Emulsions* (second paper). By Herbert B. Berkeley.
12. *Theory of the Destruction of the Undeveloped Photographic Image.* By Capt. Abney, R.E., F.R.S.
13. *On the Production of Enlarged Photographs of Microscopical Objects.* By Edward Viles.
14. *Stray Thoughts on the Exhibition.* By Edwin Cocking.

It is in connection with the success of the photographic exhibition of the past year that your Council have to offer their heartiest congratulations, both from the financial as well as the art-scientific point of view. At no past exhibition have so many of the public been present, the number of persons who visited the exhibition of 1877 being 6,772. Several reasons conduced to such a result, two of which your Society, through its Council, may claim to have caused, viz., firstly the offering of medal awards in competition, which most undoubtedly brought together a collection of works upon which much thought and time had been expended, and which illustrated the advance made both in the art and science of photography; and, secondly, by securing the large series of Arctic photographs, which, being their first public exhibition, naturally attracted visitors.

Almost for the first time in the career of this Society there was a superabundance of pictures—many more, in fact, than could be hung. This enabled a more careful selection to be made than in former years, and your Council cannot help thinking that this was one of the prime causes of the superiority, in respect of the general excellence, of this exhibition over many previously held.

It is hoped that the next exhibition may be as successful as the last, though it must be mentioned that this year there have been special attractions to visitors which may not exist for the future.

The following analysis of the exhibition, by the Assistant Secretary, is appended, the records of which may be found to be valuable.

"There were 130 exhibitors. Of these 95 were professional and 35 amateurs; 44 exhibitors from London, 71 from the country, and 15 from abroad; 51 were members of the Society, and 79 non-members.

"Of the 51 members 24 were from London, and 27 from the country; 35 were professional and 16 amateurs.

"Of the 79 non-members 20 were from London, 44 from the country, and 15 from abroad; 60 were professional and 19 amateurs.

"551 frames were hung, containing 1,382 photographs. Of these 565 were portrait and figure subjects; 491 landscapes and architectural views; 126 animals and birds; 43 flower subjects; 38 pieces of sculpture; and 118 reproductions, &c. Included amongst these were 77 enlargements, consisting of 35 portraits, and 42 landscapes and others.

"On the table were some of the Arctic photographs, several books and albums containing photographs, making altogether, with those hung on the walls, an exhibition of more than 2,000 separate photographs."

With much regret your Council have to record the loss by death of one of the Society's most distinguished honorary members, viz., W. H. Fox Talbot, D.C.L., F.R.S.—a name which will ever be associated with the pioneer discoverers of photography, and of whom we, as Englishmen, must always be proud as the discoverer and investigator of that branch wherein lay the germ of its future practical utility and universal popularity.

In conclusion: your Council trust that the future year will furnish new matter for investigation and discussion, and that your Society will be aided in its endeavours to extend the field of scientific research, not only by the hearty co-operation of its prominent and more active members, but by the accession to its ranks of all who can appreciate, and consequently benefit by, the social reunions which the Society was established to promote.

Obituary.

W. H. Fox Talbot, D.C.L., F.R.S., was born in 1800. Educated at Harrow School, he went to Cambridge, and distinguished himself at that university by gaining the Porson prize, being Chancellor's gold medallist, and graduated in 1821 as twelfth wrangler. After sitting two years in Parliament he retired into private life, and devoted himself to science and literature. He contributed during his lifetime about fifty papers to the Royal Society. In 1826 he published a paper on light, viz., *Some Experiments on Coloured Flames*, and in 1827 *On Monochromatic Light*, and as late as 1872 he contributed a paper to the Royal Society of Edinburgh *On the Early History of the Spectrum Analysis.*

But it was in connection with chemistry that his researches were destined to become so valuable, and some of his earliest papers on the subject were written in 1833—*Researches on Chemical Changes of Colour*, and *Iodide of Silver*, &c. On January 31, 1839, Fox Talbot read a paper before the Royal Society, entitled *Some Account of the Art of Photogenic Drawing, or the Process by which Natural Objects may be Made to Delineate Themselves Without the Aid of the Artist's Pencil*, as also at the British Association the same year he read a paper on the same subject Early in 1840 he published the calotype process—being a wonderful advance on everything that up to that time had been produced—a patent for which he took out in 1841. The next patent that Fox Talbot took out was registered under the title of *Improvements in Calotype*, in which, amongst other things, he included fixing the photographic image on paper by means of the now well-known hyposulphite of soda—a solvent for the salts of silver which Sir John Herschel had discovered in February, 1840. Fox Talbot, in another patent, claimed the use of a transparent and flexible support in lieu of glass, consisting of paper rendered transparent and non-absorbent.

In 1852, at the united request of C. L. Eastlake, President of the Royal Academy, and Lord Rosse, President of the Royal Society, Fox Talbot presented his inventions connected with photography to the country, with the exception of, to use his own words, "photographic taking for sale to the public."

Of late years Fox Talbot appears to have turned his attention to other matters besides those connected with light and chemstry, and was engaged for some time in assisting to decipher the cuneiform inscriptions brought from Nineveh.

Hereafter, whenever the early history of photography is alluded to, the name of Fox Talbot must always occupy a prominent place, and his whole life is another instance of the power which independent means, when used for the culture of mental gifts, can become. His is a bright example, and it adds a lustre to English science.

The Treasurer read his financial statement of the affairs of the Society, as follows:—

BALANCE SHEET OF THE PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN,

For the Year Ending 31st December, 1877.

CASH ACCOUNT.

1877. Receipts.	£	s.	d.
To Balance from last year	253	5	10
,, Amount in hands of Treasurer and Assistant Secretary for Petty Expenses ..	6	15	5
,, Entrance Fees and Subscriptions	223	10	0
,, Sale of Journals and Advertisements	50	17	0
,, Admission to Exhibition and Sale of Catalogues	201	2	6
	£735	10	9

1877. Payments.	£	s.	d.
By General Expenses, including Rent of Gallery..........	161	4	9
,, Refreshments supplied at the two *Soirées*	18	2	2
,, Journal Account and Assistant Secretary's Salary.....	119	7	6
,, Exhibition Expenses, including Medals, Advertisements, cost of Arctic Photographs, and Printing the Catalogue	170	13	6
,, Balance in hand	266	2	10
	£735	10	9

ASSETS AND LIABILITIES.

1877. Assets.		£	s.	d.
Entrance Fees and Subscriptions due	£145 19 0			
Say less 30 per cent.........	43 15 9			
		102	3	3
Advertisements outstanding ..		25	3	4
Furniture, Tea Service, Black Board, &c.		18	18	1
Arctic Photographs and Surplus Medals		6	6	0
Cash Balance		266	2	10
		£418	13	6

1877. Liabilities.	£	s.	d.
Gas Arrears and Carrier, say..	12	10	0
Balance in favour of the Society	406	3	6
	£418	13	6

Audited and found to be correct,

(Signed) ROBERT C. MURRAY, F. BEASLEY, Jun., } Auditors.

February 11, 1878.

The following is a list of the Council and officers for 1878-9:—*President:* James Glaisher, F.R.S., F.R.A.S.—*Vice-Presidents:* Capt. W. de W. Abney, R.E., F.R.S., F.C.S., Francis Bedford, Professor G. G. Stokes, M.A., D.C.L., F.R.S.—*Treasurer:* John Spiller, F.C.S.—*Council:* W. Bedford, Walter S. Bird, Valentine Blanchard, J. H. Dallmeyer, F.R.A.S., T. Sebastian Davis, F.C.S., Hugh W. Diamond, M.D., F.S.A., W. England, Samuel Fry, Jabez Hughes, Lord Lindsay, F.R.A.S., Peter Mawdsley, W. Mayland, H. B. Pritchard, F.C.S., H. P. Robinson, J. Traill Taylor, R. W. Thomas, F.C.S., G. Wharton Simpson, M.A., F.S.A., Colonel H. Stuart-Wortley.—*Hon. Secretary:* H. Baden Pritchard, F.C.S.—*Assistant Secretary:* Edwin Cocking.

EDINBURGH PHOTOGRAPHIC SOCIETY.

The second "popular" evening of this Society for the session was held in Queen-street Hall, on the evening of Wednesday, the 13th inst., when Mr. W. H. Davies delivered a lecture, entitled *Here and There in England*, which was descriptive of a tour from the English lakes through Yorkshire, Derby, Stafford, Worcester, Warwick, and Oxford to London, introducing a large number of very beautiful transparencies supplied by Mr. F. York, 87, Lancaster-road, Notting-hill, W. These views were exceptionally fine, and elicited constant expressions of approbation from a keenly-appreciative audience, which was kept in great good humour by the pleasant manner and graphic descriptive power of the lecturer. In introducing his subject Mr. Davies said:—

Before authentic British history had an annalist the natural features of our country must have had a very similar aspect to many of the views I shall have to bring before you this evening, while many of the others are connected in a very curious way with the present war in the East—a war which is not of today or yesterday, but one which extends backwards into history more than a thousand years. It is, in my mind, beyond a doubt that but for the crusades and crusaders with their numerous followers we should not have had many of the magnificent examples of architectural beauty which will be presented to you this evening. It is certain that at the time when we in this country were little removed from barbarism, letters, science, and the arts—more especially the art of architecture—were either in their full glory or were even then in their decadence in the East; and but for that unceasing war of the cross against the crescent the barbarous western believers in the cross would have remained barbarians for a much longer period than they did. If the wars of the crusades did nothing else they taught the Christian warriors and their followers many of the sciences, notably that which lies at the foundation of photography—chemistry. Without the potent aid of that natural magician we could not have shown you, as we will tonight, by the aid of the so-called magic lantern, the verisimilitude of many of those baronial and ecclesiastical monuments of art of which our country is so proud, and with which she is so well endowed—edifices that show how well our forefathers studied Eastern architecture and adapted, beautified, and glorified it until it seems as if in the culmination of what we call, or miscall, "Gothic," the very pinnacle or acme of architectural design and execution had been reached, and that nothing was left for us but to admire and, if possible, imitate it. I might go on talking and amplifying for an hour on this and cognate subjects connected with the views we have to display this evening; but I know, from a tolerably long experience in the Society and of these meetings, that the audience naturally do not come so much to hear as to see, and therefore I will draw my brief address to a close with two observations. The first is that we are obliged to Mr. Frederick York, of London, for the use of most of the slides to be used tonight, and to whom the Society is under a debt of gratitude, not only for this evening's exhibition but also for several previous ones. My second remark is that those of the present audience who are not already members of the Edinburgh Photographic Society should join at once. It is not necessary that you should be photographers, but merely that you should wish well to the art-science of photography, as this is, and has always been, essentially an amateur society. It has nothing to do with photography as a profession or a business, but simply as a science and an art; and it may be joined by ladies as well as gentlemen. Lastly, though not least, but yet little, the annual subscription is only five shillings, and this year we intend presenting every member who has paid the subscription a fine photographic picture, which will be worth more than the entire value of his or her subscription. We are enabled to do this partly by the large mass of gratuitous labour which the council and office-bearers undertake, and partly by the large amount of *lay* element—if I may so call those members who join us mainly, if not entirely, to support what is at this moment one of if not *the* most flourishing photographic societies in the world, and who financially form the backbone of the Society. Our secretary, Mr. Pillans, or some of his friends, will be in waiting in the side room to take the names of ladies and gentlemen who may wish to be proposed as members of this flourishing Society; but I am bound to warn them that they must pass through the ordeal of the ballot before they can attain the high honour of being a member of the Edinburgh Photographic Society.

At the conclusion of the lecture, on the motion of Dr. Thompson, a hearty vote of thanks to Mr. Davies concluded the proceedings.

BERLIN PHOTOGRAPHIC SOCIETY.

A Meeting of this Society was held on the 4th ult.,—Dr. Vogel, the President, in the chair.

The President commenced the proceedings by reading a communication from Herr Wilde, of Görlitz, upon dry plates. The letter was accompanied by a number of landscapes on dry plates. He (the President) remarked, with reference to the foregoing, that he had compared Herr Wilde's developer with Mr. Warnerke's, and found that they were very much alike, only Wilde's contained a little gelatine dissolved in glacial acetic acid, which acts as a retarder. The absence of this gelatine was, he thought, the principal reason why a shorter exposure was sufficient with Warnerke's developer.

The developer recommended by Herr Wilde for use with his dry plates is as follows:—

A.

Pyrogallic acid	5 grammes.
Alcohol	25 c.c.
Distilled water	25 c.c.

B.

Bromide of potassium	5 grammes.
Distilled water	75 c.c.

C.

Gelatine	3 grammes.
Glacial acetic acid.......................	20 c.c.
Distilled water	400 c.c.

D.

Carbonate of ammonia.....................	25 grammes.
Distilled water	150 c.c.

(The carbonate of ammonia must be pounded very fine and dissolved in warm water.) Shortly before use mix—

A	40 drops.
B	20 ,,
C	10 to 15 ,,
D	15 c.c.

Mixed in these proportions, with a proper exposure, the negatives developed will, almost without exception, be good.

Herr Wilde also wrote to say that the glass printing process of the State Printing Establishment was already described by Herr Lemling in his book on photo-verrotype. To this it was objected that no one had seen any results of Lemling's process, while the State Printing Establishment was certainly the first to produce superior results in glass printing.

Herr Liebmann had found by experience that the results of glass printing depended very greatly upon the sort of printing ink chosen, and regretted that that point was so seldom touched upon.

Herr Burchard said that the ink used for lichtdruck in this case should be very weak and thin, and that it was, therefore, impossible to get a good impression from a lichtdruck that required a fatty ink.

Herr Quidde remarked, in reference to Herr Wilde's method of preparing emulsion cotton, that when the ingredients were first poured together the water of the gelatine emulsion precipitated the collodion cotton, and the alcohol of the collodion threw down the gelatine, and, on redissolving, the cotton only dissolved, the gelatine remaining still insoluble in alcohol. It seemed to him not impossible that the cotton might be improved by this process, and that perhaps it combined the properties of precipitated and of gelatinised cotton. Still he did not see why Herr Wilde used a gelatine emulsion and not a simple gelatine. The experiment was so conducted that the bromide of silver of the emulsion was obtained in the precipitate, because, as was well known, it did not dissolve in alcohol; and, besides, it adhered so fast to the gelatine that, after redissolving, the greater part of it would remain in the gelatine.

Herr Schaarwächter exhibited a number of portraits taken with Seavey's backgrounds, and also a few glass etchings from the establishment of Göbel, of Witten, partly etched by acid and partly by sand blast. The Brothers Burchard also showed etchings on flashed glass. The last two exhibits gave rise to a discussion as to their suitability as permanent emulsion solution supports for carbon transparencies, the majority coming to the conclusion that while Burchards' etchings were suitable those of Göbel were scarcely fine enough.

The President then exhibited three views taken by the Baron des Granges of an object from the same standpoint but with different lenses, viz., a Steinheil aplanatic, a Steinheil wide angle, and a Dallmeyer D lens. The pictures were all sharp alike.

Herren Burchard showed a large photograph, being a reproduction of the celebrated map of the world, drawn by Professor Schmidt, of Athens, and consisting of twenty-five sheets fifteen inches square. The original represented the labour of thirty years. It had been purchased by the Government for 14,000 thalers, and entrusted to the Brothers Burchard to be reproduced photographically. Herr A. Burchard described the difficulties of the work.

It was then mentioned that M. Scotellari had applied for a German patent for his objective shutter, and a discussion followed on the patent law.

The President said that Herr Obernetter, of Munich, had received from Herr Gutekunst, of Philadelphia, a panorama, 3.24 metres in length, of the Philadelphia exhibition. This panorama Herr Obernetter had forwarded for exhibition to the Society, and he (the President) herewith produced it, remarking, at the same time, that such a long strip of paper would be silvered by the help of rollers which guided the paper equally across a silver bath.

Herr Schaarwächter thought that the negatives had been stripped off, placed together, and then all printed at once, otherwise the equality of depth shown in the prints before them could scarcely have been obtained.

Herr Reichard asked how the faulty varnish he had complained of at a former meeting, and a sample of which he had given to the President to experiment with, had turned out.

The President had not yet observed any change in the plates he had varnished with it.

Herr Reichard had not observed any rents in those he had himself varnished with Besler's varnish, which he had been using since the failure of the one he was accustomed to use.

The meeting was then adjourned.

Correspondence.

Voyage to Australia.—Photography in Capetown and On Board Ship.—The Government Printing Office in Sydney.

Were it not the fear of certain frowns, long scratches of the pen, and other unmistakable signs of editorial displeasure, I should have been tempted to have commenced my Australian correspondence with a dissertation on the brotherly love of the Melbourne freemasons, the beauties of Sydney harbour, with its lovely islands, bays, rivers, &c., &c.; but I remember having read some years ago in your valuable Journal the letters from your special correspondent in the east, and, being personally acquainted with him and much respecting him, have taken his advice, viz., to keep as near as possible to the doings of our brethren in the colonies. Though at that time he was rather inclined to wander from his subject, I suppose now (being fourteen years older) he knows better.

I will not weary your readers with the details of the voyage, which has become an ordinary undertaking. I embarked at Gravesend on board the steamship "Stad Amsterdam," on October 25th, 1877. We called at Plymouth to take in mails and passengers, and sailed thence, with 368 souls on board, including the crew, October 31st. We crossed the line on November 14th. On the 25th we again sighted land, and in a few hours the steamer was alongside the wharf at Capetown. The passengers here landed, and were soon to be found scattered about in different parts of the capital of the Cape Colony.

It being Sunday we had nothing to do but wander about, visit churches and chapels, hear sermons, and drink Cape wine or drops of whiskey. On Monday morning, early after breakfast, we commenced seeking after sights, and with the characteristic curiosity which distinguishes correspondents in general, and photographic ones in particular, I soon found myself among the objects of my researches.

There are several well-to-do photographers in Capetown, and one or two exceptionally good artists. I first visited Mr. Bernard—a gentleman who has long been a leading man in Capetown, and has acquired a very good business. I then went over the establishment of Mr. Bruton, late of Port Elizabeth, who showed every kindness that a gentleman could do to a poor wandering photographer. His studios are the first in the colony, the waiting saloons being large and elegantly furnished, reminding one more of a London West-end establishment than of a South African one. All the walls were covered with specimens of the carbon process, which is well represented, and Mr. Bruton informed me that a gentleman was at that time receiving final instructions at the Autotype Company's works preparatory to coming out to work that very beautiful process in his establishment. That, however, is only one portion of this gentleman's programme. Mr. Bruton is one of those genuine photographers who love their art and consider no sacrifice too great to further its progress; so he was shortly going to introduce some photo-mechanical process into the colony, and intended visiting England very shortly for that purpose. I much regretted not being able to accept the proferred hospitality of Mr. Bruton and visit his country house; but, not wishing to make a longer and forced stay at Capetown, I returned to my quarters, having brought away with me a material memento of my visit to Mr. Bruton in the form of some very nice cabinet portraits of Stanley, the African traveller, and some of his Arab attendants.

I could not leave the Cape without expressing my surprise that the Government should not have followed in the steps of our other colonies and introduced photography into their various departments, it having elsewhere proved so useful.

We bid adieu to Cape Colony, and were soon being rolled about in one of those big seas only to be encountered in the neighbourhood of the Cape.

I now began quietly to get ready for trying a few plates, by the wet process, on board; and it soon became known that there was a disciple of photography among the passengers. As soon as we got out of the heavy sea my first care was to find a place that would serve the purpose of a dark room, and, thanks to the doctor—a thoroughly-good and kind-hearted Irishman—I soon found where I might not lay my head, but my bottles. Collodion, glasses, bath, and all the other photographic items were soon in place, and having again requisitioned my good friend, the doctor, I began the sacred rites. No. 1—over-exposed; No. 2—everybody had moved by a sudden lurch of the vessel; No. 3—all right; No. 4—ditto. Great was now my confidence. All difficulty seemed to have been overcome, and in the future tradition will speak of the fine old "Stad" by means of photography. Alas! how fickle is fortune! and how soon the brightest hopes may become blighted! In my excitement I had momentarily forgotten that I was not on *terra firma* but in the middle of the Indian Ocean, lat. 40° 28', long. 61° 11' east of Greenwich, steaming away at the rate of thirteen miles an hour.

Soon Father Neptune (who, I suppose, had been watching me, and was not at all pleased with the liberties I was taking) became angry, and matters around me were gradually growing more and more unsteady. I managed at first to baulk the grey-headed old gentleman by propping up this and putting that nicely into a corner, but not to much purpose; for all at once a roll a little heavier than the preceding ones sent us to leeward, and bath, bottles, and correspondent had the same and sudden impulse to proceed to the other side of the cabin as quickly as possible, regardless of all obstacles. My object was attained without changing the graceful position that photographers sometimes assume when working in very small tripod tents. The result was visual and chemical confusion and double decomposition. Suddenly I remembered that my three-legged friend might perhaps have had a similar inclination; so by a sudden rush up the companion ladder I arrived in time to find that camera and stand had been slightly displaced by old Neptune, had only just missed knocking a little boy and girl into the sea, and finally had found its centre of gravity in the lap of a quiet, elderly lady, who naturally imagined that the machine could do nothing less than explode. I quickly, however, calmed her, and apologised for the apparent rudeness of my apparatus, which, like herself, was not used to rough weather at sea.

This little episode caused great diversion on board, and at the same time put a stop to further proceedings for that day. I soon, however, got things into shipshape again, and was urgently requested to take some little groups (I only had quarter-plate glasses) of my fellow-passengers. It will not be difficult for my readers to understand that I felt myself the most independent of photographers, knowing that my clients could not go over the way to a rival establishment; so I had it all my own way, and they kept me hard at work printing for two or three days afterwards. I will send the Editors some specimens by another mail.

If ever any of my brethren of the photographic fraternity "go down to the sea in great ships" they should take their apparatus with them. It is a pleasant pastime, and need not be altogether unprofitable. But what is that cloud-like line on the horizon? Surely it is land! Yes, the dear land again! It is Kangaroo Island, lying just outside our point of destination. For an hour we run about talking to everybody, telescopes and opera glasses being in great requisition. At 9.30 p.m. we passed the revolving light on the island, and saluted the inhabitants generally—kangaroos and others—by sending up some rockets and firing off two guns. Our salute was replied to by the burning of blue lights. The voyage was now all but ended. To pass Adelaide and Melbourne, and finally find ourselves safely housed at Sydney, was but the work of a few days; and now memory comes in to fill up the place of a very agreeable and well-conducted voyage. We have left the old world behind us, and, now, hurrah for the new!

Having come out here for the purpose of introducing some of the photo-mechanical processes into the photographic department of the Government printing office, I at once reported myself to the Government printer, Mr. Richards, sole director of this intelligently-conducted and important department. I find that photography has been largely employed here for some years past, the general sizes used being 15 × 18 and under. The department possesses, however, a very fine apparatus, by Dallmeyer, for plates about double the size.

In my next communication I hope to say something more particularly photographic, and trust your numerous readers (as also yourselves) will grant me indulgence for all shortcomings in a simple lover of his art.

Sydney, January 1, 1878. L. H.

"THE GELATINE PROCESS."

To the Editors.

Gentlemen,—I congratulate the Rev. H. J. Palmer on surmounting a difficulty with reference to the use of ox-gall in the production of gelatine films for photographic purposes.

Just forty years ago, when occupied in the laboratory at Giessen in researches on the bile, I discovered that the mucus of the gall bladder is a most energetic *catalytic* body, and that in its presence, especially at a temperature over 70° Fah., the bile becomes rapidly decomposed. Having, then, obtained perfectly fresh ox-gall, the first step is to precipitate the mucus by means of alcohol, glacial acetic acid, or lactic acid, which, for certain reasons, I prefer.

Mr. Palmer is quite right in modifying his original formula by diminishing the quantity of ox-gall, as it is exceedingly hygroscopic, and in too large a proportion yields a tacky film.

There are many other details necessary for producing a suitable film, with which, I have no doubt, Mr. Palmer is acquainted. Wishing him every success,—I am, yours, &c., Geo. Kemp, M.D.

February 19, 1878.

P.S.—The film I enclose was made before I saw Mr. Palmer's communication in your issue for February 15th.—G.K.

[The enclosure is one of the most perfect films we have ever seen.—Eds.]

PREPARATION OF OX-GALL.

To the Editors.

Gentlemen,—As the Rev. H. J. Palmer observed in his paper on *A Further Improvement in the Gelatine Process*, read before a meeting of the Liverpool Amateur Photographic Association, ox-gall as supplied by the butcher is not a pleasant article to deal with. Its important quality of rendering a film of gelatine non-adhering to glass may, however, bring it into use in the preparation of portable gelatine negatives.

The following directions for purifying it, extracted from Spon's *Workshop Receipts*, may be of use:—

"Evaporate fresh ox-gall to a syrup, and then spread it out to dry in a thin layer on a plate placed near the fire. This is the pharmacopœia plan, but it takes none of the colour out of ox-gall; it simply desiccates the bile, which can in this condition be preserved from putrefaction for any length of time in closely-stoppered bottles. If fresh ox-gall is evaporated on a water bath, and then treated with alcohol, the mucus and epithelium are precipitated; but the colouring matter still exists, and is not precipitated or discharged by digesting. Again: boil one pint of fresh ox-gall with one ounce of alum, and in another vessel a second pint with one ounce of common salt; after standing three months in separate bottles the clear portion from these solutions is to be mixed for use. But the solutions do not become altogether clear, although they keep very well without putrefaction. Ox-gall may be thoroughly decolorised by slightly acidulating it with acetic acid and passing through it a stream of chlorine gas."

My own experiments have been confined to what is above designated the "pharmacopœia plan." The resulting product dissolves readily in the gelatine solution, and the films, when dry, are easily stripped from the glass.—I am, yours, &c., J. D. Lysaght,

66th Brigade Depôt, Naas, *Lieut. Royal Madras Fusiliers.*

IMPROVEMENTS IN CARBON PRINTING.

To the Editors.

Gentlemen,—We shall not trespass further upon your columns by continuing a controversy which can scarcely have the slightest interest for your readers. All that we ever complained of was that Mr. Johnson, by an erroneous quotation, in what may fairly be considered one of the text books of photography, placed us in a false position before the public as regards the manufacture of tissue in *permanent* pigments. As we could not in any other way rectify this misconstruction we had no alternative but to appeal to your columns.

But even in his last letter Mr. Johnson seeks still to establish his position by a reference to an edition of the *Autotype Manual* published two years ago, and then naïvely asks—"Where is the offence?" We think we have already pointed out the "offence" to him with sufficient clearness.

In conclusion: we again assure Mr. Johnson that we are in no way affected by his claims; that we at once concede to him the *publication* of *a* method of treating alizarine; and, further, assure him that the process employed by Mr. Sawyer is based upon the one indicated to Mr. Johnson in May, 1876, in which neither lime, magnesia, nor any other similar matter is, or has ever been, employed.—We are, yours, &c.,

February 19, 1878. The Autotype Company.

THE CONSTRUCTION OF GLASS HOUSES.

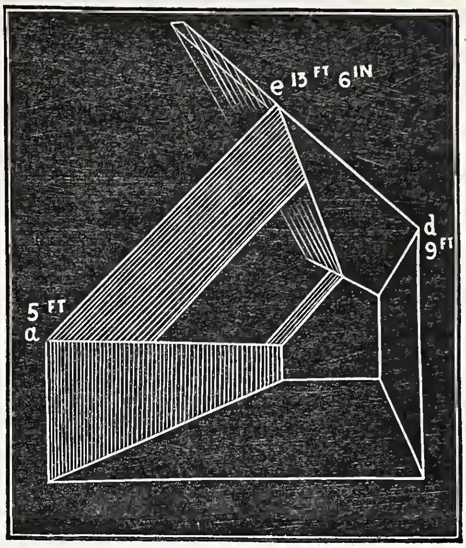
To the Editors.

Gentlemen,—In The British Journal of Photography of the 8th inst. Mr. H. Hamilton gives a description of a studio he is about to build, and wishes for information as to the modifications of the proportions given.

Many competent men have written books and articles on their experience under different lights which have been a great assistance to the advancement of our art; whilst others have run off to the Patent Office with their proportions for the "perfect studio." But as this is a subject of the greatest importance to photographers, being the foundation-stone of good work, too much attention cannot be given to the study of light and lighting.

Considerable practice and careful study in some of the leading studios in England and America convince me that, with the slight modifications suggested below, Mr. Hamilton will have a studio which, for simplicity and facility in working, will be difficult to improve upon.

The sketch of the interior is given in proportionate measurements, so as to show the pitch of the roof. The eaves being five feet high (*a*) the light below this would never be wanted in *this* studio, and it will give more freedom for working the backgrounds. It would even be advisable to raise the eaves of the opaque parts or ends as high as seven or eight feet. This would not look quite well, but would be more than compensated for by the great power thus secured over the background, which is of the greatest importance, as a little thought will readily show.



The ridge is not in the centre, but eight feet six inches from the north wall, and four feet six inches from the south wall. It is thirteen feet six inches high, and gives a full, open light of about twenty feet by twelve feet. The point *d* is nine feet high, and the room thirty feet by thirteen feet, and five feet opaque at each end—not less (this is a point often overlooked), as it does not allow space to move the backgrounds at any desired angle, or to keep them well from the sitter. I have used the same background six feet from the sitter, and at other times as close as possible, to produce a harmonious effect in the picture. *e e* is a sun-shade, the supports being carried out about four feet, and at the same angle as the opaque roof, made very strong. There are many ways of doing this; but I should think the supports could be carried out from underneath the slating. On the top of these lay planks six or seven inches wide—not flat, but similar to half-open Venetian blinds. This will prevent splitting by heat, and will give free play to the wind to pass through without the fear of finding the shade in a neighbour's yard some fine morning. Great importance should be attached to the erection of this shade, as any rays of sun striking the glass are most injurious to the production of good work.

The next suggestion I strongly recommend, as there are about a dozen advantages attached to it; that is, to use blue glass for two feet up along the bottom of the light, and also blue glass in each end sash from top to bottom. There may be a matter of difficulty in getting the right shade, but it is worth more money and trouble than it will cost. Neither blue muslin or staining will give the desired effect to be got with the glass. This is no theoretical suggestion, but a practical hint. I have never seen it in exactly this form, but careful study of different effects points this out as the simplest form of perfect studio. It can be worked almost without a blind, and will be very quick. In this instance the studio should be kept to the west end of the space if possible. Do not be afraid of a little extra expense in making a firm and solid floor. Use iron sash-bars to carry the glass, and do not forget ventilation.

Hoping that the importance of the subject will be accepted as an ample apology for the length of these suggestions,—I am, yours, &c.,

Twyford Villa, Quarry-road, Ryde, John Cowell.

February 13, 1878.

P.S.—The blue glass should be a decided blue, but very transparent.—J. C.

Spontaneous Explosion of Toughened Glass.—In the *Bohemia*, Professor Ricard, of Trchewan, tells the following tale:—"A child's drinking glass was bought one day at Saaz, for about seventy kreuzer, and for six months it sustained its character of unbreakable glass. But about nine o'clock one evening in the sixth month it was used in drinking *eau sucrée*, and was then placed, with a silver spoon in it, upon a large oaken table. Suddenly I heard from my room a violent explosion like a pistol shot, and a metallic sound. I ran in, and saw the whole floor strewn with needles and splinters of glass scattered thinly and widely—and not only upon the floor, but the bed, the table, the washstand, the carpet, and the clothes hung up were covered with these shreds. I looked everywhere for the cause of this explosion, and at last remarked that the child's drinking cup was gone. The empty glass had exploded—without apparent cause, without the approach of a light, and having a spoon in it—with such extraordinary force that the whole household was frightened. I relate this story, therefore, not only for the information of chemists and natural philosophers, but also of those families who believe that in this so-called unbreakable glass they possess remarkable and unspoilable playthings or useful household goods, to show them that when such an explosion occurs it may cause not only fright but mischief." To the foregoing the editor of the *Polytechnichen Notizblatts*, adds that such explosions of tonghened glass, often without any apparent cause, have been pretty frequent of late, and appear to be on the increase—a circumstance likely to prevent people from using toughened glass until the cause of this evil property has been discovered and removed by a change in the process of manufacture. The explosion is, doubtless, caused by some change in the extreme tension of the fibres of the toughened glass, and it is probable that if the tension were removed the glass would no longer be tough.

EXCHANGE COLUMN.

A new camera lucida, by Elliott, optician, Strand, in case complete and in perfect order, will be given in exchange for a No. 1 Steinheil doublet, back focus 3½ inches, in good condition, or for a portable bellows camera for plates 7½ × 5, in good order.—Address, W. Mackay, 15, Ness Bank, Inverness.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

Notice.—Each correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a *nom de plume* as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

⁂ Several articles and notices are left over in consequence of a press of matter.

T. B. Howe.—The forms will be forwarded.

J. W. G.—Yours, containing the misdirected letter, with the other enclosures, received.

George Fox.—A "kit-cat" picture measures three feet six inches by two feet four inches.

W. W. W.—Try Solomon or Marion and Co. But we do not believe that what is wanted can be obtained.

C. G.—You cannot be prevented from photographing any of the buildings unless you create an obstruction.

C. Magram.—We are not able at present to give the information, but hope to be able to do so, privately, in a few days.

Lambertypist.—The only fault we have to find with the *cartes* is their peculiar tone, which is strongly suggestive of "plum jam."

S. Wolstenholm.—This is a matter for the county court. You will certainly gain your case if you elect to have it decided in that manner.

W. M.—Your proposed method of using ferrotype plates seems quite feasible. After development the films might easily be transferred to glass plates if required.

Richard.—We do not think that the fault is attributable to the paper. It is probable that the exciting bath is not in a condition to work harmoniously with the paper.

Alfred Swan.—Your query ought to have been addressed to a journal devoted to mechanical pursuits. *We* cannot offer any opinion on the merits of rival safety-valves.

J. B. Street.—The *Art-Student* was a journal devoted to art. It was conducted by Mr. A. H. Wall, but its existence did not extend beyond the publication of two volumes.

Subscriber.—Without entering into the queston of the permanence of the aniline colours, we advise you to make use of the pigments ordinarily employed by painters in water-colours.

J. Ekralc.—Our acquaintance with the "new" Voigtlander lens is confined to the description given in the patent specification we published three weeks ago; it will, therefore, be evident that we are not in a position to offer any opinion on the merits of the lens as a photographic instrument.

Argosy.—While we quite agree with your statement that a "scientific fact can never be written down," we are at variance with you respecting the basis of this assertion; because your imaginary "scientific fact" has not, cannot have, and never will have, any existence so long as the human eyes and the optic nerves are formed in the fashion in which they now exist. If you call when you are next in town we shall have pleasure in giving you a demonstration of the unsoundness of your position.

J. Schofield (Heaton Norris).—Received just as we are going to press. Will have attention in our next.

Ajax (Leeds).—Try the following:—Coat the glass plate with albumen; when dry immerse in a strong solution of nitrate of silver for a minute; then wash thoroughly, and immerse in an aqueous solution of the aniline dye.

One in a Fix.—Why not reduce the strength of the bromide? Let the salting solution contain only eight grains of bromide of potassium, the sensitising bath being of the strength of seventy grains to the ounce.

G. R. B.—A solution for gilding by means of the galvanic battery may be prepared by mixing a strong solution of chloride of gold with a saturated solution of cyanide of potassium. Pour the latter slowly into the gold solution, and dilute by the addition of three times its volume of water.

Varnish (Belfast).—We have made good varnish by a formula similar to that adopted by you with the exception of the mastic, which we omitted. It is probable that in your case the oil of lavender may have been impure. Without receiving a sample of the varnish to try we could not give you any further clue to the failure.

Country Parson.—The chief difference between the two toning baths is this:—The carbonate bath must be used within a brief period after preparation, as it rapidly decomposes, whereas the acetate bath will keep good for a considerable time. To be used under the circumstances described by you the carbonate bath will prove much the better of the two.

Verango.—The great hopes that were at one time entertained of the services to be rendered to photography by magnesium have not been realised. The reason for this is to be found in the fact that the *sodium*, which is the key to the production of magnesium, can be utilised otherwise to greater pecuniary advantage than in manufacturing magnesium in large quantities and at a low price.

H. A. S. O.—A wet collodion plate *can* be developed by the alkaline pyro. method. Before applying the developer it is requisite that the free nitrate of silver be washed off. It is singular that you should have given yourself the trouble of "pondering over this matter for three weeks" without putting yourself to the further trouble of making a single trial, by which your doubts would have been instantly dispelled.

H. J. H. D.—Your enclosure reminds us of what has been said of Queen Elizabeth and her portraits, in which that strong-minded royal lady would not allow her artists to paint any shadows. It is, of course, quite a matter of taste; but if you wish to secure fame as a skilful photographic artist it is indispensable that the shadows be much deeper. The portrait is somewhat insipid, owing to the fault we have indicated.

"Negative Bath."—1. If the bath be acid and out of order add a weak solution of bicarbonate of soda until a permanent milkiness (in a slight degree only) is produced; then place it in the sun for a few hours.—2. A bath is neutral when upon immersing slips of blue and reddened litmus paper neither undergo a change of colour.—3. A saturated solution of iron would prove quite unmanageable as a developer. Try fifteen grains to the ounce of water, with a drachm of glacial acetic acid.—4. A silver bath will not sustain any harm whatever by being exposed to daylight when not in use.

Received.—W. J. C.

"Photographic Rays of Light."—Under this designation a new journal has been started by Mr. Richard Walzl, of Baltimore, U.S. It is to be issued quarterly. Judging from the present number its conductor, Mr. Walzl, has not lost any of the energy with which he conducted his former journal, the *Photographer's Friend.* When space permits we shall give some extracts from this new candidate for the suffrages of the photographic community, and to which we offer a cordial welcome.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician.
For the Week ending February 20, 1878.
These Observations are Taken at 8.30 a.m.

JOURNAL OF PHOTOGRAPHY.

No. 930. Vol. XXV.—MARCH 1, 1878.

ON DUST AND DUST PREVENTIVES.

There can be little doubt that dust, always one of the photographer's greatest enemies, has latterly assumed an even greater importance—at least to dry-plate workers—in consequence of the discovery that it is the chief, if not only, cause of the numerous sorts of spots to which emulsion plates are found to be liable. It would, perhaps, puzzle anyone to give a definition which would cover every phase of the evil, if looked at from every possible point of view; but for the purposes of the present indictment against dust we may define it as any matter whatsoever which becomes suspended in the atmosphere in minute particles, with apparently the sole object of causing irregularities in various operations, but especially those of the photographer.

Mr. M. Carey Lea's remarks in our last number come opportunely as a reminder at a time when many of our readers are probably thinking of commencing their preparations for the coming season; and just now, before things have been got into order, a good opportunity occurs of putting into practice any modifications in our dark room or other arrangements which may have been suggested by the results of recent researches in connection with spots and dust. But it unfortunately happens that, though the evil is so common and so apparently simple, the remedy—at least a perfect one—is by no means easily found; and whatever efforts we may make to circumvent the foe it can only palliate, not cure. However, knowing what we have to contend against, our attention must be given fully to the subject; and, forewarned, let us be forearmed to grapple with the foe to the best of our ability.

It is in the dark room itself where the greatest care is most urgently needed, for the injury performed there by dust is not only of such a character as to be subsequently irremediable, but it makes itself known in the most aggravated form. Moreover, as has been pointed out by several writers in our columns, it is in the dark room that the greatest liability to the formation of dust exists—chemical dust, active and dangerous. With regard to dry-plate spots, however, we are not inclined to hold the latter description of dust so blameworthy as do some other writers—notably, Mr. Carey Lea. In the course of our experiments a few months back in connection with the formation of spots (artificially we may call it) by the application to the film of various chemical substances in extremely fine powder, we found that the most common types usually met with in ordinary practice were invariably formed by comparatively innocuous substances; that such active agents as hypo., soluble bromides, silver nitrate, and pyro. gave peculiar and exaggerated markings of a character fortunately very rare in actual practice. The effects produced by all the substances named would be more correctly described as "patches" than as spots, being irregular and ill defined in outline, and covering sometimes an area nearly as large as a sixpence. The hypo. markings were invariably visible before development, and frequently before moistening the film. It is true that the particles of matter we employed were possibly not so fine as those to be found floating in the atmosphere, but we draw our deductions from the fact that the markings produced were entirely different in character from those common to dry plates—a distinction which could scarcely be produced by mere difference in the state of division. We are inclined to agree with the opinion expressed by Mr. Warnerke—the first who ever attempted to explain the cause of washed emulsion spots—that particles of organic matter are, if not the most active, at least the most common source of the evil, as it was by this means we were able to most nearly imitate the "real article." Still we cannot lose sight of the assistance which chemical agents are capable of lending to the formation of organic dust; the corroding or rotting action of the chemicals upon wood-work, cloths, or other organic substance which may find a place in the laboratory, tend to aid their disintegration, and help to load the atmosphere with particles of matter which would be infinitely better elsewhere. It is quite possible that nitrate of silver (to take a single instance) may give a very different description of spot, if it find its way on to a film in its pure state, to that produced by a particle of matter abraded from a silver-stained developing table, or a minute filament shaken from a duster impregnated with the same salt.

The precautionary measures which we have to adopt are of two distinct classes—the first aiming at reducing the chances of the *formation* of dust to a minimum; the second rendering it, when formed, as harmless as possible. Presuming that the dark room is confined to its legitimate uses, the liability to dust from ordinary causes is small in comparison to a room which is in constant occupation, and in which a variety of operations are carried on. But the spilling of solutions, the scattering of small quantities of solid substances, and the other *etceteras* of chemical manipulation, introduce a fresh danger, of which we have already spoken.

Now, the remedies for this evil are simple enough in theory. "Never spill a drop of solution," says one writer; "let floors and shelves be frequently and carefully washed," says another; but surely to carry out these recommendations in their entirety would occupy the greater part of a photographer's time, and render his life a burden to him. With regard to the spilling of solutions or crystals upon the floor, or, more commonly, upon the work table, no doubt much greater care might be exercised; but, granting the exercise of every possible care, a single unavoidable accident would counteract the efforts of months. Then, as regards washing—be it frequent or otherwise, setting on one side the necessary inconvenience, the upsetting of all arrangements, including the removal of bottles and all the paraphernalia of a photographic room—it is doubtful if the remedy be anything but a very temporary one. The operation of scrubbing the floor and shelves rubs out from the interstices of the wood innumerable particles of dust which have escaped the action of the broom, and these, together with freshly-abraded matter, remain, in great part, in the condition of a thin layer of *mud*—harmless while damp, but actively dangerous as soon as dry. The only way to thoroughly get rid of the dirt altogether is by copious flooding with water, which, it is needless to say, is an impossibility in most studios.

Wood-work is no doubt the most dangerous material we could employ, but, unfortunately, the exigencies of modern civilisation compel us to its use. For the tops of tables and for shelves, however, we might with advantage replace it with slate, which may be now obtained in slabs of varying thickness at a comparatively small expense, and which offer the greatest possible facilities for cleanliness and freedom from dust. The floor presents a greater difficulty. Although the system of laying it with asphalte may be practicable in connection with a professional studio, we imagine that few amateurs are so situated as to be able to adopt it in their laboratories, so we must search for an efficient substitute. We need not go far, however, for a covering, as waterproof baize or oil cloth, if properly laid down, will be found to answer the purpose very well. It entirely protects the wood-work, and when washed presents no grain or hollows to hold the moistened dust particles, which may thus be entirely removed.

The work-table as well as all shelves should on no account consist of bare wood. A good coat of paint effectually prevents the absorption of liquids, and renders the removal of dirt by washing quite easy; but many of the solutions in general use will be found capable of destroying or removing it. Shellac and other varnishes are liable to the same objection; but black varnish or Brunswick black are free from it. The sombre appearance may be somewhat unsightly, but we do not think that should weigh against its efficiency. Perhaps the best plan of all consists in giving the wood-work a thorough coating (or two or three thin ones) of bees'-wax, or, better still, from an economical point of view, paraffine. The wax may be applied in solution, and allowed to soak into the pores of the wood, or it may be laid on by friction with a lump of the substance; in either case, if the operation be properly performed, the woodwork will present a surface quite impervious to aqueous solutions, and but slightly affected by ether, alcohol, or even by acids, and may be washed with the greatest ease perfectly free from all foreign matter. It may be renewed periodically with very little trouble.

When it is possible to so arrange matters, all shelves where bottles or apparatus are stored should be placed at a distance from the table at which plates are coated or set to dry. By adopting this plan, any slight dust which may arise from the removal of a bottle from the shelf will have less chance of reaching the films. The drying closet also should be placed in such a position as to be exposed as little as possible to atmospheric disturbances, or dust will be drawn into it with the current of fresh air. Mr. Carey Lea's suggestion as to the use of glycerine in connection with the drying box is likely to be useful, and reminds us of a similar contrivance we saw some years ago fitted to a drying-box which worked with a current of air. The orifice by which the air-current was admitted was fitted with a framework a little larger than the opening, in which, at intervals of half-an-inch, were fixed diaphragms of perforated zinc; these latter were smeared on both sides with treacle, and the quantity of dust adherent to the zinc after the current had been in operation for an hour or two was really surprising.

For the rest, every precaution having been taken to prevent the formation of dust, we have only to take care not to disturb the small quantity which must inevitably find its way into the room. Several hours should always be permitted to elapse before using the workroom after any cleaning operations, in order that the dust may have time to settle. No plate-cleaning or polishing should be carried on in the same room in which plates are coated; nor should tripoli, chalk, or other powder on any account be used for that purpose, as it is almost impossible to remove the last traces of the powder. We would not even allow a duster a place in the dark room; a *damp* cloth may be kept for wiping up any solutions which may be spilled, and this should be at once washed and wrung out after use. Even the shaking up of a bottle of emulsion had better be performed outside to avoid agitating the atmosphere.

PRINTING SURFACES.

When, on Monday evening last, we saw the deft manner in which Mr. Thomas Bolas, F.C.S., illustrated his lecture—one of the Cantor series—at the House of the Society of Arts, we could not help wishing that the large and highly-appreciative audience had contained more of the photographic element. The lecture was, as we have said, one of the Cantor series periodically delivered before the Society of Arts, and the subject of this special discourse was the production of surface blocks by means of photography.

This is a department of photographic work to which a peculiarly intense interest attaches, if we are to judge of this from the great mass of correspondence which followed the publication of a few chapters on this subject in our Almanac for 1876. Indeed, the correspondence inaugurated by the publication of those articles is still in force.

Mr. Bolas explained in a very happy manner the general characteristics of each process to be described; then followed a detailed technical description of the process and the reactions consequent thereupon; this, in turn, being succeeded by a demonstration in detail of how each part of the process was accomplished—the lecturer adopting the best method of illustrating this, namely doing it in the presence of his audience, the results being in every instance handed round for inspection.

Our object in directing attention to this matter at present is to make a remark or two on one phase intimately associated with the production of surface blocks by the electrotype process—we allude to the best method of rendering the surface of the gelatine relief one upon which copper may be deposited in the best, quickest, and simplest manner. We have referred to an article in a previous Almanac. It is there stated (page 24, 1876) that the surface of a gelatine relief may be rendered "conducting" by means of plumbago or bronze powder, or by the precipitation of silver upon it through the agency of an application of the nitrate of that metal, followed either by exposure to light and subsequent treatment with pyrogallic acid, or by its subjection to the well-known reducing action of phosphorus.

Photography makes rapid advances: since the statement in the Almanac alluded to in the preceding paragraph was written the physical condition of bronze powder has also been making rapid progress. This powder, we may state, forms an electrical conductor better, as we have proved it to be, than plumbago. This reduction of silver, to serve the same purpose, has in our hands been quite successful; but it has demanded the exercise of much patience, knowledge, and skill in effecting its uniform reduction over the surface of a gelatine relief. Till a recent period it was a matter of indifference whether we should avail ourselves of the conductivity of plumbago or of bronze when trying competitive experiments with silver reduced in the manner at which we have already hinted; but, owing to recent improvements in the manufacture of bronze powder, we have now no hesitation in recommending this as the best method for rendering a gelatine relief picture a conductor of electricity. The objections which in this Journal have been suggested against bronze powder as contrasted with the more finely-atomised plumbago (or reduced silver) arose out of the coarseness of the former as compared with the latter. With much gratification we are now enabled to say that such objection no longer holds good. From Mr. Richard J. Allen, the manufacturer of the well-known Bessemer bronze powders, we have received samples of the latest productions in this direction, which are as much superior to what on Monday evening was exhibited, in its effects, by Mr. Bolas as *that* was superior to plumbago. The supreme degree of fineness, as regards impalpability, to which this has now been brought may be deduced when we say that the mere application of a little of the powder to the nail of the finger will, with slight friction, suffice to give the nail surface a coating of the bronze powder so fine and yet so continuous as under a magnifying glass to present an unbroken metallic film without obliterating any of the details of the surface.

The application of this will be obvious. When by means of one or other of the processes which have already been often described, and to which we do not here further allude, a gelatine picture has been obtained in relief or in heights and hollows, it only suffices that after the removal of the surface moisture by means of blotting-paper the fine bronze powder be applied by a camel's-hair brush. The physical condition of the bronze powder now within reach of all is such as to render quite easy the obtaining of metallic or electrotype casts from surfaces the details in which are almost microscopic.

A NEW METHOD OF TESTING SILVER SOLUTIONS.

A new mode of determining the amount of silver present in a liquid by volumetric analysis has recently been published in a scientific contemporary, and as it requires neither apparatus or chemicals that may not be found in many photographers' studios we hasten to place it before our readers in a form suitable for photographic use.

The method, which is simple, easy, and, withal, very delicate—its publication being due to Mr. J. Volhard—is based upon the reaction of sulphocyanide of potassium, ammonia, &c., with persalt of iron—one of the most delicate tests known to chemists. It is so delicate that if a single drop of iron developer, well oxidised (say) by nitric acid, were placed in a good-sized test tube and then filled up with water, emptied, and again filled up with water, a very perceptible coloration would be produced upon the addition of a solution of a sulphocyanide. In large quantity, though still minute, a deep blood-red coloration is instantly formed.

The alkaline sulphocyanides, as is well known, possess such solvent powers as to have enabled them to be proposed as a substitute for the old familiar hypo. in fixing paper prints. It also throws down from silver solutions the sulphocyanide of silver; and, if a persalt of iron, which does not possess a precipitating or developing action with silver, be added to the silver solution, a typical red coloration is not permanently seen till all the silver is thrown down as sulphocyanide, the iron here playing the part of an indicator. It follows, therefore, that we may make a solution of sulphocyanide of a definite strength and use it to tell the amount of silver present in a solution by the aid of a simple calculation.

Sulphocyanide of ammonia has been recommended, but care must be taken to select a sample free from chlorine—a contamination oftenest seen in the ammonia salt. The quantity of this salt required to throw down one grain of silver is seven-tenths of a grain, or, to be accurate, the true proportion is 1000 : 704.

In the paper by Mr. Volhard it is recommended, for the purpose of obtaining a sulphocyanide solution rigidly exact in strength, that a certain quantity of metallic silver be weighed and carefully dissolved in nitric acid, then well boiled, and after cooling a small quantity of ammonia-iron alum added. This solution is then used to test the strength of the sulphocyanide solution. For analysis, when the utmost delicacy is required, such precautions are highly desirable, and if a large quantity of silver solution had to be tested for purposes of estimating its value to a nicety, such delicacy would be necessary, but for the ordinary purposes of bath testing it will be quite enough to use pure and carefully-selected sulphocyanide of ammonium well dried, and dissolve at once the quantity found requisite by calculation according to the scale used. There are two methods in common use by photographers for testing the strength by precipitation, *i.e.*, neither more nor less than volumetric analysis—one in which a measured quantity is put into a bottle and thrown down with a standard solution measured by drachms; the other, and the better one, in which the silver solution is placed in a graduated tube and the precipitator added till the silver is all thrown down. The height the liquid then stands in the tube is read off at once from the tube as so many grains per ounce.

Taking, in the first instance, the latter as our standard we may calculate from a drachm of the solution to be tested; placed in the tube, the level of its surface is marked zero. So much of the space above as would hold one fluid ounce is divided into one hundred divisions. Hence, if the drachm of silver solution took the whole ounce of precipitator, it would indicate that it was of the strength of one hundred grains to the ounce, and, as the drachm is one-eighth part of an ounce, it would contain one-eighth of one hundred, or twelve and a-half grains of nitrate of silver. All that is to be done, then, is to make a solution of sulphocyanide, one ounce of which will throw down twelve and a-half grains of silver nitrate. We have already said that 704 grains would throw down 1,000 of silver, which would be contained in 1,577 grains of nitrate of silver. We thus get the proportion—

$$1577 : 704 : 12\tfrac{1}{2} :: 5{\cdot}58;$$

i.e., 5·58 grains of sulphocyanide of ammonium are to be di[sol]ved in one ounce of water so as to make the required precipitating [sol]ution.

It will, of course, be more convenient to make a larger quantity, and so avoid fractions of a grain. This must be tried with a carefully-made test solution of nitrate of silver, and if it fall short in the estimate of strength it gives it can be easily rectified by adding a proportionate quantity of fresh sulphocyanide out of the same supply. Thus, taking a solution known to be thirty grains to the ounce, if shown as twenty-seven grains it would require an addition of $\frac{27}{30}\cdot3$, or $\frac{1}{9}$ in quantity more sulphocyanide than is already in the solution.

The proportion of the ammonia-iron alum to be added before testing is two and a-half per cent. of a cold saturated solution; allowance must be made for this in graduating the tube. The sulphocyanide solution is then added a little at a time. To employ Mr. Volhard's words:—"At first a white precipitate is produced, which remains suspended in the liquid like silver chloride, rendering it milky. On the further addition of the sulphocyanide each drop produces a blood-red cloud, which quickly disappears on agitation. As the point of saturation is reached the silver sulphocyanide collects in flocks, and the liquid grows clearer, without becoming perfectly limpid, as long as a trace of silver remains in solution. As soon as all the silver is precipitated the flocculent precipitate quickly deposits, and the supernatant liquid becomes quite clear." [The latter effect is just the reverse if the precipitation be by chloride of sodium, in which, as pointed out by Mr. G. Watmough Webster in our columns some time since, the liquid, when the precipitate subsides a little, is limpid till all the silver is thrown down, when it suddenly assumes a milky aspect which no shaking serves to dispel.]

Mr. Volhard continues as follows:—"The sulphocyanide solution is added by drops till this point is attained and till a very faint light-brown colour appears in the liquid, which does not vanish on repeated agitation. The colour is most easily perceived if the liquid be held, not up to the light, but against a white wall turned away from the window."

It only remains to be said that the new solution will keep for at least two years without decomposing; the presence of nitric acid does not at all interfere with the reaction, neither does cadmium, which, in the form of nitrate, would be found in the dipping baths. Nitrous acid and heat are the two points to be guarded against; they cause the striking colour to be entirely destroyed.

There is no part of the preparation of a dry plate which is at once such a comfort when properly performed, and such a nuisance in its performance, as the application of a preliminary coating or substratum, and it is very much open to question whether the advantage gained is commensurate with the trouble incurred. Albumen—the substance most generally employed—is troublesome in preparation if a perfectly-clear film be desired, while the length of time required in drying renders it extremely liable to attract particles of dust, which afterwards adhere obstinately to the dried surface. Add to this the fact that under alkaline development, especially if strong, the substratum gives way, forming blisters, or, in very bad cases, loosening the whole film and acting in a directly opposite direction to that desired. India-rubber is free from these objections, but presents another and, perhaps, more serious one—the liability to cracking from unequal expansion after coating with collodion. This defect may not make itself evident at first—may not appear, in fact, for months; but it is the uncertainty and treachery of its behaviour which render it the more dangerous. Other agents have not come sufficiently into use to require mention, but we wish to bring forward the value of one which, though not new, has at least claims to novelty as a dry-plate substratum, and appears to answer the purpose perfectly. We refer to wax, which has long been employed in certain branches of photography as a preliminary coating to glass before collodionising, and possesses the opposite properties of rendering the film adhesive to the glass while wet, but easily removable after desiccation. We have lately been employing it, in connection with dry plates by dissolving it in ether or chloroform to the consistency of paste. A little dab of the paste is placed on the glass and smeared over with a piece of cotton wool, and afterwards polished off with a silk rubber until no *apparent* traces remain. For small plates this is is all that is necessary, while large ones only require the addition of an edging of india-rubber. Its advantages are extreme ease of application, non-liability to dust, the formation of an artificial surface equal to the most perfectly-cleaned glass with very little trouble, and, finally, it greatly facilitates the subsequent transfer of the film, if desired.

STUDIO BUILDING.

A correspondent asks, in the issue of this Journal for the 8th ult., for some information relative to a new studio he wishes to build; and, as his wants have met with only a single response, I have jotted down a few hints for him, from which may possibly be gathered matter useful to other readers, as the experience I have gained in building three or four studios has made me familiar with many aspects of the subject. In The British Journal of Photography, November 19, 1875, I gave particulars of my own studio, with some explanation of the motives actuating me in selecting certain constructive details. I would refer Mr. Hamilton to that for additional information beyond what is here given.

Mr. Cowell, in the last number of this Journal, strange to say, has given what I may term almost an exact plan, even to its dimensions, of my own studio, which was built under more difficult surroundings than Mr. Hamilton describes; a reference to my diagram on page 555 as above will show this. I consider no advantage whatever would be gained by the single long sash without any vertical side lights such as Mr. Hamilton speaks of. I think it would be no cheaper; it certainly would not possess any advantages for illuminating the sitters, and it has the grave drawback of lessening the available space for groups. It also is sadly in the way when moving the backgrounds, all of mine, with the exception of the permanent one that is strained over the end wall of the room, being made movable on castors. This plan has many merits, not the least being the facility with which the background can be made darker or lighter by moving it sideways to or from the light. One of these screens, eight feet high, cannot be brought within a foot or two of the low side, and the window panes are always in danger of having a corner of the background poked through them. I would advise the room to be symmetrically built; that is, each side wall the same height, though a steeper pitch may be given to the north roof so as better to keep out the sun. I also gave a plan for calculating the position of the ridge to carry out that purpose.

Let Mr. Hamilton, after deciding finally on the dimensions of the studio, draw on a base line the walls as part of a section of his building, and run from one end of the line—the north end—a line making an angle with the wall estimated by subtracting 12° (not 23½°, as by an accident in a former article I am made to recommend) from the *latitude* of his studio. If the ridge fall anywhere on that line or to the north of it no sun will enter the studio. If that indicate a pitch that does not satisfy him he can make the ridge more to the south of the line, and place louvre boards, as suggested by Mr. Cowell, to keep the sun out of the studio. Much comfort will also be obtained by using the arrangement of louvre boards I described, at the west end also, to keep out the afternoon sun during the summer months.

The necessities of the position require this studio to run east and west, and the main deckground end should be the west, as, if reversed, the sitter would almost face the sun in the after part of the day—an arrangement to be avoided as much as possible. In my own studio, as I have before stated, I have light in the south side as well as the north, which is well protected from sun, when not required, by the thick blinds I use. I consider the power of using a south light to be invaluable; I would not be without it. It will not be necessary to have so extensive a surface glazed as on the north, on account of the difficulty of entirely keeping down the effect of the sun's heat. The large surface I originally devised has been lessened considerably by covering it over permanently with boards till the glazed space was diminished one-half. In summer time it is still further protected by a covering of louvre boards, with each board set at a different angle, so that from one particular point in the studio (at the west end) nothing but their edges can be seen, while from the other end nothing but boards is seen; and, consequently, after the sun passes the meridian very little sun is admitted, even when the blinds are all drawn aside. This, of course, precludes the south light being used when the sitter is at the east end of the room; but, practically, it is not needed with a double-lighted room such as I describe.

My glazing ceases at five feet from the background end of the room; and it is an advantage for it to d [illegible], as it gives more play for the screens. It is unfortunate for Mr. Hamilton that his east end is so high instead of his west. He should stand in a supposed sitter's place at the west end, and, looking through his roof all round him, mark off any part of it through which the sky is obstructed by buildings. In the marked-off portion he will find a gain in light if he put there obscured glass instead of clear.

I have had no experience of blue glass, but I know it diminishes the light and so increases the exposure. I believe Mr. W. Keith, of Liverpool, has a studio wholly glazed with it. This glass is, or was, to be obtained from Messrs. J. A. Forrest and Co.

If a greater length than thirty feet is obtainable it is quite worth while to get it, as plenty of distance is often very useful when taking large groups. The question of the material to cover the opaque part of the roof with is, to some extent, mixed up with that of ventilation, which is referred to in the number I have named, and also a little earlier in the same volume by Mr. J. W. Gough, in an article devoted to the subject. The roof may be covered either with slate, asphalte, felt roofing, or metal, such as zinc or lead. As keeping out the heat in summer and wet in winter are the great objects, I say in no case use the felting. It is not much cheaper when the labour of coating it occasionally with tar and sand is considered. Slates are good but heavy. The unglazed half of my studio is slated, and the five feet of opaque at the background end is covered with sheet zinc, the use of which entails the utmost care and watchfulness to see that every nail-hole is made secure from leakage, and this I was not able to get done without having every nail soldered. It is astonishing what a quantity of water will penetrate through the smallest of holes on a roof.

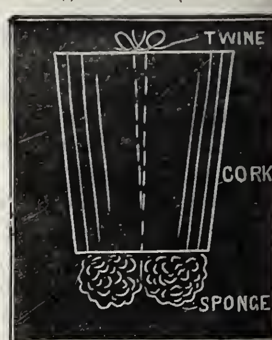
I think the above will be a fairly succinct summary of most of the leading points referred to in Mr. Hamilton's request, but if there be any further information I can give I shall be happy to communicate it.

G. Watmough Webster, F.C.S.

EDGING PLATES.

I have seen and read of many dodges for edging plates with india-rubber, &c., &c.; and, although some are very good and ingenious, still I do not know that I have ever seen any better or simpler than the one I adopt.

Procure a one-ounce, wide-mouthed bottle and a good long cork to fit it; now pierce the cork through its length twice (or in two places) with a stocking-needle, leaving about a quarter of an inch of space between the two holes. Put through them a piece of twine, forming a loop at the small end of the cork, and through this loop place a small piece of sponge not bigger than a marble, when by pulling the twine tight the sponge is held fast against the end of the cork. (See annexed diagram.)



The cork can be put into the bottle after use. The sponge being kept inside is always clean, soft, and ready for use, and by being fast to the cork forms an excellent guide, for the width of the edging depends upon the size of the piece of sponge.

W. J. Chadwick.

THE MODERN MAGIC LANTERN.

[A communication to the Manchester Photographic Society.]

This instrument—still best known by its old, unscientific title—has, I think, in no part of the world been more used and experimented upon than in my own native town of Manchester, and therefore I consider it the most fit place to make a few remarks on those in present use. In order that all honour be given to the person to whose researches we owe our present compact and powerful oil lanterns, I wish it to be more widely known that the honour belongs to Mr. Marcy, of Philadelphia, who spent many years in working out and completing what he very appropriately named the sciopticon.

The instrument itself requires no description to members of this Society, as I believe they nearly all possess one—its chief features, as you know, being a narrow double flame, placed edgeways to the condenser, and its very compact body, which does not much exceed the latter in diameter.

Now, next to inventing something useful myself, there is nothing gives me greater pleasure than to introduce a foreign invention which I think may prove of use to my fellow-countrymen; therefore, when in America some six years ago, and seeing the advantages of Marcy's invention over the clumsy ill-lit things we were using, I determined to introduce it into this country on my return, and arranged with Mr. Marcy accordingly.

As I expected, the instrument became a great favourite with the scientific public, and no greater proof of its value could be shown than in the number of imitations that have sprung up, more or less copied from it. Among others we have the euphaneron, the lucidus lantern, the eureka lantern, the excelsior lantern, Steward's lantern, Jones's lantern, and, in fact, anybody's lantern who chooses to order a sufficient number, and have his own brass plate attached. Those I have just enumerated are all manufactured by the gross and by the same firm, and, with the exception of the title-plate, are identical.

One departure from the Marcy form of wick is found in these, viz., that of dividing it at one end, which I think to be a mistake, as it nullifies the chief feature in the sciopticon, and is really bringing us partly back to the old circular or broad wick, besides other disadvantages. On my return from America I tried a variety of forms of wicks as well as the triple, but came to the conclusion that no improvement was effected.

There are also new forms of lanterns in the market, but on examination they will all be found to have some parts copied from Marcy's sciopticon. Among other illuminating powers (oxyhydrogen always holding the foremost place), we have a small lamp which the reader (Mr. W. J. Chadwick) will introduce to you, and which I have styled the "pyro-hydrogen lamp," the history of which it will be as well to lay before you.

As far back as the year 1828, in the records of a celebrated patent case, occurs the following:—Alderson, B., said—"The blowing apparatus was perfectly well known, the heating of air was well known, the tuyere was well known as applicable to blast furnaces; then what he really discovered is that it would be better to apply air heated to red heat, or nearly so, instead of cold air. That is the principle—that is the real discovery." Here, I suppose, we have the first mention of the principle which has since been applied to hot-blast blowpipes.

The first attempts that were made, as far as I can learn, to apply this principle to lighting purposes took place some seven or eight years ago, and chiefly among the members of this Society. A number of experiments were tried by Messrs. M. Noton, Webster, Fletcher, Pumphrey, Winstanley, and others. Whether these gentlemen aimed too high, or that the matter proved a failure, certain it is that for seven years it remained in *statu quo;* and when upon applying to Mr. Fletcher, of Warrington, early last year, to manufacture for me the particular form of apparatus you see here tonight, he assured me that the system had been tried by himself and others and had entirely failed, at the same time trying to dissuade me from going on with its manufacture.

The lamp before you is of German invention, having been somewhat modified by myself for lantern use. With a steady pressure of air, which I find is best obtained by turning the water pressure into a large barrel or other convenient vessel, and taking the air from a small tap at the top the light burns steadily all the evening, the lime being hardly affected, and, if put away in an air-tight case, may be used for months.

I will say nothing of its "candle power"—that I will leave to those who choose to test it; for since the introduction of those two words in connection with magic lanterns they have become so common that thousands of candles are advertised with the greatest recklessness, and without stating how many are lighted, or whether they are not the small ones in use to adorn Christmas trees.

Walter B. Woodbury.

NOTES ON OXYGEN MAKING.

There is much truth in the adage, "familiarity breeds contempt;" and it is well that it should be so, as, were it not for that, there are many occupations of such a dangerous nature that it would be difficult to find men willing to undertake them. But while this becoming accustomed to danger is so far good, it is quite possible to overdo it and neglect simple precautions, thereby converting what would otherwise be safe operations into work which is so frequently followed by disaster and death. This fact is abundantly proved by the frequent explosions permitted to occur in the production of oxygen from potassium chlorate and manganese dioxide. It is well known that, so long as the material is pure and the tubes clear, the operation may be carried on with perfect safety; but when the manganese has been, either by accident or design, mixed with carbon in one or other of its various forms, it results in the formation of carbonic acid in such volume as to make an explosion inevitable. How carbon finds its way into manganese dioxide is difficult to understand, the price of the latter being such as to put intentional adulteration out of the question. The fact is, nevertheless, patent that it is not unfrequently present; and, as a simple and ready means of discovering it has been again and again pressed on the attention of those interested, it seems little short of a crime to neglect it.

There is no better or readier method of ascertaining the safety or otherwise of the mixture about to be used than the one I published in this Journal more than a dozen years ago, which was this:—On getting a fresh stock of manganese mix a few grains of it with the suitable proportion of the chlorate, place the mixture in a test tube, and hold it over a gas or lamp flame. If the material be sufficiently pure the salt will be decomposed and the gas pass quietly off. There may be seen a few bright sparks of light playing on the surface of the mixture, arising probably from the presence of minute traces of carbonaceous matter, but they are of no consequence. Should, however, there be carbon present in sufficient quantity to cause an explosion, as soon as decomposition has fairly commenced the contents of the tube will be projected in the form of flame and incandescent particles like the burning of a squib, but much more violently. I need hardly say that the mouth of the tube must be turned away from the operator, and if that be attended to there is not the slightest danger in the application of the test.

While carbon is the general source of danger in the production of oxygen, much more dangerous substances are occasionally met with, and readers of this Journal will remember an instance that occurred in Leven, in which sulphide of antimony had been supplied instead of manganese; but the above test is applicable to this, or indeed to any other, substance from which an explosion can arise.

In a recent article on this subject the Editors directed attention to a hitherto little-suspected source of explosion, viz., the alleged fact that a drop of the oil that had been applied to the screw of the mercury-bottle form of retort might fall into the heated mixture and lead to the liberation of olefiant gas. No doubt if such were the case a serious accident might occur, as olefiant gas mixed with three times its volume of oxygen explodes with great violence; but the Editors will not be very angry if I say to those who still use that obsolete and unsuitable form of retort that they may keep their minds at rest, as the temperature required for the decomposition of the salt is far too low to break up the oil, and every trace of oxygen would be off long before an atom of olefiant gas could be produced. I am aware that the late Alexander Bryson, of Edinburgh—no mean authority on such matters—at a meeting of the Royal Scottish Society of Arts, attributed an explosion that occurred in his house to that cause; but he soon afterwards saw reason to change his opinion, as the tube, which is still in my possession, was found completely choked. It had been filled with metal to enable a suitable bend to be made, and that metal remains there to this day.

Of course all this has been stated before, but some things require to be repeated again and again before those especially interested can be induced to give them their attention, as a case that occured here a few days ago clearly shows. A well-known member of the Edinburgh Photographic Society—who has for many years been in the habit of making oxygen for lantern purposes, and who, according to his own account, had never had an explosion, and did not think he was likely to have one—sent for the usual supply of material and placed about a pound and a-half in a new conical sheet iron retort. This was placed on an open fire in a grate or stove, and in a few minutes an explosion occurred, tearing the retort as if it had been cardboard, wrenching the exit tube completely off at the junction with the cover, breaking the grate into fragments, throwing himself violently against the opposite wall of the room, and also smashing the glass in the window. Now all this would have been prevented by the application of the above simple test, as on examining the manganese it was found to contain over twenty per cent. of coal dust.

In the ordinary manufacture of oxygen, especially when the convenient Bunsen burner is the source of heat, I have reason to believe that many operators do not get the full quantity of gas the salt contains. Experience shows that, practically, a pound of the chlorate will yield about 4.3 feet, but I know that too often much less is obtained. Shortly after the flame is applied the oxygen begins to come off—slowly at first, but in a minute or so very rapidly—and continues to do so for some minutes. Gradually it decreases in rapidity, and by and by comes only in single bubbles. If the heat be continued, and especially if a little increased, the gas will in a few minutes again come off as rapidly as at first, continue for a longer time to do so, and return to single bubbles, or perhaps stop altogether. Now if at this stage the heat be withdrawn, the tubes disconnected, and the retort allowed to cool and then opened and inverted, a considerable quantity of undecomposed crystals will fall out mixed with a large proportion of manganese; and, as the usual method is to pour water into the heated retort to dissolve the chloride residue, this undecomposed chlorate is, of course, lost. The heat, therefore, should be continued, and it will be found that, in most cases at least, a third liberation of oxygen will take place. No doubt the difficulty of getting off the full quantity of oxygen arises to a great extent from too large a quantity of the mixture having been put into the retort, the heat which plays only on the bottom being insufficient to decompose the upper layer. The ordinary form of retort is also faulty; it would be much improved by being at least one-half wider at the base.

My attention was particularly directed to this subject a short time ago, on being consulted by the manager of a large theatre, who employed from eight to twenty lime lights in certain scenes in a pantomime. The oxygen was passed direct from the retort into a large iron tank, from which, under suitable water pressure, it was supplied to the burners; but the consumption was so great that the retort had to be kept constantly at work during most of the evening to keep up the supply. The retort, which was of thin boiler plate, was suspended from the roof of the tank house by a chain immediately over a rose Bunsen burner, the flame of which was large enough to cover the bottom and come well up the sides. The stock of "oxygen mixture" was kept in packets of five pounds each—four of chlorate and one of manganese—and the charge was one such packet. This should have given at least over seventeen feet of gas, but as I saw the operation carried on the product was not much more than half that quantity. This great loss was not discovered, as to save time the moment the heat was removed water was poured in to dissolve the supposed residue, and enable the gas-man to start another batch. I recommended the reduction of the charge to one-half, and I understand that they now get as much oxygen at each operation as before, and that it comes off in less than half the time previously required.

Acting on a hint given by the Editors in the article already alluded to, I have gone pretty fully into the question of the advantages likely to be derived from the substitution of some inert material for the manganese, and am forced to the conclusion that the action of the latter is more than simply mechanical. The experiments were made in a hard glass tube, one gramme of potassium chlorate being employed in each, and the heat—that of a small Bunsen burner—was the same in all cases. The chlorate, without admixture of any kind, commenced to fuse at the end of one minute, and shortly after bubbles of gas came off, the fused mass spurting a good deal half way up the tube. At the end of four minutes seventy cubic centimetres of oxygen had been collected, and it continued to come off slowly; but the tube showed indications of being about to fuse, and the flame was withdrawn. When the tube had cooled the residuum was very hard and dissolved with difficulty, so that the process of emptying a retort would be troublesome.

In the next experiment the chlorate was intimately mixed with a nearly pure silica in the shape of the beautiful white Fontainbleau sand used in the manufacture of the finer varieties of flint glass. Within thirty seconds after the application of heat the mass acquired a pasty consistence, and rapidly swelled till the tube was half full. When the gas began to come off there appeared a number of beautiful scintillations, showing the presence of carbonaceous matter in small quantity. It stopped when 160 c.c. had been collected, and no more could be got until the lapse of four minutes, at which time the glass had passed into a bright red, and was beginning to bulge.

In the third experiment ordinary river sand was used, and although the result was better it was not satisfactory. The objectionable swelling up did not take place, but the salt seemed to separate from the sand, collecting at the bottom of the tube, and behaving not unlike the fused chlorate in the first experiment, and ceasing to give up gas when 240 c.c. had come over.

In the last experiment the usual manganese was mixed with the chlorate, and the result was in every way satisfactory. The oxygen began to come off about twenty seconds after the heat had been applied, and continued steadily to do so for two minutes, at which time the receiver showed 300 c.c. The mass did not pass beyond a pasty state; it did not appreciably increase in bulk, and the salt may be presumed to have been completely decomposed, as it stopped at that stage and did not again appear, although the heat was applied till the tube actually fused.

From the foregoing experiments I suppose—at least, until we get more light on the subject—we must hold that oxygen makers are shut up to manganese, with all its liabilities to carbonaceous admixture; but, seeing that the dangers from that source are so easily guarded against, it is not a matter for any serious regret. It is just possible, however, that the state of division in which the "inert material" is used may have something to do with its action; but it is difficult to reduce sand to an impalpable state, and the operation would make it much more costly than manganese. Possibly the calcined flints used in the manufacture of pottery, and which can be got in very fine powder, might answer the purpose. I shall, by and by, give that substance a trial, and, should it prove suitable, will inform my readers of the result of the experiment.

John Nicol, Ph.D.

SUB-BROMIDE OF SILVER IN EMULSIONS.

I have read with great pleasure, in the Journal of February 15th, your excellent article on a suggestion given simultaneously by Mr. H. B. Berkeley and by myself. Unhappily my letter has not given the exact impression of my idea, so that I fear you have exaggerated the practical difficulties of the method I advocated.

I used the expression "definite quantity of silver nitrate in excess;" that is to say, that I take precautions at the end of the operations—that is, when all the Ag Br is transferred into Ag_2 Br, and when all organic matter capable of combining with silver has entered into combination—to secure the presence of uncombined silver nitrate in the emulsion in unknown quantities, but in sufficient quantity to be amenable to the testing. The aim of this is to know the effect of operations by the identical results given by successive tests.

How is this final excess of free silver to be obtained? Simply by the calculating of—1. Nitrate of silver necessary in the transformation of all the soluble bromide into silver bromide. 2. Silver nitrate combining with the organic matter; this, of course, is to be guessed at, and cannot be ascertained with precision. 3. The excess of silver, which has to be sufficiently large to allow a certain margin for No. 2. The total of these quantities will be the proportion of silver nitrate necessary to be introduced into the collodion.

You will see, now, that the organic silver compound is formed in presence of the same quantity of silver nitrate in excess in each emulsion, containing different proportions of silver bromide, but formed with the same normal collodion.

I should think it advisable to use a collodion containing but a small proportion of soluble bromide, and, on the contrary, a full amount of water, so as to facilitate the total transformation of Ag Br into Ag_2 Br. But in all cases this end will be obtained (if obtainable at all) only after a long period of time. L. O. Sammann.

NOTES ON PASSING EVENTS.

By a Peripatetic Photographer.

Tea!—blessed, tranquilising beverage, that stimulates our faculties and quickens our perceptions without clouding our intellects!—how shall I sing thy praise in becoming strains? I had been thinking about a photographic friend now far away, and someone, *apropos* of mentioning of his name, had alluded to his devotion to tea as an organifier in dry collodion processes. This suggested the reminiscence of a peculiar warmth of tone that characterised tea-organified negatives, and I concluded that tea, properly used, ought to yield transparencies possessing that rich warmth which constituted one great charm in the albumen transparencies of the late M. Ferrier. Preparing half-a-dozen plates with an emulsion containing excess of bromide, I washed and organified them by means of an infusion of "bohea" so strong as to be almost undrinkable. A short exposure, followed by a prolonged development, completed throughout by alkaline pyro., yielded six exquisite transparencies of a rich, warm tone. I offer this bit of experience as my contribution to the praiseworthy effort now being made to re-clothe the nearly dry bones of stereoscopic pictures.

The mother of one of my numerous friends has kept the eighty-fourth anniversary of her birthday. "Well, what of that?" do you ask? I'll tell you presently. When reading an article on *Exposure* contributed to this Journal a few weeks ago by Mr. W. Harding Warner—an article which, I frankly confess, I do not understand, and hence cannot appreciate—I came across this passage: "if we had much white around us our lives would become unendurable, for we should be in a perpetual glare and our brains be in such a state of activity that our existence would be considerably shortened." Here is the point of the incident I have introduced; the lady to whom I have just made allusion resides in a latitude so high as to cause her surroundings to be "friz" water and snow a great portion of the year. It seems, then, that individuals may have "much white" around them without having their brains excited to such a state of activity as to considerably shorten existence. But does the possession of an active mind abbreviate the period during which mind, or soul, and body are linked in unison? I trow not. The most intense mental activity and ripe old age are perfectly compatible with each other. Brewster was not an intellectual sloth, yet his earthly pilgrimage far exceeded the infrequent "four score." So with many others whom I could mention. Hence Mr. Warner must reconstruct his dogmas. Before I leave this gentleman I must remind him that he opened his article by putting a question which he left unanswered. He asked—"Photographically speaking, what is exposure?" and goes on to aver that "the text-books tell us it is an indefinite something which can only be judged of at the time of taking a picture." This, he says, causes bewilderment to the tyro. Will Mr. Warner permit me to inquire the name or title of any one text-book which gives such a foolish definition as that with which he accredits them all? Mechanically, optically, and chemically speaking, exposure is the act of uncapping a lens so as to allow of the impact of the image of external nature upon the sensitive surface of the plate so as to effect or set up a process of reduction to be completed by the action of the developer. Does Mr. Warner attach any occult or unrevealed significance to this act? I scarcely think he can, seeing he is writing a practical and not a metaphysical article on a practical subject. I trust that this gentleman will give me credit for writing with the desire of obtaining further information.

Mr. W. M. Ayres has it in his power to bestow a great favour upon photographers by imparting a little more information respecting his ingenious method of cutting sensitive paper than it was possible to glean from the editorial article in which that method was described. The kind of information I, and doubtless many others also, desire is a statement as to the various measurements on his guides or gauges. It is quite true that any clever man might find out for himself the best lengths in which to divide the gauges to be made use of in marking the paper; but, as I have already experienced, it takes a long time to do so, and the "waste" pieces may not be of precisely the dimensions that would be desirable. If Mr. Ayres will kindly publish a list of the dimensional values of a few pairs (if not all) of his gauges he will render a great service to others besides the "Peripatetic Photographer."

Observing that the "service medal" of the Photographic Society of Great Britain was bestowed at the last meeting of that body upon Mr. Henry White as an acknowledgment of his services as treasurer, I am led to remark that this bit of Fabian policy comes with a very ill grace so many years after his resignation of the office. Other treasurers have come and gone since Mr. White retired, and, on the assumption that he rendered excellent services while he held office, it would have been a more graceful act had there been less tardy recognition of such services. To be of full value, services of that nature should secure acknowledgment promptly and without allowing a very considerable period to elapse.

It is a good thing that the new American journal, entitled *Photographic Rays of Light*, is only to come out quarterly. Its title is sufficient to render appalling the bare idea of its becoming a weekly serial whose name might have to be pronounced more than once a day. If its proprietor or publisher wish it to thrive let him by all means have it "re-christened" ere its second number sees the light of a new quarter. An old proverb declares that "it is better to hang a dog than give him an ill name," and the same may be said in connection with serial literature.

(To be continued.)

ON GELATINE EMULSION, ORGANIFYING OF COLLODION, AND EASILY-PRODUCED, UNBREAKABLE DRY PLATES.

I made my first experiments with gelatine emulsions last autumn. They are less troublesome and take less time to produce than collodion emulsions, and they are extremely sensitive to light; but their subsequent treatment is less simple and easy than is the case with collodion emulsions. For this reason I fear the professional photographer will not soon take kindly to the gelatine emulsion process.

My experiments led me to a very important result, namely, to the organifying of already-prepared collodion emulsions with gelatine emulsion. My experiments are still only at the first stage (owing to continued ill-health), but they are very promising, especially in respect to increase of sensitiveness and ease of production. The question as to which cotton is most suitable, and all details as to washing of the plates and treating them with preservatives, are wholly excluded from consideration.

The organification proceeds as follows:—Into a slightly-warmed and but barely-fluid gelatine emulsion an equal volume of collodion emulsion is poured, the whole being stirred with a glass rod during the transfusion. The cotton and the bromide of silver contained in the last-named emulsion are thrown off, and after standing for eight or ten hours they form a coating of some consistency, which should then be taken, and, having been pressed between sheets of blotting-paper to remove any moisture present, it should be dissolved in ether and alcohol in the proportions of one gramme to ten cubic centimetres. This solution is sufficient to organify ten times its volume of emulsion collodion. At the same time that the collodion emulsion is thrown off the gelatine emulsion is also precipitated, and remains suspended in the fluid as a viscous, cohesive mass. This may also be diluted with ether and alcohol, and thereby a fluid emulsion be produced which will furnish good and very sensitive dry films, and which may also be employed to organify collodion emulsions.

The viscous gelatine emulsion, after the fluid has been poured off, should be placed in a shallow mortar, and some fifteen or twenty c.c. of ether and alcohol (nine c.c. of ether to seven c.c. of alcohol) poured over it. By warming, accompanied by vigorous stirring with a glass rod, part of it will be dissolved. When the fluid has become saturated pour it off into a special bottle, and add more ether and alcohol. This proceeding is to be repeated until the last remnant of the viscous gelatine emulsion is diluted.

In order to make the conveyance of dry plates easier when going on long excursions, as well as to steer clear of the custom-house regulations as to the carrying or sending of dry plates, I have prepared light and unbreakable dry plates, the simplicity of whose mode of preparation exceeds that of all other methods. As a support for the snesitive film, glass is replaced by sheets of uncoloured gelatine such as are to be had commercially of various thicknesses. These gelatine leaves are placed in a bath of one hundred c.c. of benzine and one gramme of best caoutchouc, and afterwards dried. When about to be prepared with emulsion and also for the subsequent development, the caoutchouc-coated gelatine leaf is laid upon a glass plate of the same size. Three corners of the leaf are covered by small glass triangles (of the same size as the glass corners in the dark slide), which are fastened down upon the supporting sheet of glass by means of wooden clamps. The fourth corner remains free in order to allow the fluids poured upon the negative to run off. The finished negative remains upon the support. To transfer the film to glass would only be a purposeless increase of the number of manipulations, and would also necessitate a different preparation of the gelatine leaves. In order to make them more durable the edges have strips of paper pasted on both sides of them. When thin gelatine leaves are used the negatives may be reversed if desired. If in the course of development flaws should appear on the reverse side of the gelatine from the picture film, being only in the caoutchouc film they may be mended with benzine.

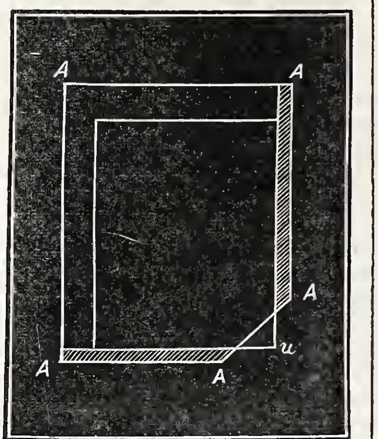
I believe that these leaves might also be used for wet plates, which would be a great advantage when reversible negatives are desired. My experiments on that point have, however, met with interruption for a time, so I recommend it to the consideration of those interested. If any such should try these leaves, it would be a good plan to fasten the edges of the gelatine leaf and the glass plate with strips of thin paper having a coating of india-rubber solution, or with very thin so-called gutta-percha paper.

Albumenised paper, rendered transparent by a mixture of mastic varnish and oil of poppies, placed, after being dried, in a caoutchouc solution gives also a good support for dry films. Gelatine leaves coated with caoutchouc are stored between wax or paraffine paper, and dry plates prepared upon them are stored with the films facing each other, and a sheet of very fine red or yellow tissue paper between each.

The interest of photographers in the emulsion process is very widespread, and it is very well suited to replace all other dry processes and to become generally used. Every photographer who is competent to overcome the difficulties of the wet collodion process will soon overcome those of the emulsion dry process. Every dry plate prepared with bromide of silver collodion emulsion permits a considerable degree of over-exposure without detriment to the negative. In this way faults of exposure may easily be avoided. Authorities amongst photographers, both professional and amateur, have borne witness that upon emulsion dry plates negatives of as great perfection may be produced as upon wet plates. Inattention while working, inexactitude in following the directions given, or other unfavourable outward circumstances are the reasons of failure, just the same as in the case of wet plates. In taking landscapes, architectural views, and interiors, also in reproductions of oil paintings and statuary, or other works of art in museums or art collections, emulsion dry plates may compete* with wet plates, and are often preferable to them.

Still, many photographers who are accustomed to take photographs at a distance from their studios prefer to work with wet plates, in spite of their many inconveniences, because at the time and place of taking the negative they wish to be assured that they have been successful. But the negative upon the emulsion dry plate developes as easily and quickly as that upon a wet plate, and the solutions required for developing are so concentrated that only small quantities require to be taken on a tour. Alkaline development seems to those who have not tried it complicated and inconvenient; but, let them try it a single time, and they will be convinced of its simplicity.

To prepare dry plates and develope negatives upon them I have a little contrivance which I can recommend. In the first place, it allows the plate to be prepared so that no corner remains free. In the second place it saves the hands from permanent stains from the alkaline developer. The way it is used may be seen from the annexed diagram. A A A A A is a glass plate. The shaded parts are strips of glass fixed on with isinglass and bichromate of potassium. Upon this plate the plate, *u*, to be prepared or developed is laid.



The developer given as Mr. Warnerke's, in the last number of the *Mittheilungen*, is the same as the one I have been using and giving out in a printed form along with my dry plates and emulsions for the last nine months. In my version I say add twenty drops of a 1·15 solution of bromide of potassium, while Mr. Warnerke has five drops of a 1·4 solution; thus the quantity of bromide of potassium is the same. For a very sensitive emulsion I always recommend fifty drops of the pyrogallic acid solution and thirty drops of the bromide of potassium solution. [For formulæ see report of meeting of the Berlin Photographic Society, page 91.] Mr. Warnerke omits the fifteen or twenty drops of gelatine solution that I give altogether. Practised hands may do without this addition, but I think it worthy of recommendation to those who are making their first attempts at alkaline development. The development certainly proceeds somewhat slower with it, but very cleanly, and it also helps to give the negative a better covering.

Mr. Warnerke speaks of a very long exposure in the printing-frame. Is that a mistake? In exposing an emulsion dry plate under a negative in a printing-frame I never find a long exposure possible. In such cases I make the emulsion less sensitive by the addition of a few drops of glacial acetic acid and bromine tincture, and then I only expose for a second if I wish to get an unfogged transparency; besides that I must use a much diluted developer, containing a great deal of bromide of potassium solution. [That Mr. Warnerke does also.] In preparing transparencies for enlarging—for which purpose emulsion dry plates, as I have often remarked before, are very suitable—the addition of gelatine to the developer is especially to be recommended. I get the best transparencies by an exposure of from thirty to forty seconds to the flame of an ordinary petroleum lamp. Here I may mention a circumstance that has fallen under my observation, but which I do not know whether others have observed; it is that transparencies printed by contact give far better enlarged negatives than those made by means of the camera, either upon wet or dry plates. The hair and beard, especially, are fine and natural in the first, and in the last remarkably and surprisingly thick. Development with pyrogallic acid always gives more brilliant and transparent transparencies than iron. I shall recur to this point at a future time.

I had always exposed emulsion plates in a dry condition only, until I read the experiment reported in the last number of the *Mittheilungen*, when Mr. Warnerke exposed a plate coated with emulsion, but not dried, and got a picture in a third of the time of exposure required for a wet plate—see page 56 of THE BRITISH JOURNAL OF PHOTOGRAPHY—induced me to try a similar experiment. The result obtained was similar, even when using the less sensitive emulsion which I employ for transparencies. From this last I think that the field for experiment on the sensitiveness of emulsion dry plates is not yet closed. I have had the following experience in that department:—It is not difficult to prepare a very sensitive bromide of silver emulsion. Those that contain a small excess of silver are very sensitive; those that are neutral are less sensitive; and a greater or less excess of bromine lowers the sensitiveness more or less. Those are most sensitive that can be used without chlorine. Unfortunately, dry plates prepared with the last in a short time become untrustworthy and lose their sensitiveness. When absolute certainty of the result becomes a question—as in long and expensive excursions—I think a not too sensitive emulsion is the most suitable; and he who has accustomed himself to a certain routine in the use of alkaline developers will, by modifications in the mixture of the same, be able to develope a good negative, even if he should occasionally find it necessary to give too short an exposure.—*Photographische Mittheilungen.* FR. WILDE.

* Only in certain cases. In spite of all the progress that has been made dry plates do not yet give such certain results as wet plates, and they continually show varying proportions in the tones.—Ed. *Mittheilungen.*

HOW TO EMPLOY PHOTOGRAPHY AND THE LANTERN AS EDUCATIONAL AIDS.

No. IV.

NEXT to the alphabet we must teach the value of the ten fingers we are endowed with—curiously the basis of the decimal system—as if to indicate the proper "natural selection" as regards all worldly calculations. Then, the child should be made to *understand* that the real advantage of mastering the letters of the alphabet and the value of the ten digits is that by simple conjunctions it can specify the names of objects, their quantity, and money value—a practical application which, with a little "tact" on the part of the teacher, may be brought "home" to the mind of even an infant-school pupil. I do not see the necessity for "parroting" over columns of words of one syllable, words of two syllables, three, four, and polysyllables, but go straight to the mark at once by making a child spell the names of such objects of daily wants as bread, cheese, tea, milk, butter, sugar, water, and so on. It is sure to take pride in being able to spell its own name and where it lives—points of practical advantage should the child ever lose its way. The game of "going errands"—"like mother or sister Polly"—is a bit of *Kindergarten* work that has its practical value without the pupil feeling that it is "learning lessons," but matter it takes an interest in. Imagine the pride of a child when it can express on a "movable alphabet" box—"I want a roll, 1d.; cheese, 2d.; butter, 3d."—and that it is thus able to lay out a total of 6d. at "the shop."

The value of MONEY up to one shilling may be readily imparted to a child through "*sight knowledge*" by making toys of four farthings, first showing their equivalent value in the halfpenny and penny; next that twelve copper pennies are of equal value to one silver shilling, six to half a shilling, or one silver sixpence, four to the third of a shilling, or a silver fourpenny-bit, three to the fourth of a shilling, or a threepenny-bit. The value of WEIGHT may be shown by aid of a cube of wood made up of sixteen smaller cubes, so as visibly to represent that one pound is equal to sixteen ounces. Again: one of these smaller cubes is also divisible into sixteen still smaller cubes, to show that one ounce is equal to sixteen drachms. The relation of the BULK of various articles to weight may be placed before the eye by a cube of lead, a cube of cork, a cubical bag of moist sugar; all of which, like the largest cube of wood, weigh exactly one pound. LINEAR MEASURE may be taught in a similar manner by aid of twelve strips of deal one inch long, wherewith to piece out one foot length: others one foot long, to piece out one yard, and so on. The value of the division of TIME may be taught by aid of a large model of a clock face with movable hour, minutes', and seconds' hands.

These examples are only suggestive of how a child may be made to see the practical advantage, *to itself* (self-interest is at the bottom of all human nature), of learning to spell the names *of familiar objects of daily want*, their number and money value, &c., &c.

Next we may approach a higher standard by aid of object lessons, wherein the lantern may begin to play its part. Take, for instance, the familiar object *bread*, which may be visibly represented by the thing itself—a model or its representation on "a slide"—as "a half-quartern of household," "a cottage loaf," "a roll," "a French roll," "muffin," "crumpet," "scone," or "bannock." Explain that all these are made from "flour" mixed with "water" and fermented with "yeast," by which "dough" is produced—the basis of all wheaten bread. Next that "flour" is produced from the "wheat" of the "corn plant" by grinding at the windmill, pictorially illustrated by slides of corn plant, wheat grains, flour, corn-field, reaping, wheat sheaf, carrying home to the windmill, grinding in the mill, with section of a mill, a bakery, &c.; whilst the history of "water" and "yeast" may be treated as fairy tales that will rest long in the imagination of youthful minds if duly illustrated pictorially by the lantern. Cake, pie, and pudding may thus be made to appeal to the brain as well as to the stomach of the infantile pupil. Beef, veal, mutton, pork, ham, bacon, potatoes, greens of various sorts, carrots, turnips, onions, herbs, salt, the local names of the common poisonous plants, or other dangerous objects, &c., all furnish words to spell, about which the teacher can also *tell* something, and show some pictures which by appealing to the eye will convey a basis of sound information through the medium of our much-vaunted "sight knowledge."

On the system of making instruction a matter of interest to the pupil, the earliest reading lessons should be, first, the old nursery rhymes; next, as a step more advanced, the standard fairy tales. These are subjects every child should be made acquainted with;* for, as shown by the investigations of Ralstone, Robert Hunt, and others, they had their origin in the myths of the early nations, and as such myths spread from common centres north, east, west, and south, according to the temperament of people they reached, so they became modified, whilst, as transmitted to us by such authors as the Brothers Grimm, they have become classic reading. Illustrated by such artistic sketches as the lamented George Cruikshank designed (to play the part of artificial memory as well as to excite interest), such reading lessons would be followed with avidity.

Passing from the infant school to those of a more advanced grade, it must be noted that at the middle-class schools, where pupils are only prepared for mercantile employment, Latin and Greek are not taught, and ancient mythology is a thing unknown. But surely every person who wishes to claim the position of being "educated" ought to have some clear ideas as to the characteristics of the mythological gods, goddesses, and heroes. This may be effected by a course of English reading on ancient mythology, illustrated by lantern slides of the most typical statues executed by ancient and modern sculptors, thus seizing the opportunity of imparting at the same time a very desirable amount of artistic knowledge. A biographical course of reading, illustrated by the lantern in a similar manner, would make the student familiar with the characteristics of the most important personages who have gained name and fame in connection with literature, science, art, religion, warfare, or commerce. Without such courses of abbreviated instruction much that a person would read in the daily papers or in modern literature, or see at public museums, art galleries, &c., would be utterly incomprehensible.

These ideas are not flights of fancy, but have been tried practically at Moscow, and the result is that the instructor finds he can teach "better and quicker" when lantern illustrations go hand in hand with reading lessons or lectures.

SAMUEL HIGHLEY, C.E., F.G.S., &c.

* Alas! how many children of the poor have ever heard of Cinderella, Hop-o'-my Thumb, or any other of the heroes or heroines of fairy-lore?

FOREIGN NOTES AND NEWS.

A METHOD OF DISTINGUISHING THE SILVER HALOIDS.—THE THEORY OF THE LATENT IMAGE.—THE BELGIAN MEDAL FOR THE BEST DRY PROCESS.

A SIMPLE method has been published, by Herr Goldschmidt, by which with the aid of the blowpipe the various haloid salts of silver may be distinguished. Take a piece of charcoal, and, having scooped out a small cavity, place in it a small quantity of the substance to be tested, together with a little sulphide of bismuth, and apply the flame of the blowpipe. If the matter under examination be silver iodide a brilliant red incrustation will be formed at a little distance from the cavity; if it be silver bromide the colour will be deep yellow, while the chloride gives a white product. The sulphide of bismuth may be prepared with the greatest ease by fusing the metal with flowers of sulphur.

Apropos of the discussion which has been proceeding in our columns upon the sub-bromide theory, the following remarks of Captain A. Hannot, in the *Bulletin Belge*, may be noticed. Speaking of the theory of the formation of the latent image, he says:—"Probably the action of light upon iodide of silver results in the formation of a sub-iodide, in conformity with the following chemical equation—

$$3\,Ag\,I = Ag_2\,I + 3\,I\ (sic),$$

and probably also this transformation takes place only in the presence of a body capable of absorbing iodine. In the wet collodion process the excess of nitrate of silver which covers the sensitive plate plays this important part, since if a plate be thoroughly washed upon its removal from the silver bath the alteration of the iodide by light does not take place. The reaction brought about by the presence of nitrate of silver should be as follows:—

$$6\,I + 6\,Ag\,NO_3 + 3\,H_2\,O = 5\,Ag\,I + Ag\,IO_3 + 6\,H\,NO_3."$$

With regard to the first equation, we may remark that the formula $Ag_2\,I$ for sub-iodide of silver represents the continental view of the composition of that substance; independently of that the equation contains a palpable misprint. The second formula introduces a new salt—iodate of silver. How would the formation of silver bromate affect an emulsion?

We learn from the *Bulletin Belge* that the gold medal of 500 francs offered by the Belgian Photographic Association for the best dry collodion process has been awarded to Mr. Warnerke. The *Bulletin* goes on to remark that Mr. Warnerke's process "is destined to work a veritable revolution in the practice of photography by its simplicity and the uniformity of its marvellous results, which will ensure for its clever inventor a distinguished rank amongst the illustrious *modificateurs* of the discovery of Daguerre and Niepce." We were not previously aware that emulsion photography was a modification of any process of either Daguerre or Niepce, and, moreover, it appears to us that our Belgian *confrères* are a little deficient in their knowledge of the history of emulsion processes, or that Mr. Warnerke has something good to publish.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
March 4........	West Riding of Yorkshire......	Oddfellows' Hall, Bradford.
,, 4........	Photographers' Benevolent	160A, Aldersgate-street, E.C.
,, 6........	Edinburgh	5, St. Andrew-square.
,, 6........	Bristol Amateur	Museum, Queen's-road.
,, 7........	South London	John-street, Adelphi.

MANCHESTER PHOTOGRAPHIC SOCIETY.

THE monthly meeting of this Society was held at the Memorial Hall, on Thursday evening, the 14th ult.,—Mr. Alfred Brothers, F.R.A.S., President, in the chair.

After the routine business had been transacted, Mr. W. Watts and Mr. William Banks were elected members.

Mr. W. J. Chadwick then read a paper, contributed by Mr. Woodbury, on *The Modern Magic Lantern* [see page 98], and exhibited the pyro-light alluded to in the paper. He (Mr. Chadwick) also exhibited one of Mr. Fletcher's air and gas apparatus. Mr. Chadwick further explained how the sciopticon was adapted for use with the lime light, showed his improvement on Mr. Woodbury's lime-holder, and concluded by presenting the Society with an oxyhydrogen burner for the sciopticon, for which the thanks of the Society were voted to him.

A member exhibited a portrait which was said to have been taken by the Vanderweyde artificial light. The portrait was a very good one.

Mr. Noton showed his swing-lens mount in its completed state.

Mr. Coventry exhibited an ingenious pocket camera and stand designed and made by himself.

Mr. J. W. LEIGH showed a transparency on a collodio-albumen plate, developed with ferrous oxalate dissolved in a solution of potassium oxalate. The colour of the deposit was not considered suitable for transparencies, although an excellent one for negatives. He (Mr. Leigh) said the developer, when first applied, became black, owing to the plate having been treated with gallic acid.

Mr. D. Young came prepared to exhibit another improved gas retort, also a perfected Keevil's lantern; but time would not admit of these being shown.

The members, and several gentlemen of the Liverpool Amateur Photographic Association who were present on a return visit, then adjourned to another room, and did ample justice to an excellent knife-and-fork tea.

The PRESIDENT congratulated the company on being favoured with the presence of their Liverpool friends, which was suitably responded to by Mr. W. H. Wilson, of Liverpool, on behalf of himself and his companions.

After the wet and dry processes had been satisfactorily worked up in the refectory, the company adjourned to the large hall to witness a lantern exhibition, conducted by Messrs. W. J. Chadwick and N. Wright. The apparatus used were two sciopticons with the lime-light arrangement, the oxygen being produced during the time of exhibition by Mr. Chadwick's generator and gas-holder. The pictures shown (including a fair proportion by members of the Society) were very choice, and the gas apparatus did its work excellently.

The walls of the meeting-room were adorned with a number of capital pictures by Messrs. Coote, Leigh, Sanderson, and other members; and, after a most enjoyable evening, the meeting was adjourned.

GLASGOW PHOTOGRAPHIC ASSOCIATION.

A MEETING of this Association was held in the Religious Institution Rooms, on Thursday, the 14th ult.,—Mr. John Urie occupying the chair.

The minutes having been read and approved of, Mr. Sloan gave an extempore sketch of a photographer's experience on the Ohio. It was very amusing and greatly appreciated by the members, and Mr. Sloan was awarded a hearty vote of thanks.

The Secretary made a statement concerning the artificial light collodion transfer process of Mr. J. Solomon, of London, and distributed some of Mr. Solomon's transfer paper. The following is the method and formula:—First soak the transfer paper for a quarter of an hour before using it. Dissolve half-an-ounce of bees'-wax and an ounce of rosin in a pint of turpentine. Clean a glass in the usual way, then with a small quantity of the above rub over the surface of the glass with a linen pad, so that the substratum shall be kept thin. Coat the glass with a collodion slightly ripe. The nitrate of silver bath is the ordinary negative one. As a focussing medium on the screen cover a piece of glass with white paper, and when focussed sharply it is replaced by the sensitised plate. Exposure—supposing the negative to be a vignette *carte de visite* enlarged up to 12 × 10—from ten to thirty seconds by the magnesium light, according also to the density of the negative. Developer:—Three grains of pyro., three grains of citric acid, and five minims of acetic acid in one ounce of water. Alcohol, if necessary, according to the oondition of the nitrate bath. Fix in hypo. and wash. Then take the wet transfer paper, place it on the image, squeegee out all the bubbles, plaee it upright to dry, when the paper will come away from the glass with the image. Mount on cardboard with glue. The transfer paper is a commercial article, and sold at a very moderate price. Mr. Solomon also sent samples of his absolute non-actinic cloth.

Mr. Solomon was heartily thanked for sending his formula, and it is expected that the members will have something to say on transfers at the next meeting.

A vote of thanks to the Chairman concluded the business, and the meeting was adjourned.

Correspondence.

PACKING NEGATIVES.

To the Editors.

Gentlemen,—It may be of interest to some of your readers to know of a safe method of packing a large quantity of negatives which have to travel a long distance and endure rough usage.

I have just transferred my printing establishment to London, and I am indebted to an amateur friend for the following plan of packing between two and three thousand valuable negatives:—

They were first placed in the ordinary grooved boxes, a layer of thick felt being placed on the bottom for the plates to rest upon. The spaces between the plates were then filled with dry sawdust; sheets of wadding were then placed on the top of the negatives and the lids fastened down, thus rendering each box a solid mass. These boxes were then packed in strong heavy cases—the whole, with printing-frames, weighing over two tons—and I am pleased to say they were delivered at Dulwich without a single breakage, or even a scratch.—I am, yours, &c.,

6, *Rosendale Villas, West Dulwich, February* 26, 1878. Payne Jennings.

THE FORTHCOMING PARIS EXHIBITION.

To the Editors.

Gentlemen,—British photographic exhibitors at the approaching Paris exhibition are in a difficulty from the necessity of appointing and naming an agent in Paris who will receive the pictures and hand them in to the exhibition authorities.

From communications I have had with a number who are similarly situated to myself I find we know no one in Paris to whom we can entrust this, notwithstanding the enormous number of applications. Can you or any of your readers assist us? If a united scheme could be devised to send the cases for collection to some centre, and some agent takes charge of the whole lot, much expense and difficulty would be saved.—I am, yours, &c., Samuel Fry.

Surbiton, February 27, 1878.

[The publication of this note will, doubtless, evolve a solution of the difficulty.—Eds.]

VOIGTLANDER'S NEW LENS.

To the Editors.

Gentlemen,—My attention has been drawn to your issue of the 1st ult., wherein you quote some paragraphs from Herr Voigtlander's specification, and, in a few sentences, proceed to draw therefrom inferences which are erroneous and the result of a misconception.

Any person reading the concluding paragraph in your notice of the new lens would at once infer that the visual and chemical foci were *for all practical purposes* not coincident, as in the old form of lenses made a generation ago; the visual focus having been obtained the chemical focus had to be arranged according to a scale. I need hardly say that no person in his senses would, at the present day, purchase such an instrument.

It is, no doubt, difficult to give a very clear description in a foreign language of any subject in which technical expressions are of the greatest consequence, and it is still more difficult to convey the same meaning as in the original language. I will content myself with making a statement only, viz., that, in point of fact, having with the new lens obtained the visual focus you have in the same plane the chemical focus of the highest intensity. For all practical purposes, therefore, the two foci are coincident, and this holds good for all distances.

With regard to the other suggestion respecting the quality of the glass used, permit me to state there is every reason for believing that a period which might be measured by a man's lifetime would be necessary for bringing about a change in the colour of the dense flint glass of the quality used by Herr Voigtlander, and at the expiration of such a period of time the character of the lens as a photographic instrument would in no way be altered. I need hardly say that Herr Voigtlander is thoroughly acquainted with everything that has been suggested or written about the manufacture of glass for optical purposes.

A much denser flint glass than that used for the new lens was employed in the manufacture of old telescopes by Fraunhofer and Dolland at a period when the manufacture of optical glass was imperfectly understood. I think that no person would have hesitated to purchase telescopes of those makers even with the certainty that, say within fifty years, they would have become useless, but a much longer life may be predicted for the new symmetrical lens by Herr Voigtlander.—I am, yours, &c., R. W. Thomas.

London, February 26, 1878. *Agent for Voigtlander.*

[If Mr. Thomas compare the account of the lens given in the Journal with that in Herr Voigtlander's final specification he will find it to be what it purports to be, viz., a *literal* and complete transcript, and not merely the quotation of "some paragraphs." It is matter for regret that the patentee had not employed a patent agent conversant with English idioms; because in all English works devoted to photography the over-correction of the *visual* image in order to obtain the *chemical* image as perfect as possible has, by universal consent, been held to signify that these two images are not coincident. We are pleased to be informed that Herr Voigtlander's own very decided words do not here correctly interpret his meaning; for, like our correspondent, Mr. Thomas, we are of opinion that the most useful lenses are those in which both the visual and chemical foci are brought to the same plane.—Eds.]

TERRIBLE EXPLOSION OF A CYLINDER OF OXYGEN GAS.

To the Editors.

Gentlemen,—Your issue of January 25th contains an account of the explosion of an oxygen retort which possesses more than ordinary interest for many of your readers on this side of the ocean, from the fact that a similar accident has recently occurred in our neighbouring city, Baltimore, with fatal results. If a brief statement of the facts will give emphasis to the necessity for care in the use of oxygen gas, your space and my time will not be employed in vain.

On the afternoon of January 23rd, a few minutes previous to the commencement of a *matinée* performance in one of the theatres of Baltimore, the gas was turned on from a copper tank of compressed hydrogen gas, which exploded with terrific violence on a lighted match being applied to the jet. The operator received injuries from which he died in the course of a few hours, and one or two others were seriously hurt.

The apparatus for the production of the light consisted of two copper tanks or cylinders, each about ten inches in diameter by forty inches in height—one containing the ordinary house gas, used in place of pure hydrogen, and the other oxygen, each being under a pressure of about eighty pounds per square inch. The blowpipe, tubing, &c., were of the usual form.

This apparatus had been used the evening before with perfect safety, and the testimony at the inquest showed that the only thing that had been done in the interval was to add ten pounds pressure per inch to the oxygen cylinder. The result shows that a mistake must have been made, and that the ten pounds of oxygen was added to the wrong cylinder, forming an explosive mixture.

The cylinder was blown into fragments, which flew in every direction; the bottom, passing through the floor on which it stood, broke a floor beam in two and went through a second floor below. The explosion was undoubtedly less violent than it might otherwise have been from the weakness of the cylinder, which was made of sheet copper not more than the one-twenty-fourth of an inch in thickness.

The mistake of compressing oxygen gas into the wrong cylinder was due to carelessness and the absence of any adequate means of distinguishing between the cylinders.

The use of these gases compressed in this manner has become so common with us as to afford a profitable business for one company in New York. Their method of making the gas and precautions against accident may, perhaps, interest your readers at another time.

With one exception they have had the good fortune to escape serious accident for many years. In August, 1877, a cylinder exploded at their works, from a cause so singular and unlooked for that I trust you will spare me a few lines more of your valuable space in which to state the facts.

A workman had been engaged, during the dull season, in soldering on to each cylinder a brass plate giving the name and address of the company. One of these cylinders contained oxygen gas, compressed to 225 pounds per square inch. It was made of iron about three-sixteenths of an inch thick, was eight inches in diameter by thirty-six inches in height, and had been tested to 500 pounds per square inch. The workman had filed a bright surface for the plate, which was 3 × 4 inches, and applied a heavy soldering iron, the heat from which caused such an expansion of the compressed gas as to explode the cylinder, killing the unfortunate man almost instantly.

These two accidents show that the danger of explosion is not confined to impure chemicals in the retort, but may be caused by a mixture of the two gases, however strong the cylinder containing them, or by the application of a considerable amount of heat to a full cylinder.—I am, yours, &c., J. J. Wilson.

New York, February 16, 1878.

MR. M. CAREY LEA'S FERROUS OXALATE DEVELOPER.

To the Editors.

Gentlemen,—I have been using Mr. M. Carey Lea's ferrous oxalate developer, and can confirm all that Dr. Huggins says about it. It is a most admirable developer, and I strongly recommend all dry-plate workers to give it a trial.

The most convenient way to use it is in a dipping bath, the plate being washed with water before immersion. It must also be well washed with water after development and before fixing.—I am, yours, &c., Joseph W. Swan.

Newcastle-on-Tyne, February 27, 1878.

"TRIAL OF LANTERNS."

To the Editors.

Gentlemen,—The report of the "trial of lanterns" at the last meeting of the Bristol and West of England Amateur Photographic Association renders the following account necessary. It will be remembered that the above mentioned was not considered conclusive or satisfactory. I afterwards received a letter from Messrs. Newton and Co. expressing much surprise and dissatisfaction at the result, which you will see was warranted.

It appears that Messrs. Newton and Co. had extended permission to other opticians to make their patent refulgent lamp, and unfortunately some of them were made in an incorrect manner; one of these I was using in the lantern referred to in the last report. Messrs. Newton and Co. at once sent me one of their own phantasmagoria lanterns and refulgent lamp complete. It was then at once evident where the defect lay; the lamp used on the former occasion had inadvertently been constructed with half an inch *less* burning surface on each wick.

Last week, therefore, a most careful and crucial test was applied, with the following result:—1. As to triple-wick lamps. The only two I believe in the market were tried. Result: Newton's triple-wick refulgent lamp was superior to Hughes's triplexicon as to volume, quality, and diffusion of the light.—2. As to double-wick lamps. Newton's plantasmagoria lantern and refulgent lamp was decidedly superior to the sciopticon, there being better illumination and more even diffusion of light.

It will, therefore, be seen that the triple-wick lamps *both* gave a little more light than the double-wick, but it was considered that none of the three-wick lamps at present in the market gave enough extra light to make it worth while to use them in preference to the double-wick lamps, when the extra heat given out and the extra trouble of management is taken into consideration.

The opinions here stated I give as they may interest your readers, and were the *unanimous* ones of all the exhibitors and others present, viz., the President, Vice-President, Treasurer, and Secretary of the Bristol and West of England Amateur Photographic Association. There were many other merits and demerits discussed, but these I will not enter upon, the light being that really under consideration.

I probably should not thus have troubled you had not the former communication on the subject been sent.—I am, yours &c.,

February 27, 1878. H. A. H. Daniel,

Hon. Sec. B. and W. of E. A. P. A.

"A GROWING GRIEVANCE."

To the Editors.

Gentlemen,—Respecting the above, which appeared in the Journal a fortnight since, I have been much impressed with the importance of bringing such a subject under the discussion of the photographic public. I should have written this last week, but I fully expected to see the matter thoroughly taken up in your last issue.

Although I cannot say I have suffered as a principal in this increasing evil of repeated and unnecessary re-sits, as an operator I have had my patience often tried, and none would be happier than myself to see its removal.

I quite agree with what you say respecting the present plain-fitting garments and soaped-down locks of the fair sex, and think it is the cause of *many* re-sits; but there are other sources from which the evil springs.

The first—and worst, I believe, if not the original cause—is the practice of photographers advertising "No orders completed unless the proofs are approved." I believe this plan is dying out—not before time; it has taught the public a practice that will take years of the strictest application of a system in the opposite extreme to erase. The firm I am connected with—one of the oldest in the north—carried on this approval system to perfection until they became aware that an astonishing number of negatives taken during the year were either retaken or never ordered from; the proofs, of course, as the sitters were not pressed for payment at the time of sitting, were never returned, therefore involving a dead loss in each case.

A few instances will give you an idea of the effects of this system. A lady was photographed seven different times during an interval of about nine months; she changed her dress every time, and even at the end of the performance was not satisfied, but ordered six cabinets, and was quite surprised when she found she was charged for all the previous proofs. She said:—"I thought I could be taken until I approved of the proofs, free." Another had three re-sits for half-a-dozen *cartes de visite;* and another buxom dame, wanting one cabinet, expected two to choose from, and because there was not *would not like it,* but sat again, and after all took the first. I could give numerous other instances, but these will be sufficient to show that the approval system ought to be stamped out.

And now I have a word to say about the system at present so much adopted—that of prepayment for orders at the time of sitting. It is certainly much better than the above, but my experience of it convinces me that it encourages re-sits, for the simple reason that when people pay in advance they expect you to please them, and if you are strict enough to limit all re-sits to those whose proofs are photographically at fault then people look upon you as rather given to sharp practices. The following is the usual way of transacting business under this head:—A party comes to have a photograph taken, and upon returning to the show-room to leave the name and address, he or she is asked the extent of the order, and politely informed that it is the custom to pay at the time of sitting. Of course such a thing was never heard of, and the question is asked—"What will be done if the proofs are not liked?" Now, there you are. In nine cases out of ten the visitor is told he or she can have another sitting, and pay on these conditions. Now where will you find the lady who can resist the temptation just to try once more when she has paid on such conditions as these? You grant a privilege, and of course it will be used. You can answer this question another way if you like. You may say "provided there is any fault on our part;" but refuse to re-take them on these conditions and you find you are looked to for a good expression, or even to make a bad-fitting dress fit well, or an ugly face charming, or your clients are mortally offended if you don't give them one more trial.

Another mistake from which re-sits spring is the custom among photographers of never turning a sitter away however bad the light; they get what they can and consider they have done their duty. But I think it would be wiser to mark all those down as failures, and send an intimation to the sitter to come again in better weather than to retouch and print from a bad negative, and draw down upon the photographer the criticism of the customer's friends, while it impresses upon their minds that if they don't like their proofs they can sit again.

You will now think it time I was suggesting a remedy for the evil I have written so much about. Well, first of all, let photographers drop that pernicious custom of sending a circular out with their proofs in which is expressed an invitation amounting to this:—"If the proofs are not approved of we will be happy to give you another sitting." I would suggest that in every show-room should be placed a list of prices drawn out as follows. Supposing the charge is twelve shillings per dozen for *cartes de visite,* and twenty-four shillings for cabinets:—

"*Cartes de Visite.*

Per sitting of two positions.	Per dozen.	Re-sits, one position.
3s.	10s.	2s.

Cabinets.

5s.	20s.	3s.

All sittings to be paid for at the time, and all orders to be paid for when given."

I think if the above be placed where everyone who enters could read it you need not care how many times the person came to be retaken, as you always pay yourself for pleasing them. In this way you give your sitters fourteen *cartes de visite* and receive 13s.; or fourteen cabinets, and receive 25s. I think this is reasonable on both sides, and I believe it would stamp out re-sits in most instances; for I have found that when you enforce extra payment some beauty is generally discovered in the proof which hitherto had "blushed unseen."—I am, yours, &c., Reflex.

February 25, 1878.

EXCHANGE COLUMN.

No charge is made for inserting these announcements; but in no case do we insert any article merely *offered for sale*, that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a *nom de plume* be thought desirable), otherwise the notice will not appear.

Postage-stamp camera and six lenses, diamond cameo ditto, stereo. ditto, and other articles will be given in exchange for posing chair, backgrounds, and enlarging camera.—Address, H. DUNBAR, 74, Paradise-street, Liverpool.

Wanted in exchange, a Dallmeyer's 1B ordinary lens, a curtain background and studio camera, for a 10 × 8 burnisher, solar camera (complete), printing press, type, &c.—Address, PHOTOGRAPHER, Broadway, Victoria Park, London.

Wanted, anything useful in photography, in exchange for the following:—Stereo. camera, focussing glass and dark slide (for one lens only); 20 × 15 tilting bath; porcelain washing trough and colander (Harvey's); a Leach's enlarging apparatus for reducing or enlarging from fifteen inches; also, two tripod stands for field work (very strong), and several plate-boxes.—Address, WM. JOHNSON, 2, Tower-street, Stockton-on-Tees.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

NOTICE.—Each correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a *nom de plume* as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

B. JONES.—See a letter by Mr. R. W. Thomas in the present number.

J. J. WILSON (New York).—Thanks. Such an article as you suggest will be very useful and interesting.

J. R. JOHNSON.—Our correspondent will have something to say on carbon printing improvements in our next number.

H. HAMILTON tenders his thanks to Mr. John Cowell for his able letter in answer to the query put to the latter gentleman. His advice shall be acted upon.

HENRY SWAN.—The intensity of the illumination does not depend upon the diameter of the condenser, but upon the relation existing between the distance of the light from, and the diameter of, the condenser.

GEORGE BROWN.—Try the effect of adding an ounce of nitric acid to the washings containing the chloride, and then stirring well with a glass slab. This will cause the precipitation to take place more rapidly.

Z. X. (Perth).—To reduce the over-printed proofs place them in a weak solution of cyanide of potassium—say of the strength of half-a-grain to the ounce of water. A little solution of chloride of gold may be added with excellent toning effect.

MARY B.—No method exists by which a negative from a print on albumenised paper can be obtained that will yield proofs quite equal to the original. The best way of proceeding will be to produce an enlargement, work it up carefully, and then from it obtain the negative.

A PLYMOUTH "BROTHER."—1. No. 3 is by far the most artistic picture of the collection; the others are very indifferent indeed.—2. No copyright exists.—3. Calomel is a sub-chloride of mercury, and for photographic purposes will not answer as a substitute for the bichloride.

GEORGE WOOD.—You have misunderstood us. We distinctly said that *previous* to sunning the silver bath it should be rendered alkaline, whereas you appear to have placed it in the sun in an acid condition and then rendered it alkaline before using it. No wonder you could not obtain presentable negatives. Read our directions again, and follow them to the very letter.

J. H. J.—Tannin forms a most invaluable preservative, and plates prepared by its aid will keep well for several years. But this applies only to the unexposed plates; for, after exposure, if the development be delayed for any lengthened period, the latent image will be found to have been slowly but surely flying away all the time, until at length by no process of development whatever could an image be made to appear.

PHOTOLITHO.—Engravings may be copied *quite well* by means of collodion emulsion. You labour under a great mistake in supposing that blacks free from fog cannot be obtained. By making use of a bromide of silver film you may obtain a greater control over the quality of the resultant negative than by any other process, because by increasing the proportion of soluble bromide in the developer you may go on increasing the density up to absolute opacity without veiling, in the slightest degree, the finest lines of the engraving.

J. SCHOFIELD.—Our correspondent observes that he is unable to understand Captain Abney's formulæ. He says:—"I have made ten ounces of bromide of zinc emulsion, as given in Captain Abney's work, page 83, but cannot understand why so large a proportion of solvent should be used, viz., six to eight grains to two ounces of ether and alcohol. Is it the ordinary proof spirit that is meant? I have used methylated ether ·720 and methylated alcohol ·805, and have got a very thin emulsion, which, I know, will not matter, as it has to be washed. Can I save the ether and alcohol by adding more cotton and silver without affecting the emulsion at present made?"—We see no reason why the proportion of solvents should not be reduced.

BELPER.—Kindly put your queries in a more definite form and number them, retaining a copy for yourself. We shall then be enabled to give the required information.

REV. W. G.—It not unfrequently happens that the pyroxyline with which collodion is prepared has been made under such conditions, as regards the strength of the acids, as to render it soluble in alcohol. This explanation will suffice for explaining the cause of your negative film becoming dissolved when attempting to varnish it. The remedy in this case will consist in the reduction of the strength of the alcohol by adding a few drops of water to the varnish.

W. J. SHIRTCLIFFE.—The maker of the lens has an excellent reputation. When it is to be employed in portraiture the small lens must be laid aside. Unless we examined the combination we could not indicate the manner in which the small lens is to be utilised. If your drawing be strictly accurate, the position of the back lenses has been reversed; the *convex* lens must be placed nearest the end of the tube. In the drawing the concave lens occupies that position.

ROBERTA.—The lens you describe is a "triple achromatic." It is a form that is not now manufactured, although it was much in use at one time. You must not remove the small concave lens when using it; for, although by such an act the focus would be shortened and the rapidity of its working greatly increased, the area of definition would be *very* much reduced and the image altogether greatly inferior to that which would be obtained by retaining all the lenses in their proper places.

R. H. H.—The mere specifying of an invention without going into details will be held as a suggestion only, which is not susceptible of receiving protection by patent. Here is one test by which the soundness of a patent may be ascertained: the specification must contain such a clear statement of the details of the invention as to enable one of that class of the public conversant with the subject in its general aspect to carry out the invention to a practical issue. The following is what Mr. Hindmarch, one of the commissioners appointed to inquire into the working of the law of patents, says in his report:—"Specifications of inventions are frequently prepared in such a manner as to occasion great difficulty in construing them, and in ascertaining the nature and extent of the claims of inventions they are intended to make, and from this cause the cost of litigating patent rights is often greatly enhanced. There is too much reason for believing that specifications are frequently thus prepared with a fraudulent object. A specification ought to define the invention intended to be comprised in a patent so as to enable any person of ordinary skill and intelligence upon reading it to ascertain without difficulty the nature and extent of the right conferred by the patent. If an alleged invention cannot be so described it is one which, if it deserves to be called an invention, ought not to be made the subject of a patent." From the preceding will be obtained *data* upon which to determine the soundness of a patent so far as the specification is concerned.

RECEIVED.—*The Artists' Annuity Fund Almanac.*

SOUTH LONDON PHOTOGRAPHIC SOCIETY.—The next meeting of this Society will take place in the Rooms of the Society of Arts, Adelphi, on Thursday next, March 7th, when Mr. Wratten will illustrate the development of an emulsion plate.

THE ESTIMATE OF ENAMEL PHOTOGRAPHY BY ROYALTY.—On Friday last Mr. A. L. Henderson was summoned to Windsor, where he had the honour of submitting to Her Majesty the Queen a number of enamels intended for the Paris exhibition. Of these Her Majesty expressed her approbation, and retained for her own collection several of the specimens.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. STEWARD, Optician.
For the Week ending February 27, 1878.
THESE OBSERVATIONS ARE TAKEN AT 8.30 A.M.

Feb.	Bar.	Wind.	Wet Bulb.	Dry Bulb.	Max. Tem.	Min. Tem.	Remarks
21	30·62	W	42	44	55	37	Foggy

JOURNAL OF PHOTOGRAPHY.

No. 931. Vol. XXV.—MARCH 8, 1878.

DIRTY PLATES.

Of all the troubles which beset photographic operations there is, perhaps, nothing more annoying than a dirty plate; for though, in a general way, it is a matter of no difficulty to secure immunity from the evil, it will crop up unexpectedly at inopportune times without any apparent cause and without any departure from the ordinary routine of plate cleaning. The occurrence of these accidental dirty plates is, of course, dependent in a very great degree upon one important point—whether the glass is new or has been previously used; but, although this difference between new and old plates does exist in practice, there is really no just reason why it should be so, for the extra liability of the used plates to produce stains under a second development arises solely from carelessness or want of method in the treatment of glasses which are set aside to be cleaned and re-used.

The constant recurrence of failures attributable to this cause has had, no doubt, much to do with the general spread of the practice of using a preliminary coating both in wet and dry-plate work. In the latter branch the substratum was found necessary on account of the great tendency of the film to leave the glass during development, especially with certain preservatives; but in the wet process, where no such tendency exists, the very general practice of albumenising the plate can only be looked upon as a safeguard against dirty plates. Even in dry processes, though it has been found that, for small and medium-sized plates, a mere edging of india-rubber or albumen is sufficient to retain the collodion film in its place throughout the operations of developing, fixing, and washing, many operators still prefer the more troublesome course of covering the whole surface. This, then, forms another argument in favour of viewing the substratum in the light of a preventive against stains on development.

In dry-plate work, however, during the last few years there has been much less trouble arising from dirty plates—a fact which may be accounted for in two ways:—Firstly, by the introduction and general adoption of emulsions in place of the bath; and, secondly, by the substitution of alkaline pyro. for the older silver development. It was long since noticed that in using an emulsion process much less care in cleaning the plates was necessary than when the bath was used, and this was explained by the supposition that the free silver contained in a bath film produced the stains by its action upon the organic or other matter adhering to the surface of the glass, but that in the case of an emulsion film, there being no free silver present (we speak of the old collodio-bromide process), the stains were not produced. How far this may have been true or how much dependent upon the fact that alkaline pyro. development was employed we do not now pretend to say, but we are strongly of opinion that the latter was more probably the correct explanation.

That the employment of alkaline development secures a remarkable immunity from stains arising from imperfectly-cleaned plates there cannot be a doubt. First noticed accidentally, we have frequently proved the fact by actual experiment, and within the last few days we have had it brought to our notice in a particularly striking manner. In experimenting upon the comparative density of the image rendered by various modifications of the alkaline developer a developed picture was "bleached" by means of bromide of copper, and, after re-exposure, again developed with alkali. This treatment was repeated four times without any abnormal reduction, a perfectly clean development resulting from the last application of the alkaline pyro. The effect of silver intensification was then tried, but before any accession of density was noticeable the plate was completely covered with markings running in a circular direction, and evidently caused by a particle of some impurity having been rubbed over the surface of the glass in polishing. To place the cause beyond doubt we repeated the experiment upon a plate purposely smeared with a damp duster, and afterwards only lightly polished, and the result proved to be in every way identical with that just described.

We do not wish it to be inferred that we put forward this feature of alkaline development as an encouragement to carelessness and want of cleanliness—quite the contrary; our reason for mentioning it is simply this:—We have on more than one occasion expressed an opinion in favour of silver intensification in preference to completing the image with alkaline pyro. alone, and we have heard several objections to the silver method on the ground of its liability to stains and markings. Now, as this defect was not laid to the charge of silver development when it was the only means available it appears to us that those who bring it forward at the present time have by long use of the alkaline method unconsciously fallen into habits of carelessness in the matter of plate-cleaning; they have found that a comparatively small amount of trouble suffices to clean a plate so as to pass the ordeal of alkaline pyro., but when tested against pyro. and silver it is found to be wanting. In justice, then, we ask those who object to the use of silver on the grounds stated to give it a fair chance, when, we have not the slightest doubt, they will find their objections groundless.

Upon other grounds also we put in a plea for greater care in cleaning the plate. It seems probable that the new developer—ferrous-oxalate—will play an important part in dry-plate photography in the future, and it may be as well to state that it is not endowed with the same latitude in this respect as alkaline pyro.; moreover, from what we can, so far, see of its action silver intensification will, in the majority of cases, be indispensable, hence any shirking the work of plate-cleaning will, in all probability, lead to the unjust condemnation of the new method.

Let us now turn to another phase of the "dirty plate" question in which there is room for some reform. It is the practice in many cases we know to allow dirty plates to accumulate until the stock of clean ones runs short. The excuse is invariably that it is not worth while cleaning two or three at once, so they are put on one side until a quantity probably representing a day's work has to be done. Independently of the magnitude and unpleasantness of the job (for plate-cleaning is not the most amusing of occupations), a large amount of unnecessary trouble is thus incurred.

If immediately a plate is spoilt in development it were washed free of the developing solution and put away until such time as it might be found convenient to clean it, matters would not be so bad; but in many work-rooms a receptacle containing a detergent solution is kept, to which all spoilt plates are consigned to wait the completion of the cleaning process. There exists a mistaken notion that by the adoption of this course the after-treatment of the glass is facilitated, but the contrary is the case. Excellent though the detergent may be when properly used, its over-use is as injurious as it is otherwise beneficial; whether it consist of soda, potash, or the mixture of bichromate of potash and sulphuric acid recommended by Mr. M. Carey Lea, it gradually acts upon the glass in such a manner as to necessitate a special course of treatment to neutralise its effect, if indeed that is always possible. Powerful alkalies are known to act upon the surface of glass by corrosion after long contact; indeed, the mere presence of pure water between two surfaces is sufficient to produce an indelible mark upon photographic glass. The action of the chromic acid solution is peculiarly powerful, as it appears to be absorbed into the pores of the glass, producing a strongly-marked metallic mottling which only appears when a subsequent picture is developed.

By far the better and, we think, the proper plan is to clean spoilt plates at once. As soon as a plate is found to be useless wash off the developer, and *before it has time to dry* remove the film. The moist film may be removed with the greatest ease by merely passing the finger over it, or if of a very adherent nature it will yield to gentle friction with the flat end of a good-sized cork; if allowed to dry the collodion contracts into a hard, horny state, and becomes much more difficult of removal, breaking up into minute fragments which adhere most tenaciously to the glass. By following this system, too, the films are easily collected and stored in a receptacle kept for the purpose, and will be found in the course of time to form a respectable item in the silver residues. After removing the film the plate only requires rinsing well under the tap, or for extra security may be rubbed on both sides with a pledget of cotton wool dipped in dilute nitric acid, rinsed, *and dried* with a clean cloth. If so much of the cleaning be performed without delay the expenditure of labour is a mere trifle, and the plates may then be stored away with perfect safety to await the final polish when required for use. The general adoption of a systematic plan of this sort will render the occurrence of a dirty plate a matter of rare occurrence, and entirely do away with that periodical *bête noir*, a day's plate-cleaning.

There is one more alteration we should like to see made in the system of plate-cleaning, namely, the abolition of detergent *powders*, at least in dry-plate work. They are, no doubt, extremely convenient as well as effective, but, however carefully applied, they are liable to cause much trouble in the shape of pinholes and spots. The electrical condition of the glass when submitted to friction favours the adherence of the particles to its surface, and the rough edges of the plates are almost certain to retain some of the powder, no matter how carefully it may be removed. The polishing cloth in this manner becomes impregnated, and the atmosphere loaded with the germs of innumerable spots, which the most careful operator is entirely at a loss to account for.

In conclusion: we may employ one more argument in favour of a thoroughly clean surface. It is in itself but little inferior to a substratum in merely retaining the collodion film upon the glass. If greater care were observed in securing a chemically-clean and well-polished surface we should hear fewer complaints of films slipping during development or splitting when dried; in very many of the cases of this sort we have no doubt the inducing cause is a dirty plate.

THE FUTURE OF CARBON PRINTING.

It is now no secret that the carbon patent of Mr. J. W. Swan expired on the 28th ult., and with it the monopoly in the making of carbon tissue with which the possession of that patent was so intimately associated. Up to this time the production of carbon tissue has been the sole right of the Autotype Company, but with the lapse of the patent such exclusive right passes out of their hands; and not only so, but the double transfer process of Swan is also thrown free to all. Let us see in what position this places photographers, by which designation we here mean professional artists.

First of all: the photographer can in future make his own carbon tissue with no more hindrance than applies to his manufacturing his own albumenised paper; or, if that be inconvenient, he can purchase it ready prepared in any or every market that is open. Secondly: he is now entirely at liberty to make use of the process of double transfer printing patented by Mr. Swan. This process consists in cementing, by means of a solution of india-rubber in benzole, the face of the exposed carbon tissue to the temporary support upon which it is to be developed, which support, after the picture has been developed and attached to its final resting place, may be removed by treatment with benzole or other solvent of india-rubber.

Now, so far as we are able to ascertain from the practice of carbon printers, the method of Swan to which we have alluded is not, and has not for several years, been practised by any photographer, having been entirely superseded by Johnson's method of developing, viz., attaching the tissue to its temporary support by the mere contact imparted by the pressure of the "squeegee." So far, therefore, as concerns the process of double transfer now thrown open by the expiration of the patent, the public gain nothing, seeing that that process has long since fallen into a state of desuetude.

The relations existing between the Autotype Company, who are the holders of Johnson's patent, and those who make use of the double transfer process now in universal use, is one possessing interest for all. It is competent for that Company to couple the granting of licenses for using the process with any conditions they may choose to impose, and it is quite legal for them to insist upon the purchase of all the tissue as manufactured by themselves as one of the conditions. We are glad to be able to say that they have adopted a more generous policy, and will allow their licensees to provide themselves with tissue in any suitable market. Now, when we consider that the Company possess the legal power to insist upon those who employ the ordinary method of double transfer printing to use only such material as they themselves manufacture and supply, it will be acknowledged that they are treating the public in a liberal spirit by making the concession of free trade in the manufacture of tissue.

We observe that the Autotype Company have strengthened Mr. Johnson's patent for double transfer by removing certain branches which added no strength to the main trunk. We have hitherto refrained from expressing any opinion concerning the validity of this patent; but we may now, and once for all, say that in our judgment the patent for Johnson's method of double transfer rests upon an incontrovertible basis. Its existence may be distasteful to a few—although *why* it should be so we are at a loss to understand. Still, there the fact remains—the patent, always good, has now been rendered impregnable by the judicious disclaimer of certain parts that have been lodged without opposition.

In conclusion: what we have said applies to double transfer only; single transfer has long been free to all.

STANDARD SOLUTIONS.

The want of a recognised standard of reference whereby to refer many solutions and liquid chemicals employed in photographic manipulations is often a source of considerable trouble and, when describing any process where definite exactitude is necessary, the cause of much loss of time, by the periphrasis rendered necessary. Thus we often have processes for making gun-cotton given where the sulphuric acid has no strength or specific gravity appended to it, although a variation of one half per cent. in strength would make the difference between a free-flowing and a ropy collodion. Or, again: take ammonia solution as recommended for alkaline development; this is made of all strengths, and is liable to great fluctuation, according to the source of supply and the manner in which it is kept. It is evident that when a difference of twenty or thirty per cent. can be frequently found in samples of the same assumed strength, a corresponding difference and uncertainty must prevail during the important operations of bringing the latent image to view.

We have, therefore, deemed it desirable to call attention to the fact that there does exist a recognised authority for definite strengths of various solutions and liquids, and that such solutions are now to be purchased, and also test liquids, by which to verify their strengths, at almost any chemist's in town or country. The authority we allude to is the British pharmacopœia, which, published in the form of a book, fixes by Act of Parliament the various chemicals, &c., used in compounding medicines and the requisite tests; and, as these include almost the whole of those made use of in photography, it is evident that a more suitable standard could not be found, for we do not think we are wrong in stating that ninety-nine out of every hundred photographers go to the nearest chemist and druggist's establishment when they wish to replenish their stock of chemicals.

Again: it is a convenient plan to have solutions of frequently-employed chemicals on the dark-room or laboratory shelves to economise time in the preparation of such liquids as developers, &c. Some of these, too, have their strengths laid down in the pharmacopœia, and hence may be purchased ready for use at the chemist's. The purity of the chemicals we employ being a matter of vital importance, some ready mode of determining their strength is a matter of considerable convenience; this also is rendered an easy matter by the same means. We now proceed to give some notices of those chemicals whose strength is liable to variation or sophistication.

Nitric Acid.—This is to be had of all strengths in commerce, but the pharmacopœia recognises only one strong acid—that of specific gravity 1·42. This acid is of a definite degree of hydration, is not liable to change when kept out of the light, and is altogether the one most generally to be depended upon. Mr. Hardwich, in his classical researches on gun-cottons, recommended an acid of specific gravity 1·5; but it is not a desirable acid to employ, owing to the quickness with which it loses strength, the first-named being available for all purposes of pyroxyline making. One thousand grain measures of a test solution of soda, which is described in the pharmacopœia (under the name of "Volumetric Solution of Soda"), should exactly neutralise ninety grains of nitric acid. This test solution, which we shall refer to again, is of great importance in estimating the strength of acids. It is referred to oxalic acid as an original basis of calculation, and requires considerable care in making; as it can be purchased ready made we shall not further describe it beyond saying that one thousand grain measures is capable of exactly neutralising "one equivalent in grains of any monobasic acid." With regard to nitric acid: it would be found very convenient to keep a dilute solution of it in distilled water in the proportion of ten per cent. for the purpose of adding to baths or, indeed, in any case (where water is admissible) in which drops are given in a "published formula."

We next have to refer to *Hydrochloric Acid.*—The pharmacopœia strength of the acid is specific gravity 1·16, and of the volumetric solution of soda one thousand grain measures neutralise 114·8 grains of acid. This acid contains 31·8 per cent. by weight of the hydrochloric acid gas dissolved in water.

Other acids employed in photography are tartaric and citric, and, when pure, seventy-five and seventy grains of each respectively are capable of neutralising one thousand grain measures of the volumetric solution of soda.

Acetic Acid we have lately treated very fully, and we, therefore, have no need to add much to what we then said. The glacial acetic acid of the pharmacopœia will neutralise the soda solution in the proportion of 60 to 1,000, while of the ordinary acetic acid 182 grains are required. The officinal glacial acid is to have the specific gravity 1·065 to 1·066, which, as also explained by us in an article devoted to the subject a little time ago, is stated to increase in density by the addition of ten per cent. of water. It is further stated to crystallise when cooled to 34°, and to retain its crystalline form till its temperature is raised beyond 48°.

The solutions of ammonia are two in number — "solution of ammonia" and "strong solution of ammonia"— of the specific gravity ·959 and ·891 respectively. Their strength is ascertained by the volumetric solution of oxalic acid, of which one thousand grain measures is required to neutralise 52·3 grains by weight of the strong ammonia, or 170 of the weaker solution. This standard solution of oxalic acid is very useful, serving, as it does, from the constant action of the crystals, as a special standard to which many other solutions may be referred or calculated from. It is made by dissolving 630 grains in distilled water to the bulk of 10,000 grain measures.

Passing now to solutions which are less recognised articles of everyday sale, we have acetate of soda, phosphate of soda, sulphate of iron, and carbonate of ammonia, the three first named being ten per cent. strong, but the last five per cent. The chlorides of gold and platinum need not be described; the usual method of keeping them cannot be improved upon. This exhausts the useful solutions to be found in the officinal list; but there are other chemicals used by photographers which are far more easily used in solution than in bulk. We may name, for example, citric acid and pyrogallic acid. They will be found most useful kept in solution. While holding a decided preference for uniformity of strength in stock solutions, we make in our own practice an exception with these two chemicals, owing to the fact that the pyrogallic rapidly changes when dissolved in water, and the item of alcohol becomes expensive if used too freely. We, therefore, when opening one of the well-known ounce bottles of "pyro.," at once dissolve it in spirit to make up a bulk of four ounces of solution, each drachm of which contains as near as may be seven grains of pyrogallic acid. For wet collodion work when intensifying with pyro. we find it convenient to use an equal weight of citric acid, and we therefore make the citric acid solution of similar strength, so that a small quantity of intensifier is instantly extemporised by adding an equal measure of each of these two solutions to a suitable quantity of water—a plan we advise all to adopt who have not done so already. The scattering about of a few filaments of the pyrogallic is liable to occur if it is constantly handled in its usual form, and nothing is more likely to lead to spots and stains.

Solution of Hyposulphite of Soda and Sulphate of Iron are not at all novelties; they have long been recommended to be kept in saturated solution—a plan which is certainly easy in theory, but practically far from it. A saturated solution of a crystal will not form by mere standing unless the crystals are suspended on the surface of the fluid, a considerable amount of shaking being required if they are merely placed in a bottle and allowed to sink to the bottom; in fact, we doubt very much if in one case out of twenty a so-called saturated solution approaches that state within ten per cent. Hence we should always recommend a given weight of the crystals to be dissolved in a definite quantity of water. It is more scientific, systematic, and far more conducive to that exactitude which should always be aimed at in all photographic operations in their scientific aspect, and which it is our wish and endeavour to inculcate.

In connection with the description in the Paris correspondence of Professor Stebbing's apparatus for the precipitation of emulsions, we notice that the precipitation is performed by hot water. In an article in our Almanac for the current year, Mr. H. G. Rogers, of Naples, also recommends the same course. Now, though the operation is performed with greater certainty, and independently of any special quality of the pyroxyline when hot water is employed, and the product is more easily collected, it will be found that with most samples of pyroxyline a serious loss of density is incurred when the powder is re-emulsified. Why this should be so it is impossible to say, unless some portion of the pyroxyline which is specially favourable to intensity is soluble in hot and not in cold water. We were formerly under the belief that the result was due to the partial removal of some of the organic silver compound, but we have had reason to alter that opinion recently, as we have failed entirely in discovering the slightest trace of silver in the waste liquid remaining after such precipitation. It is rather remarkable that, while the majority of samples of cotton lose density in this manner, we have occasionally met with one which exhibited not the slightest difference in character upon re-emulsification, whether hot or cold water were used. A sample made by ourselves was found to possess the property of withstanding the effect of hot water, but a second batch made from the same formula was totally different in that respect, though unchanged in general qualities. There is another fact which renders the matter more difficult of explanation: if the cotton itself be precipitated with hot water and then emulsified no loss of density ensues, unless hot water be again used in precipitating the emulsion. It would seem that, if the loss of density depended merely upon the solubility of a portion of the cotton, it should be immaterial whether the heat were applied to the cotton by itself or in the state of emulsion. The appearances, however, would suggest that the silver compound is involved in the change; it certainly is not dissolved out, but we may suppose it to be robbed of a part of its organic matter by some sort of decomposition under the action of the hot water.

OUR APPARATUS.

No. I.

In anticipation of a coming season most photographers overhaul their apparatus, and make the requisite alterations and repairs rendered necessary by past work and modern improvements. Intending photographers debate upon the kind and quality of the apparatus they will use; and for the benefit of these last, more especially, I propose to devote a few short articles to apparatus, noticing such matters as I have found in my own experience useful or otherwise.

As a preliminary remark, would-be photographers must make up their minds to rely on themselves, and not exclusively on their apparatus, for the production of good work; and, as far as practicable, I would suggest that they should construct their own of any suitable materials that may be at hand, for the double purpose of gaining a thorough knowledge of the whys and wherefores of construction, and the power of repairing a breakage or extemporising something else if the orthodox apparatus gets out of gear. Many may, perhaps, think that the royal road to perfection is sufficiently well paved to exonerate them from the trouble of noticing or caring for the thousand-and-one little things that are so essential to success. For my own part, I believe a thorough knowledge of the principles involved, and of the modes and requirements of the work, however seemingly insignificant, will lay foundations with which the full-blown photographer will never regret having had a full acquaintance.

The drudgery (if I may so term it) of photography will, as in any other business, secure a solid basis for refined and finished work afterwards, and in it, as in chemistry, to which it is so closely allied, the initials "S. A." are pregnant with meaning—a formula to be compounded. "S. A." suggests that some peculiar care must be taken in putting it together, and presupposes the compounder to be fully acquainted with the mysteries of his art. I am afraid the *secundem artem* to many photographers would convey no hint at all, for this reason—the royal road to photography is the only one they have travelled, and which is constantly leading them into morasses and quagmires out of which, with much waste of time and material, they may manage to struggle, or somebody lends a helping hand (for a consideration) and they are extricated for the time; but their notions of how to prevent a recurrence of the difficulty are considerably "mixed," and the chances are that they plunge in again before very long—another extrication, another compensation, till by a series of disbursements and annoying failures the right plan for avoiding the trouble is eventually learnt.

An excellent photographer of my acquaintance made himself a proficient in the art without the assistance of the apparatus-maker. He constructed his own cameras and made his own chemicals, guided chiefly by Hunt's *Manual of Photography*—one of the *Encyclopædia Metropolitana* series; and it was not until he had in a great measure mastered the art that the experience and information derived from other workers helped him along. But in that struggle to help himself he laid a foundation that was of immense importance to him in after years. I, therefore, cannot too strongly urge upon photographers *in esse* to well learn the little things before they attempt the higher flights of the profession. In doing so they will incidentally acquire a vast amount of information that will be extremely useful to them in other arts than photography. It may also be borne in mind that a *good* photographer will, with the most homely materials, make a good photograph, whereas one who has only a superficial—therefore defective—knowledge will with the most elaborate outfit that ever was made produce but rubbish. With these remarks we will proceed to examine our apparatus, beginning with the

Bath-holder—

those for studio work, and those for travelling, or outdoor work.

For the studio nothing can supersede glass. In the dark room the most convenient way of placing it is by sinking a well in the counter (a plan frequently described), to be covered from dust and dirt by a hollow lid sufficiently deep to allow for the projecting end of the dipper, which should be long enough to be conveniently held and used. A hook or projection may advantageously be fixed to the back of the dipper to rest on the bath and prevent it from disturbing any sediment that may have accumulated.

In selecting the holder one should be chosen with the sides slightly curved *outwards*. They vary much in this respect. If straight or curved inwards there is a great probability that the film will be damaged in either removing or placing the plate in the solution by its scraping against the curved surface. In most cases one side of the holder is curved more than the other. The straightest side should be placed for the back, as with a fairly smooth and concave surface presented to the film there is little or no danger of damaging it. The dipper for general use is best made of ebonite, those made of glass being frequently broken and too fragile for use by any but the *most* careful workers, introducing a risk both to plate and bath-holder.

Horizontal baths, swing or otherwise, are, perhaps, the *very* best that can be used, no dippers being required. The plates can be thoroughly drained and silver solution economised. They are easily made and easily kept in repair. The only objection that can be raised against their universal adoption is the space required for their use—in many dark rooms a very important consideration, there being no room for the most trivial addition; in fact, the laboratory, which should be one of the most convenient rooms in the establishment, is frequently the opposite. However, this subject will be considered subsequently, under the head of "Dark Rooms and Tents."

For outdoor work the glass or ebonite holder must be contained in a wooden case with a watertight top—ebonite by preference, on account of lightness. Care should be taken that the pressure of the screws is exerted not only on the rim of the case, forcing the bath down against the bottom of it, which is the general way, but is distributed by two thin metal bands that entirely surround it and remove the pressure from the bottom, which will, after a time, owing to the corrosion of the screws, give way, and no amount of screwing down will prevent the solution from leaking out during a journey.

If glass baths be used the bottom should be lined with pure india-rubber—not less than an eighth of an inch thick—which will not injure the solution or break the plates if they should accidentally slip off the dipper. As one of the most important pieces of the photographer's outfit he should never trust it beyond his own control, or the probability is that it will "come to grief." It should always be carried separately from the rest of the apparatus when filled, and never packed in a box with other things; for the chances are that the jar and vibration during transit will loosen the screws and let out the solution, no matter how tight they may have been made at the outset.

Cameras.

With respect to cameras, whether for the studio or the field, the fewer loose pieces about them the better; screws will get misplaced, and loose pieces are frequently out of place when wanted. "A place for everything and everything in its place" is a rule hard to enforce. With regard to weight or solidity of construction: the rule of convenience is the only one to be studied. All, unless very small instruments, should focus from the back, and possess rectangular bodies. The cone-shaped bellows are frequently (in these days of short-focus lenses) very much in the way and troublesome to manage, part of the fold of the bellows cutting off the light from the side or end of the plate, so damaging the picture. When lenses of different lengths of focus are used this will from time to time occur, to the great annoyance of the user. In case a camera of this description has to be used the bellows should be carefully pressed forward towards the lens, and wedged in position, if they will not retain it without, as soon as the image is properly focussed. For studio work alone the sliding body is to be preferred, and is the most useful, as it can be used equally well for copying or portraits. The parts can be entirely separated to lengthen the focus, and the open space thus left can be made light-tight by a couple of laths and a dark cloth. Of course this is impossible with the bellows-body arrangement.

E. Dunmore.

CARDBOARD SLIDES FOR GELATINE FILMS.

[A communication to the Liverpool Amateur Photographic Association.]

Since our last meeting I have employed my leisure in further efforts to diminish the weight and frangibility of the tourist's photographic *impedimenta*, and I have jotted down a few notes of the result attained in the hope that they may prove of interest to our meeting tonight.

Which of us who has enjoyed the pleasures, or mourned over the discomforts, of photography in the field has not at times discovered to his horror that the focussing-glass has met with an accident, and can in nowise be replaced by impromptu ingenuity? This misfortune has befallen me on more occasions than one, and I am, therefore, in a position the better to appreciate the chance discovery of an efficient substitute for ground glass for the use of the tourist. No one would desire to supersede the ordinary focussing-screen in the studio; but something lighter and less breakable is clearly a desideratum for out-of-door work. The focussing-slide before you was made by myself at the cost of about threepence, and it combines the qualities I have mentioned above. The following are the necessary directions for the production of a slide 9×7 inches:—

Soak fifty grains of gelatine in one ounce of water for a few minutes; add one drachm of fresh ox-gall and one drachm of skimmed milk. When dissolved by heat and thoroughly mixed pass through the filter, and flow the solution over a clean and dry glass. Now place the glass upon a level stand, and pour the remainder of the gelatine upon it before the first coating has had time to set. As soon as it can be raised, it should be placed in a current of air and allowed to dry where no dust can settle upon it. A piece of moderately-thick cardboard is next to be divided with rule and compass into (say) four sheets of the required size; and from each of these the centre is to be removed with a sharp knife, so as to leave a margin on all four sides of half or three-quarters of an inch in breadth. Three of these pieces are now to be superimposed, closely glued together, and placed under a weight till dry. I have named three as the number of layers to be used; but this obviously depends upon the thickness of the board, and the depth of the dark slide from the surface which touches the camera to that of the sensitive plate. As soon as the gelatine and cardboard are dry, insert the point of a knife round the edges of the former, and strip it from the glass plate. It may now be trimmed with a pair of scissors to the required size, so as to overlap the edges of the aperture in the cardboard by about three-eighths of an inch. Allow it to lie flat upon the glass, and bring down upon it carefully the surface of the thicker cardboard frame, upon which some strong paste has been sparingly spread. The whole may now be raised, the remaining cardboard pasted upon the gelatine, the white surface bound neatly with leather or dark paper, and you have a focussing-slide which will bear any reasonable amount of wear and tear, and which will weigh hardly as much as the glass of a slide of similar size.

In order to give additional strength to the whole it will be well to pierce each of the corners and insert a small brass paper binder with double points before the final leather or paper covering has been employed. To prevent warping it is better to place a considerable weight upon the slide for some hours.

The cardboard dark slide I now produce has been prepared for use with my sensitive gelatine films, and is, as I have ascertained by frequent experiment, perfectly adapted for its purpose. The size of my wooden slides is $7\frac{1}{2} \times 5\frac{1}{4}$ inches, and accordingly, for a single slide, I cut with a penknife a sheet of cardboard of these dimensions to form the bottom of the slide. I next prepare a number of strips three-eighths of an inch wide, a number also of one-quarter of an inch in width, one piece of the size of the bottom with an aperture $7 \times 4\frac{1}{4}$ inches, and another piece to form the shutter $4\frac{1}{2}$ inches wide by 8 inches.

The building-up of the slide was easily accomplished as follows:— Sheet No. 1 was placed on the table and three-eighth inch strips glued upon three sides of its upper surface, the opening in the fourth side being designed for the insertion of the sensitive sheet. Upon these strips half-inch widths were fastened, and the vacant side of the first layer was bridged over with a half-inch strip of board. Next followed three sides covered with the three-eighth inch strips, the vacant end being left for the admission of the shutter. Lastly: over all I glued the piece containing the aperture; the shutter was cut from the cardboard and fitted into its place, the whole was covered and made neat with black paper and colour, a weight superimposed for the night, and in the morning I found myself possessed of a fairly-effective dark slide, of home make and of inappreciable cost. When the sensitive gelatine has been slipped into its place, I have a small piece of black card ready, which I insert from the inside, in the opening through which the gelatine has been passed.

This dark slide was so easily made, and proved so efficient, that I set to work and made a double one of the same description, and also a double one for use with glass plates. The latter is not yet complete; but you will see that it has sufficient stability and strength to answer its purpose, and the method I have adopted for securing the sensitive plate in position without admitting light seems to me to be ample and satisfactory. H. J. Palmer, M.A.

NOTES ON PASSING EVENTS.*

By a Peripatetic Photographer.

They manage some things better in Scotland, if we can accept statements made at a public meeting attended by those who were in a position to controvert them had they been untrue. It appears that the Edinburgh Photographic Society contrives to exist upon an annual subscription of only five shillings from each of its members. Not only does it exist upon this modest sum, but it actually "waxes fat" upon its small annual increment, for it appears that the committee are about to present an excellent photographic picture to every member. Now, there are two photographic societies in London, one of which secures from each member the sum of twenty-one shillings as his or her annual subscription, with the addition of a second guinea as entrance fee for each new member; the other society confines its subscription to the more unpretending sum of half-a-guinea, which is still more than double the Edinburgh "figure," but neither the one nor the other can manage to give a presentation print to its members. True, the society representing the smaller of the two sums mentioned *does* occasionally present its members with a picture, but such presentations are "few and far between," and are of a sadly retrospective character even then. In what way the prudent north countrymen arrange their financial affairs so as to do so much with so small a subscription is unknown to me, but it is exceedingly desirable that they would infect the conductors of the metropolitan societies, in order that they may be seized with a similar malady.

Observing that the subject of silvering glass by modifications of the Drayton system has been again introduced by the Editors, I am reminded of a pretty experiment that was once exhibited, many years ago, at the Royal Institution. Two large plates of glass are joined together by the margins in such a manner as to form a bath not unlike the photographic vertical dipping-bath for negatives. This is open at the top for the reception of as much fluid as suffices to nearly fill it. All things being in readiness, the bath is filled with a clear and well-filtered solution of silver, and mounted upon a table in the middle of the room in such a manner as to enable those who look through it to see distinctly those on the other side of the thin plate glass tank. The lecturer now adds the reducing agent, directing the spectators to keep their eyes on their neighbours on the other side of the vessel, which, owing to the limpidity of the liquid, they are in a position to do very easily. No sooner is the reducing agent added than the objects of their attention gradually disappear, and each spectator sees only his own face reflected in the perfect mirrors which each side of the glass vessel has now become.

If collographic or any other kind of ink photographic pictures of jewellery be printed upon bronze paper, it is evident that in this class of work the jeweller or worker in any description of metallurgical art will find a powerful ally in the production of specimens yielding perfect pictorial representations of such art. I was interested in reading the account of M. Leon Vidal's photochromie, and at once saw in such a process of printing the "very thing" that commercial travellers must highly appreciate, inasmuch as the perfect form of any article reproduced in all its delicacy of light and shade would be allied with the very metal of which it was constructed. I read several months ago of gold chains having been photographed, and then printed upon yellow paper by the heliotype process in such a manner that the ground upon which the chains were represented was all made black or dark, leaving the "counterfeit presentment" of the article in various shades of yellow. Obviously, by making use of a gold-bronzed paper for this purpose, instead of a plain yellow paper, the illusion would be magnified in a corresponding degree. Thinking over the possibilities of this and cognate applications I have been led to try the effect of printing a fish upon a piece of silver-bronze paper, supplementing the natural lights and shadows of the *quondam* denizen of the deep by slight washes of colour. The effect is quite magical. The scales of the fish—a salmon—glitter like silver, and the irridescent sheen and play of colours are quite wondrous.

I have already alluded to the silvering of glass. I do so once more because the recent publication of the article on the subject in the Journal, coupled with the exhibition of a photograph of the sun

* Concluded from page 101.

at the last meeting of the Photographic Society of Great Britain, brought somewhat vividly to my recollection certain experiments in taking solar photographs which I made several years ago with optical appliances of the most primitive kind. In a former one of these "Notes" it was placed upon record that a photograph of the sun could be obtained by making use of a simple concave spectacle lens of long focus, using it as a reflector. One side of this lens must be roughened on a piece of sandstone and coated with black varnish; the other then acts as a reflector, by which an image of the sun is produced. It might at first be imagined that too small an amount of light would be reflected from this plain glass surface; but when I state that a wet collodion plate has been impressed with an image in less than the twentieth of a second, the picture being over-exposed, it will be seen that the amount of light reflected is by no means so inconsiderable as might be imagined. Having during the past week obtained a glass one side of which was ground to a curve of longer radius than any I had previously seen, and having ascertained that owing to its long focus it gave an image of the sun exceeding in diameter any that I had previously obtained by similar means, I roughened one side, as before described, and upon the other I deposited a thin film of silver. This produced a reflecting surface of exquisite delicacy and perfection; but to ensure the removal of marginal errors I reduced, by means of an annulus of black card, the reflecting diameter of my little mirror to somewhat over half-an-inch. At the time of writing this I have not taken a photograph of the sun by its means, but I have focussed the solar image, and find it so sharp that I have no doubt that when I do expose a plate I shall obtain, in the sixtieth of a second, a fully-exposed negative sufficiently vigorous to bear being enlarged up to three or four inches without apparent loss.

DIRECT PRINTING FROM GLASS NEGATIVES, USED FOR PRODUCING LINEAR REPRODUCTIONS OF VIEWS FROM NATURE AND FROM LICHTDRUCKS.

A communication which I made in 1876, respecting printing from glass negatives, was received with great interest in Berlin photographic circles, and from many quarters requests to sell the process reached me; but I could not make up my mind to do so, as I intended to work it myself, though circumstances have as yet hindered me. As, at the request of Herr Reising, the subject was lately broached again at Berlin, I shall throw a little light on the matter, and, for the benefit of those who busy themselves with similar experiments, shall publish the process and its applications for the general use.

Usually, in order to render negatives printable, they are coated with a solution of chrome gelatine when they have become perfectly dry. Thus one always gets a film of bichromated gelatine *above* the collodion film. It is also perfectly well known that by exposing such negatives to diffused light the lines become somewhat broader, because, even when the film is thin, the light works in from the sides. Towards the end of 1875 I tried to prevent this by forming a film of bichromated gelatine *in* the collodion negative film. In this attempt I succeeded completely, by taking the negative immediately after development, without drying it, fixing it, and washing it with water, and, *while still wet*, placing it in a thin solution of bichromated gelatine. When dry the upper surface was matt, and there was no coating of gelatine to be seen, though the collodion film had absorbed a sufficient quantity of gelatine and bichromate to render it printable after exposure to light.

Now, in order to produce with advantage such plates, in which, so to speak, the collodion films are rendered capable of being printed from, I proceed as follows:—Having developed, though not very powerfully, in the usual manner a negative upon an albumenised glass plate, and having fixed and washed the negative, it is placed in a solution previously prepared thus:—4·5 parts of gelatine are put to soak in water, and then, the superfluous water being poured off, fifty parts of distilled water are added, and it is allowed to melt; a solution of 5·5 parts of bichromate ammonia in one hundred parts of water is then added, and the whole heated to 60° R. The plate remains about five minutes in this bath. If large plates be used the solution may be poured over them, but then, before coating, the plate must be quickly rinsed with a little slightly-warm water, and the coating with the gelatine solution must be frequently repeated. A sufficient quantity of the solution being poured upon a plate, the latter must be warmed in a horizontal position over a spirit lamp. If fumes rise from the solution lift up the plate for a moment; then warm it again in a horizontal position until it becomes quite dry, but do not let it become so hot that the palm of the hand cannot easily be drawn across the back of the plate.

As the duration of the exposure of such a negative can never be exactly measured by merely looking at it or by using the common photometer, having well washed the back of the prepared negative I take a piece of sensitised albumenised paper, or paper prepared with a solution of a bichromate, and place it upon the film side of the negative; then, placing the whole in a frame, light through the glass. With the aid of this simple expedient I can always ascertain how far the action of the light has gone, cover parts that are too dark, and so on; but this requires skill, as in silver printing. Of course I use a black backing, in order to prevent any reflection of the rays of light. By this process, however, in spite of the white albumenised paper, reflection is little to be feared, as the chloride of silver absorbs all the rays of light.

When the finest lines of the image are distinctly visible, the ammonium bichromate should be washed out by laying the plate in cold water, and, when dry, the negative may be handed to the printer. For printing the finest rollers should be used. When damping it is advisable to put a little gum arabic on the edges, and to rub the surface of the picture with it. With regard to the preparation of the negative, I may mention that every collodion does not take up the same quantity of chrome gelatine; indeed, many do not absorb the solution at all, and with such one only gets a gelatine film *upon* the collodion film. The lithium collodion prepared by Dr. Kurz, of Wernigerode, is the best suited for this purpose. I believe that the lithium salt in this collodion plays a not unimportant *rôle*,* but as yet I have had no opportunity of experimenting in this direction.

Not only does this process furnish linear reproductions with the greatest delicacy in the lines, but it can also be made very useful in the case of photographs from nature.

It is principally for portraits that direct printing from the glass cannot be employed, since it does not admit of retouching the negative. Still, if a negative be prepared in the manner directed above, but only exposed until the shadows of the picture have become visible on the albumenised paper, and if the negative be then washed with water whose temperature is continually increased until it dries up, the negative will bear any required degree of retouching with a No. 2 Faber's lead pencil, and then with fine graphite rubbed on with a stump. If for such special cases a rough surface should be desired, add to the heated gelatine solution twenty parts of spirits of wine in which is dissolved one part of colophonium. When the necessary amount of retouching has been done coat the surface with a dilute solution of ammonia, and when that has dried let a coating of albumen and water-glass (such as Professor Husnik has repeatedly described) follow, and then employ the process described at the same time by Professor Husnik, or any other good lichtdruck process in which sheets of prepared albumenised paper are used instead of a scale photometer.

By the process just described lichtdrucks in several colours (chrome-lichtdrucks) may be produced by taking as many negatives of the subject in question as there are colours to be printed, and treating the negatives by the first process. All the parts that are not required are then worked out with a stump and graphite, and the outlines with lead pencil. With a certain degree of practice it is not necessary to prepare separate plates for the secondary colours, like green, orange, and violet, as by covering the parts more or less with stump it is possible to obtain with ease the most beautiful transitions and mixtures of tints. With the assistance of the bits of albumenised paper one may make any change during the exposure that may be thought desirable. Since Albert's process cannot be used by everybody, the process I have just described may yet find many uses. Hans Brand.

FOREIGN NOTES AND NEWS.

Varnish for Melainotypes.—A Novelty in Test Papers.—White Pigment Tissue.

The *Photographisches Wochenblatt* gives the following directions for the black backing of ferrotypes or melainotypes:—Cut the iron plate to the proper size and heat it to about 80° R. Then brush upon both sides of the plate the following varnish:—

Alcohol	100 grains.
Yellow gum lac	10 ,,
Sandarac	5 ,,

The mixture should be slightly warmed for half-an-hour in a glass

* Apart from the fact that the metals combined with the halogens exert an undoubted influence on the greater or less fluidity of the collodion, it is very possible that in the case in question the quality of the pyroxyline may exercise a real influence.—Ed. *Ph. Cor.*

vessel, and the clear part decanted off. The black varnish, with which one side of the varnished plate is to be coated, consists of—

Chloroform	80 grains.
Asphalte	80 ,,
Canada balsam	20 ,,

When in the course of a few days the varnish has become perfectly dry the plates may be used, but it is as well to dip each of the four edges into the above solution, a sufficient quantity of which for the purpose has been poured into a groove made in a piece of wood. The object of this is to prevent the varnish from slipping off the edges of the plate and thus permitting the iron to come into contact with the silver bath and spoiling it. Before collodionising rub the plate with a tuft of cotton wool to remove all dust. The most suitable collodion is lithium collodion, which contains a little free acid. The developer is—

Water	500 grains.
Glacial acetic acid	30 ,,
Alcohol	30 ,,
Sulphuric acid	30 ,,

Intensify and fix as usual.

From the *Correspondenz* we learn that Herr Dieterich, of Dresden, has introduced a novelty in test papers. By means of a machine, parallel stripes of red and blue litmus solution are run down the same sheet of unsized paper. The sheet is then made up in books, each leaf of which has one edge red and the other blue, so that the preliminary testing of solutions for acid and alkali may be done simultaneously. The object of this contrivance is, of course, to save time; but it is to be feared that in this case the saving, minute as it is, will be effected at the expense of accuracy.

Herr Honikel, of Leipzig, has, according to the *Wochenblatt*, proposed the following amendment of the carbon process:—Starting from the assumption that the shadows and half-tones of all carbon prints are uncommonly rich in details, while the lights and high lights are extremely poor, Herr Honikel proposes that instead of mixing black or dark colouring matter, as has hitherto been the custom, with the gelatine destined to form the pigment tissue, white pigments should be used, and the sensitive tissue exposed under a positive and developed, and transferred to black or coloured paper. Besides the more beautiful appearance claimed for such pictures, this method is said to possess the advantage of indefinitely increasing sensibility. According to Herr Honikel the sensitiveness of white pigment tissue is from twenty to twenty-five times as great as that of ordinary carbon tissue. And yet another advantage claimed is that by means of white pigment tissue it is possible to produce direct enlargements upon paper with the camera. It is scarcely necessary to remind our older readers that the late Mr. William Blair devoted much attention to this kind of pigment printing, an account of it having been published by him nearly ten years ago.

,, 13	Cheltenham Amateur	Savings' Bank.
,, 14	Manchester	Memorial Hall, Albert-square.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

The monthly meeting of this Association was held on Thursday evening, the 28th ult., at the Free Library, William Brown-street,—Mr. H. A. Wharmby, President, in the chair.

The minutes of the previous meeting having been read and confirmed, Mr. B. J. Sayce and Mr. Arthur Hall were elected members of the Association.

The Rev. H. J. Palmer exhibited a scenograph to which he had invented a base-board giving perfect rigidity, and which could be used on any stand. He (Mr. Palmer) then read a paper on *Cardboard Slides for Gelatine Films.* [See page 110.] In illustration of his paper Mr. Palmer exhibited gelatine films as substitutes for ground glass, new non-actinic muslin, and some simple cardboard dark slides for the scenograph.

Mr. J. H. T. Ellerbeck suggested that the latter would be stronger and stiffer if made with what was known as shalloon board, which was much harder and thinner than cardboard.

Mr. Palmer said that at the last meeting he had been unnecessarily abusive on ox-gall. It was quite usable when fresh, but he found it to vary. The best plan was to purchase the gall in the bladder and suspend it in a cool place for a day or two, by which time the filmy mucus sank to the bottom; the ox-gall on the top could then be used without filtering. It was also paler in colour, and thus better.

Mr. Ellerbeck then passed round a number of Mr. C. Ferranti's artistic studies, which had been lately so favourably reviewed in the photographic journals. Many of these were exceedingly beautiful, and, though some might object to their highly-polished, glass-like surface, it was no doubt in consequence of this surface that the brilliant tones and permanency of the pictures were secured. He (Mr. Ellerbeck) then read the following communication, which excited considerable amusement by the manner in which he had contrived to bring into use the names of the members of the Association:—

Our Society.

Some time ago one of our members remarked that during the whole of his attendance at our meetings he had never seen a smile on the face of any present. This struck me as such an unenviable reputation that I suggested a comic song; but he, being perhaps the most solemn of us all, declined. The wish to infuse a little more liveliness into our meetings is my only apology for the abominable play upon words in the few lines I have to offer.

As the leading amateur photographic society in England we ought to be proud of our position, eclipsing as we do even the aristocratic Londoner. Have we not tonight a new Hall? A King has led us to the field; a Banner floats on our outer wall—aye, two (Whalley). Do we not recognise the abilities of our Castellain to guard the gate—our Clarke to give us safe advice in trouble—our Cooke to look after the inner man? The Potter's art is frequently in requisition, and the Palmer relates round the fire stories of his travels in the land of the Bruce. Let us further see what we have to boast of. Stretching lazily in the sun as far as eye can reach the Shannon waters our land, skirting the Greenwood and the Moore. There cattle free from murrain (Murray) seek the river and Wells. In a secluded spot is the Kirk by the Green meadows, where a grave has been dug—a whole grave (Houlgrave)—in which a man can, if he find his pen dull, bury (Pendlebury) the work of his brain. (It's a pity a large proportion of our would-be authors don't do it, or practice cremation.)

Still generation follows generation—Will's son follows William's path, and a warm boy (Wharmby) he is. Roberts and Robertson, John's son and Parkinson follow in the footsteps of their 4 fathers, and thus the good work is perpetuated. By-the-bye, it is a remarkable fact that, though we have such a great Forrest, it is transparent as glass, bearing only a single Twigge, so that we have, even in its deepest recesses, no difficulty in seeing the heavens (Evans) above—a great consideration for photographers. I should like to make a suggestion: it is that we admit to our ranks any lady who may wish to join us. We promise not to tire her (Tyrer), and though we cannot offer her a tirewoman, we can provide a Tyerman. But what would be Seddon such an occasion? One might feel inclined to put a rope around (Roper) *his* neck whoever suggested the idea, only we Houghton to. But I'm getting rather Heyes y on this point, and when a mans *led on* (Sleddon) to make such remarks as these the sooner he stops the better. Was it not in Pickwick Sam wEller beckoned to the Rev. Mr. St Higgin s whispering the advisability of "drawing it mild" and nothing Riley d him so much as humbug with a long tongue (Longton). We would soon get Hughes to the ladies and not go Spoon(i)ly paying too much attention to the fairer members unless at our annual *soirée* we could Danson the "light fantastic toe" to the tune of Weber's last waltz—they in ball costume, flowers looped on (Lupton) their beautiful tresses, or Dod ging their partners through the intricate mazes of the polka rejoicing at kin dred feelings awakened. What ling ering glances! what soft speeches!

I have again to apologise for reading such rubbish as this, fit only for a booth rodomont (Boothroyd), but it was conNiven at by our Secretary; so I thought I would bring it as it was the Best I could do, and *say* something (Sayce) that might amuse though it won't instruct. I hope nobody will be offended at being left out in the cold. There is one I can't introduce except in the old saying—if Phipps and haws were little jackdaws, there'd be no work for tinkers. This does not seem to be the correct saying, but Mauds lying down as I write this, and I don't like to disturb her to ask which is the right one.

"A little nonsense now and then
Is relished by the wisest men."

Mr. Ellerbeck also exhibited a knapsack for camera, &c., which was arranged so that the weight shall rest on the back instead of on the shoulders.

After votes of thanks had been passed to Mr. Palmer and Mr. Ellerbeck, a number of slides taken by Mr. Potter, Mr. Kirkby, and the Secretary were shown by aid of the lantern, and the meeting was then adjourned till the 28th instant.

PHOTOGRAPHIC SOCIETY OF VIENNA.

This Society met on the 23rd January, Dr. Hornig occupying the chair as usual. The minutes of the previous meeting having been read and approved,

The Chairman briefly mentioned the arrangements that had been made for placing the Society's exhibits at Paris, and stated that he hoped to get Herr Winter's imitation Gobleins hung as wall decorations in another part of the building apart from the other photographs.

The prize jury then gave in their report and made the following awards:—

I. *Voigtländer Prizes.*—The Voigtländer silver medals were thus awarded:—1. For lantern slides adapted to educational purposes, to the competitor whose motto was "Much pain, little gain." 2. To Dr. Simony, for his dry-plate views in the higher Alps and in the Dachstein region. 3. To Dr. Heid, for his excellent home-made collodion cotton. 4. To Herr Winter, for his applications of enlargements to decorative purposes, especially for his imitations of Gobleins. 5. To Herr Max Jaffé, for his photolithographic and lichtdruck polychrome combination prints, and for his endeavours to apply photography to manufactures. The Voigtländer bronze medal was awarded to Herr von Stefanowski, for his efforts to popularise the carbon process. The work, which arrived late, but was admitted to the competition by a resolution of the meeting of the 11th December, was not considered suitable by the jury, and had, therefore, no prize awarded to it.

II. *The Society's Prizes.*—Dr. Bauer, Prof. Husnik, Herren Martin, Leipold, and Scamoni—the experts who were asked to give their opinion of the *Treatise on the Reactions of the Chromates*, signed with the motto "*Si quid novisti rectius istis, candidus imperti; si non, his utere mecum*"—reported that the paper in question was a very elaborate treatise, based upon diligent study of technical literature and upon exact experiments on the reactions of chromates on organic substances, especially gelatine. They, therefore, recommended that the gold medal, valued forty ducats, be awarded to the author of the treatise, and that, further, a money prize of one hundred ducats should be added if the author would undertake to complete the elaboration of the subject in one direction, and to arrange the whole subjects under distinct heads. The Society's silver medal was awarded to "Helios" for the excellence of pose and arrangement of his *genre* pictures, and for the success with which he had printed them in carbon.

On opening the envelopes with the mottoes it was found that the one on which "Much pain, little gain" was inscribed contained the name of Herr von Reisinger; that Herr Täschler was "Helios;" and the author of the treatise with the motto "*Si quid novisti*," &c., was Dr. J. M. Eder.

The Chairman reported on the progress made by the Society during the last year and the present state of its funds.

Baron Schwarz-Senborn showed some specimens of Whitburn's xylographic process.

Dr. J. M. Eder remarked that Dr. Janecek had lately brought the subject of the restrictions placed on the transport of collodion cotton before a meeting of the Austrian Railway Official Club, and that his lecture had been taken down by a stenographer and reproduced in the *Verkches Zeitung*, where it had made such a good impression that there were great hopes of the oppressive restrictions being removed.

Dr. Janecek showed how slightly explosive collodion cotton is by placing a quantity upon an iron anvil and striking it with a heavy hammer without producing the slightest change in the cotton.

The last matter of business before the meeting was the annual election of office-bearers and council, most of whom were re-elected. Dr. Hornig, who was unanimously re-elected, only consented to act if it were distinctly understood that he was likely to be absent for a few months at Paris. The meeting was immediately afterwards adjourned.

PHOTOGRAPHIC SOCIETY OF BERLIN.*

A meeting of this Society was held on the 19th January, when, owing to the absence of the President, Herr Brasch, and of the Vice-President, Dr. Fritsch, the Secretary, Herr E. Düby, occupied the chair. After reading the minutes of the previous meeting,

The Chairman made the official intimation of the death of M. Adolphe Braun, of Dornach, who was an honorary member of the Society, and the assembly testified its respect for the memory of the deceased, in the usual manner, by rising *en masse*. He (the Chairman) then exhibited a direct portrait, some 40 × 50 centimetres in size, of M. Braun, which his firm had presented to the Society.

Herr Max Kanneberg offered to present the Society with a tasteful frame, so that the portrait might be worthily hung.

The meeting resolved to send a laurel wreath tied with silk, and accompanied by a suitable inscription, to Dornach, to be placed on M. Braun's grave.

The Chairman then placed on the table a number of original and dusted-on negatives, made by Prof. Husnik, of Prague, and accompanied by the following directions for the dusting-on process:—

"Each flagon has Husnik's trade mark, and contains about eighty-five grammes of concentrated dusting-on solution. For use, the contents of each flask should be diluted with three times its volume of distilled water and filtered. The portion first filtered should be poured out, so as to remove any dust that may have been upon the filter or that the fluid may have carried with it.

"In order that the glass plates may allow themselves to be easily coated with the dusting solution they must either have a weak solution of caustic potash or, better still, a dilute solution of water-glass rubbed upon one side, wiped off, and then dusted; and before pouring on the powder solution they must be *strongly breathed upon.* Thus the fluid spreads on the plate like collodion, and the breathing especially facilitates the operation. The solution is to be poured off the glass plate either into another vessel or back into the same one through the filter, only as much being left on the plate as remains there when the plate is much tilted up. The plate is then dried in a horizontal position, by an equal temperature—somewhere between 35° and 40° R.—either over a spirit lamp or a petroleum oven, or in a drying-box. If a spirit lamp be used touch the under side of the plate often with the hand in order not to exceed the requisite degree of warmth, and the operation had better be carried on at some distance from the window. In this way large plates do not dry equally and their development is defective.

* This is not the society presided over by Dr. Vogel, whose meetings are usully reported under the heading of the Berlin Photographic Society, but whose title might be more correctly rendered as the Berlin Association for the Cultivation of Photography.

"A small drying-box is much better, the under part being mounted with a sheet of iron, in the centre of which a horizontal plate is placed, upon which the plates to be dried are laid. Cloth is stretched over the lid of the box, and at the bottom there are one or two small openings made for the entrance of the currents of air. The heat is produced either by gas jets or by a small petroleum stove placed under the box. Great heat during the drying is apt to cause decomposition of the chromium salt, thus rendering the film non-sensitive.

"When the coating of the plate has dried until the edge no longer feels sticky to the touch, the still warm plate should be laid upon the negative, and upon that again a black cloth; it should then be exposed from half a-minute to five minutes in the sun, or from six to fifteen minutes in diffused light. After the exposure—which can only be exactly determined by practice or by the help of a photometer—the image is so slightly visible that it cannot be judged of before development by dusting-on. Supposing the light to have been strong and the exposure to have lasted but from half-a-minute to five minutes, so that the plate has not had time to cool much, one then proceeds at once to dust on the graphite. If, however, the exposure be longer, or the air be damp, or the plate be brought into a warmer room where vapour would be deposited upon it, then it must be slightly, but equally, warmed by the lamp or in a drying-box before proceeding to develope.

"In a dry condition the plate is very sensitive, and must be protected from strong light. The warming of the plate before dusting-on can never do any harm, as it makes it take on the graphite more slowly, and thus makes the development slower, but more sure and finer in tone, and one must watch carefully and compare with the original so as to stop the development at the proper moment. A plate which is too damp and which has not been warmed would take on the graphite too quickly, and become coarse in the grain.

"If, owing to the dryness of the atmosphere, the development proceed too slowly, breathing upon the film will make it take on the graphite more rapidly. Still, this must be done with great circumspection, as by unequal development the picture might easily be spoiled. Parts that are too weak in the original may also be assisted in their development by breathing on them.

"For the development proper use a good stump and Faber's best graphite rubbed down in a saucer to a fine powder, and put on to the plate in considerable quantities by means of a pencil. The graphite may also be worked into the film by the pencil.

"If the exposure be too short the picture developes quickly and is flat; when over-exposed, on the other hand, the picture is hard. Thus one has complete power over the intensity of the picture, and by regulating the time of the exposure and development powerful copies can be produced from weak, and soft copies from hard, negatives.

"If the solution be very old, or the weather too dry, the picture will be too slow in developing, and it will be well to add two or three drops of glycerine to the solution before using it.

"When the picture is sufficiently developed and dusted, it is placed in a flat vessel (containing not too weak alcohol, to which twenty parts by volume of nitric acid has been added) to have the chromium salt completely washed out of it. It should then be dripped and set up to dry, after which it may be varnished. The negative so reproduced will be reversed; but, if it be wished to get a reproduction of a negative in the same position as the original negative, the developed picture should be coated with plain collodion, and, when that has stiffened, a knife should be passed round the edges and the plate laid in a vessel of cold water, to which a few drops of nitric acid had been added. In a short time the collodion film is loosened, and may be drawn off under water by a pair of pincers, turned over, and placed upon another glass plate, care being taken to avoid air-bubbles. It should then be coated with a thirty-per-cent. solution of gum and set up to dry. To render them more durable these copies may also be varnished. The same manipulation may also be applied to reversed negatives, only in that case the plain collodion must be poured over the whole of the plate, edges included; and when the collodion has set the chromium salt must be washed out in acidulated water, the film remaining on the same glass and is not turned over.

"If it be desired to produce dusted-on pictures directly from views taken in the camera the manipulation is the same, only another clear glass plate must be laid upon the dry, but still warm, plate to prevent the film from absorbing moisture during a long exposure.

"Very thin films upon which, after drying, a soft, fine pencil is worked about in every direction give equally good results with Siberian graphite and the ordinary sorts of graphite.

"If blisters or flakes appear while the picture is in the spirit bath, then the spirit is too strong and must be diluted with water.

"The dusting-on solution No. 1 may be treated with the acidulated spirit as well as with the plain collodion. The dusting-on solution No. 2 is best treated with the plain collodion, as in a weak spirit bath the film dissolves off from the glass, but with strong spirit it does good service."

A point of law was next discussed, after which the question-box was opened and a variety of articles placed on the table. The meeting was shortly afterwards adjourned.

Correspondence.

STEBBING'S APPARATUS FOR THE PRECIPITATION OF EMULSIONS.—A NEW REVERSING LENS.—VIEWS IN THE INDRE.—PROCESS FOR DIRECT REPRODUCTIONS.—THE SCIOPTICON.

The ordinary monthly meeting of the Photographic Society of France was held on Friday, the 1st instant,—M. Peligot in the chair.

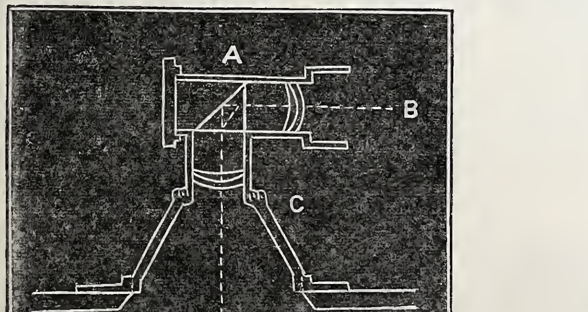
After the election of MM. Castellani and Sauvager, the French and foreign photographic journals were reviewed, and M. Davanne, on behalf of Mr. E. Stebbing, exhibited the apparatus of the latter for the preparation of emulsions—a diagram of which is inserted at page 60 of this year's British Journal Photographic Almanac, which represents the instrument, but several changes have since been made in order to perfect it as much as possible. Precipitated emulsions having at last become the fashion in France, an apparatus was required which would precipitate the emulsion, and at the same time distil the ether and save the alcohol employed in the collodion. After much expense Mr. Stebbing, aided by the suggestions of the ingenious M. Bardy, succeeded in constructing such an apparatus, which has been in constant use in his laboratory for more than six months, and which, with the improvements latterly made, fulfils admirably the duty demanded.

In the diagram referred to *a a* represents a copper boiler having handles on its sides by which to lift it, and near the bottom, at one side, is a tube with a rectangular bend, in which to insert the thermometer. *b b* is an alembic or still, having a broad flange at the top to rest upon the upper edge of the boiler, together with a felt collar to permit the cover being fixed upon it with clamping screws. Inside of this still is a circular vessel of porcelain, having at the bottom a silver thimble, into which is pivoted the lower end of a round shaft bearing a number of arms, now made of silver sheet, of a parallelogramic shape, inclined at a certain angle like the blades of a ship's screw, which act as beaters, the top of the shaft carrying a horizontal toothed wheel revolved by the action of another toothed wheel working perpendicularly to the other, which is turned by hand with the handle adapted to its axle. A funnel and glass tube *d* in the domed cover enable the collodion to be poured inside the porcelain vessel in a fine stream. The pipe *e* is connected with an ordinary condensing apparatus for the condensation of the vapour of the ether thrown off by the hot water.

In order to set the apparatus at work the boiler *a* must be filled about a quarter full of water; the still is then introduced, which displaces the water, and makes it rise to the level indicated; the porcelain vase is then put in and filled about half full of distilled water, and a small quantity of water is introduced between it and the still. The dome bearing the shaft and beaters is then fastened on and hermetically joined by means of clamping screws. The tubular funnel is fastened into the dome by means of a cork, as also the glass tube connecting the apparatus with the ether condenser.

The still being now ready is placed upon a gas stove, and as soon as the thermometer indicates 149° Fahr. the fans or beaters are set in motion, and the prepared emulsioned collodion is poured gently into the interior by means of the glass funnel. In coming into contact by falling into the hot distilled water a great dilation takes place by the rapid evaporation of the ether; at the same moment the cotton of the collodion is precipitated, and is drawn violently downwards, by the inclination of the beaters, towards the bottom of the porcelain vase, and there retained by a stationary silver partition extending from the side of the vase up to near contact with the shelf. The height of the partition leaves space for the lower beater to revolve; this collects the precipitated cotton, preventing its rising to the surface, and there coming into contact with the freshly-precipitated cotton from the continuous stream of falling collodion. The ether escapes out of the dome by the glass tube, whose diameter is large enough to convey it quickly into the cooling apparatus, where it is condensed and collected. As to the alcohol and soluble and miscible salts of the collodion, they are absorbed by the hot distilled water. When the whole of the emulsionised collodion is precipitated, the residue is collected and again washed in distilled water and finally in alcohol, after which it is retained in a damp state until required for use, and final solution in ether and alcohol. The hot distilled water containing the spirits of wine is set apart until sufficient is obtained to pay for its distillation. The precipitated cotton emulsion obtained by this process has a honeycombed appearance, dissolves readily in the solvents, and gives a very creamy and even solution.

M. Perrot de Chaumeux exhibited, on behalf of M. Derogy, optician, what he called an "aplanatic lens," intended for the production of



A, prism. B, axis of lens. C, cone to advance the lens from the camera. D D, camera front.

reversed negatives for the photolithographic and single transfer carbon processes, and which presented, from a photographic point of view, the novelty of a prism placed in the interior of the tube between the anterior and posterior lens at the position of the stop. So the prism need be no larger than the stop required, being thus much smaller than when placed outside the lens, as is usually done, and consequently lighter, of very diminished cost, while giving much better results, for the surfaces of smaller dimensions are obtained perfect with much greater facility. The prism can be replaced by a parallel glass, the silvered surface being thus effectually preserved from the action of the atmosphere and the dangers of handling or contact with the fingers of the operator or other persons. M. Perrot de Chaumeux handed round a *cliché* produced with the lens, the image of which testified to the excellence of the invention, being sharp up to the edges.

M. de Potok had been announced to make a communication in connection with a process for the direct photographic reproduction of black lines upon a white ground. M. de Potok said he regretted that the inventor himself, M. Artique, was not present to explain and demonstrate the process, which would have been more satisfactory to the members; for, being very little versed in photographic manipulations, he (M. Potok) could not do justice to the invention. He might, however, to show that it was practicable, state that the railway company of the Midi paid a royalty of 300 francs a year for its use. M. de Potok then showed some paper which resembled in appearance carbon tissue paper, having a thin film of black-coloured gelatine. This paper was in an inert state, and, to render it sensitive, was placed in a bichromate bath, after which it was dried and exposed under a design or engraving. He then produced an exposed sheet which, he said, had been afterwards inked as in the lithographic transfer process, and, showing the print from a wood block of a rolling-press, proceeded to place gently in a tray of cold water to develope the exposed sheet. In a short time the image appeared—black upon a white ground. M. Davanne, however, observed that this image was a negative one of the print of the rolling-press. In reply, M. de Potok said that was the case, and that there were two ways of producing the positive—namely, one to use the negative first obtained, which would give an unlimited number of positives on being exposed in contact with fresh pieces of prepared paper, blackened *as if with charcoal;* and, secondly, before developing the first print (the negative), attaching to its surface another unexposed sheet by being passed through water, and united together by the action of a squeegee left for ten minutes in contact, and then separated whilst still humid. The one sheet would give on development a negative proof, and the other a positive proof. In reply to a question, M. de Potok said he had not a specimen obtained in this manner to show to the members, which left a doubt on the minds of several of them as to the value of the results, and therefore ocular demonstration is still required.

M. Davanne said that, one or two years ago, he exhibited before the Society for the Encouragement of National Industry, and also in the course of lectures on *Photography* he delivered at the Ecole des Ponts et Chaussees, a process analogous to one which had been shown to him by M. Roger, Director of the Photographic Section of the Museum of Artillery of St. Thomas d'Acquin, which was, in general terms, to the following effect:—A sheet of ordinary salted albumenised paper was floated upon its back on a bichromate bath, dried, and exposed, the back being in contact with a design on tracing-paper, or on drawing-paper rendered translucent in the usual manner so as to shorten the time of exposure. The albumenised paper was now laid on a marble slab and inked all over with the roller; it was then plunged into water, the albumen dissolving off with its covering of ink where the light had not acted, the other part remaining insoluble. This produced quickly, and with very little labour, the print ready for transfer. M. Roger said he inked before or after exposure; and thick, even very thick, drawing-paper gave equally good results. He then transferred the print to stone, when the inked image was immediately produced.

M. Perrot de Chaumeux remarked that M. Poitevin had published very much the same thing; but M. Davanne said that was done in general terms, although he used the words "*albumenoide*" and other "*succeedanées*" for the preparation of his surface.

M. Fleury Hermagis sent for the examination of the members two portfolios full of photographic views by M. Verdot, photographer, of Chateauroux. The most remarkable of these were views of ruins, monuments, and streets in the department of the Indre and in Berry, printed upon dark blue paper, giving very appropriate effects of moonlight, and quite in keeping with the subjects chosen.

MM. Charconnet and Laverne exhibited, for the first time in France, Marcy's and Woodbury's sciopticon, and projected on the screen pictures by MM. Lachenal and Favre, Lamy, and Leon Levy. The additions made to the instrument consisted of the closing up of each end of the lighting chamber with the unbreakable glass of M. de la Bastie, and the adaptation of a cone upon the condensers, having a truncated end, at an angle of 45°, for the insertion of *cartes* and cabinets, and at right angles thereto is screwed on the quarter-plate lens. by which enlargements were made 16 x 12 inches upon collodionised glass with an exposure of thirty seconds.

MM. Teisserenc de Bort (Minister of Public Works), Kranz (Commissaire General), and Georges Boyer (Director of the Foreign Sections), have paid a visit to M. Paul Baudry, in whose *atelier* they have minutely examined the magnificent design he has completed for the diploma to be awarded by the jurors to the successful exhibitors at the forthcoming universal exhibition in Paris. M. Baudry has symbolised "France, Supported by Peace, Protecting Labour" in a noble work, whose artistic merit will contribute a new and additional value to the prizes in connection with which it is to form the certificate. M. Baudry's admirable creation is to be reproduced by MM. Goupil and Co., and a *facsimile* obtained by M. Rousselon's process of photo-engraving, and under his direction. My English readers will learn with pleasure that this engraving process is based, to a great extent, upon the labours of an English gentleman, whose process is alone known in France as the process of "photoglyptie," being no other than that of Mr. W. B. Woodbury. W. Harrison.

Asnières (Seine), Paris.

PACKING NEGATIVES.

To the Editors.

Gentlemen,—Referring to a letter on packing negatives which appeared in your last issue, I would suggest the omission of sawdust as being not only unnecessary but heavy.

Four years ago I brought with me from Calcutta and Simla a quantity of negatives of all sizes, which I placed in the usual plate-boxes, carefully pressing between each negative a small quantity of cotton by means of a thin paper-knife; a layer of carded cotton was then put on the top of the plates, and the lid pressed down and secured by the hooks.

The negatives reached England without mishap of any kind, and it is scarcely possible for heavy baggage to be more knocked about than it is during the overland route from India. Had my plate-boxes been filled with sawdust the enhanced payment for freight would have been a serious consideration in such long journeys.—I am, yours, &c.,

Honiton, March 2, 1878. A. A. Mantell, M.D.

THE CONSTRUCTION OF STUDIOS.

To the Editors.

Gentlemen,—As the subject of studio building is again attracting attention, I beg to offer the following suggestions for the benefit of any who, like myself, are having additional studios constructed.

I observe in Mr. Heighway's work, in which the dimensions of a studio are described, that ten feet is suggested as a most desirable length, and width in proportion. This, I should think, must be intended for the natives of Lilliput, as twenty-five feet is the most useful length on the average, but more if it can easily be obtained; width about fifteen feet; height of the sides not less than eight feet, and, as rather a steep pitch gives the best results, about twelve or thirteen feet to the ridge makes a good form. The room, if the view be uninterrupted, should face the north, and be glazed *only* on the north side, the south and ends being all brick and slate. It is a wonderful advantage to have all the sashes of iron instead of wood.

A system of ventilation, at once simple and effective, may be arranged by opening the two end lights, and having a pair of boards below the side light to swing like Moore's ventilators, thus letting off the hot air above, and admitting a continuous stream of cool air below, but allowing all to be shut off if desired. The bottom of each pane of glass should be cut on a slope towards its centre, to form a medium for letting the rain run down the centre instead of the edges of the glass, thus greatly saving the paint and putty from rotting.

It is an undoubted advantage to have the top lights all of white Hartley's roll, and the sides of British or patent plate.—I am, yours, &c., Arthur Debenham.

Royal Photographic Studio, 28, *Union-street, Ryde, I. W.*,

THE SUBSTRATUM.

To the Editors.

Gentlemen,—May I add the result of my experience of substratums to what you say in your sub-leader on the subject last week? After much and very varied failure with albumen, gelatine, and with india-rubber edging, I have found never-failing success attend the very simple use of cocoa-butter applied as a "super"-edging (if I may thus distinguish it) just before development, as recommended by Mr. J. A. Spencer in The British Journal of Photography last year.

I have not only never found a film thus treated to slip, but have also never experienced any trouble from solutions, such as water, getting under and causing the film to burst. A negative thus secured would obviously offer no obstacle to the transfer of the film, and, as a very narrow edging is sufficient, it does not encroach beyond the limits of the strip of bare glass round the negative, so that there is no unsightly line round the picture, as I have found to be the case with the india-rubber edging.

A notch should, of course, be cut at one of the angles of the piece of cocoa-butter, and applied to the edge of the sensitive plate, rubbing the "butter" well and evenly along each side. The smell of the substance is not unpleasant, and the handling of it tends to fortify the fingers against the action of the solutions. But if desired it would be easy to invent a carrier into which a moulded stick of the "butter" might be fitted.—I am, yours, &c., A. J. Corrie.

THE FORTHCOMING PARIS EXHIBITION.

To the Editors.

Gentlemen,—I send you herewith a copy of a letter I have received from the Secretary of the Royal Commission of the Paris Exhibition which explains itself, and is, I think, a satisfactory answer to Mr. Samuel Fry's inquiry in your last issue, as I presume that the same concession will be made to all British exhibitors of photographs.—I am, yours, &c., William Bedford.

March 5, 1878.

[Copy.]

"20*th February*, 1878.

"Sir—I beg to inform you, in reply to your letter of the 9th inst., that the Royal Commission are prepared to unpack and arrange the works you send for exhibition at Paris this year, at the same time expressly stipulating that they will not be responsible for loss or damage of any kind.

"Charges for transport (which must be prepaid), storage of empty cases, &c., will have to be borne by the exhibitor. The Royal Commissioners will provide screens at the rate of one shilling per superficial foot.—I am, Sir, yours, &c ,

"T. Cunliffe Owen, *Secretary*."

[We may here observe that Mr. W. Harrison, our Paris correspondent, has expressed his willingness to act as agent for any of our readers who intend to send pictures to the forthcoming Paris exhibition. We feel assured that this announcement will be received with great pleasure.—Eds.]

EXPOSURES.

To the Editors.

Gentlemen,—It would be discourteous on my part if I did not explain my seemingly abstruse meaning to your friend and contributor, the "Peripatetic Photographer." I gather, however, from his questions that he is an old hand and in no need of the information himself, but rather wishful to "draw me out" for the general benefit of the amateur readers of the Journal.

And first let me wish his wonderful old lady many happy returns of her birthday, and to express a hope that she may long live to bear any amount of exposure to "friz" water and snow; but, in spite of what is stated, I still maintain that to live constantly surrounded by white objects would be very miserable. Snow, even in Switzerland, gets of a dirty white, and so pleasing to the eye, as is attested by some relatives of my own who reside there. Constant white (especially from snow) produces paralysis of the eye and blindness, which condition of happiness (?) may possibly be the one alluded to by your correspondent. The sense of sight being removed to the others, mental activity and ripe old age are in the ascendant. The late Dr. Brewster was my neighbour at Gattonside, near Melrose, Scotland, in a house surrounded by dark spruce firs planted by himself, as he disliked a strong glare of light.

But, photographically speaking, what is exposure? This question is already in one sense answered by the questioner, but it bears a second meaning, and I regret the dulness of your "Peripatetic" friend in not seeing it. The mere capping and uncapping of the lens was plain enough to anyone, for without so doing you could not get any picture at all; but unless "exposure" be rightly understood the whole composition and trouble you have been at in preparing your plate may be spoilt for want of knowledge. Exposure consists in being able to rightly judge from the objects before you forming your subject what time is to be allowed for the rays of light to act on the sensitive film. This may be a moment of time, a minute, or even an hour; and therefore is an "indefinite something which can only be judged at the time of taking the picture."

In my communication I plainly laid down certain points to be observed as to the colour of objects and locality, and as they have been acted on by myself during an experience of more than twenty-one years with constant and unbounded success, it was in the hope of being an aid and help to others I wrote as I did.

If your contributor will personally write to me, it will give me great pleasure to explain any points in which he may not have understood me.—I am, yours, &c., W. Harding Warner.

March 5, 1878.

IMPROVEMENTS IN CARBON PRINTING.

To the Editors.

Gentlemen,—The mouthpiece of the Autotype Company, the editor of (the later editions of) their *Manual*, notwithstanding many excellent qualities, is highly sensitive, very easily offended, and not easily appeased. He has already given three different explanations of the cause of his offence in respect of my article on the above subject in your Almanac (see his first and last letters), and I verily believe that none of the three contains a statement of the real cause of his anger, which, put into plain language, is that, although not professing to write a history of carbon printing, but merely that of my own labours to supply an acknowledged want, I made no reference to his own claim to have done the same.

Well, having failed to conciliate the editor (of the later editions) of the Autotype *Manual* by my expressions of regret for having caused him annoyance by my withdrawal of the erroneous quotation—not by my reticence—let me more frankly state that I avoided the discussion of those claims, because had I alluded to the subject I must necessarily have raised doubts as to whether he has succeeded in rendering the manufacture of those colours so regular and definite as to entitle it to be called a practical process.

My doubt is founded upon the facts—1. That I have always failed, as has my *employé*—a very competent person—to obtain satisfactory results with the supposed new process communicated to me. 2. Because I have been assured by eminent persons that the manufacture of the photographic tints of pigment paper was never so irregular and unsatisfactory as at that time (a few weeks ago).

Some of your readers may naturally ask how it was that the discovery of a process so important as that which, it was supposed, would render the special pigment prints demanded by photographers permanent instead of fugitive should have been communicated to me—a person evidently, but erroneously, regarded as inimical to the Autotype Company, and capable of meanly attacking them by means of a garbled quotation?

Well, "thereby hangs a tale," which will not be found in the sixth nor in any subsequent edition of the Autotype *Manual*, but which may some day be written when the printing of the photographic tints in permanent pigments with brilliance equal to those of silver and gold has become an accomplished fact not resting upon the *ipse dixit* of myself or others, but based upon the proof of the regular production of the pigment papers, their uniform qualities, and the stability of the tints duly certified after sufficient experiment.—I am, yours, &c.,

London, March 6, 1878. J. R. JOHNSON.

"A TRIAL OF LANTERNS."

To the EDITORS.

GENTLEMEN,—In your valuable Journal of the 1st inst. appears a letter from Mr. Daniel, who therein relates a story of what he is pleased to call "a most careful and crucial test" of the respective merits of rival magic lanterns. I gather from the first and second paragraphs that a little bit of a muddle was made on some previous occasion, and the tests of the learned society of which he is Secretary are not all "careful and crucial."

Well, there having been a muddle in their first struggles after light, no doubt these western *savants* determined to be right next time, and lo! as the result Messrs. Newton and Co. were invited to send and did send a lantern burning three wicks, against which one of my triplexicons, without my knowledge, was fitted. Doubtless, the fall of the triplexicon was great, and "the opinions," "the unanimous ones," as we are told *(in the choice sentences with which the record of this precious trial concludes)*, of all the exhibitors were adverse to my lantern!

May I be pardoned if I suggest that it was scarcely fair to my invention that I, its father, was not informed of these proceedings, nor was I invited to be present to take care of my child and see that no tricks were played upon him. Of course I do not assert that to have been done, but all who know anything about magic-lantern lamps knows how much depends upon the careful trimming of the wicks, the proper adjustment of the lenses and lamp itself in the lantern, &c., &c.

However, gentlemen, I am quite content to allow the question of the superiority of my lantern to rest upon the verdict you recorded concerning it—a verdict made after repeated comparative trials—in which you say, only a few weeks ago, that my triplexicon gave the most intense light of all the lanterns you had tried.

I do not think it necessary to trespass further upon your valuable space. The fame of my lantern is already well established; and I conclude with a challenge to Messrs. Newton and Co., or any other manufacturer of lanterns, that I am prepared to submit and exhibit my lantern, personally, at the Inventor's Institute, 4, St. Martin's-place, Trafalgar-square, on Thursday, the 28th inst., at eight o'clock p.m., against any mineral oil lantern they may bring, not an imitation of mine or an infringement of my patent. The members of the said Institute and others will testify to the relative merits of the lanterns exhibited.—I am, yours, &c., W. C. HUGHES.

151, *Hoxton-street, N., London, March* 5, 1878.

[We have no intention of entering into the discussion which has been raised by the experiments recorded by some of the members of the Bristol and West of England Amateur Photographic Association, which, we may say, do not quite accord with some that we have ourselves made; but we may here observe that we do not attach much importance to comparative trials of the intensity of the light in lanterns unless the other optical conditions are identical in all cases, such as the diameter, form, and focus of the condensers and objective. Uunless these be absolutely alike in every respect, and the intensity of the illumination of the disc be tested photometrically, trials of lanterns made under other conditions cannot be held to establish the comparative merits of lamps of diversified forms of construction. Here let the discussion of the subject terminate.—EDS]

OBJECT GLASSES.

To the EDITORS.

GENTLEMEN,—While agreeing with Mr. R. W. Thomas in his statement respecting the non-deterioration of the qualities of the object glass of an astronomical telescope by the discolouration of the flint glass, I am dubious about the same holding good as to a photographic lens. Will the fact of the discolouration of glass not interfere with the transmission of the actinic rays?

It has always been considered that the employment of *any* good portrait lens in solar camera work rendered its action somewhat slower.—I am, yours, &c., ASTRONOMICUS.

March 6, 1878.

KEEVIL'S LANTERN.

To the EDITORS.

GENTLEMEN,—Will you permit me to testify to the extreme convenience and utility of Keevil's duplex lantern? I have given three public exhibitions with it—the last to 600 people—and it has answered admirably, throwing a picture of close upon twelve feet of perfect brilliancy with the safety jet; and, what is of equal importance, there is no perceptible difference between the illumination of either disc. The "visions" in *Gabriel Grub* were rendered quite as distinctly and brilliantly as with two separate lanterns.

I can most strongly recommend the lantern to intending purchasers of such an apparatus, as being not only economical at first cost but (unlike many economical things) absolutely efficient.

I do *not* advise amateurs, however, to attempt to make the oxygen during the lecture, as the bubbling noise produced every ten minutes or so is very confusing, besides the probable inconvenience of burnt fingers. I have thankfully gone back to the old familiar *bag*.—I am, yours, &c., C. H. FYNES-CLINTON.

Blandford Vicarage, March 4, 1878.

VOIGTLANDER'S NEW LENS.

To the EDITORS.

GENTLEMEN,—In reference to Mr. R. W. Thomas's letter in your last issue, respecting Voigtlander's so-called *new* lens, we, as the appointed agents in the United Kingdom for Messrs. C. A. Steinheil Söhne, cannot now refrain from making some few remarks thereon.

We understand from Herr Voigtlander's specification, given in THE BRITISH JOURNAL OF PHOTOGRAPHY, dated the 1st ult., that that gentleman claims as part of his patent the use of two symmetrical menisci lenses composed of flint glass of different densities. Now the following will clearly show that Messrs. Steinheil claimed the same for their well-known aplanatic symmetrical doublet lens more than *eleven* years ago, their first patent having been obtained on the 12th November, 1866. A detailed description of their lens will be found in THE BRITISH JOURNAL OF PHOTOGRAPHY for October 18th, 1867, by Dr. D. van Monckhoven; and another description, with a diagram, also appeared in the same Journal on November 15th of that year; while again a full description, with a diagram, was given in THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for 1870, by the Editor, in a very able article upon *Photographic Lenses*, in which he says:—

"This objective consists of two symmetrical achromatic menisci, each of which is composed of *two flint glass lenses* of different thicknesses. It possesses diaphragms which are inserted between the two lenses, and extend the crispness of the definition over a large area. With its whole opening the objective works very quickly, and can be used for portraits in the open air, groups, the reproduction of animated objects," &c.

We will further refer your readers to a detailed description in a letter from Messrs. Steinheil, contained in your Journal of January 8th, 1875, in which they give the forms of the lenses, the densities of the glass employed, and other information.

We think, therefore, the foregoing will be quite conclusive in showing that Herr Voigtlander's *new* lens is identical with the one invented and patented by Messrs. Steinheil over eleven years ago, and which has been regularly advertised, and supplied by us to our numerous friends, for the last nine years.

In conclusion: we believe that had Herr Voigtlander known the whole of the particulars which are on record—at least in this country—he would have hesitated ere taking a step which must cloud his well-earned reputation, by obtaining a patent and bringing forward to our English photographers, as a *novelty*, a lens which has for so many years been in extensive use.—We are, yours, &c., MURRAY AND HEATH.

69, *Jermyn-street, S.W., March* 5, 1878.

HOW MR. GLADSTONE WAS PHOTOGRAPHED AS THE WOODCUTTER.—An action was heard at the Bolton County Court on Wednesday, the 6th instant. Mr. James Chambers, law stationer, sued Mr. Wm. Currey, photographer, Bolton and Manchester, for the sum of £8 8s. for assisting in photographing Mr. W. E. Gladstone, M.P., in the act of tree-felling, and for other services. On the 4th of August last the members of the Bolton Liberal Association had a trip to Hawarden Castle. Plaintiff and defendant were amongst the excursionists, who in the course of the day had the opportunity of witnessing Mr. Gladstone and his son, Mr. W. H. Gladstone, M.P., in the act of tree-felling in the park. On their way back to the station plaintiff suggested to defendant that with a little influence Mr. Gladstone might be induced to stand for his photograph in the character of "the woodcutter" at the foot of the tree he had commenced to hew down. Plaintiff and defendant accordingly returned to the park, and after a little persuasion obtained permission to photograph the tree only on the Monday following. Whilst making the journey to Bolton, plaintiff suggested to defendant that a letter should be written to Mrs. Gladstone soliciting her to use her influence with the right hon. gentleman and endeavour to induce him to sit for his photograph. This letter was despatched, and on the Monday plaintiff and defendant went to Hawarden Castle. On the way defendant said if he were successful in photographing the right hon. gentleman, and it turned out to be a profitable speculation, he would reward him (the plaintiff) handsomely. Mr. Gladstone consented to be photographed along with his son, in his dress as a woodcutter, with axe in hand, and defendant secured about half-a-dozen negatives. Subsequently he photographed the servants at the castle and the inmates of Mrs. Gladstone's Orphan Home, plaintiff assisting in the operation. The London Stereoscopic Company offered defendant £1,000 for the negatives without any further claim upon them, but this he declined. Eventually the plaintiff concluded an arrangement with another firm for the sale of a half share for £500, reserving certain rights, &c. Defendant sent for plaintiff to London to witness the signature of the agreement, but before his arrival everything had been concluded. His Honour held that there had been no contract on the part of the defendant, though there might have been the promise of a present, and gave a verdict for the defendant, with costs.

EXCHANGE COLUMN.

I will exchange Woodward's patent solar camera for a 10 × 8 camera and lens, or anything useful in photography.—Address, E. Plowright, Week-street, Maidstone.

A *carte-de-visite* camera, repeating back, very little used, by Garland, will be given in exchange for a good Albert or neck chain.—Address, Photographer, 60, Pentonville-road.

A new cabinet lens, with stops, and a new mahogany 5 × 4 camera, is offered in exchange for a watch and gold Albert.—Address, Photographer, 133, Heeton-road, Bermondsey, London.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

P. S.—Thanks; but not at present.

Obliged Reader.—A swing-back is infinitely preferable to a swing-front.

Not a Yokel.—Try the effect of adding nitrate of uranium to the printing bath. Ten grains will be sufficient for a first trial.

Thomas J. Smith.—By reducing the strength of the albumen a finer result will be obtained. To each ounce of albumen add two drachms of water.

Trim.—The harshness of the shadows may be entirely overcome by the use of white screens to act as reflectors. The picture marked No. 3 is the best, that of the little girl being the worst.

Genduon Morgan.—Immerse the plates first in a hot alkaline solution (potash or soda), and after removing the film by friction with a hard brush treat the surface with nitric acid.

T. E.—We recommend you to keep a few lumps of charcoal in the water cask, and to protect the inner end of the exit pipe by a filter formed of *coarse* sand and roughly-powdered charcoal enclosed within two thicknesses of felt.

D. G. & Co.—The varnish films may be entirely removed from your old negatives by immersing them for a few seconds in a boiling solution of common washing soda. Transfer them afterwards to a vessel containing plain warm water.

P. Senoj.—A process similar to that which you describe was patented several years ago in this country and on the continent, by M. Tessie du Mothay. The knowledge of this fact need not interfere with your experiments, which, if assiduously conducted, may lead to your discovering much more than you at present anticipate.

"Chromotypes."—We are pleased to learn that Mr. Witcomb, of Salisbury—of the excellence of whose "chromotypes" we have formerly spoken—has opened an establishment for the printing of these pictures for the special class of licensees of the Autotype Company who have the right to issue chromotypes. He has our best wishes for his success.

C. B. M. P.—No indication of the ridges in the negative will appear on the printing paper. We strongly advise you neither to remove the varnish or apply a second coating until you have first submitted the negative to a careful printer. Seeing that it possesses so great a value, you should obtain from it a large transparency which could be utilised in the production of other negatives.

P. Vinaga del Valle (Havana).—This correspondent inquires—"How can I prevent the blistering of double albumenised paper? I have used all the solutions and water of the same temperature. I have also diluted the fixing solution to half-an-ounce for twelve ounces of water. An American paper recommends the use of alum, but another says that alum endangers the stability of the prints."——Can any reader supply the information? We have never had blistering of this kind.

F.R.S.—From experiments made during the summer with dry plates and the pantascopic camera we are quite convinced that this instrument may be most effectively employed with plates of this kind. Of course, to secure "instantaneous" effects the plates must possess at least the sensitiveness of wet collodion; but this is now a matter that presents no difficulty whatever.

A. B. C.—The rapidity of the lens may be ascertained either by comparing it, in action, with one of whose rapidity you are already assured or by ascertaining the relation borne by its aperture to its focus. From the description you give of the lens we think it probable that the front lens, if employed alone as a landscape lens, will cover a plate of 24 × 20 inches. Let the stop be about four inches from the flat surface of the lens.

Constant Reader.—There are two kinds of opal glass, namely, *flashed* opal and *pot metal*. In the latter the opaline substance of the glass extends from back to front of the plate; in the former it is confined to a thin layer on the surface. A picture taken on pot metal has a dull, sunk-in appearance as compared with the brilliance of one on flashed opal. If the wet collodion process is to be employed see that the collodion is rather old, and abstain from carrying the developing too far, otherwise the picture will be heavy and sombre. A very rapid exposure will be necessary in order to keep the shadows clean.

Sportsman.—You have no right to produce for your own use, or exhibit in your show-room, the portrait of any sitter without obtaining permission. Photographers do not usually ask for such permission; but after an objection to such a course has been intimated it is necessary to withdraw it from public exhibition. The negative is your own property, but you must not make use of it in the production of a print unless authorised to do so by the individual for whom it was taken. In other words, the glass and collodion film belong to you, but the *portrait* does not. You may either destroy the negative, retain it, or sell it to the parties concerned. You must be guided by circumstances as to which course you had better adopt.

J. J. H. writes as follows:—"I am trying to print from collographic plates, and though I think I succeed in the preparation of the plates the rolling up knocks me down! If your diversified genius could bring anything to bear on the subject by telling me where I am wrong I should be thankful. I have got proper lithographic ink and leather-covered roller, and I have tried various liquids to damp the plates, as also various exposures; still the ink will attach itself where it should not, and when I use thicker ink it tears off the film."——The remedy we propose is of a very practical nature. Let our correspondent obtain a lesson in the art of lithographic printing (for collography and lithography have much in common) from some one skilled in that method of graphic reproduction. To accede to the wish of "J. J. H." and tell him where he is *wrong* will involve him coming to London, bringing his printing plant with him, and going through the whole operation in our presence.

Photographic Society of Great Britain.—At the next meeting of this Society, to be held on Tuesday next, the 12th instant, at 15a, Pall Mall East, a paper, by Dr. D. van Monckhoven, will be read, entitled *The Fading of Carbon Prints, and Carbon Printing Without the Use of Bichromates.*

"The Graphic Portrait."—Under this designation Mr. A. Ford Smith has introduced portraits surrounded by floral and other artistic devices. The effect is striking, and will suit the tastes of that portion of the community who think that vignette portraits are improved by artistic surroundings. Judging from several specimens we have received, Mr. Smith displays excellent taste in the artistic composition and arrangement of the *materiel* (ferns, flowers, &c.) of which these surroundings are composed. We need scarcely say that the effect is produced by double printing.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician.
For the Week ending March 6, 1878.
These Observations are Taken at 8.30 a.m.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 932. Vol. XXV.—MARCH 15, 1878.

ON THE CONSTRUCTION OF ACTINOMETER SCALES.

In the construction of an instrument for taking actinometrical measurements by means of a graduated scale, the chief difficulty consists in obtaining a satisfactory range of tints or "steps" possessing at the same time the requisite delicacy and freedom from error in reading off the result. In order to secure this end it is necessary that the material of which the "scale" is made should be as even and homogeneous in texture as possible, as the slightest inequality or "grain" in the tints impressed upon the sensitive paper will be found to militate greatly against the correct reading of very delicate shades.

For use in carbon printing and comparatively rough work—that is, where two or three minutes, more or less, are of little consequence—the ordinary scale, composed of different thicknesses of thin, even paper, answers well enough; but when we come to apply such an instrument to more delicate purposes—as, for instance, testing the comparative rapidity of a dry plate—it is found to be quite inadequate to the end. Not only are the gradations too abrupt and the whole scale too dense, but the slight texture produced by the paper screen renders it extremely difficult to judge of the comparative action in two separate experiments. On this account we have for some time been endeavouring to find a better material for the graduated scale, for use not only in the manner just mentioned but also in outdoor work; for both of which purposes a more delicate instrument is required than the ordinary paper scale—that is to say, one which is more easily impressed over a comparatively large range of tints by a short exposure.

In this respect we have succeeded tolerably with thin paper rendered transparent by waxing; but, unfortunately, the permanency and uniformity of action of such a scale is not to be depended upon. One which we constructed some few months ago has become decidedly yellow, while the granularity of the lighter tints impressed is much more marked than if the paper were unwaxed. Long before this had occurred, however, we had altogether discarded paper for gelatine, and this, in one form or another, will, we think, be found the best material that can be employed, as when the screen is once made it is not liable to change, nor, if ordinary precautions be adopted, to injury from use and exposure to the atmosphere. Under the head of gelatine we include not only the method of superimposing various thicknesses of suitably-prepared gelatine tissue in the same manner as the paper scales are constructed, but also various modes in which the tints are formed by the action of light upon bichromated gelatine, either with or without pigment.

In our experiments with the first description we have employed gelatine tinted by chemical means, and by the addition of soluble colouring agents, in preference to using insoluble colours in suspension; this, we think, gives not only a more homogeneous film but permits the passage of the light through a large number of thicknesses of the coloured gelatine, and thus gives a greater range of tints. If the colour be composed of finely-divided particles of insoluble matter the film lacks transparency; and, though a single thickness may offer no greater resistance to the passage of the actinic rays than one in which a soluble colour is employed, it will be found that as the "steps" increase in number the opacity of the former, independently of their non-actinic colour, exercises a much greater retarding action than do the others, and the tints become more abrupt and less delicate. For some purposes, no doubt, this would be more suitable, but, as we have stated, our aim has been to obtain a scale capable of rendering the most minute gradations.

Potassic permanganate forms a convenient means of colouring the film, but it must be applied in very weak solution on account of the extremely non-actinic character of the colouration. It is a matter requiring considerable care to hit the right point, as even with a weak solution, if the gelatine be immersed for too long a time, the effect will be similar to that produced by a stronger solution; moreover, the permanganate can only be applied to the film after it has been poured upon glass, and not to the gelatine "in bulk," as it renders it insoluble. A second plan which gives a very fine tint, but requires some care, consists in treating the film, when well set, with ferrous sulphate followed by pyrogallic acid. The difficulty in this case is that there is no means of judging of the extent of the action of the iron until the pyro. is applied, when, perhaps, it is found to be overdone. The gelatine may probably be treated in bulk, and, when afterwards dissolved, diluted to the right tint by the addition of a plain solution.

The best of many colouring agents we have tried is saffron; its use is attended with no difficulties, and, as far as we can judge, the colour appears to be permanent. The saffron is digested in water till the colouring matter is extracted, and the liquor is then filtered and diluted with three times its bulk of water; gelatine is then added, allowed to swell and absorb as much of the colouring liquid as it will, and then dissolved by heat. Different samples of the saffron of commerce vary in the amount of colouring matter they give up to water; hence it is possible the dissolved gelatine may require "letting down" in colour, but the sample we have used works well when treated as above and poured upon glass so as to form a film of the thickness of thin note-paper when dry.

The films are prepared by pouring out the gelatine on to a sheet of plate glass previously waxed, collodionised, and washed. Immediately before pouring the gelatine the glass is dipped for a few seconds into hot water, rapidly drained, and placed upon a levelling-stand, where it is allowed to remain till the gelatine has set sufficiently to bear removal; it is then reared up to dry in some corner free from dust. When quite dry the compound film is readily stripped from the glass, and may be cut up and arranged in the form of a scale in the same manner as paper.

The chief objections to this form of scale are the inconvenience arising from the number of separate pieces of which it is composed, and the difficulty, if not impossibilty, of securing in one instrument a considerable range of tints of sufficient delicacy. This is, perhaps, not a matter which very closely affects its application to mere actinometric measurements of light, though it does to a certain extent; but, in testing the sensitiveness and other qualities of dry plates, it is of paramount importance that the tints should be as finely graduated as possible. Now, in the scale instrument, constructed on the above principle, the range of tints available is very limited. If the pellicle of which the screen is formed be sufficiently transparent to permit the impression in a reasonable time of (say) a dozen tints or degrees, by the time that the fifth or sixth, or perhaps seventh, is impressed numbers one and two are indistinguishable, having acquired the same strength of colour. If the pellicle be made denser, then the number of degrees it is possible to impress by *any* exposure is curtailed, so that in either case the range is limited.

In measuring the power of the light we have nothing to do with any but the highest degree impressed; that represents the actual extent of actinism expended, the intermediate steps having lost all value. But if we are testing the properties of a dry plate, its power of rendering delicate gradations, or, better, the capabilities of some particular form of developer in giving density without obscuring the half-tones, each individual tint of the scale, from absolute transparency to perfect opacity, has its own value and must be clear and distinct from every other; but to attempt to vie with nature in the immense variety and delicacy of the gradations of light and shade which it presents to the camera is more than we could hope to do by any artificial means, however perfect.

With a view of removing, or at least abating, these objections to the use of the graduated scale we sought the aid of bichromated gelatine, the successive tints being formed by means of progressively-increasing exposures to light. We first tried the ordinary pigmented tissue, but were soon compelled to relinquish that, as the "texture" conferred upon the gelatine image by the paper support destroys the finer gradations, and the quantity of colouring matter present limits the range of the scale too considerably. We next tried films of specially-coloured gelatine extended upon collodionised glass, and when dry stripped off in the form of a tissue, as in Swan's original process. In this manner we entirely escaped all traces of texture arising from the physical nature of the support and obtained altogether better results; but the preparation of the pigmented gelatine in a sufficiently homogeneous condition is a troublesome operation, and one which amateurs as a rule will not care to undertake.

As the best method we finally fixed upon colourless gelatine, or so slightly tinted as to render the development of the image more easily distinguishable, as in the entire absence of colour it is impossible to judge of the action of the developing water. The graduated film of gelatine thus obtained may be easily and satisfactorily coloured by the subsequent application of a variety of solutions. The great advantage of this plan is that the absence of opaque colouring matter permits the light to act through a greater thickness of the gelatine, and at the same time considerably shortens the exposure necessary, enabling us to secure a very wide range of tints.

An unusual press of matter compels us to leave over until next week the description of our *modus operandi*. We shall also have some remarks to make upon the graduation of scales by mechanical means.

THE PHOTOGRAPHIC USES OF BITUMEN.

From what we can learn bitumen, or asphaltum, was pressed into the service of photography in the year 1844, or nearly thirty-five years ago. M. Nicephore Niepce ("glorious old Nicephore," as the late Mr. C. J. Burnett delighted to designate him), the *confrère* of Daguerre, was the first to discover the extraordinary photographic properties of bitumen of Judea, or "Jews' pitch," as it is sometimes termed. The discovery of M. Niepce consisted in the following:—

Asphaltum, when dissolved in essential oil of lavender and poured upon a tablet of plated silver or other polished metal, forms a varnish sensitive to light, the action of which renders the layer of bitumen insoluble in proportion to the duration of the luminous action. If an image be impressed upon a sensitive surface of this description, and the tablet be afterwards treated with a solvent of the resin by which it was sensitised, it will follow that those portions corresponding with the action of the light will remain unchanged, while the shadows will be dissolved out. Various surfaces prepared in accordance with this principle were made use of by M. Niepce, some, as we have indicated, being metal, while others were of glass or stone. This earliest of experimentalists having obtained pictures upon metal plates, subjected these plates to the solvent action of nitric and other etching fluids. This, in the estimation of most writers, was the first practical photographic process that was published. Be this as it may, it is a process which, after having been improved and modified by subsequent experimentalists, has proved of great utility and is likely to receive further development.

Those members of the Society of Arts who, with their friends, listened to the explanation given on Monday evening, the 4th instant, by Mr. Thomas Bolas, with regard to the photographic uses of that most unphotographic-looking substance, asphaltum, must indeed have felt that the force of manipulative facility could no further go. To show the photographic sensitiveness of one of the most common of substances Mr. Bolas, among other experiments, developed in the presence of his audience a picture formed of the common Brunswick black of the oil shops. Nor was the resulting picture one that required any apology, for, when exhibited to the audience by means of the lime light, it was found to possess all the delicacy characteristic of the best bitumen pictures.

Asphaltum is well known to be specially adapted as an etching ground when engravings are to be produced, owing to its capability of resisting acids and other etching fluids. This led to its employment for this purpose, in connection with photography, by M. Niepce de St. Victor, who devoted much time to ascertaining its capabilities. Of Gallic origin it has received its chief development through Frenchmen. In the hands of several experimentalists and professional men in Paris, the production of photographic engravings by the agency of bitumen has been carried to an extent and has attained a degree of refinement altogether undreamt of a few years since.

The chief differences existing in the methods of carrying out bitumen engraving processes are to be found in the solvents for the resin both before and after the exposure. Oil of lavender, as we have already stated, was the solvent employed by the elder Niepce. Those who followed in his footsteps employed other solvents. Ether was at one time strongly recommended as the best solvent for bitumen, especially when it was applied in photolithography, and we have seen several excellent prints of this kind produced by the late Mr. Macpherson, of Rome, who advocated the employment of this solvent. Oil of turpentine is a favourite solvent with many. Some refinements upon its use are adopted, such as keeping it in an open bottle for a month previous to dissolving in it the bitumen, the proportions of these being as one to fifteen in the hands of at least one skilful operator.

We are aware of one highly-successful photo-engraver who adopts as a solvent for the bitumen a mixture of chloroform and benzole, in the proportion of two parts of the latter to one of the former; but for all practical purposes benzole, without any addition whatever, will answer most effectually all the functions desired in a solvent of the sensitive resin. This, too, was evidently the opinion entertained by Mr. Bolas, inasmuch as it was the solvent adopted by him in the preparation of his plates on the occasion to which we have referred.

The applying of a uniform coating of this resin to a plate of metal or glass has sometimes been attended with difficulty. By the method exhibited in action by Mr. Bolas this was effected in a perfect manner in somewhat over a minute of time. Upon a circular table of small dimensions, capable of being rotated very rapidly in a horizontal direction, was placed the copper plate to be coated. A little of the sensitive solution, of about the consistence of collodion, was poured upon its centre, and the services of a close cover were utilised in order to prevent the sparks caused by the rapid rotation of the table, which followed the closing down of the cover, from damaging the dresses of those in its vicinity. After a few revolutions of a handle connected with multiplying gear the plate was removed, and, when handed to the audience for examination, it was found to be coated in a very uniform manner, the surface being also quite dry.

However diversified may be the idea of experimentalists respecting the best solvent of the asphaltum previous to exposure, not less are the differences of opinion as to the best solvent after exposure. Benzole is used by some, but the complaint preferred against it is its too energetic action. To curb this one Parisian engraver, who has the reputation of having produced some of the finest line engravings from photographs, prefers to almost saturate the benzole with asphaltum previous to employing it as a developing agent. Oil of turpentine is preferred by many; but as the solvent action of this substance, when employed alone, is very slow a developer having a manageable degree of rapidity is found in a mixture of these two liquids.

As a basis for success in operations which depend upon bitumen it is of paramount importance that the proper kind be obtained.

RIPENING OF COLLODION.

The subject indicated by the title of our article is one which forces itself upon the notice of every photographer—from the busy professional portraitist who uses up a pint or two a day to the amateur whom a pint would last a whole year or more so far as the actual coating of plates is concerned, but who, alas! for his pocket, finds that for every ounce he puts on his plates he pours five times as much away, owing to its having "lost its power," to use the expression he frequently employs.

It is with regard to the keeping properties of collodion that we are impelled to write now by the results of a few experiments we have had in progress for some time. They have quite led us to the conclusion that the popular ideas relative to the ageing of collodion are open to considerable correction.

The veterans of our art will well remember the time when it was the fashion for most of them to make their own collodion, and when the number of makers of a really good commercial article were very limited. This was before the time that Mr. Hardwich and others published their researches on the manufacture and properties of pyroxyline, and when the photographer was a happy man if he managed to make most of his gun-cotton dissolve, and, above all, if he managed also to dissolve the bulk of his iodide and bromide; for in those days it had yet to be learnt that it was in the pyroxyline rather than in the sensitising salts that the cause of differences in the working properties and the sensitiveness of the collodion were to be sought.

The knowledge of the chemical principles involved in the manufacture of collodion being thus limited, such popular terms as the "ripening" and "maturing" of collodion were naturally invented, and have remained in use up to the present time, and are still, to a limited extent, serviceable as representing a fact without involving any theory. But the compositions of collodion now varying among themselves, as they do, have a distinctive character they did not possess in the early days of photography. Then, iodised collodion only was employed, and iodide of potassium almost was the only salt made use of for iodising.

The action of iodide of potassium on the collodion is to make it flow more freely, and gradually to lose its setting powers—a property valuable if glass positives are taken, where complete purity of shadows is essential to perfection of results; but fatal for negative work where rapidity is wanted—such rapidity as we now consider a necessity. The further action of the alkaline iodides upon the collodion is to make it give an intense image—a point, again, of importance under the old *régime*, when negatives in their high lights used to be as opaque as if they were cut out of sheet metal. The collodion then was considered ripe, and after a while to be perfect if a little slow. Its colour was considered a complete guide to its properties, and unless it was almost like port wine it was used with doubtful confidence.

Then came the more general use of cadmium and different metallic iodides; and ammonium, with the other alkaline and alkaline earth iodides, and then the bromides, all sorts of changes being rung upon them. Potassium gradually got "edged out," and at the present day cadmium and ammonium are the sheet anchors of collodion makers. During all these changes the old dislike to a colourless collodion remained, and became perhaps intensified by the use of cadmium iodide, which, when not combined with other iodides, has the property of causing the collodion to become ropy and gradually solid—a state which cannot be remedied by the addition of fresh solvents. A further objection to the colourless collodions is the greater skill needed to use them successfully to avoid fog and flat negatives.

Were we now to poll the whole fraternity of photographic operators, we believe that by a good majority the following would be their judgment upon them:—"Any colourless collodion not fit for regular work; red collodion works well, but slow; deep-sherry colour best; finally, no collodion is any use till mixed a few days."

We now wish to point out that the results of our experiments show that with a suitable collodion the best and cleanest results can be obtained with an absolutely colourless collodion. We have used one made entirely with cadmium salts and a *suitable pyroxyline*, which would hold its own against the best collodion to be had anywhere. We have used it two months' old and two years' old, the older being as quick as the newer, but working cleaner and freer from spots. We cannot but think that if collodion makers would send out ready iodised such a collodion it would meet with a favourable reception. For those whose use for it is only occasional it would be a boon; while to others who use it daily it would be a collodion of constant character, its sensitiveness not changing from week to week. If any difficulty were found in working it, a small quantity of iodine added would make it amenable to the treatment of the most unskilled.

With regard to the question of newly-mixed collodion, we can only say that it is our habit to keep a store of plain collodion by us sufficient to last a considerable time; and when we wish to obtain the highest possible amount of perfection we do not hesitate to mix it with the iodiser *immediately* before use, fully confident that neither cleanliness nor evenness of result will be in the slightest degree inferior to that obtained by using the mixture when a week old. This we find not with one kind only, but with all kinds and with all makers' collodions.

Making, as we do, numerous experiments as to sensitiveness of various plates, we have found that the colour is not at all to be relied upon as to the rapidity of working a collodion will possess. It is usually considered that so long as a collodion is pale its sensitiveness is at its highest pitch. This we do not find to be invariably the case. A newly-mixed collodion (the plain collodion well kept) will usually after an hour or two become considerably darker in colour, and after a few days lighter again, owing to the absorption of the liberated iodine by the ether, which appears to possess the property of combining to form a colourless compound with iodine, especially in presence of bromide, and more particularly with methylated solvents.

It would appear that this evolution of iodine at first is too sudden to allow of the colourless compound to be formed, but that afterwards as fast as the iodides are decomposed by the change which ensues on keeping the collodion the evolved iodine is re-absorbed till a certain stage is reached, after which it is given off too quickly to be taken up. This, however, with an average good collodion does not occur till after the lapse of some months, the collodion meanwhile being pale and working well. Now we have little hesitation in affirming that, contrary to the usually-received opinion, this slightly-coloured collodion is not necessarily a quick collodion, nor does its character remain the same though the colour be unchanged. The result of a considerable amount of experience and of some special experiments is that week by week the sensitiveness is diminished; along with this diminution a more intense character is given to the negatives.

The final results we would point out are that a colourless cadmium iodide, and bromide collodion will work well and quick; that a newly-mixed collodion containing alkaline salts as well as cadmium is perfectly fit and excellent for immediate use; and that the mere colour of a collodion is no test of its sensitiveness or its working qualities. We are aware these conclusions are contrary to usually-received notions, but we have not adopted them carelessly nor without mature consideration.

A FIFTY-POUND PRIZE DRY PROCESS.

It is with no small degree of pleasure that we are enabled to announce that the substantial prize of £50 has been offered by a private gentleman as an incentive to progress in dry processes. Mr. Joseph Paget, through whose liberality this prize is offered, considers that several of the requirements of a perfect dry process have not yet been secured—a chief defect, in his estimation, being the uncertainty in producing the best possible result when the development of a negative is deferred for a period of three or four months after exposure.

No one experienced in dry-plate photography is unaware of the fact that by the majority of dry processes plates will not keep well after exposure. We here use the term "keep" in its conventional sense, namely, that the longer after exposure the development of the latent image is delayed the more surely does such latent image return to—nothingness. Supposing that three plates, alike in every respect, have received the same amount of exposure today, and one of them be developed within a day or two, it will yield a good and vigorous negative compared with the second plate the development of which is delayed for a month; while the third plate, if developed six months after exposure, will not yield more than a feeble, shadowy image, if it produce an image at all, which is somewhat improbable. This is in a most marked degree the case with plates in which tannin has been employed as an organifier or preservative; and in working with that process it is necessary to counteract the rapid action of time as a destroyer of the latent image by giving a prolonged exposure to the plate, the degree of prolongation bearing a strict relation to the probable duration of the time intervening between exposure and development.

We have mentioned the tannin process as a well-marked instance of one which yields plates that do not keep after exposure. An image impressed upon a collodio-albumen plate will, on the contrary, remain in an excellent state of preservation for a long period before development. We have developed an image upon a plate of this kind twelve months after exposure, the particular form in which the process was employed being a modification of Dr. Ryley's hot-water process. It has long been believed that an albumen preservative, aided by a final wash of gallic acid, provided the only means by which plates possessing keeping qualities after exposure could be prepared; but recent experiments have indicated gelatine as not unlikely to rival albumen in this respect.

With regard to the keeping properties of plates *previous* to exposure we need say little. It has been abundantly demonstrated that several years after preparation dry plates, when prepared with care, will yield negatives of the highest quality. The most recent instance of this we have seen was the exposure and development within the present month of some of a batch of "Russell plates" that were prepared at the same time as, and under precisely similar circumstances to, those that were taken by Mr. H. M. Stanley as part of his outfit for his tour in connection with African exploration. With respect to that outfit we may observe that the plates exposed two or three years ago by him and developed at, or soon after, the time of exposure have yielded successful negatives, while those of which the development was deferred till his arrival in this country have scarcely shown even the trace of an image; nor is this more than what would have been anticipated by those conversant with dry plates having a tannin preservative.

It is a healthy sign when we find a gentleman like Mr. Paget adopting the means to which we have referred for promoting the progress of dry-plate photography, and his action in this respect contrasts favourably with that of those, whether they be societies or individuals, who offer prizes for *results* of processes—a course which cannot stimulate investigation or research. We may state that one condition under which the above prize is offered will be not merely the demonstrating to the satisfaction of the jurors who may be appointed that the process is the best, but also that such full details of its nature be given as to enable others to work it successfully in like manner. It would be desirable that the Photographic Society of Great Britain should supplement the well-timed generosity of Mr. Paget by offering its silver medal for the second best of the processes exhibited in competition, and in doing so take care to avoid incurring the stigma that attached itself to the council of the now extinct, although at one time influential, Photographic Society of Scotland, which offered a *bronze* medal for the best process and a *silver* medal for the best results of the bronze medal process. Hitherto very little encouragement has been given to inventors and discoverers when contrasted with that bestowed upon those who work by the light of such inventions and discoveries; let us indulge in the hope that the example so nobly set by Mr. Paget will be speedily followed by other gentlemen.

ON THE STRENGTH OF BICHROMATE SOLUTION USED IN PIGMENT PRINTING.

The memory will not be severely taxed in going back to a time when the journalism of photography was a means of showing how opposed ideas may be on so simple a subject as the best strength of the nitrate bath for silver printing purposes.

The means for at once determining this point seemed to be so simple that it would appear to the uninitiated a question so easily settled as to afford no scope for any prolonged discussion. Yet the opinion thus formed would be speedily altered could a glance at the variety in the quality of negatives produced in different studios be obtained. Clearly, to get the best result a dense negative would require different treatment to one of those thin, weak negatives barely removed from a positive. Seeing it has been found that no hard and fast rule can be laid down to determine the strength of the positive bath (except it be a strong bath for thin negatives and a weak one for dense ones, this again varying with temperature, time of floating, &c.), it seems reasonable to expect a like variety in the strength of the sensitising solution employed in the process of carbon printing.

Solutions of bichromate of potash varying from one to seven and a-half per cent. have at times been recommended, and no doubt that each in the circumstances gave the best result; hence it becomes of interest to ascertain the particular conditions that would lead one to select a strong sensitiser and another a comparatively weak one, and also the reason for so doing. The rule is a strong solution for dense negatives and a weak solution for thin negatives. But why? A little reflection will soon determine.

The gelatine of which tissue is made is mixed with a given quantity of pigment sufficient to reproduce the deepest blacks, as is evidenced by its appearing black on the white paper upon which the compound is spread; but, to be understood, it will be better to dispossess the gelatine of its pigment and then follow the action of light on the simply-bichromatised gelatine. If a sheet of such gelatine be looked at by transmitted light it will be seen to have properties in common with yellow glass, so far as regards opacity to the so-called actinic rays, and the greater the proportion of the bichromate the more non-actinic such gelatinous film becomes.

Now, if two such films—the one containing a small proportion of bichromate of potash comparatively to the other—be exposed to the action of light, each would permit a certain proportion of actinic rays to pass entirely through; but in one case more of the rays would be arrested and employed in producing that decomposition resulting in insolubility of the previously-soluble gelatine, and hence it would print quicker. There is also another difference to note, viz., more rays would be arrested at or near the surface in the case of a strongly-bichromatised film, and fewer allowed to proceed than in one containing less of the salt. Thus, of two sheets—one having more bichromate in than the other—it is evident there will be a difference, both in rapidity of becoming insoluble under the action of light and in the relation between surface insolubility, and the total insolubility produced by prolonged exposure; that is, with a large proportion of bichromate in the gelatine the surface exposed to the light would, *comparatively* with the rest of the film, sooner become insoluble than in one containing a smaller proportion of the chromium compound.

Let this action now be followed in the pigmented film, and the reason why a strong bath is selected to sensitise tissue to print dense negatives is obvious; for what is wanted to produce harmonious results is a comparatively rapid surface action to secure all the delicate but over-dense half-tones, and thus to compensate for want of harmony in the negative. With a weak negative the reverse is required. With a strong bath the half-tones would be over-printed before there had been time for the light through the deepest shades to bring about the decomposition necessary to secure the requisite vigour, which can only be ensured by a weak sensitiser and longer printing. The truth of all this will readily be seen when it is remembered that in pigment printing the action of light does not produce the pigment, but simply imprisons what is already there by making the gelatine insoluble.

I have known it attempted to secure this desired variety in sensibility of tissue by immersing it for a shorter or longer time in a given sensitising solution. This is a practice that cannot be too strongly condemned; for with a short immersion, if there be the least inequality in the thickness of the pigmented gelatine, there is certain to be a corresponding difference in the sensibility of the tissue, and hence stains. Of this more will be said at a future time.

A ready way to determine (when it is desired) the best strength of the bichromate bath to use is to prepare a series of baths varying in strength (say) from one to seven per cent. Sensitise a small piece of tissue in each bath, and then expose under an average negative; develope, compare results, and the knowledge gained will repay the trouble. W. E. Batho.

A RÉSUMÉ OF THE GELATINE PROCESS.

[A communication to the Edinburgh Photographic Society]

The Corresponding Secretary has been good enough to invite me to contribute a paper on gelatino-bromide as a subject for discussion at the meeting of the Edinburgh Photographic Society; and I willingly respond to the invitation by transmitting the following remarks, in the hope that a short *résumé* of the results of several years' work may not be without interest, and may stimulate those who are willing to do so to give this process a trial in the coming season.

Of progress and improvement in the character of the gelatine emulsion I have nothing of novelty to record. Long experience has convinced me of the reliability of my own gelatino-beer emulsion, and I continue perfectly satisfied with the formula I have published in The British Journal Photographic Almanac for 1877. The plates prepared with it are somewhat slow; but I am convinced that in this process, as in all others with which I am acquainted, rapidity can only be attained at the sacrifice of reliability. Moreover, it will be found, I think, that the slowest gelatine plate that can be made is still in advance, in point of rapidity, of every other reliable dry plate. The use of an organifier in this process has recently been condemned; but, after hundreds of experiments with emulsions concocted with every possible combination of ingredients, and with all the bromides to be obtained, I still maintain firmly that uniformity of action and adequate density in the negative are unattainable without it.

Of the various substances which may be used as organifiers of the gelatine emulsion, sugar and beer have proved the most efficient in my hands. The former, however, confers an objectionable stickiness of surface upon the film, and this evil is intensified whenever damp weather supervenes. In spite of recently-suggested improvements in the method of eliminating the nitrate salts from the emulsion, I still adhere to the old plan of washing, as involving, in my hands, less trouble and complication. In the hottest weather the gelatine will readily set in our latitudes if the dish into which it has been poured be placed for a minute or two upon a slab of stone or sheet of iron. Nothing can well be more simple, and certainly nothing can be more effective, than merely to place the dish of emulsion in a vessel of water over night and find it ready for use in the morning.

Messrs. Wratten and Wainwright's discovery will be invaluable for dealing with large quantities of emulsion, and also for use in the tropics; but, in my opinion, amateur workers in this country will do well to leave dialysis and the alcohol process alone, and trust solely and implicitly to a bath of cold water.

Many amateurs have been frightened away from the process by the multiplicity of the apparatus recommended in the preparation of gelatine emulsion and plates, and I fear that I myself am, to some extent, guilty in the matter. A drying cupboard with levelled shelves is a most useful adjunct to the laboratory; but I quite agree with Mr. Kennett that it is by no means an essential to success. An accurately-levelled surface upon which the newly-coated plates may be laid till the films have set is all that is really necessary, and the plates may be stored for drying on any convenient shelf or receptacle where fresh air can, and dust cannot, have access to them. In the operations connected with this process it is better to trust as little as possible to artificial heat; although, in the case of the dried film, the application of a high temperature will prove an infallible mode of preventing blisters.

I will repeat at this point directions for making the most reliable emulsion I know:—

Gelatine	40 grains.
Bromide of ammonium	20 ,,
Nitrate of silver	40 ,,
Spring water	1 ounce.
Table beer	1 ,,

Place the bromide and gelatine in seven drachms of the water, and the silver (in a separate vessel) in the remaining drachm. Give both solutions a warm bath till the gelatine has dissolved. Then, in the dark room, thoroughly mix and leave the emulsion in a warm bath for four hours at least. This is most conveniently done in an infant's food warmer, a very small flame being applied below. As soon as the bromide of silver has had time to form—*i.e.*, in four hours—pour out the emulsion to the depth of a quarter of an inch, and, when the gelatine has set, place the dish over night in a pail of cold water, and in the morning it will be ready for use. The ounce of beer is now added to the warm emulsion; the whole is well shaken and passed through a pledget of glass wool in the neck of a funnel, and then the plate may be coated with it. A fair latitude may be taken in the exposure of the negative; but it is necessary to remember that the mistake of over-exposure is more readily obviated than that of under-exposure. Some quarter-plate negatives which I have sent by post may be taken as samples. Particulars of light and exposure will be found upon each.

It will be unnecessary to give details of development. Suffice it to say that the best results are obtainable with a three-grain solution of pyro., to which a drop or two of a one-in-sixteen solution of strong ammonia has been added.

I now pass on to a further development of the gelatine process, by means of which the tourist may avoid the weight and danger of his glass plates. I have already supplied the details in a paper read before the Liverpool Amateur Photographic Association; but I have since perfected and simplified the process, and will, therefore, give the revised directions.

A sensitive gelatine film may be made and stripped from the glass as follows:—

Gelatine	30 grains.
Bromide	10 ,,
Silver	20 ,,
Water	4 drachms.

Proceed in accordance with the directions already given until the emulsion has received its five or six hours' immersion in a cold bath. Now take two drachms of fresh ox-gall and two drachms of table beer; warm, and add to the half-ounce of emulsion. Filter and coat the plates. It is necessary, however, to obtain a much thicker film than the ordinary process supplies, and therefore the plate, when thinly coated, should be laid on a level glass plate, and an additional supply of emulsion poured upon it—to the depth of about the eighth of an inch. It will be found that the gelatine will not flow over the edge of the plate unless too much has been added; and when the film is set it should be placed in a position where no dust can have access to it, and where as much air as possible may stream over its surface. When dry a knife-point is to be inserted round the edge, and the sheet will come away with the greatest ease. The underside will be found to give the best surface for exposures in the dark slide. It is possible that some may find this process too extravagant in the quantity of emulsion it will require to coat the plates satisfactorily—*e.g.*, three ounces are needed for one dozen quarter-plates. I prefer, therefore, to coat my plates with plain gelatine first, and then with the usual amount of emulsion. The following are the details of this process:—

Gelatine	30 grains.
Water	7 drachms.
Ox-gall	1 drachm.

Pour this on to clean plates, and add the liquid gelatine on the level surface to the depth of an eighth of an inch.

As soon as the film has thoroughly set it may be sensitised with emulsion, and when dry stripped from the glass. The emulsion for this purpose, however, must contain thirty grains of gelatine per ounce. In other words, the proportion of gelatine per ounce in the sensitive layer of the film must be the same as that contained in the preliminary coating. To use these sensitive sheets in the field I recommend that each dark slide be provided with its own sheet of glass to support the gelatine.

The sensitive sheet may be simply backed up by these glasses; but a still better plan will be the following:—Coat the glasses with a solution of forty grains of gelatine, twenty grains of sugar, a few drops of red aniline dye (to prevent blurring), and one ounce of water. When dry these sugared plates will have a slightly tacky surface, and the stickiness may be augmented to any extent by breathing upon the film. Take, then, the sensitive sheet, lay it face down upon a piece of smooth paper, and press the sugared glass firmly upon it. It may now be placed perfectly flat in the slide, and be readily removed when the day's work is done, to give place to another sensitive film by a repetition of the same process, and without disturbance to the sugared gelatine. Another method is to construct home-made slides of cardboard for these gelatines. I enclose a hastily-made specimen as a sample. The exposure required will be a trifle longer than that of the ordinary beer plate.

Development must be carried out as follows:—A dish, a few inches longer and broader than the film, is to be filled with water and the negative plunged in, and allowed to soak till expansion has ceased—*i.e.*, for about two minutes. Should there be any indication of uneven expansion, or of awkwardly prominent wrinkles, this may be remedied by the application of a large camel's-hair brush, which should always be at hand. When the alkaline pyro. has been applied a novel process of photographic enlargement will be witnessed, for the resulting negative will be considerably larger than the original picture.

Intensification, if needed, should be employed before fixing, so that detail in the shadows may be brought out. Washing must be very thorough, both before and after fixing, and care must be taken to hold the film with the camel's-hair brush whenever the solutions or washing water are poured off. As soon as all traces of hypo. have been eliminated, the dish must be again filled with water, a glass plate of sufficient size inserted under the film, and, the film being held on the glass with the brush, the water is allowed to drain off, leaving the negative on the glass plate. Any bubbles of air or water between the film and the glass may now be removed with the aid of the brush. The glass is then placed in the air till dry, and then the negative will come away in a firm and even sheet, from which any number of prints may be taken.

I have sent one or two negatives taken on these films; but since my discovery of this process I have been favoured with neither light nor opportunity to enable me to obtain satisfactory negatives. Those I have sent by way of illustrations of the process should be looked upon rather as indications of what may be done under more favourable circumstances than as specimens of the excellence of this process. The two marked films are curious from the fact that the preliminary layer is composed of common glue.

I must say a few words with reference to the ox-gall. It is better to obtain the gall bladder from the butcher, and to allow it to hang in a cool place for a day or two. During this time a slimy mucous will subside to the bottom of the bladder, and, with a little care, the pure, clear gall may be poured off by making an incision in the upper part of the duct. I find that it will keep sweet and fresh for a week at this time of year. Another application of gelatine which I desire to mention is for the purpose of focussing. The slide I have sent by post was made by me of gelatine and cardboard, the film being composed of a forty-grain solution of gelatine with one drachm each of skimmed milk and ox-gall. Detailed directions will be found in THE BRITISH JOURNAL OF PHOTOGRAPHY of the 8th instant.

At this point I bring my *résumé* to a close; and I do so, not because I have reached the end of my subject, but rather because I fear that I have exhausted the patience of the members.

H. J. PALMER, M.A.

THE ELIMINATION OF THE NITRATE SALTS FROM GELATINE EMULSION.

[A communication to the South London Photographic Society.]

IT was proposed by Mr. J. T. Taylor, at the close of the February meeting, that I should on this occasion demonstrate to the members my latest published method of washing gelatine emulsions. It was also announced in the journals of Friday last that I would demonstrate to the members the development of a washed emulsion plate. I have come prepared to do both. We will take the subject of gelatine emulsion washing first.

In order that I may make my proceedings both interesting and useful to the members and visitors present, I will first proceed to describe the method of compounding the emulsion, and give a useful working formula. To many here present I doubt if I have the ability to teach anything. What I have to say will be to them as an "oft-told tale," but I know their patience and rely upon it for their attention. I shall feel myself amply compensated if but the least experienced member here present shall gain one new idea. I can leave the rest to him, satisfied that it will not remain dormant.

In a gelatine emulsion the simplest form of emulsion is exemplified. Its components are almost invariably only bromide of silver and gelatine. It is true there is now and then a talk of adding thereto a chloride, an iodide, or a fluoride, but I doubt if many experiments include either of these ingredients; the bromide alone absorbs all, or nearly all, the attention. I cannot doubt, from what I have done already, the benefit to be derived from the addition of an iodide, especially for scenery in which foliage and trees predominate. The outlines appear to me to be more sharply cut against the sky; in point of fact, the picture seems to bear a closer resemblance to the wet plate. The only necessary ingredients of a gelatine emulsion are three—the gelatine, the bromide of any base—ammonium, potassium, cadmium, or any other, according to taste and fancy—and nitrate of silver.

Let us suppose we have to compound ten ounces of gelatine emulsion. We shall require (say) 200 grains of gelatine (I like Nelson's No. 1 quality), ninety grains of bromide of ammonium, 150 grains of nitrate of silver, and nine ounces of water. During the operation of washing the gelatine will take up the remaining ounce of water. We will select a bottle which has a good stopper—one that fits closely and well. We will place therein the gelatine, the ammonium bromide, and six ounces of distilled water; shake well until the gelatine is well covered by the water, and then stand it aside to soak for half an hour. Now we take a similar bottle and place therein the nitrate of silver and the remaining three ounces of water to make up nine ounces. When the gelatine has been well soaked we stand the two bottles in warm water (say) of a temperature of 100° Fahr., and solution will soon come about. Then we unite the contents of the two—not slowly and with frequent shakings between, but empty the one bodily into the other, and shake well for some minutes. This plan of adding the whole bulk at once would not do if the solutions were not *aqueous*, as in collodion; but there is no drawback to it whatever in gelatine emulsion work, for both the bromide of ammonium and the nitrate of silver being perfectly soluble in water incipient decomposition cannot take place. In other words, there can neither be "locked-up" silver nor "locked-up" bromide, as might be the case if the solutions were overcharged, as in adding nitrate of silver in alcohol to bromised collodion. We have now a crude emulsion containing both free bromide of ammonium and nitrate of silver; for the resistance presented by the viscidity of the gelatine operates effectually to prevent instant decomposition of the whole of either.

Now, what is double decomposition? Simply interchange of elements—exchange of bases. In this case the nitrate of silver and the bromide of ammonium exchange bases, forming bromide of silver and nitrate of ammonium; whereas, before this is brought about, we had bromide of ammonium and nitrate of silver. A very simple experiment will illustrate this to the uninitiated. Here I have two bottles; the one contains nitrate of silver in water, the other bromide of ammonium, also in water. I unite the two, and instantly you see the result; there being no preventing medium, insoluble bromide of silver subsides, and nitrate of ammonium, being soluble in water, remains in solution. In this case it is easy to separate the two by simple decantation and rinsing with fresh water.

It is perfectly natural for one at first sight of this experiment to say—"Well, if this be so easy why not make your bromide of silver in this way, and add it after washing to the gelatine solution?" Exactly; but for the most cogent of reasons this will not do. Bromide of silver thus formed is only sensitive to light in a very minor degree—a degree totally useless for photography. It is necessary that it should be formed in combination with organic matter; and in gelatine we have organic matter capable of imparting to bromide of silver the highest degree of sensitiveness with which we are yet acquainted. But when we employ gelatine the bromide of silver formed therein does not subside but remains in suspension, while the by-product (nitrate of ammonium) remains in solution; hence they may be said to be in juxtaposition, and simple decantation will not achieve our object—it will not separate the one from the other. Here, then, we are in the presence of a difficulty which must be overcome. We must get rid of this by-product or it will crystallise on the surface of the dried film and render it useless, and the question arises how best to surmount it.

There have been already published five methods of eliminating the nitrate salt, and, with your permission, I will recapitulate them and say a word or two in regard to each in succession. First, we have the beautiful principle of dialysis; second, we have the method of pouring out to set in a dish and washing with a running stream or frequent changes of water; third, it has been recommended to pour the warm emulsion into a bottle and, holding it horizontally, to roll it round under a running stream from the tap until it has set in an even film round the sides; fourth, we have alcoholic precipitation; and, fifth, we have the method I wish to demonstrate to you this evening.

1. As to dialysis. Here we have an instrument—a bell glass—specially made with a returned edge for this purpose. We tie over the bottom a piece of bladder or parchment paper. We pour into the dialyser the warm gelatine emulsion so soon as we deem it ripe, stand it upon a support in warm water, letting the warm water come up its sides as high as the depth of the emulsion. Gelatine is a colloid body, and nitrate of ammonia is a crystalloid. This method of separating crystalloid from colloid was the discovery of Mr. Graham. He found that gelatine and other analogous colloid bodies would not pass through the septum—that is, the parchment paper—whereas the crystalloid salt would do so; hence, theoretically,

this ought to be a perfectly good and useful method. But it has one serious drawback—we cannot allow time enough for the operation, for our material may decompose and be useless when finished. Moreover, we can only apply it for small quantities; hence we may dismiss it as being theoretically perfect but practically almost useless.

2. Now we come to the second method of pouring out into a dish to set, and then washing by repeated soakings and changes of water, or with a running stream. This method is perfectly effective if you will give time, and can always determine *how much* time and *how much* water will accomplish your purpose. But, inasmuch as one does not always wish to make up an exactly similar quantity of emulsion—but one day may have requirement for a large quantity and another for a small—variation in thickness of film will lead to the obvious uncertainty that at the expiration of a given period of time the required amount of work has been performed. I think, therefore, No. 2 may be dismissed without further comment.

3. We have the method of pouring the emulsion while warm into a bottle, holding the bottle horizontally under a running stream from the tap until it has set round the sides. This plan, while open to the same objection as the washing in a dish, is more troublesome and difficult to perform. It is not always possible to prevent the formation of clots varying in size from that of a hazel nut to a walnut, and, these once formed, it is simply impossible to get rid of the whole of the nitrate salt by any amount of washing. It is none the less a very ingenious plan, and served me well on more than one occasion.

4. We come to the method of precipitation by alcohol. I found this method very useful to me when, for the want of a more effective plan *than either dialysis or washing* in dishes or bottles—when, in fact, the hot weather had nearly reduced me to despair—the gelatine would hardly set and the cistern water was tepid, and what was I to do? Necessity stared me in the face, and *who* can afford to despise necessity? Gelatine plates were required, and I must make them; but *how?* In this dilemma, after much cogitation, I suddenly bethought me of the result which sometimes comes about when that useful mountant, "parlour paste," is made, namely, the subsidence of the gelatine or dextrine when alcohol is stirred in, and I, at once, and for the first time under the sharp spur of necessity, saw clearly the principle underlying this subsidence. I could now understand that the strong affinity of alcohol for water caused the latter to leave the gelatine to unite with the alcohol, and I felt sure that in leaving the gelatine it would take with it the nitrate salt. I tried it, and with complete success. Others have tried it as I published it, and successfully. *One* gentleman, I know, precipitates with alcohol twice, and is a firm advocate for the *modus operandi* at this time. Another gives the emulsion a preliminary washing and afterwards precipitates with alcohol, and I am bound to say with the most complete success. Alcohol has also, I believe, a preservative influence in gelatine emulsion, and it certainly renders the task of coating the plates much easier. The emulsion flows more freely to the edges, and does not recede. Thus much for alcoholic precipitation.

5. Now for the method I published in The British Journal Photographic Almanac and *Year-Book* for 1878, and which I now proceed to demonstrate to you. I must premise that the emulsion has been made, that decomposition is completed, and that it has been poured into a dish, scraped up with an ivory knife, and transferred to this bag made of marking canvas. The box before you is made with sloping sides, which render a ledge inside unnecessary. To make my dish I employ two concentric oblong frames and this piece of calico. I do it in this manner:—I now fill the trough with water, and the tray is floating thereon. Two or three twists of the bag and one draw through the thumb and forefinger effect the purpose. The gelatine lies in the tray in extremely fine division, and I have reduced the time of washing from five or six hours to five or six minutes, and, what is better, the washing is well and perfectly done.

F. Wratten.

NOTES ON TRANSPARENCIES.

[A communication to the Edinburgh Photographic Society.]

Photographic transparencies are of various kinds, their manufacture much depending on the special end they are intended to serve. Probably at the present time the most useful description of transparency for us to consider is that which is simply a means to an end—the reproduction of negatives.

Many secret-mongers have profited not a little by being sharp enough to select some well-known good process, and by application master the working details or special peculiarities, and then for a consideration make known to the gullible that which they might have known by simply reading the weekly journals devoted to photography.

The conditions necessary for producing satisfactory transparencies for our purpose are a *structureless* film capable of rendering in a printable form all the detail existing in the original, and if the transparency is of such a nature as to permit after-modifications for the removal of objectionable portions or the addition of improvements, so much the better for the process.

In my own practice I find that for small transparencies gelatine is decidedly preferable to any other method with which I am acquainted. At one time I employed a commercial pigment tissue. When it could be obtained good this served its purpose well; but, as it was unreliable, I made some in small quantities, using a solution of alizarine as the colouring matter, which, being a purely transparent colour, produced a simple stain, and was eminently satisfactory.

The disadvantage of having to prepare my own tissue, the time necessary even when made to dry, &c., the slight uncertainty always attendant on pigment printing, and the several stages necessary to go through, made me eventually adopt a suggestion thrown out by our good friend, Dr. Thompson, and I tried a bromide of silver emulsion in gelatine. Here I found every good advantage of pigmented gelatine with a great number of advantages to which the latter could lay no claim.

I will hurriedly run over the heads:—1. Manufacture of emulsion (or pigmented gelatine): 2. Coating of glass or other support. 3. Drying. Thus far the pigmented gelatine and emulsion are similar, but from this point everything changes.

The pigmented tissue after having been sensitised rapidly deteriorates, and in a very few days is utterly useless. The emulsion improves by keeping, and when dry seems to keep indefinitely.

Exposure.—Pigmented gelatine requires a certain time, extending from minutes to hours, with the chance, not at all remote, of getting an imperfect print. The resulting print is unalterable in size, but gelatine emulsion only needs an exposure of a few seconds, and so long as we give *time enough* there need be no error. The film is absolutely structureless, the print is a stain of unsurpassable delicacy, the results are certain—no blistering, no frilling of the edges, no reticulation, no troubles as to solubility or insolubility, no fear of solid particles of pigment that are sure to come on the wrong place, and, the plates being ready for use at any moment by day or night, no anxiety, no floating, no drying.

I regret I am unable to give the exact formula by which I prepared the emulsion that produced the transparencies now on the table, but any good formula will do if it be only slow enough. I constructed mine after the formula of Mr. Aird's collodio-emulsion. With the salts as used by that gentleman I got a thin, blue film, so I greatly increased the amount of salts per ounce, and, if my memory serve me, I employed two and a-half times the quantity used in collodion. I think I used one ounce of gelatine to twenty ounces of water, and proceeded somewhat in this manner:—I divided the dissolved gelatine into two equal parts, added the bromide to one half, the silver (ordinary, at 3s. 3d. per ounce) to the other half, poured the bromide solution into the silver solution a little at a time, shaking well till all was thoroughly mixed and combined. I then placed the vessel containing the emulsion in hot water, so as to keep it fluid for some hours, shaking occasionally. Then I allowed it to get cold, broke up the jelly with slips of glass, and allowed it to soak in running water for a night, so as to remove the nitrates; then drained, added methylated alcohol to abstract a considerable quantity of water, drained again, warmed to redissolve the emulsion, and made up to the original quantity with methylated alcohol.

I made several pints at this time, have used it ever since, and shall be very sorry when it is finished, as it has proved the most convenient, simple, and reliable method I have ever tried for the production of transparencies. There are those who may think the transparencies on the table too thin to be really so serviceable as they are; but I can assure such that they are mistaken. It scarcely matters how thin they are so that all the detail is there. Some of us will be aware of the fact that a good glass positive of the times that are past will sometimes produce first-rate enlarged positives when employed as transparencies. Yet from the granular nature of the deposit they were much thinner practically than the gelatine film, besides possessing a considerable structure.

It sometimes happens that it is found advisable to make a large transparency instead of one the same size as the original negative. Here our gelatine emulsion stands alone for simplicity and certainty, for as yet we are unable to employ pigmented tissue in the camera. Then there are no large and expensive baths to make and to keep in order, no collodion to use and spill, no unevenly-coated plates, the size of the plate being absolutely immaterial. Not having tried larger than twenty-four-inch plates I do not think I could coat with collodion larger plates than that size; but I should find no difficulty with gelatine emulsion. First warm the plate, then level it on a table, pour a pool of hot emulsion on the plate, distribute it over the plate with a glass rod or piece of cardboard, leave till cold, and dry.

Let the exposure be long enough and develope; when all the detail is out fix with hypo. If the exposure have been very much over-done, and the development not in accordance therewith, the image may *possibly* be too thin. If so, intensify with ordinary acid pyro. and silver, having previously flooded the plate with a solution of iodine. Any amount of intensity immediately comes up, and there is much risk of overdoing it.

Now, if you are in a great hurry, and wish to make a negative the same size, flood with weak methylated alcohol kept in a bottle for the purpose; pour back into the bottle and drain well. Pour on some fresh alcohol stronger than the preceding, drain back into its bottle, and now pour on ordinary methylated spirit of full strength; drain, and the plate will be dry in a few minutes. When quite dry varnish with matt varnish, touch up as may be desired, and print your large negative direct by contact on another of your prepared plates.

I suspect the advantages of large transparencies are not so well known as they deserve. I believe if they were better known that better home-made enlargements would be sent out. From very inferior materials to begin with we may easily get very surprising results—altogether photographs without hand work—and superior, in regard to fidelity, to the hand-finished productions of the public companies and at much less cost; besides, when you do them yourself you get *exactly* what you wish. If you do not it is your own fault.

I am not disparaging the work of the public companies. I simply urge the merits of a method that any mechanical photographer can employ, and get first-rate results at a nominal cost—equal to or better than he can get done for him at a high price. As a practical example I lay on the table a *carte* which is of great value as being the only one in existence of a very celebrated lady. Copies the same size were required, besides enlargements and reversed negatives for collotype printing. The prints were required to look like pure, unmanipulated photographs. They were neither to look coarse nor flat. I first collodionised and burnished the *carte* and then took a *carte* negative of it, giving a very long exposure, and slightly under-developed the negative. From this small negative I produced the transparency before you as I have previously described. The touching up took but a few minutes. You can see the amount, and from this transparency I produced the *cartes*, cabinets, and imperials now before you. I think you will agree with me that they are better than the average run of direct portraits of similar size. They are absolutely faithful reproductions of the original small *carte*, every minute wrinkle and freckle being unobtrusively present, and no indication of enlarging, coarseness, or flatness being apparent after the most critical inspection.

Wm. T. Bashford.

Meetings of Societies.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

The usual meeting of this Society was held on Tuesday evening, the 12th instant,—Mr. J. Glaisher, F.R.S., President, in the chair.

The Chairman, having announced that the Council had re-elected Mr. H. B. Pritchard as Honorary Secretary for the ensuing year, read a letter which had been received from Mr. Joseph Paget, in which he offered a prize of fifty pounds for the best dry process. [An article on this subject will be found in another page] This offer had been discussed at a meeting of the Council, and a committee had been appointed to carry the matter into effect. He proposed that the thanks of the Society be awarded to Mr. Paget for his liberal offer. The proposal was carried unanimously.

Captain Abney then read a paper by Dr. van Monckhoven, *On the Fading of Carbon Prints; and Carbon Printing without the Use of Bichromates.* This paper will appear in our next. Pending the publication of the paper, we may observe that Dr. Monckhoven expresses the opinion that the washing in water and subsequent treatment with alum will not perfectly fix a carbon print; he proposes, instead, the employment of a solution of bisulphite of soda. A portion of the paper was also devoted to the subject of the colouring matter of carbon tissue.

Mr. W. S. Bird, on being called upon by the Chairman, observed that the paper was a scientific one which required careful investigation. With respect to the alleged fading of carbon prints, he had looked out some of the oldest prints taken by his (the Autotype) Company, and the members had an opportunity of examining them, as they were hanging on the walls beside them. Several of these prints were over five years' old, and none were more recent than two years. In none of these pictures would there be found any indication of fading whatever. They did not contain any of the alizarine compounds alluded to, regarding which Dr. Monckhoven's experiments threw a suspicion and warning.

Mr. J. R. Sawyer, too, considered that the paper required careful investigation before he would offer any remark upon it. Of course experiments could be conducted in a variety of different ways, and there might be several methods by which alizarine colours could be prepared. So far as a reasonable test could be applied in a short time, the alizarine colours prepared by themselves (the Autotype Company) withstood the action of light to an unlimited extent. Before introducing these calours into their tissue he had had a careful interview with the producer of them, and he, too, had found them quite permanent. He would repeat the experiments of Dr. Monckhoven, whose method of preparing alizarine might possibly be such as not to give the most permanent results. Of course it must be borne in mind that Dr. Monckhoven had not been a tissue maker for a very long time; and, although he possessed great chemical knowledge by which he might be led to adopt what he considered improved methods, yet in regard to long experience his Company had an advantage. With respect to fading, it was very difficult to say what would *not* fade; even the pigments they employed to paint their street doors succumbed to the action of light and exposure. Their great effort was to endeavour to discover what pigment was *least* liable to fade, and if Dr. Monckhoven's experiments be correct he will have conferred a great benefit upon manufacturers of carbon tissue.

Mr. Jabez Hughes, in the course of some observations on what had been termed the *fading* of carbon prints, corrected a mistaken idea entertained on this question by a few who were imperfectly conversant with the subject. When a silver print faded it became of a sickly yellow colour, and sometimes disappeared altogether; but, if a carbon print faded, all that would take place would be a subduing of the ruddiness of its tone, which, in the case of some descriptions of tissue, was considered by many to be rather an improvement than otherwise. The whites, half-tones, and blacks could never possibly fade. But he doubted whether the experiments submitted by Dr. Monckhoven were fair examples of what they would get if the tissue in the market were experimented upon in a similar manner. He could testify to the fact of some carbon prints, at anyrate, having remained in an unchanged condition, as an instance of which he indicated *The Zealot*, by Mr. Blanchard, which several years ago formed the presentation print of the South London Photographic Society. The paper of Dr. Monckhoven was a valuable one, inasmuch as it opened up entirely new ground in carbon printing.

A vote of thanks was unanimously awarded to Dr. Monckhoven for his paper.

Mr. E. Cocking then read a paper *On the Non-Convergence of Perpendicular Lines in Architecture.* A discussion followed the reading of this paper, in which Captain Abney, Messrs. F. Bedford, Jabez Hughes, Sawyer, Davis, York, Bird, Vernon Heath, and others took part. The paper and discussion will appear in our next.

Thanks having been awarded to Mr. Cocking,

The Chairman announced that the next meeting would be held on April 2nd (the *first* Tuesday of the month instead of the second Tuesday as usual), and he directed attention to a large and very fine collection of pictures on the walls, exhibited by the Autotype Company, together with a very fine collection of works by Mr. Vernon Heath, which were to form his contribution to the forthcoming Paris Exhibition.

After an announcement that at the next meeting Mr. England would read a paper on *Dry-Plate Processes*, the proceedings terminated.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

At the last meeting of this Society, held on Thursday, the 7th instant, the Rev. F. F. Statham, M.A., President, occupied the chair.

Mr. F. Wratten read a paper on *The Elimination of the Nitrate Salts from Gelatine Emulsion.* [See page 124].

Mr. R. Kennett, in reply to a question by the Chairman, said he had no doubt the method described would answer quite well the purpose intended.

Mr. William Brooks, in response to a similar appeal, said he did not make use of gelatine emulsion; he much preferred a collodion emulsion.

A desultory conversation here ensued on the subject of collodion emulsion, and the probability of its superseding the use of the nitrate of silver bath. In the course of this Mr. Samuel Fry observed that he had recently, under Mr. Mawdsley's tuition, acquired a knowledge of the method of using emulsions with great satisfaction to himself and advantage to his business.

Mr. F. Bridge, too, bore testimony to the value of emulsion photography to professional photographers.

Mr. Adkins exhibited several gelatine negatives which had been developed by means of the ferrous-oxalate process of Mr. M. Carey Lea.

Mr. Cobb exhibited a variety of portraits taken in his studio on collodion emulsion.

A number of gelatine negatives were exhibited by Mr. Bennett, one of them being an interior of a room taken by ordinary gaslight, the exposure being one hour.

The Chairman having tendered the thanks of the meeting to Mr. Wratten, the proceedings terminated.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

THE Board of Management of the above Association held their monthly meeting at 160a, Aldersgate-street, on Wednesday, the 6th instant. The minutes of the previous meeting were read and confirmed.

An application for relief was then placed before the meeting, and after full investigation of the case the relief asked for was granted.

Mr. Lavender proposed and Mr. Thorne seconded—"That Mr. Emil Gromann be elected an ordinary member of the Association."

Grants for various purposes were issued, and after some general discussion on the business of the Association, the meeting was adjourned to Wednesday, April 3rd, at 8 p.m.

EDINBURGH PHOTOGRAPHIC SOCIETY.

THE fifth ordinary meeting of this Society was held at 5, St. Andrew-square, on Wednesday, the 6th instant,—Mr. John Lessels, President, in the chair.

The minutes of the last meeting having been passed, the following gentlemen were unanimously elected ordinary members :—Messrs. Yule, R. Pringle, W. Cruickshank, John Morrison, Jun., Wm. Jenkinson, John F. Pillans, John Heggie, C. E. Cowdell, Arch. Craig, R. H. Shaw, and James Stoddart.

Mr. W. T. BASHFORD intimated that since he had arrived at the meeting a very important paper by the Rev. H. J. Palmer, M.A., had reached him, and that he would immediately read it to the Society in place of that indicated in the billet, as he believed it would be of far greater value and much more acceptable than that to which his own name was attached, and which really was only an apology for a paper, the committee of management having unexpectedly found themselves at the last moment short of matter for the present meeting. The paper alluded to will be found on page 123. It was illustrated by a large number of examples, including some very perfect film negatives—the latest outcome of the author's investigations; also several cardboard dark slides in various stages of manufacture, and an admirable substitute for glass as a focussing-screen, the latter being a tough sheet of gelatine resembling fine horn, prepared as described by Mr. Palmer in his paper. The cardboard slides are very ingenious, compact, light, and admirably suited for use in conjunction with the above screen. Their mode of manufacture will be found in a paper contributed by Mr. Palmer to the Liverpool Amateur Photographic Association [*ante* page 110].

After the members had examined the negatives a lively and interesting discussion ensued, much surprise being generally expressed at the exceedingly short exposure given to the negatives, and also to their uniform freedom from stains and other imperfections.

Mr. W. H. DAVIES said that he fancied the gelatine negatives exhibited (except one, an interior) indicated those unfortunate peculiarities common to all dry processes that had come under his notice, namely, under-exposure and a liability to halation. He did not in any sense undervalue the advantages of the process, but he believed that as yet there was no *dry* process that could give the delicacy of detail and tender gradation of light and shade that can be obtained by the old wet process. He (Mr. Davies) directed the particular attention of those who might employ a glass plate in front of the film during exposure to the necessity of selecting such plates with the utmost care, as the slightest scratch or bubble appeared as a glaring black defect in all prints, as those knew to their cost who were in the habit of making reversed negatives by copying carbon transparencies through the glass.

Mr. BASHFORD said he was personally indebted to Mr. Palmer, and so was everyone interested in photography, for so kindly supplying the important details of that process which Mr. Palmer had made so peculiarly his own. The information came with authority. They had now a truly reliable process thrown open to them—a process that combined exceeding rapidity with certainty, and one that supplied absolutely structureless negatives of infinite value for the production of enlargements. There was no difficulty in reproducing the most delicate detail, and the defect of hardness could be wholly overcome by supplementing a suitable exposure by a suitable development. He (Mr. Bashford) understood that the gelatine films were sufficiently rigid to be used without glass plates in front of them, and in that case, of course, their attendant evils so judiciously pointed out by Mr. Davies would not exist.

Dr. NICOL considered that Mr. Palmer had very nearly solved the problem of a substitute for glass. He had seen nothing so likely to turn out a real success, and believed that even these were inferior to what would soon be obtained. The best thanks of all amateurs would be awarded to Mr. Palmer, for he doubted not that thousands would use the process during the coming season, and that they would find it thoroughly successful.

Mr. PRINGLE directed attention to the marvellous detail of the negatives. One very trying subject was peculiarly well brought out—a distant flagstaff against a clear sky. It was so small and fine that a magnifying glass was necessary to distinguish it, yet when so examined it was found to be as sharp as if it had been engraved.

Mr. ALEXANDER MATHIESON thought Mr. Palmer had not done his process justice when he called it "slow." He noticed that many of the negatives exhibited had only received an exposure of thirty seconds instead of thirty minutes, as would most likely have been given if the beer process, which had once been the favourite of the Edinburgh amateurs, had been employed. He believed that this process was a very great advance in the right direction; at anyrate he would certainly adopt it on his first trial trip, and would lay the results before the Society.

Mr. J. G. TUNNY remarked that the non-actinic colour of the film was very deceptive, and he generally found a difficulty in printing from gelatine plates. He could get four or five prints from ordinary negatives during the time it took to get one print from a gelatine film. He recommended that the negative be always toned to the colour of an ordinary negative. By doing so the disadvantage in printing was materially lessened.

At the conclusion of the discussion, on the proposal of Dr. Thompson, seconded by Mr. Tunny, a hearty vote of thanks was awarded to Mr. Palmer.

Mr. Bashford was then called on for his paper as in the billet, and as some members would take no denial he read some *Notes on Transparencies.* [See page 125].

An album of beautiful Indian views was submitted to the meeting by Mr. W. Leitch.

The usual votes of thanks terminated a very interesting meeting.

GLASGOW PHOTOGRAPHIC ASSOCIATION.

A MEETING of this Association was held on Tuesday, the 28th ult., at the Religious Institution Rooms,—Mr. John Urie in the chair.

The minutes of the previous meeting having been read and approved,

Mr. BIRRELL gave an interesting description of his patent automatic apparatus for the manufacture of oxygen gas, and exhibited the oxy-hydrogen light in the lantern. The pictures on the screen were sharp and clear, and the light was very steady. The gases were very quickly made, and the apparatus was quite under control.

The CHAIRMAN asked if it would not be a good thing to have a safety valve on the retort.

Mr. BIRRELL replied that it could easily be done, but he did not think there was any need, as it was quite safe.

Mr. ROBERTSON said the greatest danger in making oxygen gas arose from using impure manganese.

Mr. Birrell was heartily thanked for bringing his apparatus before the Society.

Mr. M'Hattie showed a negative taken on one of Truefitt's dry plates; it was exposed in Mr. Stuart's studio. There was a wet plate exposed at the same time, and it was found the dry plate was the quicker.

Mr. ROBERTSON was present when the plates were exposed, and had no doubt the dry plate had the advantage in speed. He thought the emulsion process was to do good service in the future of photography.

The CHAIRMAN then read some remarks, in which he congratulated the members on the successful issue of their endeavours in preventing a renewal of Swan's carbon patent. The result, he thought, would be the harbinger of great good to them all, and impel their energies in the way of progress. He concluded by suggesting the formation of a printing company in Glasgow, which, having relation to a matter of purely commercial enterprise, need not here be entered into.

A vote of thanks to the Chairman for presiding brought the proceedings to a close.

BRISTOL AND WEST OF ENGLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE ordinary monthly meeting of this Society was held on Wednesday, the 6th inst.,—not at the usual place of meeting, but at the residence of one of the Vice-Presidents, the Rev. W. J. Whiting—the President, Mr. W. W. Stoddart, F.R.S., F.G.S., in the chair. The minutes having been read and confirmed, the President called upon Mr. E. Brightman to read his paper, entitled *Whims of a Landscape Photographer.* [The paper being received at the last moment, we are obliged to defer its publication till next week's issue.]

The PRESIDENT, in remarking on the interesting character of Mr. Brightman's paper, could not help differing from him in regard to his remark as to distilled water. He much doubted the existence of organic matter in it if properly distilled—that is to say, the first eighth of the water that came over should be thrown away. He (the President) also preferred alcoholic ammonia one part, rouge one part, and water one part, to Mr. Brightman's formula for cleaning plates, having always found it most satisfactory when cleaning microscopic glass. Ammoniacal alcohol, he remarked, differed very much from ammonia, as all liquor ammonia contained a certain degree of tar, which the former did not.

The Rev. W. J. Whiting had generally used saturated solution of bichromate of potash twenty ounces, sulphuric acid one ounce, for cleaning plates, and had found it most certain in its work, the plates being immersed in it.

The Rev. W. J. Whiting then introduced Mr. Keevil, the inventor of the ingenious lantern, and, speaking of the honour he felt at having the inventor of such a scientific piece of apparatus present at the meeting, dilated on some of the chief points of the lantern.

Mr. Keevil then clearly explained its construction and working. The lantern is a single one with a cone and lens in front, in the ordinary form, and another at nearly right angles projecting from one side. The lens in the latter is prismatic in its construction, so that the rays of light are taken up by the lens and reflected at nearly right angles to the screen, the adjustment for superposing the discs and focussing being most perfect. Quite contrary to the almost matter-of-course prejudice, the light of the prismatic lens—that is, the lens *parallel* to the screen—is, if anything, a little the more powerful of the two. The automatic arrangement for moving the lime light and dissolving the pictures simultaneously was greatly admired, as was the whole demonstration.

Votes of thanks to Mr. E. Brightman and Mr. Keevil brought the meeting to a close.

Correspondence.

Photography at the Forthcoming Paris Exhibition.—Hints to Intending Exhibitors.—The Transit of Mercury.

The scheme under which the French Section of Photography at the Paris Universal Exhibition of 1868 is being carried out is as follows :—

A jury for the admission of exhibitors in Class 12 was appointed by the French Government; this jury appointed a certain number of its members to act as a Sub-Committee of Installation. Voting papers were then sent out by the jury of admission to each exhibitor, submitting to them a list of four names for their selection of two of them; those having the majority were added to the Committee of Installation. This was the only partially-free election the exhibitors were called upon to perform. This Committee contract with the exhibitors—about 200 in number—

1. To construct a *salon* or court for Class 12, which is about thirty-five yards long by seventeen and a-half yards wide, subdivided by screens into three saloons, in which will be exposed the entire collection of the pictures of the French photographers. The works of each artist will be hung together by the Committee—a matter of great importance, presenting under the best light and in the most agreeable manner *un grand ensemble.* In the Paris Exhibition of 1867, if I remember rightly, a great outcry was made against the system under which the contributions of the English photographers were hung; for they were scattered, more or less, about here and there wherever a vacant spot could be found, which produced a failure as regards the importance, the easy and just estimation by the public of their intrinsic value, and the general artistic effects of their united labours.
2. To furnish and fix up in the most artistic and scientific way the *velum* of linen and muslin (no easy matter in the present atrociously-ugly building) for the proper lighting of the saloons.
3. For the general decoration of the saloons.
4. To provide uniform glass cases for instruments, lenses, &c.
5. To fix the necessary *tablettes* and elbow-rests before the pictures.
6. To insure against fire all objects and decorations common to the saloons.
7. To nominate and pay the keepers, and to clean daily the saloons, pictures, frames, and glasses.
8. To insure against the breakage of glass, from whatever cause, during the exposition.
9. To pay a certain sum to the general administration for the expenses of the decoration of the chief passage.
10. To keep a sum in reserve for any unforeseen general expenses.
11. At the close of the exhibition the balance in hand will be returned *pro rata* to each exhibitor. The charge for wall space to exhibitors is £3 per square yard, and £8 for glass show-cases.

For the Vienna exhibition the arrangements were more consistent with the principles of self-government, for the exhibitors assembled together and elected MM. Davanne, Rousselon, and myself their delegates, and gave us the necessary powers to fully represent them without the unnecessary interference of officials. Great economy and most excellent results were the consequence; for out of £2 per square yard charged the exhibitors for wall space we returned about twenty-five per cent. of the amounts collected, and for which sum we built and decorated an excellent court or saloon for the exhibition, allotted equitably the space, hung all the pictures, cleaned them and the court daily, protected the same with guardians, unpacked and repacked the pictures, stored away the packing-cases, and arranged with the railway companies a very low scale for the transit in one lot of the whole of the packing-cases, with a cheap return fare from Vienna and delivery at Paris. The whole operation was a great success, both financially and artistically, and exhibitors were well recompensed with numerous prizes.

From the experience I gained at the Paris Universal Exhibitions of 1855 and 1867, and also of Vienna in 1873, where I gained a medal of progress, I should recommend that the glass of each picture frame sent to Paris this year should be insured during transit, and that bands of stout brown paper about two inches wide should be pasted in parallel lines all over the glasses, leaving not more than about an inch of space between each band. When this is done there should be pasted on the top of these rows of bands, at right angles to them and with the same separation apart, a second row of brown paper bands, and so intersecting the whole surface of each glass as a means of security against breakage. I always do so with mine, and glass-covered pictures, one yard long, to Vienna or England have always arrived in perfect safety. Even in the event of a regular smash there would be no loose, broken pieces to lacerate and utterly destroy the prints from the constant shaking during the voyage. I would also diminish as much as possible the number of packing-cases, and so reduce the expenses of transit and storage of them during the exhibition. I would further suggest that the whole body of English photographic exhibitors in Class 12 should unite together and appoint a sole agent for the reception, unpacking, and placing their pictures, &c., in the hands of the exhibition authorities; storing the packing-cases away until the close, and repacking and delivering them to the railway companies for return to England; to keep clean the objects exposed; to take measures to rectify articles or pictures damaged or broken; and to represent generally the exhibitors during the period the exhibition remains open. This arrangement would be more efficacious as well as economical to the exhibitors individually, as I have shown by the Vienna results. It was with this view I offered my services to my *confrères.*

M. Vidal will have a court to himself, and will exhibit and work the machines and the process by which he produces his admirable reproductions in photochromy, and will also illustrate the whole manipulations of Woodburytype.

M. Walery will exhibit pictures in carbon, silver, and enamel, and in order to do justice to his art-creations has established in his *ateliers* the different branches for preparing himself all the works he will exhibit.

The Academy of Sciences has organised a scientific mission which will observe the transit of Mercury across the sun's disc, in the neighbourhood of Payta, upon the coast of Peru. The direction of this scientific mission is confided to M. G. Fleurias, who in 1874 directed with so much success the mission charged to observe the transit of Venus at Pekin. M. Fleurias has for his second in charge a naval officer, M. Lemercier, whose works have attracted to him the attention of the learned members of the Academy. The Minister of Public Instruction has charged M. Ch. André with the direction of another mission to whom M. A. Angot has been added as second in charge. Both missions are furnished with the instruments which were used during the great expeditions of 1874. M. Maindron, Secretary of the Academy of Sciences, was charged to send off to Valparaiso the cases containing the instruments destined for M. Fleurias on board the "Magacienne," of the French navy.

The planet Mercury will pass before the disc of the sun on the 6th of May, and will be observed from a most favourable station chosen by the Institute of France, namely, at Ogden, in the state of Utah, North America, by M. Angot, who has been going through a course of instruction, under the direction of M. Davanne, in the Taupenôt and the bromide of silver emulsion processes; and from the well-known capability of M. Angot we look forward to interesting results from a photographic point of view. MM. André and Angot observed the passage of Venus in New Caledonia; and a millionaire, a friend to science, M. Bishoffsheim, has placed at the disposal of the two travellers £1200, which was the sum necessary for their voyage. They start by the Transatlantic Company's service *via* Havre.

Asnières (Seine) Paris. W. Harrison.

THE CONSTRUCTION OF GLASS HOUSES.

To the Editors.

Gentlemen,—In The British Journal of Photography of the 22nd ult. I recommended the combination of blue and clear glass in glazing a studio. Having had many inquiries as to the practical advantages to be gained by it, I thought perhaps there might be others I have not answered by letter who would like to know my reasons for suggesting such.

As a starting-point, let any photographer take a thoroughly good photograph as regards lighting, full of half-tone, round, and brilliant. Have this as your standard and compare it with every picture you see, either in your own album or with your ordinary work. Even compare it with the photographs you will see in a publisher's window, where you will find good work by many different photographers. There will be many of them very good, and in some otherwise good you will find there is a deficiency of half-tone in the light side of the face. It is too white. They may be brilliant, but there is neither indication of modelling or texture. A little consideration will compel you to acknowledge that fifty per cent. of the photographs taken are spoiled by a too powerful direct, low side light.

How strongly some photographers do "stick" to the erroneous idea that to produce good full-length pictures it is necessary to use side light down to the floor! The effect of low direct side light is to make a deficiency of half-tone on that side of the face, destroying the beautiful modelling there should be round the corners of the mouth, the chin, down the side of the nose, and round the eyes. What is more beautiful than the ear when lighted so as to preserve all half-tone, which is also lost? It makes the face broad, hard, and devoid of all texture; makes the shadows too heavy, necessitating reflection; and brings retouching to a maximum in endeavouring to produce softness by piling on lead pencil and colour in the shadows of the face. How few photographers have been able to produce those beautiful effects—the face in soft shadow and the strongest light falling on the ear and temples—simply because they have used the side light too strong or the strongest light too low!

I will endeavour to explain how all these defects can be reduced to a minimum by the combination of blue and clear glass. I do not hold that the dimensions of the studio should be fixed. A good picture can be made in any ridge-roof studio where the light is brought well into the room and the eaves are not too high.

In answer to one correspondent who is about to alter his studio I advised him to have the eaves seven feet high, six feet opaque at each end, the side light glazed to within three feet of the floor, and five feet at each end of it to be blue glass, the light eighteen feet long, instead of ten feet, as it is at present. The blue glass in each end of the skylight to be two feet wide, with the sunshade and four spring roller blinds on the roof, it will be a very easy matter to produce good pictures as regards lighting, and very quick. I mention this to show that the blue glass will require special treatment according to the peculiarities of the studio. I acknowledge that blue glass is *slightly* slower than clear glass; and if it were not so it would not have the desired effect, as it softens the light and gives a coolness to the half-tone without producing harshness or a glare, which is so often produced by blinds. As these two latter points are so destructive to a natural expression, they require more consideration than many photographers have given them.

The practical advantages to be gained by its use are—1. A beautiful soft effect on the light side of the face, with every degree of half-tone. The light from the clear glass above gives those delicate and sharp lights on all prominent parts so necessary for excellence. 2. The modelling is a delicate, cool grey, and not so easily lost in development. 3. It makes the shadows very soft, and dispenses with reflection *(a very important point)*. 4. It wonderfully reduces retouching. 5. It gives the power of using more light without the loss of any roundness or brilliance, and consequently shortens the exposure.

As regards a south light, so highly recommended by Mr. Webster in the Journal of the 1st inst., I certainly think that in some cases it would be as useful as Mr. Webster states. Supposing a studio of the dimensions given by Mr. Debenham in the Journal of the 8th inst., the eaves being not less than eight feet (a steep pitch is generally supposed to be at an angle something above 45°)—but supposing, I say, 50°, this will not be very steep, but even with that and the ridge not more than twelve or thirteen feet high, the light would only be brought into the room about four feet; and, as Mr. Debenham gives the width of the room as fifteen feet, it would leave eleven feet opaque. For single figures, and especially the so-called Rembrandt effects, this would be a very good studio, but the south light would be found most useful in it, as there would be very little light from the walls of the room; they are so far from the light, and the shadows would require lighting a little in many cases (even for single figures) either by reflection, *which ought to be avoided if possible*, or by direct light. The difficulty would be increased when taking large groups in a studio of these proportions, as the figures nearest the opaque side would not have so much light as the others, and would be compensated for by light from the south side, producing a cross light, which would be wrong.

It is not a studio for one special class of picture that will meet the requirements of the photographer of the present day, but one that is capable of producing any and every effect with the greatest simplicity. Under the latter heading neither these proportions or a south light can take the first place. Undoubtedly a south light would be useful for an occasional study. The one aim in the use of blinds, head-screens, reflectors, &c., is to produce a broad, soft light with a predominating light from one point. The simplest way to achieve this and secure the best effects is to bring the light well over the sitter. As the glass recedes from the sitter at different angles it partially produces the broad, soft effect without assistance; but the direct light overhead, and especially at the side, requires softening to get the required half-tone. If blinds are used it makes the front light predominate, and consequently produces flatness; the use of blue glass, as described, remedies these defects, giving the power to use the whole light in most cases.

Before concluding I will give the dimensions of a studio that would be best suited to the combination, and in which a south light would be of no service:—Width, fourteen feet; ridge, thirteen feet high at a point nine feet from the glass side, and five feet from the opaque side; length of light, eighteen feet; eaves, seven feet high—six feet opaque at each end if possible; blue glass only in the side light to within three feet of the floor, and also blue glass at each end of the skylight two feet wide; clear glass in the remaining portion. The south side and roof to be opaque, with the sunshade four feet wide, and at an angle of about 45° with the ground, and four spring roller blinds working from the top. It will not be necessary to have blinds on the side light.

This will be found a most useful studio, producing any effect at will with the greatest simplicity. It will not be quite as quick as the modifications of Mr. Hamilton's plan in *dull* weather, but both will produce equally good pictures. There will not be quite as much freedom for the use of a background in Mr. Hamilton's dimensions as Mr. Webster states. I also pointed this out, with the means of partially remedying the defect. The suggestion by Mr. Webster to get more than thirty feet in length would be found most useful. How many photographers there are that would have one or two foregrounds made up on platforms of a few inches high if they only had a convenient place to put them out of the way! This, if carried into effect, would be found most useful, as there is no limit to the number of imaginary foregrounds that could be made up at spare moments, ready for use when there is a rush of business. The platforms, if on castors, would be easily moved to any desired position without making a "dirty mess." This would necessitate sweeping up and making a dust before the next sitter could come in, which would be a waste of time and patience, if they were waiting.

As a concluding remark, I would say use less powerful side light and more sky light, and you will give more satisfaction.—I am, yours, &c.,

Ryde, March 9, 1878. J. Cowell.

IMPROVEMENTS IN CARBON PRINTING.

To the Editors.

Gentlemen,—We confess to some feeling of surprise in reading in your issue of last week a letter signed by Mr. J. R. Johnson under the above heading. This letter deals in *inuendo*, in mysterious allusions, and is highly seasoned with personalities; but we look in vain for any contribution likely to be of use or of interest to your readers.

We should be extremely sorry to follow Mr. Johnson's lead into personalities; the intrusion of such discredits the writer and renders no service whatever to the discussion of the subject.

Mr. Johnson has chosen to single out Mr. Sawyer for his strictures, styling him the "mouthpiece" of the Company, attributing to him various faults of temper, &c., &c. All this is nothing whatever to the purpose. All correspondence signed by the Autotype Company is written and revised jointly by the partners, and when Mr. Johnson assumes that Mr. Sawyer is the "mouthpiece" of the Company, and points his strictures with personal offensiveness, he simply commits an act ef gross discourtesy.

The simple fact remains that Mr. Johnson misquoted the *Manual*. Surely the present editor of that work was perfectly in order when he called the attention of your readers to this fact, and laid before them what the *Manual* actually did say. Had Mr. Johnson retracted in a fair and honourable manner the discussion would at once have ended; but, on the contrary, whilst professing to regret his inadvertency, his explanations have actually aggravated the original injury.

It is a little strange that these representations should coincide in time with Mr. Johnson's attempt to prospect a new patent, an important part of which relates to the production of photographs in permanent pigments. It seems as if by some "unconscious cerebration" Mr. Johnson had made his quotation square with his own ideas rather than with published facts. Mr. Johnson now goes further, and raises doubts as to the success of the Autotype Company's methods of producing permanent tissues.

For eighteen months we have sent out all our single-transfer prints, amounting to hundreds of thousands, in tissue made with permanent pigment, the basis of the formula for which was given to Mr. Johnson in May, 1876. For twelve months we have replaced the cochineal in our ordinary tissue (those made to special formulæ only excepted) with the new permanent pigment, and though we are not prepared to assert that in such a difficult and critical business as the making of tissue absolute perfection h s always been attained, there have been no difficulties attendant upon the employment of the new permanent colour that have not been entirely overcome, and we have the satisfactory experience of a very large body of our customers to oppose to that of Mr. Johnson and his "intelligent *employé*."

What can Mr. Johnson mean by posing himself as a person possibly "inimical" to the Company, and suggesting that it was a mysterious and unlikely thing that Mr. Sawyer should confide to him his experiments? Is Mr. Johnson, then, unconscious that at that very time, and even at the present moment, he is, *de facto*, a sharer in the profits of the Autotype Company? It is true that at a time when autotype looked "dangerous" he exchanged his ten years' interest in the profits of the Company for a lump sum of money down, but the commutation of this reward can scarcely have absolved him from the loyal co-operation contemplated in the original deed. Under these circumstances it does not seem unlikely that Mr. Sawyer should, whilst enjoying the hospitality of Mr. Johnson at his charming retreat at Neuilly, talk over the hopes and fears, the progress and processes, of autotype; and what more likely than that he should communicate to Mr. Johnson in May, 1876, the progress he had made?

Mr. Johnson is bound by agreement to give the Autotype Company the refusal of any novel invention in carbon printing patented by him; in the present case this *devoir* has not been neglected.

To Mr. Johnson's overture we (as men of business) replied that, in addition to the specification, practical proof of its commercial value must be produced before terms could be discussed. Mr. Johnson promised that with the assistance of his friend, Mr. Oliver Sarony, he would produce examples of his improvements, and give us the data upon which to form an opinion. We are not conscious of having ever injured Mr. Johnson in word or deed. It is certainly through the present proprietors of the Autotype Company that he has ever received anything approaching an adequate acknowledgment of his eminent services to carbon printing, and certainly one of the partners exerted himself considerably to secure him advantages both in France and the United States. The general question of improvements in tissues and in processes for permanent photographs cannot be neglected by ourselves, and is of some importance both to the profession and the public; and surely Mr. Johnon will be employed to greater advantage in producing better materials and more perfect tissues, and thereby adding to the honourable services already rendered to a good cause, than by publishing misquotations "from memory," appropriating other peoples' inventions "by inadvertence," or by casting injurious reflections on gentlemen who were once his co-workers and believed themselves until quite recently to be his friends.—We are, yours, &c., THE AUTOTYPE COMPANY.

March 12, 1878.

[This discussion has now arrived at the stage at which it may be fittingly terminated.—EDS.]

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

RECEIVED.—M. Carey Lea. In our next.

SYNTAX.—The process you suggest for producing chromotropes by means of photography is excellent. But can the requisite variety in pattern be obtained?

W. F. BROWN.—The perfection of top light may be obtained even with a single sloping roof, provided, of course, that the slope be carried to a sufficient distance over the head of the sitter.

F. O. B.—To produce an enlarged print by means of the magic lantern you must make use of a *much* more powerful light than that produced by your paraffine lamp. Try the magnesium light.

R. M. C.—It is probable that the water of which the bath has been made is impure. Render it neutral by the addition of a solution of bicarbonate of soda, and expose it to sunlight for a day; then filter and slightly acidify.

A. EPPS.—It is probable that the fogging propensities in your lens arise from the brasswork inside not being *dead*. Try the effect of coating the interior of the tube with either a thoroughly mat black varnish, or of lining it with black velvet.

CONSTANT READER.—The common protosulphate of iron as sold to the dyers will answer your purpose sufficiently well. Try one picture by it, and another by the ammonio-sulphite, and see which produces the better result. Tone after fixing.

REV. J. THOMAS.—The ferrotype plates which form such an important element in the construction of the telephone are those in common use for taking cheap collodion positives. They can be procured from nearly all dealers in photographic materials.

A. B.—If you read carefully Mr. Hare's specification you will find that he does not make any claim to be the inventor of "changing-boxes," but of a special kind of mechanical adaptation by which an improvement upon the original changing-box has been effected.

SUBSCRIBER.—From your statement of the matter we incline to the belief that you will gain the case, provided it be carried farther. But you know the old saying—"one story is good till the other story is told;" and in the meantime we have only heard one side of the story.

"LITTLE CARBON."—We cannot tell from a mere inspection of a carbon print whether the purple pigment contained therein is permanent or not. We would require to know the nature of the pigment first, and even then we might not be able to speak with confidence as to its permanency.

C. J. (Leeds).—We presume that by taking from the medallion a cast in stearine, and from that mould obtaining a cast in plaster of Paris, a *facsimile* of the original would be produced. If several casts are wanted it will be advisable to utilise the excellent reproductive properties of the electrotype.

H. E. D.—Instead of an ounce it should have been half-an-ounce. This gives the proportion mentioned. One drachm of a one-hundred-grain solution will contain a little over twelve grains. We are quite ignorant of the nature of the plates mentioned, knowing nothing concerning them except what has appeared in this Journal.

BLISTERING OF PRINTS.—A. M. R. (Aberdeen) wrttes as follows:—"If your Havana correspondent would take the advice given by Mr. J. Stuart, in the ALMANAC for 1878, page 78, blistering of prints would be a thing of the past I have found it a perfect preventive of blistering; and I may mention it is used in the largest printing establishment of this town with the same success."

K. P. T.—Although a solution of Castile soap in alcohol has been much employed as a lubricant for prints when subjecting them to the action of the burnisher, an ethereo-alcoholic solution of wax is now beginning to supplant it, the latter being alleged to have several valuable qualities which the other does not possess. The formula for this preparation is as follows:—

White wax	120 grains.
Ether	2 ounces.
Alcohol	16 ,,

The wax is scraped into shavings and dissolved in the ether, after which the alcohol is added. When it is to be used the bottle must be shaken so as to mix up through the liquid a white sediment that falls to the bottom after standing. This mixture is applied to the photograph by means of a sponge. We believe that benzole will make quite as effective a solvent for the wax as the ether and alcohol in the foregoing formula.

R. SUTTON.—There is rather too much water in the solution. We have found a suitable bleaching fluid to consist of eight parts of water to one part of a saturated solution of bichloride of mercury in hydrochloric acid. This mixture is improved by the addition of a little alcohol and nitric acid.

H. M'GILL.—Your error consists in not having allowed the gelatine sufficient time to soak in the cold water previous to applying heat. Obtain a basin capable of holding a quart, half fill it with gelatine, and pour in cold water in such proportion as to stand above the top of the gelatine. Allow it to stand for three or four hours, then drain off the superfluous water, and place the vessel in a hot oven for a few minutes, by which the gelatine will be liquefied. Then add the alcohol.

J. Y. (Manchester).—The instrument in question consists of a wide tube bent like a U, one of the limbs, however, being bent outwards near the top, something like the spout of a porcelain teapot. Any viscous fluid, such as albumen, is poured *in* at one limb and *out* at the other. The formation of air-bubbles is thus avoided. Of course the tube must be very wide, and a plug of tow may with advantage be inserted loosely so as to ensure the filtration of the liquid previous to being poured out.

G. P. W.—Seeing that the lens has a focus of eight inches it is imperative that, in order to produce a transparency of the same dimensions as the negative, the camera be constructed in such a manner as to enable the focussing-screen to be placed sixteen inches from the centre of the lens. The negative must also be placed at the same distance from the lens. If the transparency be required to be twice the dimensions of the negative, or two diameters, then the camera must be capable of being expanded to at least twenty-four inches, the negative being twelve inches from the lens.

G. L. LEE, Jun.—The best way to apply bronze powder to the gelatine surface is to make use of a large camel's-hair brush, the hair of which has been shortened very much, first, by cutting with a sharp knife, and then pressing the stump against a bit of hot metal until the surface is burnt in a uniform manner. Now rub the stump against a piece of coarse emery paper, and the brush is complete. The bronze powder should be of the *fine* kind about which we wrote a fortnight ago. Brush it well into all the interstices, and when the gelatine presents a uniformly-coated surface immerse in the solution of sulphate of copper, a one-pint Smee's battery affording sufficient electric power to effect the coating.

EXCHANGES.—In our next.

NON-ACTINIC MUSLIN.—We have received from Mr. J. Solomon, 22, Red Lion-square, a sample of a new description of non-actinic muslin he has prepared. It is of a rich ruby-orange colour, is very transparent, and must prove very useful now that such an exalted degree of sensitiveness has been obtained in our films.

GELATINE NEGATIVE FILMS.—We have received several specimens of gelatine negative films exhibited at the recent meeting of the Edinburgh Photographic Society, in illustration of the interesting communication made to that Society by the Rev. H. J. Palmer, M.A., which will be found in the present number of the Journal. These pellicles are exceedingly uniform, and the experiments of Mr. Palmer will necessarily prove of great value to photographers.

PHOTOGRAPHY IN COURT.—PORTRAIT CLUBS AGAIN.—At the Bloomsbury County Court, on Tuesday last, the case of Bowell *versus* Pearce was heard before Mr. Judge Russell. The plaintiff, a licensed victualler, carrying on business at the Artichoke Tavern, Kentish Town, sued the defendant, a photographer in Malden-road, Kentish Town, to recover the sum of twenty-one shillings—money paid to the defendant's portrait club—and for which sum the plaintiff was to receive a handsomely-framed portrait similar to one placed in the plaintiff's bar for inspection, and which, together with one sent to the plaintiff, were both in court. The Judge asked the plaintiff what he had to complain of. The plaintiff requested his honour "to look on this picture and on this," as the one he received was very inferior to the one he expected to receive, and consequently he declined to have it. The defendant said the plaintiff did not sit for the portrait in question, but requested him to enlarge a guinea club-portrait from a *carte de visite* taken by another photographer. He told the plaintiff he had better sit again, but he refused, as he said his wife persuaded him to have the original copied. It was one to which the plaintiff's wife was partial, it being taken prior to their marriage. (Laughter.) The Judge, looking at the portrait in question, considered it was a very fair reproduction of the *carte de visite*, although not perhaps so good a likeness of the plaintiff since his marriage as it might have been before; but as the plaintiff had, like every wise man in trifles like these, consulted the wishes of his wife, still the defendant could not be held liable for them, as he had simply done what he was ordered to do and no more. Therefore judgment must be entered in his favour with costs, and the plaintiff was entitled to the picture.

No. 933. Vol. XXV.—MARCH 22, 1878.

ON THE PRODUCTION OF ACTINOMETER SCALES.

In continuation of our article of last week we now proceed to detail the later methods we have adopted with greatest success. With gelatine our *modus operandi* was as follows:—A solution of gelatine, of the strength of about fifty grains to the ounce, was coloured by the admixture of a small quantity of Prussian blue as supplied for artists' use in the moist state. Other means may be adopted; the readiest would, perhaps, be to utilise the laundress's "blue-bag." Whatever the means employed we should recommend blue as the colour, presenting, as it does, the strongest colouring power with the least obstruction to the action of light. The coloured gelatine was extended, in the ordinary manner, upon a plate of waxed and collodionised glass, and when dry stripped and exposed in the manner of ordinary tissue; or the exposure may be made through the glass, though this is not recommended. The attachment to the developing support would, probably, be best performed by means of india-rubber, but we made use of glass prepared with gelatine and chrome alum; this was moistened with water and allowed to drain, and the exposed tissue applied to it in the dry state, the collodion side next the glass, and pressed into contact with the squeegee, a sheet of clean paper being interposed. After an interval of ten minutes the development was proceeded with in the ordinary manner. We may, however, call attention to the necessity for more than ordinary care at this part of the operation. The development should not be hurried by laving the film with warm water, as is ordinarily done, as this would cause a tendency to inequality. A gentle rocking of the developing tray and plenty of time must be allowed to do the work.

When the development is completed allow the plate to rest for a few minutes in cold water, and then rear it up on blotting-paper until it becomes surface dry; it is then in a condition to be treated with the chemical colouring agent, which may be potassic permanganate or ferrous sulphate followed by pyro. The latter is the one we prefer, and we recommend the use of very weak solutions, the treatment being repeated if the first application prove insufficient.

The plates we have experimented with were of the quarter-plate size, and the number of tints sixteen. The exposure was effected as follows:—A piece of stout card the size of the opening of the printing-frame (four inches by three) was ruled with a series of lines a quarter of an inch apart, and parallel with the shorter side. The lines were then partially cut through with a sharp penknife, so as to enable the card to be easily folded at each cut. This mask was then fitted into the front of the frame, and by folding back each strip in succession at certain intervals of time a series of sixteen tints was obtained with ease and regularity. The plate when finished may be cut into three or four narrow strips, and will then form as many scales, which will all be uniform.

As may be easily understood, the length of the successive exposures is a matter requiring a considerable amount of care and calculation, in order to secure a series of regularly-progressing tints. It is a well-known fact in silver printing that a comparatively short exposure to light suffices to produce a distinct and marked difference in the colour of the previously-unsunned paper, and that the first colouration of the paper takes place rapidly with the production of a succession of well-defined and easily distinguishable shades. But in proportion as the exposure is prolonged the visible action of the light diminishes, and a considerably longer time is required to perceptibly alter the tint of the silvered surface. The same rule holds good with the exposure of the gelatine tissue; hence, if we give a series of exposures increasing regularly by equal increments of time (or by arithmetical progression) we shall produce a scale in which the lighter gradations are well marked and distinct, while the portion which should represent the middle and deeper shades forms an almost uniform tint.

To obviate this difficulty it was proposed some years ago, by Mr. H. J. Burton, to substitute geometric for arithmetical progression in the actinometer scale, and theoretically the change seems to be quite desirable. But between the scales for use in connection with carbon printing and the more delicate instrument such as we require, there exists a wide difference in the applicability of the principle consequent upon the greater number of tints comprised in the latter. Thus we might construct a practically useful scale of five tints for printing purposes, the number of thicknesses of translucent material forming terms of the geometric series 1, 2, 4, 8, 16; but, if in constructing a scale as we have described by successively-increasing exposures to light we used the same rate of progression, the first term in the series being *one second*, the sixteenth tint would require an exposure of *over nine hours*. It is scarcely necessary to remark that no sensitive surface, so far known, is capable of successfully rendering such widely different exposures; but it is obviously open to us to apply the principle by reducing the rate of progression. Thus, if the first term of the series be thirty seconds, and the rate of progression 1·1, the sixteenth term will be (discarding fractions) two minutes five seconds, or a little more than four times the first.

The result of such a system of graduation will be found greatly dependent upon the sensitiveness as well as the density or thickness of the sensitive surface. Any variation in the sensitiveness will of course, with a given ratio of exposures, produce a different gradation of tints, and the same may be said of variations in the thickness of the gelatine. The best plan, but one requiring some care and calculation, appears to us to be the following:—Ascertain by experiment the minimum exposure necessary to produce a decided tint, and also the length of time requisite to give the desired opacity to the deepest end of the scale. Having thus found the limits of exposure, the interval may be roughly divided according to the number of tints into a series of logarithmic spaces—that is to say, gradually increasing the difference between the exposures of each succeeding pair of tints.

As an instance we may give the details of an actual experiment performed by ourselves in the early part of last autumn. Having exposed a strip of gelatine tissue for various periods, from a few seconds to half an hour, in bright sunshine, it was developed and subsequently treated with iron and pyro. in solutions of known strength and for a measured time. When dried it was found that the shortest exposure which had produced a distinct impression was twenty seconds, and when exposed in contact with a piece of silvered paper no change in the latter occurred under the tints exposed for eighteen minutes and upwards. We, therefore, took twenty seconds and seventeen minutes as the limits of exposure for the sixteen tints, and having found by calculation the necessary rate of progression we constructed a geometric series of exposures with twenty seconds as the first term. Rejecting, of course, fractional parts of a second, and, in the higher terms, slightly modifying the figures for convenience sake, the series runs as follows:—Twenty, twenty-six, thirty-four, forty-four, fifty-seven, &c., seconds—the intervals up to four minutes between the two last terms. We do not wish to convey the impression that it is necessary to be thus minutely particular, but merely to indicate the principle upon which we think a properly-graduated scale should be constructed. For all practical purposes it will, doubtless, be sufficient to observe the gradually-increasing difference between the tints, without entering into calculations.

Perhaps the most theoretically-perfect mode of securing a graduated scale is that proposed by Captain Abney, in which a plate is exposed upon a rapidly-revolving star cut out of blackened cardboard. The light passing through the converging apertures between the rays of the star produce upon the sensitive film a vignette effect, to which any degree of delicacy or "abruptness" may be given by modifying the shape of the star. The operation is, however, beset with practical difficulties of a mechanical nature which preclude its general adoption. We shall, however, describe a modification of the same principle with which we are at present experimenting, and which, though perhaps not as perfect in its results, is easier of application.

Briefly, it consists in the exposure of a plate by the rapid passage across its surface of a shutter, in which is cut a wedge-shaped opening; it is obvious that, however rapidly this may be effected, the portion of the plate which coincides with the base of the wedge will receive a proportionately longer exposure than the part which comes under its apex, and that by rendering the lines of the opening more or less convergent the difference between the two extremes may be increased or diminished at pleasure. The apparatus by which this is effected is extremely simple: a piece of three-quarter-inch deal, about fourteen inches by seven, has cut in its centre an aperture large enough to hold a quarter-plate, and a door carrying a spring is fitted to it as in an ordinary dark slide. Upon the front of this frame are glued two strips of wood which act as guides for the sliding shutter, which is of such dimensions that when pushed to either end of the frame it just covers the opening containing the plate. A broad slit is cut in the shutter and an adjustable slip of wood attached by means of thumb-screws, in order that any degree of convergency may be given to the opening; a stout elastic band stretched over two projecting screws causes the shutter to pass rapidly across the opening containing the plate.

We have not yet had sufficient experience with this apparatus to warrant us in saying much of its capabilities; but we have already met with difficulties in connection with the use of collodion films which will require to be surmounted before this form of scale can offer to compete with gelatine. We have as yet only experimented with dry films and alkaline development, and there appears to be a strong tendency to the destruction of delicacy in the half-tints in securing a sufficient amount of density. This is, perhaps, a matter which depends more upon the proper adjustment of the shutter than upon any defect in the mode of development; but after a few more trials we shall be able to decide upon the practicability or otherwise of the system.

FACILITIES IN COLLOTYPIC PRINTING.

Between the professional lithographic printer and the amateur collotypic printer there is a great difference. The former always has his ink and rollers in working order ready for use, whereas the latter cannot conduct an experiment, however trivial it may be, without entailing much preparation in this direction—preparations which, although involving the expenditure of time and trouble, yet count for nothing when, after the lapse of a few days or weeks, another experiment is about to be made.

It is this dread of encountering a great amount of trouble for the sake of obtaining a slight result that acts in a large degree in preventing amateurs from making themselves more familiar with collotypic printing than they are. The preservation of the inking rollers in a state of efficiency necessitates their being carefully washed and stored away after each experiment, while the charging of the inking slabs uniformly with thick, viscid printing ink forms the step preliminary to all others in conducting the operation of printing.

In the exceedingly interesting and instructive lecture on collotypic printing delivered before the Society of Arts on Monday, the 18th instant, Mr. Bolas alluded to the difficulty we have here raised, and to which he had given much attention. The remedy he proposed in the case of the printing rollers was to supply the place of those of leather and india-rubber by rollers formed of the ordinary glue and treacle compound—time honoured in this connection—"veneered," so to speak, with vulcanised india-rubber. The lecturer, being practical throughout, exhibited to the audience his method of constructing such a roller. This, as far as we can recollect, is as follows:—

A piece of wide rubber tubing several inches in diameter is placed inside of a brass tube of corresponding capacity, having a longitudinal slit from end to end to permit of its being forced open so as to admit the rubber tube with facility, which then adapts itself to the interior surface of the brass tube. A thick wooden rod having in its interior a thin brass tube is now inserted in the shell—of course placed in as central a situation as possible—and the space between is filled up with a mixture of glue and treacle, and when it has become cold the roller is finished. A roller of this kind is, in the estimation of Mr. Bolas, more easily retained in good working order than any other, while it also enables the finest results to be obtained. After being used it is sponged with turpentine, and then remains ready till it is next wanted. We are aware of india-rubber inking rollers having for several years been made use of for collotypic printing, but are uncertain whether they are formed in this particular manner.

With regard to the ink: instead of removing a portion of this thick, viscid substance to the inking slab and spending much time in spreading it uniformly—a condition absolutely requisite if uniform prints are desired—Mr. Bolas prefers placing a portion of the ink in a wide-mouthed bottle, and adding sufficient spirits of turpentine to dilute it. A piece of linen is now tied tightly over the mouth of the bottle, and a small portion of the contents is poured out upon the inking slab. Being thin, the ink is evenly distributed by means of a few strokes of the roller, a "photographic tone" being imparted by the admixture of a little iron violet, which is procured in tin tubes from the artists' colourmen.

These hints will probably prove as useful to our readers as the carrying of them into practical operation appeared to be to those who were assembled at the House of the Society of Arts on Monday evening last.

THE AMENDED DOUBLE TRANSFER PATENT.

We stated in a previous number that the Autotype Company had disclaimed a portion of the patent of Mr. J. R. Johnson under which double transfer in carbon printing, as practically carried out, is embraced. The "disclaimer" has now been published, and we are in a position to give details.

Speaking in general terms, the whole of those claims attached to what in the specification is designated respectively the "first," the "second," and the "third" improvement have been surrendered on account of some doubt having been expressed as to whether they are new; at any rate, these improvements, which have not been adopted in general practice, have not been retained. With this explanation we introduce the pith of the disclaimer, which is as follows:—

Now know ye that we, the said John Robert Mather Sawyer, Walter Strickland Bird, and Paul Frederick Bird, by and with the leave of Her Majesty's Solicitor General, do hereby, for the reasons aforesaid, and for effecting the objects aforesaid, insert after the word "in" in the eleventh line of the seventh page of the print c the said specification printed by the Queen's printers, and published at the Great Seal Patent Office, the words "some of." And we strike out of the said specification the whole of the passage commencing with the words "1. Now my first improvement," in the seventh line of the eighth page of the same specification, and ending with the words "behind them" in the thirtieth line of the tenth page thereof; and we also strike out from the thirty-first line of the same tenth page the figure and words "4. My fourth improvement consists," and we insert in lieu thereof the figure and words "1. My first improvement consists;" and we strike out from the thirty-seventh line of the same tenth page of the said specification the words "and the tissue be well exposed;" and we strike out from the said specification the whole of the passage commencing with the words "even if" in the seventeenth line of the eleventh page thereof, and ending with the words "impure surface" in the eighteenth line of the same page; and we strike out from the said specification the whole of the passage beginning with the words "or the resinous cement" in the fourteenth line of the twelfth page thereof, and ending with the word "together" in the seventeenth line of the same page; and we strike out from the thirty-fourth and thirty-fifth lines of the same page the words "under this fourth head of my improvements," and insert in lieu thereof the words "under this first head of my improvements;" and we strike out the word "permanent" in the last line of the said twelfth page, and we insert in the said last line of the same page the words "herein referred to" after the word "support;" and we strike out from the eighth line of the thirteenth page of the said specification the figure and words "5. My fifth improvement consists," and insert in lieu thereof the figure and words "2. My second improvement consists."

And in order that it may be clearly understood what is the invention which we now consider to be secured by the hereinbefore in part recited letters patent, we shall proceed to repeat (omitting preamble and testing clause) the said specification as proposed to be amended by this present disclaimer and memorandum of alteration, as follows:—

Now know ye, that I, the said John Robert Johnson, do hereby declare the nature of my said invention, and in what manner the same is to be performed, to be particularly described and ascertained in and by the following statement thereof, that is to say:—

My first improvement consists of a new mode of obtaining photographic images in pigmented gelatine or its analogue upon plates of metal, glass, or other substance impermeable to water, which plates may be used either as permanent or temporary supports, dispensing in the latter case with the india-rubber paper heretofore used for this purpose.

This improvement is based upon the observation that, if the support be impermeable to water, no cementing material is necessary to effect the adhesion necessary for mounting the tissue upon its support, all that is necessary being the perfect exclusion of air between the moistened surface of the tissue impressed by light and the impermeable surface to receive the picture as its support. I effect this by wetting the tissue and laying it upon the metal or other surface, and sponging or rubbing the back of the printed tissue so as to drive out air with the superfluous moisture, as in mounting a print upon card.

To effect perfect and permanent adhesion, the surface of the glass or metal forming the support must be chemically clean, particularly when such surface is polished. To avoid the necessity of thus cleaning the surface I occasionally cover the surface with a very thin layer of plain collodion, using for this purpose a collodion containing about one or two grains of cotton to the ounce of ether and alcohol forming the solvent. When the collodion is set, but not dry, I plunge it into water to wash off the solvents until the greasy appearance has ceased; I then lay upon the plate thus prepared the wetted tissue. When the picture is completed it adheres to the glass with great tenacity by surface adhesion only. Pictures thus mounted upon glass or metal as their permanent support may not only be used as pleasing pictures, but can be employed in various processes as a model or pattern to obtain casts or impressions, either by means of pressure, by the electrotype process, or by casting.

The hardened gelatine picture, either negative or positive, on a plate of zinc, copper, or steel, may be also used as a resist, which enables us to etch the plate or to gild it for the purpose of etching it, subsequently, with the object of producing a plate in intaglio or relief for the purpose of printing therefrom. When the plates of metal, glass, or other impermeable substance are used as temporary supports, such plates must have received some slight smear or coating of wax or other fatty body to prevent the absolute adhesion of the picture film. Instead of wax alone, I find equal parts of wax and yellow resin dissolved in turpentine to give the best smearing compound. This is rubbed over the plate and immediately rubbed off again with a piece of clean flannel, leaving only a very thin coating.

When polished glass plates are used as the support instead of the wax and resin, I prefer to use a coating of the thin collodion already described to prevent the adhesion; but in this case the collodion coating must be allowed to dry before immersion in water. The film so formed then readily leaves the glass attached to the print, which retains the polish of the temporary support. Plates thus prepared allow of pigment gelatine images being formed on their surface, not only by development in the way described, but indirectly, by employing the image formed by development, and as a model or pattern for obtaining a mould from which other and similar gelatine images are obtained by casting, and images thus formed may equally be transferred to paper in the way described. The nature of the surface of the support will determine the resulting surface of the gelatine image.

A polished surface will give a polished surface to the print. If a mat or grain surface be required, the support must be grained or tooled to give that surface.

The gelatine image may be transferred to paper while in the wet state by bringing into contact with it a piece of paper coated with gelatine or other analogous substance, or, which is preferable, the image may be allowed to dry upon its support, and the prepared paper soaked in water may be laid upon it, air being carefully excluded. I also transfer the print from its temporary support to a sheet of imitation ivory, as in the so-called eburneum process, or to a sheet of imitation porcelain or marble formed of plaster or other plastic substance.

When the print is required to be mounted upon a fabric I take fine muslin or other porous fabric, and after wetting it I lay it over the print upon its temporary support, and I spread over the muslin or fabric any of the before-mentioned cements mixed with whiting or other pigment. This compound penetrates to the surface of the print, thoroughly expelling air, and when dry perfect contact is effected. The muslin or fabric can then be lined with canvas, as is well understood.

If the picture be very large, and be formed of several negatives, I mount the several parts upon paper or other flexible support, either coated with india-rubber, as already practised, or as above described. I cut out the several parts, wet them, and lay them down well matched upon a drawing-board, and I then proceed to mount them upon, or rather under, the muslin or fabric as already said.

I claim as my invention under this first head of my improvement:—

First. The formation of the mounting of the gelatine image formed, as described, upon a sheet of glass, metal, or other impermeable surface serving as the support herein referred to, without the intervention of any cementing material, to be used as pictures or as models, moulds for producing engraved plates, or otherwise.

Second. The mode of transferring images of gelatine mounted upon the surface of plates of glass or metal from such surface (serving as a temporary support) to the surface of paper or the like material, by means of an intervening film of wax or other substance having the like properties.

2. My second improvement consists in another mode of transferring the picture in one or many parts from its temporary to its permanent support for the purpose of being painted upon in oil or being varnished. I mount the picture in this case upon paper rendered transparent by wax, paraffine, or any fatty matters not fusible at the temperature used for developing the gelatine pigment prints. When the developed print is quite dry I varnish the surface of the permanent support which is to receive it, such as wood panel or oil canvas. I varnish also the face of the picture, and if of several parts I carefully match these. The two varnished surfaces, when nearly dry, are then rubbed down together, and when in perfect contact the back of the waxed paper is warmed, and then leaves the pigment film perfectly attached to the panel or canvas. Before the picture is transferred it may be tinted or painted, and if painted with opaque colour it may be laid over another picture without the latter being seen. Thus I form composition pictures by laying down a landscape background, for example, upon the canvas, and upon it I place figures trimmed to their contours, and which have received a coating of white or coloured opaque varnish at the back. These then show as perfect forms without the landscape or other background interfering, and as the gelatine film is extremely thin the superposition is not visible.

From the foregoing amended specification will be perceived the precise nature of the patent under which carbon printing by double transfer now takes rank. This patent, we may observe, remains in force till 1883, or for about five years from the present time.

We have some little doubt as to the advisability, at the present time, of introducing another new developer to compete with ferrous oxalate; but as there may, doubtless, be some with whom the latter will not find favour, and as our introduction is only a modification of alkaline pyro., we have decided to give it for what it is worth. It consists of the substitution of a compound of gelatine and potash for the ammonia usually employed in connection with pyro., and we have found it to combine in a remarkable degree the qualities of energy and regularity of action. The solution is prepared by dissolving gelatine in solution of potash and boiling for a few minutes, and, after the liquid has cooled and become clear, it is decanted and used in the same manner as the dilute ammonia. We are scarcely in a position to state the *best* proportions of the ingredients, but the following has answered well in our hands:—Caustic potash, half an ounce; Nelson's opaque gelatine, half an ounce; water, five ounces. Dissolve the potash, and then add the gelatine and boil until dissolved, stirring during the operation. The cold solution, when clarified, may be used in the same proportions as the solution of ammonia (one to seven), and works rapidly, producing very vigorous images; but the quantity may be increased, when necessary, to a much greater extent than is permissible with ammonia, owing to the potash exercising no solvent action upon the developed image. The presence of the gelatine acts as a restrainer upon the otherwise too powerful potash. If the same mixture be boiled gently in a narrow-necked flask for three or four hours it acquires an acid reaction, and when set aside for a few days it deposits a granular crystalline precipitate, together with a pasty substance similar in character to unaltered gelatine. If the thin, supernatant liquid be poured off and the residue treated with alcohol the crystalline matter is dissolved, and the solution forms a most useful addition to emulsions for the purpose of conferring density. It is probably a mixture of several of the decomposition products of gelatine. It is acid in reaction, and gives a white, milky appearance with solution of nitrate of silver.

It will be remembered that in our report of the last meeting of the South London Photographic Society we stated that Mr. C. Bennett had exhibited, among other negatives, one of an interior of a room taken at night by gaslight on a dry gelatino-bromide plate. This negative, with a transparency printed from it, together with some other negatives by the same gentleman and process, are now in our office on exhibition, and they have elicited expressions of the most lively interest from several experts in the gelatine process to whom we have shown them. The circumstances under which they have been taken will be ascertained from the following extract from a letter from Mr. Bennett:—

"I think it may interest many of those amateurs who work gelatino-emulsions to know that it is quite possible to photograph interiors of rooms, &c., by gas or paraffine light without the aid of any other illumination. I send you, therefore, a stereoscopic negative of a room to show what can be done in that direction. The light consisted of two candles, one gas chandelier fully lighted, two duplex paraffine lamps, and one single ditto. By experiment I found the two duplex lamps to be more effective than the others combined. One lamp was placed on each side of the camera, a foot from the floor, to illumine the carpet and articles near the camera, and one lamp was on the supper table. On viewing the transparency through a stereoscope the difference of the aspect of this lamp fully burning and the moderator lamp, which was not lighted, is very curious. The candles have burnt down during exposure an inch or so, consequently their flames appear (in the negative especially) ridiculously long. The lenses were Dallmeyer's six-inch focus single meniscus—time of exposure one hour. With gelatine emulsion as usually made, and with ordinary development, I think the light would have to be increased, or compound lenses used; but should you think it will interest your readers I would give further particulars, which would enable them to work with the same power of lens, in the same time, and with the same light. I also send you two other ordinary gelatine negatives of the same class of emulsion as I now speak of."

One of the negatives here alluded to is an instantaneous view of a boat scene on the river, and it bears the label—"Exposure by drop shutter—say twentieth of a second—by Dallmeyer's 10 × 8 group triplet." Another is also a river scene—exposure four seconds—by Ross' seven-inch slow symmetrical. On behalf of our readers we request Mr. Bennett to kindly send full particulars of the method by which he has obtained such excellent results.

ON NEW DEVELOPERS.

Towards the end of last spring I sent to The British Journal of Photography an account of some observations which I had made on new developers and new modes of development. The number of facts to be stated was so large that much brevity was necessary to prevent the communication from extending to an excessive length, and much had to be omitted. I therefore add here a few remarks which I thought to have sent before.

And, first, it may be worth while to advert again to the necessity of clearly distinguishing between those modes of development in which the image is built up by additions to the film and those in which it is formed at the expense of the film itself. Generally these have been distinguished as the wet and dry developments, or as the acid and alkaline. This method of classifying is completely erroneous, as follows from the facts rapidly stated in the above-mentioned paper. It happened that the one method (that of additions to the film) was generally used with wet plates, and the other (decomposition of the film) with dry—the one by means of an acid, the other with alkaline development. This concurrence was, however, fortuitous. For example: a film containing no soluble silver salt (and therefore producing an image by decomposition of the film) can be developed in a very acid solution of ferrous oxalate. This gives rise to a very curious experiment. If a well-washed and dried film be thrown after exposure into a solution of ferrous sulphate absolutely nothing will appear; but the simple addition of a solution of oxalic acid will cause the image to appear. Here is a developer that has only become one by the addition of a powerful acid!

After I had proved, many years ago, that in bromide dry plates the image was produced by a decomposition of the bromide in the film, it was the general belief that this capacity was one belonging exclusively to silver bromide, and indeed it seems difficult even now to have this error corrected. About two years since I showed that silver iodide could be emulsified with entire facility, and would yield an image by alkaline development; and, if I am not mistaken, the late Mr. Sutton proved the same with respect to silver chloride. Silver iodide exhibits a very considerable degree of sensitiveness to alkaline development, though less than bromide, and both less than the two taken together.

A solution of cuprous oxide in ammonia is a powerful developer. It is a curious and interesting fact that the two oxides, ferrous and cuprous, are capable of forming powerful developers, with this essential difference—that the one must be in acid or neutral, the other in alkaline, solutions; though, with respect to cuprous oxide, this must be stated with some reservation. As yet I have only found alkaline solutions of cuprous oxide active; but with ferrous oxide it may certainly be stated that the solution must *not* be alkaline.

For example: if to a solution of ferrous sulphate we add an alkaline carbonate there is, of course, a precipitation; but this may be prevented by the addition of cane sugar to the iron solution before the alkali is added. We have then a strongly-alkaline ferrous solution, and sugar has no tendency to prevent development. *A priori*, we should expect such a solution to combine the advantage of the ferrous wet developer and of an alkaline developer for dry plates; whereas on a washed film it does not bring out the vestige of an image—at least with exposures that respond instantly to other modes of development.

The powerful reducing properties of *stannous salts* seemed to indicate that they ought to afford good developers. Some years ago I tried them without success. Last spring I repeated these trials and varied them, but with no better results. Ordinary stannous chloride could, of course, not be expected to give results, but even compounds of stannous oxide with organic acids did no better. Hopes were entertained that stannous oxalate dissolved in potassic oxalate would give interesting results, but it did not give a trace of an image; nor did lactate. Besides stannous salts of organic acids the sulphate was tried, but without effect. Stannous oxide dissolves freely in solutions of potash. This solution acted quite differently from the previously-mentioned tin compounds. Whilst they had no effect this solution of potassic stannite instantly blackened the whole film.

Amongst many interesting results perhaps the most valuable was the discovery of the developing powers of ferrous oxalate. Its development is singularly beautiful—I think the most so of all that I am acquainted with. Within the last few days I have gone over my specimens, and have been greatly struck with the beauty of those obtained with ferrous oxalate.

In all photographic negative processes it has always seemed to me a great object to be able to shorten the exposure as much as possible. The exposure must always be a full one, but "full" is a relative term. It is desirable to obtain modes of operation for which a very short exposure will be a full exposure. Still days are always exceptions, and with every additional minute of exposure to a landscape the danger of motion to foliage increases. And what vast numbers of otherwise exquisite negatives have been ruined by blurred leaves! No one would now, I suppose, employ the older dry process for which half-an-hour's exposure was found none too much; for, even when so wonderful a thing is found as a day when foliage remains quiet for half-an-hour together, it is not desirable to expend that half-hour in obtaining a single exposure.

There are two quite distinct modes of shortening exposures—by heightening the sensibility of the plate, and by increasing the power of the development. Of the two directions in which we may search for improvement, whilst both are valuable the latter seems to have some advantages. Increased sensitiveness of the film, excellent as it is, is often accompanied by inferior keeping properties, by greater tendency to stain, and by greater difficulty in obtaining printing density. But increased power in the developers is, or may be, free from counterbalancing disadvantages.

For this reason I am inclined to think that the ferrous oxalate developer will prove valuable. It brings out an image with materially less exposure, and this result is not obtained at the expense of detail or accompanied by a tendency to fog. On the contrary, when in my experiment of last spring I compared it with development by alkaline pyrogallol, I found that in cases where the alkaline treatment yielded only poor, slate-coloured images, with a tendency to fog on pushing, the ferrous oxalate gave clear, bright images with a singular absence of fogging. These oxalate images have often a beautiful metallic appearance resembling red gold, which is quite peculiar to them. They seem also to be of singularly fine texture.

Very strong solutions of this developing liquid (solution of ferrous oxalate in potassic oxalate), if set aside for a long time—a year or so—will sometimes deposit a crop of green crystals. This separation of green crystals from a deep red liquid seems curious. The crystals are, however, not the developing substance, but consist of ferrico-potassic oxalate. The last-named substance is formed by oxidation, through the gradual penetration of air through the cork of the vial, and, though very soluble in water, seems rather insoluble in solution of ferroso-potassic oxalate, the developing solution.

There is another curious remark. Ferrous salts are mostly green; ferric yellow or red. In the case of the double oxalates of iron this characteristic is exactly reversed, the ferrous salt being yellowish red; the ferric salt green.

M. Carey Lea.

P.S.—I notice in a recent number of The British Journal of Photography mention made of Mr. Willis in connection with the ferrous oxalate developer. I cannot suppose that it would be intended to attribute to him a discovery which I made a year ago, and published in your columns about nine months before him.—M. C. L.—[Certainly not: our invariable rule is to give the credit of discovery to the first to *publish* such discovery—in this instance our esteemed contributor, Mr. M. Carey Lea.—Eds.]

ON THE FADING OF CARBON PRINTS, AND THE SUPPRESSION OF BICHROMATES IN CARBON PRINTING.

[A communication to the Photographic Society of Great Britain.]

Many photographers have already noticed the alteration which takes place when carbon prints have been exposed for a few weeks to the influence of the solar rays. These prints lose their beautiful colour, and become yellowish or of a dingy green. This fact has been attributed by everybody to the employment of fugitive or unstable colouring matter—such as cochineal, for instance—in the manufacture of carbon tissue. But as will be shown by this *memoir*, there is another cause in addition to the preceding.

It is generally admitted that light, in acting upon bichromate of potash in combination with organic matter—such as gelatine—reduces this salt to the state of sesquioxide of chromium, which locally renders the organic matter insoluble. Warm water will wash away that which remains unaltered. I should not be inclined to argue against this *theory*, if it were not that the *facts* are so contrary, as the following experiments will prove:—A sheet of paper is immersed in bichromate of potash and dried. It is then exposed for an hour to daylight; next washed for an entire hour in boiling water, to be afterwards immersed in an alum solution for several hours; afterwards washed in cold water, and finally hung up to dry.

According to the before-mentioned theory this paper should contain nothing more than a salt of sesquioxide of chromium, absolutely unalterable by the action of light. But this paper is *yellow*, while the salts of sesquioxide of chrome are *green*. But, moreover, if this paper be exposed to light, a part being covered by a mask of black paper, it undergoes an alteration in the course of a few weeks, and a sharp, distinct impression of the mask is brought to view. Now, where the light has acted the paper is *green*, like the salts of sesquioxide of chromium.

This experiment, and many others which we have made in this direction, prove, to our thinking, that neither hot water nor alum *fix* carbon prints. It is true the excess of bichromate is removed by these means; but the chromic salt which has rendered the gelatine insoluble not only *remains*, but this salt itself *undergoes a change by exposure to daylight*. And while thus deoxidising, it accelerates the action of light upon the organic colours which constitute the image, and so these colours fade much more rapidly than they would otherwise.

Naturally I have endeavoured to find a fixing agent, and have succeeded. Thus, in the case of the paper immersed in bichromate, exposed to light, and washed in boiling water, if instead of alum it is immersed in *bisulphite of soda*, it will, when dry, be absolutely unalterable by any subsequent exposure to light. Knowing these facts, and with the object of rendering carbon prints unalterable, I have directed my attention to the mineral and organic colouring matters which are reputed to be unfading—such as indigo, madder, the oxides of iron, &c.

Indigo (purified by a preliminary dissolution in fuming sulphuric acid, &c.) is a blue colour reputed permanent, and useful for the manufacture of tissue of a purple tone. Experiment, however, has proved to me that in carbon tissue it changes its colour by the influence of light. It will, therefore, be best to abandon the purple tone, for, with the exception of indigo, there does not exist any solid or permanent blue colour. And now as to madder. It is known that the roots of madder, boiled in an alkaline solution, give up their colouring principle, and that alum added to the above alkaline solution precipitates the colouring matter, forming an aluminate. This product is known as *madder lake*.

Mr. J. W. Swan, in a private letter dated 1875, called my attention to purpurine—a substance which I studied at this period, as well as alizarine. These two products constitute the colouring principle of madder. Here is the method which I have made use of, and which gives a very good lake:—Sixty grammes of alizarine are dissolved in three litres of boiling water, to which has been added 180 cubic centimetres of ammonia, of a density of 0·910. The whole is then well shaken and filtered boiling. Another boiling solution, consisting of 300 grammes of alum, dissolved in seven litres of ordinary water, is then poured into it at one dash, without stopping. The mixture is left for twenty-four hours to settle, and then filtered. The filtered liquid ought to be colourless, and not rendered turbid by the addition of a weak solution of carbonate of soda, which would denote an excess of alum. The precipitate is pressed, mixed intimately with glycerine, and ground up.

If this method be exactly followed, the aluminate of alizarine thus prepared will not stain single transfer paper, because it no longer contains alizarine, and will not render the film of gelatine subsequently insoluble, because it does not contain an excess of alum. I place, however, at the disposal of the Society the alizarine employed, and the lake madder prepared according to this method. This lake madder has been for some years commercially obtainable.

Instead of ordinary alum, use can also be made of *iron alum*, or of a salt of peroxide of iron. The precipitate obtained would appear, on a cursory glance, to be black; but it is of a very beautiful red—provided an excess of iron has not been employed. I have employed this lake for certain colours for a considerable time past. The lakes of madder, or compounds of alizarine, have the reputation of not fading under the influence of light, because in dyeing and painting they have been used for many years. However, these colours employed in carbon tissue *are* alterable by light, and it suffices to expose a print to the sun under a band of black paper during ten days or a fortnight to discern very plainly the part which has been protected by the mask.

And now I place in the hands of the members present the proofs of what I have stated, and every one will be able to make a similar trial. Pictures exposed in October last are today completely changed in colour, having become yellow like the old silver prints. (This can be seen better in daylight than in the evening.)

That which specially proves that the action of the light is aided by the chromic salt is that, if the colour be spread by itself upon paper, it resists infinitely better, although if laid on thinly it does alter. When we say that indigo and madder do not fade under the influence of light it is true only in wool, silk, and cotton fabrics, which are stained through a considerable thickness of material; but it is not true when the same colours are spread out in thin films precisely as we find them made use of in carbon tissue or carbon prints.

And now let us proceed to the consideration of the metallic oxides. Students of mineralogy are well aware that among the oxides of iron are some of a superb and varied red. But painters know also that these oxides, ground up with oil or water, give dull and muddy tones. Now, for photography, it is necessary that the colours used shall be *transparent*, because it is the various thicknesses of the coloured film which form the half-tones.

A chance experiment led me to the discovery that, if the oxides of iron lack transparency, it is due solely to a physical cause, namely, that they are too hard to be reduced mechanically to their finest state of division. As a proof, if strong solutions of perchloride of iron and of soda, *thickened by sugar*, are mixed, peroxide of iron will be formed in a spongy and finely-divided state. Dry one-half of the product. It gives, after grinding up with the gelatine, an opaque film upon glass. Now let us make use of the other half gathered moist, upon a filter, mixed with glycerine and gelatine, and we shall obtain a transparent film upon glass, because the colouring matter is actually dissolved.

By varying the temperature pressure, and other purely physical conditions, we can obtain from oxides of iron and of certain other metals red or brown colours very beautiful to the eye, and absolutely and infallibly unalterable by exposure to light.

These, then, are the colours which I now use, which I shall continue to use henceforth, and the adoption of which I recommend strongly to all manufacturers of carbon tissue. I could easily have taken out a patent for these colours; but it is my opinion that patents are the best-contrived means for retarding the general adoption of the carbon process.

I possess prints (and I shall be happy to place them at the disposal of any persons who may ask me for them, in order that my statements may be verified) which have been exposed to the sun for about eight months, and which have undergone no change whatever. No organic matter—cochineal, madder, or indigo—could withstand a similar trial.

In conclusion: I shall lay before you the experiments I have made with a view to do away with the use of bichromate of potash in the carbon process. A piece of ordinary carbon tissue is immersed in an aqueous solution (twenty per cent.) of citrate of iron and ammonia, dried (in the dark), exposed behind a negative, wetted and transferred to glass—the usual operations. On developing with warm water NO TRACE OF AN IMAGE IS VISIBLE! But if after exposure to light the carbon tissue, instead of being wetted in ordinary water, is put into a solution of bichromate of potash, and be then immediately transferred to glass and developed with warm water, the action of the light upon the iron salt is transmitted to the bichromate of potash, and a picture appears. Instead of wetting the print in bichromate of potash before transfer, use may be made of bichloride of mercury and some other substances which I shall point out on a future occasion. If tannin be employed the action of light is reversed, and a negative is obtained.

Instead of the ferric salts I can also make use (with some modifications) of the stannic and other metallic salts, the bases of which have several degrees of oxidation; but the detail of these experiments would occupy too much time. Let it suffice to say that the greatest difficulty I have had to conquer has been the preservation of the half-tones.

I shall continue to prosecute my researches in this direction, and I hope soon to be able to submit to the notice of the Society a new carbon process, wherein the bichromate will be suppressed, and double transfer for the *redressement* of the pictures rendered unnecessary.

In bringing these facts before the public, my great object has been to cause others to make still further researches, and I shall be most happy if they lead to practical results—whether myself or others find them out. D. VAN MONCKHOVEN.

STEREOSCOPIC TRANSPARENCY PRINTING.

MR. BREESE'S METHOD.—No. I.

THOSE who are acquainted with the best of Mr. Breese's stereographs will probably expect to read something novel in an account of his process, and will, doubtless, be surprised when they find the formulæ he employed, and by which he produced so great a variety of effects, were very common, having been repeatedly published a few years ago. To many photographers the subject I am about to treat of will, to a certain extent, be a new theme; so perhaps it will be as well to begin at the beginning, then. If there be a fault, it will be rather that of saying too much than too little. I propose to deal first with the formulæ, apparatus, and accessories, and to follow these with some remarks on manipulation, which I shall endeavour to make clear by describing various kinds of effects and how obtained.

The first thing requiring consideration is the *Glass*. This should be of the French kind, which is nearly colourless and very thin. It can be procured, both plain and ground, through Messrs. Marion and Company or through a commission agent in France. Great care must be taken to store it in a dry room, or something like a decomposition takes place, which so softens the surface as to make the glass utterly unfit for the purpose. It is best cleaned with a mixture of carefully-prepared tripoli or rouge in spirits of wine, followed by the application with a tuft of cotton of a little old collodion to which a little water has been added, the final polish to the surface being given by the removal of this with an old silk handkerchief. Substratums must not be resorted to; the operations and results are too delicate for anything of that kind to be successful.

The *Collodion* most suitable for general use is a ripe sample, simply iodised, such as was formerly supplied by the first-class makers for the old-fashioned pyrogallic development, that made by Mr. Thomas being especially good. For special classes of work one or two kinds are necessary; but more about these when I come to the circumstances requiring them.

The preparation of the *Nitrate Bath* is as follows:—Dissolve three ounces of pure triple-crystallised nitrate of silver in twelve ounces of distilled water; iodise this by the addition of two and a-half grains of iodide of potassium previously dissolved in a drachm of water. After thoroughly shaking, pour this strong solution into the remaining twenty-four and a-half ounces of water necessary to reduce it to a strength of thirty-five grains per ounce, filter twice or thrice through some filter paper, test for free nitric acid, which, if present, carefully neutralise with oxide of silver, filter again, and acidify with from eight to ten minims of glacial acetic acid. The latter should be of the utmost purity, otherwise it will prove a source of much trouble. When great richness of tone is desired the formation of acetate of silver by the addition to this bath of two or three grains of acetate of soda dissolved in water will be found to contribute towards its production. A caution respecting the use of this bath, especially with the last modification, is necessary to those photographers whose experience has been wholly confined to the use of nitric acid for acidifying. It is exceedingly sensitive to dust and dirt; many kinds of spots, streaks, and comets make their appearance, which one does not see when using the hardier bath commonly in use at the present time. Care in preparation and cleanliness in manipulation will, however, be amply repaid by the absence of these defects and the delicate beauty of the results in other respects.

The *Developer* for all purposes of printing is composed of—

English pyrogallic acid	12 grains.
Glacial acetic acid	½ ounce.
Water	4 ounces.

The bottle containing it should be labelled "strong." An ounce or so of this is poured into another bottle, labelled "weak," and is diluted with one and a-half or twice its amount of water. In cold weather the amount of acetic acid may be reduced to two-thirds the quantity given above.

The *Fixing Solution* should be of cyanide of potassium, about seven grains per ounce in strength. Also have in readiness on the same shelf with this a ten-grain tincture of iodine for use in the production of atmospheric effect; biting out those portions of clouds obtruding themselves in the wrong place; or for purifying the reflection of the moon from the sea, by reducing intensity or removing entirely the monotone of the moon glass in those portions which come immediately behind the part reflecting when this has not been stopped back in the printing.

The *Toning* of the slides is accomplished by one of the following solutions, according to the requirements of the subject:—A one-grain-per-ounce of the developer as given above, a very weak solution of bichloride of mercury, and a solution of chloride of gold one grain to eight ounces of water. Many others have been tried, but were ultimately abandoned because of the fugitive nature of the effects produced. The only doubtful one retained is the bichloride of mercury. This, by the use of a weak solution followed by copious washing, does not occasion much cause for complaint. Its beautiful blue tone in moonlight effects cannot be surpassed.

The *Varnishes* required are of two kinds, namely, a transparent one for the front glass or glasses of the transparency, and a ground-glass substitute for the back one. Amber varnish, composed of gum amber dissolved in methylated chloroform, is most suitable for use in the first case, being very free from structure. A few grains of white wax dissolved in this (as I have before stated) deadens the surface considerably finer than the finest French ground glass, and for the back one answers the purpose very much better.

Such are the formulæ. Very antiquated some, perhaps, will say—almost like reading a page of the early history of photography;

but, nevertheless, I think I may venture the assertion, after extensive observation, that the results produced by them have never been approached. Difficulties must be expected, for much depends on manipulatory skill. There are none, however, that will not be overcome by a little painstaking, thought, and practice.

A few accessories are necessary in printing, which perform the duties of, and are much of the same character as, vignetting glasses. These were termed "masks" or "shades." In combining clouds, having a chimney-pot or other foreground with a sea view, there would of course be a necessity for a delicate softening off of the clouds from the pots upwards, and likewise with the sea view from its horizontal line into the sky, an even tint resulting when the two softened edges are superposed. For each of the above negatives a mask would be required opaque at one edge, this opacity being gradually reduced to transparency at the centre of the glass. The best known method for obtaining one of these masks, perfectly graduated as specified above, is to procure a sheet of white blotting-paper or cardboard and roll about half of it into a good-sized cylinder, under the edge of which place a sheet of yellow tissue or other paper, and spread it out upon that part of the paper unrolled. When this contrivance has been fastened with clips or pins, and placed facing a high side or other suitable light, with its flat yellow surface upwards and in a horizontal position, it will be observable that the yellow reflected on the lower portion of the cylinder merges by imperceptible degrees into that of the upper of white. If a photograph of this be taken out of focus, with the twin lenses of the binocular camera so placed that the centre of the roll may occupy the centre of the plate and fill it in length, it will, if condition of light were right, be all one can desire. Masks for printing coloured glasses from can be made by placing two of the above face to face, with their opaque sides to the opposite edges, the centre being left quite transparent. These can be again copied for one opaque in the centre.

When the landscape is of very irregular outline a piece of blackened cardboard is necessary, upon which temporarily fasten a rough paper print of the landscape, and cut out the cardboard to the outline. During the exposure of the cloud selected for the picture use the shape to screen the light from those portions not required, taking care to move it sufficiently up and down to prevent hardness. With the help of a mask already adjusted on the negative nothing need be allowed to print hurtful to the finished effect. This is what I designated in a former communication as "wafting."

Another kind of mask is one used for printing circular halos. For this a piece of cardboard a foot or so square should have painted in black upon its centre a good-sized six- or eight-pointed star. The points should be wedge-shaped and of considerable length. The longer and finer these are the greater will be the softness produced. A pin having been driven through the centre of this drawing to spin it upon, it is ready to be photographed out of focus and while spinning at a quick rate. The several uses of these masks will, I hope, receive attention further on. JOHN HARMER.

ON THE ELIMINATION OF THE CAUSES OF FOG FROM EMULSIONS.

IN papers that have been read before the Photographic Society it has been shown by what means fog on plates can be removed; but they were not, perhaps, sufficiently explicit on the removal of the cause of fog from the emulsions themselves. It is, therefore, proposed to treat of this question. In an emulsion, whether washed or unwashed, the chief basis of sensitiveness is bromide of silver, and if this can be obtained in a pure state, experiment has shown that there is no inclination to fog. In preparing bromide emulsion, however, we have causes at work which prevent the formation of the pure bromide, unless one of two conditions are fulfilled—either, first, there must be an excess of soluble haloid; or, second, something must be added in the shape of acid to the mixture if silver nitrate is to be in excess.

It must be premised, however, that anything that will act as a nucleus on which the metallic silver, produced during the action of development, can deposit will cause fog. This quantity may be very minute, as can readily be understood when the small quantity of the haloid salt, reduced to the sub-haloid state by the impact of light during a short exposure, is considered. Let anyone who doubts the fact try adding a small quantity of silver oxide to a neutral emulsion which is working brightly, and note the result in developing a plate prepared with it.

We will treat of the first case; the reason of this method giving freedom from fog is very simply explained. In the soluble bromides—and it may be sometimes in the silver nitrate—we *always* have impurities, no matter how carefully the preparations may have been made, and even if they have been originally what they profess to be, yet afterwards by contact with the air they become contaminated. The impurities may be, and often are, so small that they cannot be traced by ordinary chemical means; but light is able to detect them for us. In some recent experiments we have carried out we have found that silver bromide is formed before any other silver compound except the iodide, when the sensitive salt is formed from haloid salts, and not the halogens themselves. Thus, if potassium bromide be contaminated with potash (as is sometimes the case in appreciable quantities), and if silver nitrate be added, we shall have both silver bromide and silver oxide formed if an excess of silver nitrate be added; but if there be a defect of this salt there will not be a trace of silver oxide, but only silver bromide. Again: if we take bromide of copper, which is usually contaminated with the sub-bromide, it will be found that the bromide is all utilised before the sub-bromide is attacked at all; and if in addition to the bromide we have a metallic chloride present which may be contaminated with sub-chloride, the order in which they will combine with the silver nitrate is:—Bromide, chloride, sub-bromide, sub-chloride. Thus, if there be only sufficient silver nitrate added to an emulsion to combine with the two first on the list, the other two will be left in the emulsion as harmless compounds. The *rationale* of the elimination of fog from the furnished emulsion in which there is *at first* an excess of silver nitrate is thus demonstrated. Supposing we have an emulsion which contains bromide, sub-bromide (which can exist, as shown in a paper *On Intensifying Negatives with Copper Bromide*) and oxide of copper, and also a slight excess of silver nitrate. The addition of certain metallic chlorides or of hydrochloric acid will at once convert the sub-bromide and oxide into the chloride of silver, leaving harmless compounds behind. The metallic chlorides which are of use are those which readily part with chlorine, and which, therefore, preferably form more than one chloride, such as copper, cobalt, gold, platinum, &c. When other chlorides, such as of the alkalies, are employed, the needful substitution may not take place, because the affinity of the alkali for the chlorine is greater than for the sub-bromide, and therefore the elimination of the sub-bromide is not effected. Thus, supposing all the silver nitrate in original excess is converted into silver chloride, we have the silver sub-bromide to get rid of. Thus, supposing we are using sodium chloride as a corrective, then we should have—

$$Ag_2\ Br + NaCl,$$

which can form no new compound, since an atom of metallic silver or sodium cannot be left in a free state; but if we use (say) cobalt chloride, we have—

$$Ag_2\ Br + Co.Cl_2,\ \text{which can form—}$$
$$Ag\ Br + AgCl + CoCl.$$

The CoCl, or sub-chloride of cobalt, is harmless, and can be washed out of the film.

It will, therefore, be seen how it is that an excess of haloid salt gives freedom from fog.

Secondly. If an excess of silver nitrate be used, it is evident that something else besides a mere chloride will be required, since the sub-salts and oxides may be formed. This we find in the employment of an acid or halogen itself, or both together, added to the collodion, and to be most rapidly effective. This should be added to the soluble salts before the silver nitrate is added.

Suppose nitric acid alone be employed, then any oxide or carbonate will immediately be attacked, as also any of the sub-bromides—such as of copper. Again: if *aqua regia* be employed, we know that chlorine is evolved in an extremely nascent state, and that this would attack either oxide or sub-bromide, fully saturating the unsatisfied atom in the latter. If, now, silver nitrate be added, silver bromide and chloride would result with some compounds (perhaps such as the chlorate) which would be as inert as the silver nitrate itself.

If a halogen be employed without any acid the same result would occur. Thus, suppose we had as impurities an oxide and a sub-bromide, and that we added a solution of bromine to it, we should get the oxide changed to a bromide and bromate (the latter salt of which is experimentally proved to be inert), and sub-bromide changed to a bromide.

If the halogen be added last, when there is an excess of silver, it is probable that until all the latter is converted that it will exert no action; but if an acid, such as nitric acid, be added, it will exert its proper influence, though slowly. For it will convert any oxide or compounds of the oxide into nitrate, and from the silver sub-bromide dissolve away the loose atom of silver, converting the sub-bromide into bromide and nitrate. Thus:—

$$4Ag_2Br + 6HNO_3 = 4AgBr + 4AgNO_3 + N_2O_3 + 3HO.$$

After an emulsion has been washed, naturally any one of these agents will remove the fog; but they must be added cautiously, otherwise insensitiveness must result. W. DE W. ABNEY, F.R.S., Capt. R.E.
—*Photographic Journal.*

NON-CONVERGING PERPENDICULARS IN ARCHITECTURAL PHOTOGRAPHS.

[A communication to the Photographic Society of Great Britain]

A STATEMENT has very recently been put before the photographic world which challenges one of the most important laws regulating architectural representations. It is to the effect that vertical lines are not seen parallel to each other, and, consequently, photographers need not attempt to make them so. Now, if this assertion be accepted, and acted upon, photographic delineations of buildings will be liable to the suspicion that truthfulness in them is an impossibility.

As I think that the conclusions drawn from the theory propounded arise from a misconception of the laws of perspective and the reason why they exist, I propose to say a few words which may help to place the matter—viz., the absolute straightness of perpendicular lines in views of buildings—in a familiar way that may be easily understood.

Now, the first thing to be done when the artist begins his work is to establish the station-point of view—that is, to fix how much of the subject he intends to depict. It is absurdly evident that no one can look either straight before him, or upwards, or to the extreme right and left at the same moment of time; therefore, it has been found that the field of view may be determined by an angle of 60°—that is, 30° all round a centre, starting from the eyes; this is theoretically the limit of view, but practically a few more degrees are allowable. If a cone of card-board nine inches long and six inches wide be held before the eye, what is seen through the opening will define how much pictorially may be rightly represented; and the amount, whether the whole or part of the building is to be shown, will then depend upon the distance at which the station-point is fixed. Having settled this matter, the centre or axis of the cone must be held perfectly level, forming a right angle with the vertical lines of the building. In this position all perpendiculars seen through the cone, whether they are situated near to, or far away from, the station-point, will be parallel to each other and to the face or front plane of the cone. But if, when too close to the building, the axis of the cone be lifted in front, in order to see the top, then the plane of the cone and the plane of the vertical lines of the building become relatively altered, and are no longer parallel with each other; so that what were hitherto perpendicular lines become now absolutely horizontal, as seen through the cone, and consequently are amenable to the laws relating to horizontal lines when in perspective.

The deduction to be drawn from this is—that as the plane of the cone, or, as we will now say, the plane of the artist's drawing, cannot, and must not, be in two positions at the same time, no pictorial representation is truthful where it is attempted to show vertical lines upon different planes, amounting, in fact, to an attempt to produce one picture upon two pieces of paper where one is flat and the other tilted. And it is just this idea of the plane of the picture being movable that I take to be the main point upon which a misconception has arisen in the statement referred to. It is also argued that the laws of perspective, if carried out, would necessitate that vertical lines should lean towards each other; and, as a proof, it is assumed that a square tower 200 feet high and forty feet wide must be depicted narrower at the top, because there the building is further from the spectator than the lower part on the ground.

Now, as this possibility of the top of a high building appearing actually narrower than the base has no doubt often occurred to photographers, it will be as well to examine into this special matter more closely. First, then, what is perspective? Stated in a plain and simple way, it is the means by which, on a perfectly flat surface, objects both far and near can be depicted correctly and precisely in the same relative position that they bear to each other. What such a view should be when shown upon a flat surface, when parallel to vertical lines, we have before us every time we look out of a window, for there, apparently, is depicted a picture; and by keeping the eye at a fixed station-point of distance from the glass this picture can be outlined with white paint, the result being an absolutely literal transcript of the objects seen, both vertically and horizontally and in perspective. Now, it is from a consideration of the reasons why this natural picture on the glass is found to be true that certain geometric deductions have been laid down, and which constitute the laws of perspective; so that, with the aid of the laws, we can produce a true representation of any building on an opaque flat surface.

Having, then, shown that the station-point of distance from the building, and the parallelism of the vertical plane of the drawing-board, or window, with the vertical lines of the building, must of necessity be strictly attended to, before a single line of imitation is attempted, and as in the statement referred to the writer says—"There is no reason why the laws of perspective should not affect objects more or less distant in a vertical direction in just the same way that they do those in a horizontal direction," I will now endeavour to show that perpendicular lines do not converge, and that, consequently, vertical perspective does not exist.

We will return to our window and imagine that right opposite to us is a street 600 feet in length, at the end of which is a tower 200 feet high and forty feet wide. With the eye fixed in one place at a distance from the window about the length of the cone, paint the outline of the tower upon the glass and then measure the same, and it will be found that the two perpendicular lines are perfectly straight, that they are as far from each other at the top as they are at the base, and consequently do not converge, although the top of the tower is farther from us than the base is. The reason why this must be so will now be explained:—Suppose we attach wires to the two top corners and the two base corners of the tower and bring them altogether to the station-point where the eye is fixed. If, then, from the two upper wires other wires are suspended at equal distances from the eye the wires will be true vertical lines, being perfectly parallel with the plane of the window or drawing-board; and, supposing that a series of similar wires were suspended all along the distance between the tower and our station-point, these wires when looked at on either side must coincide, and will eventually intersect the outside vertical lines of the tower. In bringing the eye back again these wires would also represent a gradual reduction in size of the tower, and be geometrically perfect in the relation of one wire to another, so that when they arrived at the window we should find that the vertical lines were perfectly parallel with each other. Therefore, a true representation of the tower, as far as its vertical side lines are concerned, is nothing more than a section of the space enclosed between the two vertical wires (wherever they may be) cut off parallel with the plane upon which such representation is made; and, whether we cut off a small section, as seen on the window, or a large one further off, the distance apart of these suspended vertical lines must always be equal, and so cannot diverge.

The same natural law or result can be illustrated in a very marked way by supposing that the tower is brought 300 feet closer, thus increasing the angle of view to more than 60°, with the plane of the window-glass still parallel with the perpendicular lines of the tower. By keeping the eye at the station-point of distance we paint the outline again upon the glass, and, although the top is now still farther away, compared with the base, than it was in the first instance, still the lines upon the glass will measure equal distances apart as they did before. Thus, even in this extreme case, the vertical lines do not converge.

Precisely the same thing occurs when depicting horizontal lines, not in perspective, but *parallel* to the plane of the picture, as when looking at a row of houses on the opposite side of the way, and extending sideways to one side of our picture. Here, although the roof-line seems to converge, the true representation of it must be perfectly horizontal or straight, because the same law rules here as in the case of perpendicular lines, viz., that a true representation of the roof and ground lines, being horizontal, is nothing more than a section of the space enclosed between the two horizontal wires (wherever they may be) cut off *parallel* with the *plane* upon which such representation is made.

I will now illustrate, in this gallery, the result of horizontal lines seen under the conditions just named; and, by parity of reasoning, it will be evident that the same result must follow in the case of perpendicular lines.

I look at the cornice line of the ceiling on the opposite wall, and, turning my eye along the whole length of the room, the line appears to be depressed or converging. I hold a sheet of glass quite vertically, and also *parallel* to the *plane* of the opposite wall, and, keeping my eye at a fixed distance from the glass, I trace the cornice line throughout its entire length, and you see that the result is a perfectly-horizontal line, being at right angles with the perpendicular edge of the glass, and so it becomes a true representation of that side of the room, so that not only vertical but horizontal lines, when parallel to the plane of the picture, are not subject to any convergence or depression of position.

The examples I have given also illustrate what I first alluded to—the importance of the station-point of distance—because, in looking at a picture, the distance that the eyes should be from it is regulated by the angle fixed upon for the amount of subject included. Now, looking at the outline on the glass of the tower at 600 feet distance, which is represented through an angle of 60°, any distance may be chosen outside nine inches. When the tower was only 300 feet off, the angle being more than 60°, the eyes must be fixed at the nine inches distance; and when, as in this room, the angle is 90° then the distance from the picture must be less than nine inches; so that it is only when viewed from the proper point of distance that the picture is perfectly like what the original appears to be. Thus, with the eyes as close to the glass as they were when the cornice line of this room was depicted, the line which is actually horizontal or straight will then appear to converge the same as the original.

It will have been noticed that I have carefully refrained from alluding to photographic representations in any way. This has been done purposely, because the conditions under which the photographer works are so totally different to those I have described as appertaining to the artist that no comparison can be made between them. For instance:

the photographer does not cut off a section of the wires, or, as we must now say, the rays of light, running between the object and the station-point. The image has first to repeat itself, and, as it were, begin its existence over again, and what this new existence is to be must be dependent upon the perfection of the optical and mechanical instruments used to produce the second image. Therefore, the application of this matter of the laws of perspective lies in their results being accepted as standards of right and wrong; but, having this knowledge to assist him, the photographer will be expected and required to use all the skill he possesses to realise the conditions laid down, so that the representation he produces may be accepted as perfectly true, both in its pictorial and relatively scientific aspect. EDWIN COCKING.

ON THINGS IN GENERAL.

NORTH and South are often used to typify extremes; but if we go to the north and south of our island (say to the Edinburgh and South London Photographic Societies), instead of extremes I think we shall find a very gratifying uniformity in the practical and useful nature of the papers read and the attendant discussions. Quite recently, in the former society, two papers by the Rev. H. J. Palmer and Mr. W. T. Bashford have been read which deserve much praise for their usefulness and their practical character. The full manner in which the former gentleman has published the details of an important process, and the latter given a thoroughly practical essay on enlarging, are examples that may be well followed by others.

If we were to poll all the dry-plate workers, I think the supporters of gelatine emulsion in one or other of its forms would muster well to the fore. Mr. Palmer's very interesting paper will further help to swell them. That there are yet difficulties to overcome and improvements possible is a matter of course; the wonder is that there are not more in a process comparatively so new. Thus, Mr. W. H. Davies, at the meeting where the paper was read, pointed out the frequent occurrence in dry-plate work of halation and also of negatives which must be called "underdone." There is no doubt in my mind that a quality of an objectionable character, which is mainly due to halation, is more frequently seen than not in dry pictures, and gives an effect of cloudiness and unevenness in the darker parts of the picture.

A considerable proportion of under-exposed negatives may be due in the pictures of enthusiastic workers to the always-prevailing anxiety to prove that dry is as quick as wet. In connection with this point I should very much like to know the meaning of one portion of the report of the South London Photographic Society, on the 7th instant, where it describes a negative of an interior of a room taken by gaslight by an hour's exposure. If there were nothing exceptional in the size of the room or the number of gaslights I can only say it is a marvellous feat; but that an ordinary interior, with the usual objects, can be taken by the aid of gaslight alone in an hour's time I make bold to disbelieve entirely.*

The great event of the hour is the lapse of the great carbon patent, and the possibilities in the direction of rival tissue-makers. Already the air is full of rumours of new makers and wonderful tissues to come; but it is not likely the well-known Autotype Company will suffer, more especially in the face of the dignified and generous course they have taken in the matter. Some may say they could not sustain their rights if they had been infringed. That may pass; they have, at anyrate, removed difficulties, and their course is as wise as it is praiseworthy. It is difficult to say what will be the end of the alizarine discussion. Every attempt must be made to ensure permanent pigments, or pigment pictures will receive such a blow that its effect will take years to recover. I have in these letters alluded to the desirability of banishing anything connected with cochineal. It is to be hoped that the necessary chemicals used may not rob madder tints of their reputation.

There has been some correspondence lately on packing negatives, in which all sorts of very nice plans have been proposed. They, however, all appear to me to be so much paper wasted; for what packing could be better than the method in which we get the raw material—the glass plates themselves. I have seen thousands of plates unpacked after having undergone a long journey, but never saw a single one broken. If anyone wants to pack his negatives up, what could be better than simply tying them up in packets of (say) three dozen, and then putting them in a box close to one another, with a little straw well jammed in between them and the sides of the box? Eggs, even, are packed in tens of thousands in layers after this manner, and often sent hundreds of miles by rail without a single breakage. Could we have a better example?

FOREIGN NOTES AND NEWS.

CARBON PRINTS IN TWO COLOURS.—DR. RICHARD'S EXPERIENCE OF AFTER-LIGHTING.—THE ILLUSTRATION IN THE *MITTHEILUNGEN*.—AUGMENTING THE SENSITIVENESS OF DRY PLATES.—DEVELOPMENT WITHOUT PYROGALLIC ACID.—VIGNETTING MASKS.

IN the *Archiv* Dr. Liesegang has an article on carbon pictures in two colours, intended to imitate the effect of drawings on coloured paper with black and white crayons, such as Julien's well-known studies of heads—"*aux deux crayons*"—or of drawings on tinted paper, in which the high lights were scratched out with a penknife. The first method by which Dr. Liesegang would produce the effect with carbon pictures is by transferring the prints without collodion to grey paper, and when the pictures were mounted and otherwise finished he would put in the white lights with white oil colour. Another mode requires specially-prepared tissue—that is, tissue with two superimposed films, one of ivory black and the other of sepia. The late M. Braun, of Dornach, some six years ago showed Dr. Liesegang a large picture produced in this latter way, but the process never came much into use.

In the same journal Dr. Richard, of Maennedorf, says that in the winter time he makes a practice of after-lighting children's portraits, and has had a special camera constructed for the purpose. Supposing that on a particularly cloudy day, about nine o'clock in the morning, he has got a negative of a child with an exposure of two seconds, this negative, when developed, would not furnish a useful proof; so he replaces it in the dark slide and exposes it for three or four seconds longer in the special camera, after which he rinses and washes it well in cold water in the dark room and then fixes it. The camera in question is of peculiar construction; but it would appear that any camera would do for after-lighting, if the lens were taken out and a piece of white paper stretched over the opening. Dr. Liesegang thinks that the after-lighting should not exceed three-fifths of the whole exposure. Should the after-lighting be insufficient, it is not allowable, or at least it is not advisable, to repeat it.

The illustration to this month's *Mittheilungen* is a lichtdruck reproduction, by Bierstadt, of New York, of the photographs by means of which Professor Draper discovered the presence of oxygen in the sun.

In the *Photographisches Wochenblatt* Herr Düby describes several ways of making masks for vignetting. The first method is somewhat elaborate. He cuts a number of ovals—say eight—out of black and white pasteboard alternately, and, beginning with the smallest (a white one) he increases the size of each by a centimetre until the requisite number is cut. He then takes up the smallest oval and fixes the exact centre of it to the end of a stick; one centimetre behind he places the black one next in size, then at the same distance behind that again the third oval, and so on. When they are all arranged the opposite end of the stick to that bearing oval No. 1 is fixed in a horizontal position to the wall or a board, and a rather powerful negative of the series of ovals is taken of any size that may be desired, care being taken to focus so that none of the edges of the ovals are sharp. A glass plate is then rubbed with ox-gall, and over it a mixture of the following composition:—Ten grammes of good gelatine dissolved in 100 grammes of water, to which two or three drops of a saturated solution of potassic trichromate had been added for each gramme of the gelatine, is poured, care being taken to avoid air-bubbles, the mixture being assisted to spread by a glass rod. The addition of a few drops of ammonia to the gelatine is also advisable. The plate is dried in a horizontal position, and, when possible, in a warm room. When dry the plate is exposed under the negative sufficiently long to get a powerful print, and is then thoroughly washed in cold water to which a few drops of nitric acid is latterly added; and, lastly, the plate is tanned in a four-per-cent. solution of alum. If it be wished to have the gelatine mask without the glass, then before coating the plate with the mixture given above rub it with oil of turpentine and talc, and when the printed, washed, and dyed mask has become dry cut round the edges of the plate and it may easily be lifted off.

Another way of getting an unbreakable gelatine mask is given by the same gentleman. It is a combination of several other plans, and gives, he says, good results. He takes a clean glass plate and rubs it first with oil of turpentine and then with talc. He has meanwhile made a fifteen-per-cent. solution of very white gelatine, to every litre of which, stirring all the time, fifteen drops of a saturated solution of chrome alum are added, and the still warm mixture is filtered through muslin. If rather too much chrome alum has been added, so that the mixture becomes thick, fluidity may be restored by the addition of a little glacial acetic acid; but it is better if one can do without having recourse to the corrective by using exactly the right quantity at first. The prepared plate is laid in a horizontal position, and the gelatine solution poured equally over it until it forms a film three millimetres in thickness. In the same position it is left to dry. A powerful print on black or dark brown carbon tissue is now made—procured from the negative previously described. The print when sufficiently exposed is dipped for a short time into cold water and then withdrawn, and laid, pigmented film undermost, upon a glass plate and squeegeed thoroughly. It is then dipped for a short time into a solution of white wax in alcohol, and when removed from this solution it is laid upon the now dry gelatine film on the glass plate, squeegeed, and set on one side, under a weight, for half-an-hour. The print is then developed as usual, tanned in a four-per-cent. alum solution, and dried. When dry run a knife round the edge, and the unbreakable mask will come freely off from the glass.

M. Boivin recommends the following course of treatment in order to increase the sensitiveness of dry plates, but it is said to be especially applicable to the Taupenôt and similar processes:—The plate is sensitised by a rather shorter immersion in the bath than is usual with dry plates, and, after washing, is flooded two or three times with a solution composed of—

Phosphate of soda	2 grammes,
Pyrogallic acid	2 decigrammes,
Water	100 c.c.,

and allowed to dry spontaneously. The pyrogallic acid may be omitted, but the degree of sensitiveness is not so great. The development is performed by means of a solution containing both gallic and pyrogallic acids, to which a few drops of a five-per-cent. solution of phosphate of soda are added. After this has been allowed to act upon the film for a short time, a further addition is made of a small quantity of a solution containing equal parts of the nitrates of silver and lead and a trace of acetic acid. If a further quantity of this solution should be necessary a little acetic acid must be added with it. Though theoretically the phosphate might be expected to reduce the sensitiveness, practically M. Boivin finds the contrary to be the case. It is not necessary to wash the plate very thoroughly after sensitising, as any free nitrate left in the film is converted into phosphate of silver. The exposure required with plates treated in this manner is stated to be about twice that of good wet plates.

M. Queval states in the *Moniteur* that dry plates prepared with a preservative containing gallic acid may be rapidly developed in the following manner:—Lay the plate, after exposure, face downwards in a dish of rain water, so as to wet the whole surface without removing the preservative unequally. It is then completely flooded with a solution composed of four parts each of silver nitrate and acetic acid in one hundred parts of water. The development takes place rapidly. The author finishes by stating that he has only tried the method with albumen and collodio-albumen plates, and *that he has obtained very unequal results*—a statement which we can readily credit.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
March 28	Liverpool Amateur	Free Library, William Brown-st.
„ 28	Oldham	Hare and Hounds, Yorkshire-st.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

We now redeem our promise made last week of giving the report of the discussion which followed the reading of Mr. Edwin Cocking's paper *On Non-Converging Perpendiculars in Architectural Photographs* [see page 138], for which report we are indebted to the organ of the Society.

Captain Abney observed that the whole secret of perspective seemed to be in the use of the vertical plane, but it required a physiologist to tell us why that plane was chosen. Possibly it had something to do with the axes of the eyes.

The President: All vertical lines are vertical to nature.

Captain Abney said it all depended where we were looking. If he were lying down at an angle of 30° would the lines then be vertical? As a geometrician he could draw a picture on any plane and at any angle. It was a matter of conventionality that had fixed the vertical plane as the one on which pictures should be drawn.

Mr. F. Bedford thought it was a great question whether Mr. Cocking was right on one point. When he followed the line at the side of the room in his example he moved his head, and the line could only be seen as straight when he did so. The effect really was the same as that produced by the pantascopic camera.

Mr. Cocking observed that that was the point on which he laid stress. When studying at the Royal Academy he remembered it was laid down by the instructor, Mr. Knight, that the true representation of an object was not its actual appearance. Now, in looking along the line of the wall, he did not turn his head at all, only his eyes; the head represented the station-point.

The President: What applies to horizontal perspective applies to vertical; but there is no such thing as vertical perspective, as the moment you alter the parallelism of the planes the whole thing is altered.

Mr. Cocking concurred.

Mr. Woodbury contended that in the glass as held up by Mr. Cocking both ends were in perspective.

Mr. Cocking: Certainly not.

Mr. Woodbury: They are farther from the eye than the centre.

Mr. Cocking: If you admit that vertical lines come in perspective, it follows that from your horizontal points they go upwards and downwards.

Mr. Woodbury: The top and bottom are farther from you, and therefore appear smaller to the eye.

Mr. Sawyer observed that the article he recently wrote on the subject had given rise to the paper. He would not, however, then discuss point by point with Mr. Cocking, preferring to see the paper in print. What he said was simply this: if you take your stand at the bottom of a street and look down it, you notice that the sides gradually approach until they come to converging point. He carried that reasoning further, and held that if you stood at the foot of a tower and looked upwards, you saw also the lines of the tower recede from the eye until they also came together. Now, supposing the tower was 200 feet high and the camera be placed at such a distance so that the whole be brought into the field of view covered by the lens, he maintained that, supposing the lines were vertical, the camera being farther from the top than from the bottom, the lines as presented by the camera must necessarily converge. The mistake was in attributing to the camera only the same range and the same amount of subject as seen by the eye, because, in looking at the tower, the eye only saw a very small portion at a time, and it had to roam up and down in order to get any impression of the tower at all; consequently, lines appear straight, though in reality they are not so. Mr. Cocking had mentioned an experiment with wires, and he had put the spectator at some considerable distance from the tower in his illustration; but the principle was the same, though the amount of the convergence was so small it was impossible to detect it. He thought an experiment to prove this could be very easily carried out, and he would undertake at the next meeting to bring an example which would decide whether his or Mr. Cocking's views were correct. He would put on a wall of some high room a sheet of white paper whose sides were vertical, and at one-third of the height (?) place a camera perfectly level, and he thought it would be found that though the lines were vertical they were in the picture smaller at the top than at the bottom. (A member: No.) Well, that remained to be seen. If the distance from the bottom was greater than that from the top, then the bottom would be smaller. If the camera were placed exactly in the middle, then both the top and bottom would be smaller than the middle. He saw the opinion of the meeting was dead against him; nevertheless, he held to his own views.

Mr. Hughes observed that, the planes being parallel, vertical lines must also be represented parallel.

Mr. F. Bedford pointed out that although it was true that in the case of the tower the top was farther from the camera than the bottom, it must be remembered that to represent it correctly the swing-back must be used. The plane of the delineator must be parallel to the object represented. As regarded the eye, it subtended about 30°, but it was always rolling, and for the time being only represented the vertical lines towards which for the moment it was turned. When looking along the side of a wall the eye turned itself round and adapted itself immediately to the horizontal line. In drawing, the whole principle of vertical perspective was based upon the theory that the eye was actually parallel to the object represented. That was not always the case, but the distortion was corrected by the knowledge that the objects were true, and that the planes must be parallel.

Mr. Woodbury: If you lie on your side you have no parallelism.

Mr. S. Davis remembered in joining in a similar discussion some years since, when Baron Pollock was presiding, and the view he took of the matter was that the size of every object corresponded to the angle in which it was viewed. Take the case of the Victoria Tower. The top of the tower being considerably farther from the eye than was the bottom, the angle subtended of the latter in the eye would be much larger than in the former case. If, then, the extremities were connected the lines would be found not to be parallel. But that in a picture would be extremely unpleasant to the eye, although as a matter of perspective it would be quite correct.

Captain Abney thought that one point had been lost sight of, and that was that as a rule they did not see true perspective in a picture—speaking at all events of photographs. Unless the eye were placed at the same distance from the picture as the focal length of the lens, the same view of perspective as in the view itself could not be obtained. That was why the views taken by a wide-angle lens appeared false. It was impossible to look at anything at so short a distance as five inches—the focal length of some of these lenses. If the photograph be looked at at nine inches focal distance the lines of the picture would occupy the same angular position as that occupied by the view itself. The perspective would then be found to be perfectly true, and the vertical lines, if measured, found to be absolutely parallel, though, when looked at from the proper focal distance, they would appear to converge.

Mr. W. Bedford did not quite agree with Captain Abney, as in that case copies of large views would be false; the distance from the view, he thought, must be taken into consideration. If the eye were placed at the distance of the focus a correct idea of the size of the subject would be obtained; but the perspective would be still correct if that size were reduced and it was looked at as a small picture.

Captain Abney: The perspective would be correct, but you would not see it properly. Whether increased or diminished you must see it at the focal distance. That was the great advantage of enlargements.

After a remark from Mr. Bird,

Mr. Cocking said the matter could be expressed as a rule-of-three sum. As the eye was to the drawing or photograph so was the drawing to the view given. If a tall tower was to be drawn it should be drawn with perfectly parallel lines, because the drawing was in a parallel plane; but directly the eye was moved from that plane the conditions were not the same. Looking up, for instance, it would seem narrower. The whole law seemed to lie in that.

Mr. York had noticed the convergence of the lines in a tall tower. He had taken a view of the Westminster tower with a six-inch focal lens, standing at a distance, giving an angle of 45°, but had not seen the convergence spoken of by Mr. Sawyer. If the subject were to be discussed at the next meeting he would bring some examples in which such convergence did not exist. The camera, of course, should be perfectly level. A swing-back he never used.

Mr. Vernon Heath drew attention to a photograph on the wall of a large building, which was taken for the purpose of testing a Steinheil lens. In that photograph not the least convergence could be discovered.

The President said he recollected some years ago writing a treatise upon the subject. All vertical lines in nature must be vertical when depicted on a vertical plane. A view, as seen through a pane of glass, was really what a picture represented. He thought perhaps the best way would be to adjourn the discussion until the next meeting, when Mr. England would read a paper on dry processes—a subject which would be in accordance with the offer which had been made that evening.

It was then decided to adjourn the discussion until the next night of meeting.

MANCHESTER PHOTOGRAPHIC SOCIETY.

The monthly meeting of this Society was held at the Memorial Hall, on Thursday evening, the 14th instant,—Mr. Alfred Brothers, F.R.A.S., President, in the chair. The minutes having been disposed of, Messrs. Watson, Schofield, and Harrison Garside were elected members of the Society.

Mr. Pollitt then exhibited a compact folding-stand for the camera.

Mr. Colin Mather showed a little cone-shaped camera for quarter plates.

Mr. Schofield exhibited a collapsing lens mount, which he purchased some time ago. He did not know the name of the maker.

Mr. J. Holding called attention to the fact that burnt-in pictures on wood fade, or otherwise disappear, under the action of sunlight; but when the surface of the wooden block was charred first, and the lights and middle tints obtained by scraping, fading did not occur.

Mr. J. Chadwick suggested that the fading was probably due to the falling away of the particles of carbon caused by expansion and contraction, which would naturally ensue from exposure to the heat of the sun.

The Secretary showed some prints on Durand's matt paper, and said none but strong negatives would succeed with it.

Mr. D. Young exhibited one of Keevil's perfected lanterns, and showed its capabilities by exhibiting the *Gabriel Grubb* pictures on the screen. The prism disc was quite equal to the direct one. Mr. Young produced the oxygen during the exhibition by means of his generator.

Mr. W. J. Chadwick then exhibited a microscope adapted to the sciopticon, using Mr. Woodbury's lime-light arrangement, and showed a number of objects on the screen. The microscope was very good as far as it went, but the lenses were not achromatic.

After the customary complimentary votes the meeting was adjourned

Correspondence.

Carbon Printing in Australia.—Photography in Sydney.—Proposed Photographic Society in Sydney.—Spirit Varnish.—Proposed Improvements in Carbon Tissue.

Ninety-two degrees in the shade, and carbon tissue waiting to be sensitised! I think you will admit that the prospect was not very encouraging, but it had to be done, and was done. So many formulæ have been given for all sorts of preparations that it really seems of little interest to send you mine. Nevertheless I do so, hoping that it may be found useful by some one who, perhaps, has had some difficulty in warm weather. Make up the following and filter:—

Water	200 ounces.
Bichromate of potash	6 ,,
Alcohol	50 ,,

Place the bottle containing the solution in cold water, and keep cool by adding a little ice to the water. When about to use it place a lump of ice in the vessel with the solution, and on the glass slab used for laying the tissue upon for the purpose of squeegeeing out the excess of liquid put several small pieces of the same substance, moving them about until the glass is pretty cool, which will take about ten to fifteen minutes. Immerse the paper in the bichromate solution, prepared side downwards, excluding all air-bubbles; turn it over, return it, take it out, lay on the glass slab, pass the squeegee over it, and hang up to dry. In this way I have been preparing pieces of tissue thirty by twenty-four inches, and have not had any trouble or failure. You will observe that the tissue only remains about one minute in the bath, which is about the time required for it to become straight, and sufficiently long for such an elevated temperature. The tissue used was "autotype brown," bearing date "8/6/76." Whilst on the subject of carbon let me tell you that it has already been tried here, but some have given it up, finding that it was not appreciated by the colonists, who did not like to pay an adequate price for an unalterable photograph. Others found it was not practicable in such a warm climate. It is now, however, beginning to find favour with some of the best houses here.

Photographers are rather numerous here for the size of the town, and prices vary from ten shillings per dozen to one guinea, the average price being twelve shillings. There are fewer views taken proportionately to our seaport towns, and there seems to be but a very limited sale for them. Of photo-mechanical processes there is nothing at all.

Last month a circular was issued for the purpose of establishing a photographic society here. From some cause or other the attendance was most meagre, and another evening was fixed for the same purpose, but with no better result, and a final meeting was called to see if twenty persons could not be found to establish the society; but, shame to say, only fourteen presented themselves, the leading photographers being conspicuous by their absence. It would certainly be a very agreeable thing if a society could be formed out here, where, apart from the usual meetings, we could embrace the advantages nature has given us, and make one or two photographic excursions during the summer, when the wet and dry processes might be brought into competition with each other, and not only become a source of pleasure for their various advocates, but benefit the colonial photographers generally. Those of my *confrères* out here on perusing this will do well to ask themselves if that spirit of seclusion is calculated to really advance our art-science. We must look a little ahead of our personal affairs, and if we are really lovers of our work we shall then do all in our power to establish a good and useful society, by not only uniting ourselves as a photographic body, but by getting among us a few men who, although not photographers, have still interest in its advancement, and who by their talents and social position will contribute largely towards the society becoming one of renown. It is very much to be regretted that this attempt to form a photographic society has not succeeded. We must not, however, rest here. "Advance, Australia!" is a national password; let not, then, our community be the last on the list.

If Mr. Daniel requires a varnish well balanced in its gummy parts, let him take the following:—

Benzoin	10 parts.
Gum sandarac	7½ ,,
Gum mastic	5 ,,
Spirits of wine	100 ,,

Let it digest for two or three days in the sun or warm water, and when dissolved (less the insoluble matter in the benzoin) a perfect varnish will be the result. Apply with heat.

Apropos of Mr. Johnson's improvements in carbon tissue, can you inform me if any paper is yet made with two or more layers of gelatine, each layer having a different colour? I have had a great deal of trouble in getting the different layers to so bind as to form a harmonious whole on developing. There is no doubt that a great deal depends on the temperature of the liquid after the first coating. I found that thin or weak solutions at a low temperature succeeded best. Too much attention cannot, I think, be given to the temperature. I am sorry to have to say that as yet I am not satisfied with my results, and have given it up for want of time. I feel sure that if the Autotype Company could produce a paper giving the same difference of tone that the albumen paper does they would confer a boon. L. H.

Sydney, January 28, 1878.

RAPID GELATINE EMULSION.

To the Editors.

Gentlemen,—I have to thank you for directing my attention to the gelatine negatives by Mr. Bennett now in your possession.

Permit me as one of the earliest workers with gelatino-bromide emulsion to say that if Mr. Bennett could be induced to publish his formula for gelatine emulsion he would doubtless confer a favour on many amateurs who work the gelatine process. The results of his researches, as exhibited in the remarkable negatives now at your office, are in rapidity far beyond anything I have been able to produce.

Will Mr. Bennett tell us how it is done? He would thereby oblige, among others,—Yours &c., "Franklin."

March 20, 1878.

The Camera on Mount Tongariro.—We learn from our contemporary, *The Colonies and India*, that the celebrated burning mountain of New Zealand, Tongariro, has at last been explored by an Englishman, Mr. P. F. Connelly, a sculptor, who has recently succeeded in ascending to the summit. The volcano is regarded as *tapu*, or sacred, by the Maoris, who have hitherto resisted all attempts to explore the mountain on the part of the colonists. Though he did not meet with any personal resistance, Mr. Connelly found every obstacle placed in the way of his progress by certain of the natives, who took possession of his horses, guns, saddles, and nearly all his outfit, including his sketches. He, however, overcame all resistance, and, by the help of some chiefs more friendly than the rest, succeeded in thoroughly exploring the crater, took a number of sketches and photographs of the locality, and determined the positions of the most important peaks. The exploit promises to have permanent results by opening up the hitherto unexplored portions of the colony to adventurous tourists; and as it has been achieved without forfeiting the goodwill of the superstitious natives, it will, no doubt, be emulated by other explorers, and thus will be the means of affording a new field for scientific and artistic research.

EXCHANGE COLUMN.

Several good cameras offered in exchange for cabinet burnisher or good backgrounds.—Address, A. Lee, photographer, Walcot, Bath.

I will exchange a 10 × 10 square bellows-bodied camera, with three double dark slides, in leather case complete, for a good posing chair or anything useful.—Address, J. White, photographer, Littlehampton.

I will exchange a Voigtlander's rapid B lens, cost £8 17s. 6d., for a good whole-plate lens, three and a-half inches in diameter, and about nine inches focus; maker's name no object, but a trial required.—Address, H. Dyball, 3, Lower Notting Hill-terrace, W.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

*** We have received just as we are going to press, and consequently too late for insertion in this week's number, Mr. Brightman's paper on *Whims and Fancies of a Landscape Photographer.* By some oversight it was omitted to be forwarded with the report of the meeting which appeared in last week's issue.

Geo. D. Wilson.—The letter has been forwarded.

E. F. G.—You do not distinguish between moonlight *pictures* and moonlight *effects*.

Stationer.—We strongly disapprove of such an application of photography as that about which you write.

W. (Manchester).—The advantage of cadmium over ammonium lies in its producing a much more stable collodion.

S. H. Lee.—A better landscape negative can be obtained by making use of a landscape lens than by means of a portrait lens with a small stop.

Philo (Hornsey).—Of the various processes mentioned in your list the collodio-albumen yields the hardest film, and for this reason will best serve your purpose.

T. B. B.—A mixture of perchloride of iron and tartaric acid for producing ceramic photographs was patented in this country by M. Poitevin, but the patent has long since lapsed.

X. Y. Z.—Unless you support your statement by adding your name and address we cannot insert it in the Journal. It is probable that you misconceive the true facts of the case.

G. B. Stanton.—Gold is precipitated by protosulphate of iron, and silver by metallic copper. In all other respects you are correct. We shall be glad to learn how you have succeeded in your lecturing experiment.

George Scott.—By having a hinged table placed upon the top of the camera-stand the camera may be directed upwards towards the sky when you employ it in the printing of transparencies by the collodion or other process.

W. H. A. T.—Sometime ago we made numerous trials of Cook's patent camera, and were much pleased with it. We invariably succeeded in transferring the sensitive plates from the receptacle to the exposing-plane without a single hitch.

Etonian.—If a glass vessel suitable for the purpose can be obtained so much the better; but in the absence of such a vessel an enamelled saucepan will make no bad substitute; indeed, if the enamel be good, it will answer quite as well as the glass vessel.

Cyanide.—No such serial as the *Stereoscopic Magazine* now exists. About twenty years ago a magazine bearing this designation was published by Mr. Lovell Reeve. It was issued monthly, at half-a-crown, but was discontinued after a short time.

F. Anderson.—The series of articles on colouring photographs which have recently been published in this Journal will be found to form the best manual of practical instruction in that art that has yet appeared. The complete series can be obtained on applying to our Publisher, all the numbers being still in print.

Geo. Hardy.—1. To produce a negative having a granulated grain obtain a piece of granulated cardboard, and allow a beam of light to fall obliquely upon it; then photograph it.—2. A letter addressed to Messrs. Brown, Barnes, and Bell, Liverpool, will ensure your obtaining all the requisite information regarding the working of the patent process.

L. Sims.—The dingy, fogged, whites in the developed enlargements are most unmistakably due to the want of acid in the sensitising solution. Add a large proportion of glacial acetic acid to the silver bath, and you may depend upon getting perfectly clean pictures by adhering to the method you have sketched in your letter.

Obliged Reader.—1. Bitumen of Judea may be obtained from any drysalter.—2. The lecture will be published in the course of the ensuing summer; but it, and the others of the series, will necessarily lose much of the value attached to their delivery by the absence of the numerous illustrative experiments by which they were accompanied.

Opticus.—Lacquer that will dry bright when applied to cold brass can certainly be prepared—a fact of which we shall be happy to afford you ocular proof if you call at our office in the course of any forenoon, bringing with you a slip of polished brass upon which to try the experiment.

An Old Friend.—Yes, it was one of the best processes at the time the statement was made; but that was fourteen years ago, and photography has not been standing still during the period which has since elapsed. We never offer any opinion as to which lens or camera, or whose collodion and chemicals, are best; and hence recommend you to study carefully our advertising pages.

F. R. S.—Several formulæ have been published for producing alabastrine positives. The following is one which we have not tried, but which is said by a friend to produce quite as fine results as any that have ever been published. After fixing the collodion positive with cyanide of potassium wash it thoroughly, place it on a levelling-stand, and pour over it the following solution:—

Saturated solution of bichloride of mercury in hydrochloric acid	12 minims.
Protosulphate of iron	20 grains.
Nitrate of potash	12 ,,
Alcohol	½ drachm.
Distilled water	1 ounce.

The application of this will probably cause the picture to disappear at first, but it will speedily reappear, having a delicate pearliness in the whites. The full effect will be obtained after it has remained on from about fifteen to thirty minutes.

Watson and Son's Trade Catalogue.—We have received from Messrs. Watson and Son, High Holborn, their new catalogue of photographic lenses, cameras, and apparatus. The number and variety of secondhand high-class lenses and apparatus by the first makers in the world here catalogued is truly wonderful, the classification in the work being such as to render quite easy the selection of a lens to suit any given purpose or the expenditure of any predetermined amount of money. The catalogue consists of forty well-filled pages, and its mere perusal is highly suggestive.

Photographing on Wood.—It is one of the conditions under which photographs must be properly reproduced on wood for the engraver that there shall be no varnish or skin to clog or impede the free action of the graver. Hence collodion proves inapplicable. Carbon is much better, but it, too, is disliked by wood engravers on account of the gelatinous substance of the picture. Mr. T. J. West has just perfected a simple process by means of which every objection is done away with, an extremely sharp picture being printed upon the wood with great certainty. Several specimens executed in our presence, and now on view at our office, have elicited expressions of satisfaction from wood engravers who have examined them. We shall refer to this subject in an early number.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 934. Vol. XXV.—MARCH 29, 1878.

BLOCKS FOR WOODBURYTYPE PRINTING.

Those conversant with the Woodbury process of printing are well aware that in practice—that is, as carried out by the three or four firms in the world who execute work of this kind—the metal printing block is produced from the gelatine relief by pressure, the most extreme pressure being required. Up to the stage at which the services of the hydraulic press are demanded the process is one within the range of every photographer; for, as may well be imagined, in the production of a gelatine relief is not involved the necessity for possessing apparatus other than may be found in every studio.

We have received inquiries as to whether it is not possible to produce Woodbury printing moulds or blocks by other means than the expensive hydraulic press. In the following remarks will be found an answer to questions of that nature.

As an historical fact the Woodburytype process of printing had been in existence for some time, and many examples of the process had been produced and issued, previous to the conception of the idea of using the hydraulic press. All the first specimens of Woodburytype —several of which are still in our possession—were obtained from electrotypes. In the description of the process published in this Journal on March 17th, 1865—more than thirteen years ago—special mention was made of the fact that the printing surface was obtained by means of the electrotype process. As we know that some excellent results were obtained by that method, not only by Mr. Woodbury but by others—and particularly by Mr. J. W. Swan, who about that time sent us some fine specimens of the process of "photomezzotint"—we give a brief extract from the article by Mr. Woodbury to which allusion has been made. He says:—

"A copper mould is obtained by exposing a sheet of bichromated gelatine behind a negative, and exposing to parallel rays of light; then washing away the undissolved portions and taking an electrotype cast in copper. This mould is then backed with gutta-percha, and placed in a suitable press having a sheet of plate glass, with strong springs, let into the back."

In the specification of his patent, published about the same period, Mr. Woodbury described in what manner the surface of the relief might be rendered conducting, namely, "by brushing it over or otherwise coating it with bronze powder, plumbago, or silver precipitated in metallic form." Our object in mentioning this is to show that the expensive hydraulic press, although a desirable assistant in the production of Woodburytypes, is by no means an indispensable adjunct to that process.

Another and still simpler method is that of producing the metallic printing-block or mould by means of fusible metal. It has been found that if the gelatine relief be mounted upon glass so as to retain it in a perfectly flat position, and a border of wood or any other suitable material be placed round the picture, an accurate cast of the gelatine picture, with its heights and hollows, may be taken in fusible metal. This metal, as every tyro in chemistry is aware, is an alloy in which bismuth is invariably present. It may be compounded in such a manner as to have its melting-point so low as to cause little or no apprehension that the glass plate will be cracked, more especially if the plate be warmed before the molten metal is poured upon it. It is found, however, that in cooling the lower surface of the metal rises up from the glass in some parts—an objection quite fatal to its application to Woodburytype. But the ingenuity of Mr. Thomas Bolas has proved more than sufficient to meet this difficulty, as was demonstrated at a recent Cantor lecture before the Society of Arts. Running to earth the evil complained of, Mr. Bolas found that it was caused by the solidification of the melted metal being commenced at the upper surface, and he argued that if the opposite state of things were established a uniformly sharp casting would be the result. To induce this condition Mr. Bolas, when making a Woodburytype cast in fusible metal, keeps in readiness beside him a vessel containing hot sand, and as soon as he has poured his melted metal upon the glass plate, which is lying in a horizontal position, he immediately covers it with a mass of the hot sand. In this way the upper stratum of the metal is kept in a state of fusion while the lower portion is becoming solidified by contact with the glass plate.

As we believe the method just described is capable of yielding good results, and may be very valuable for experimental purposes, we shall give a few formulæ for the preparation of fusible metal suitable for the purpose indicated. First of all, we would inform those whose knowledge of metals, and especially of alloys, is limited that by melting together two metals the alloy resulting from such mixture may be one not necessarily possessing any of the properties of either of "its parents" or the components of which it is formed, but have qualities altogether distinct from them and peculiar to itself. Thus, copper and tin are both soft and ductile metals; but if only one part of the latter be mixed with nine parts of the former, the rigid "gun-metal," which can neither be drawn nor rolled, is produced. By increasing the proportion of the softer metal an alloy is obtained possessing such hardness that it cannot be cut with steel tools, while the red colour of the copper entirely disappears, giving place to a silvery whiteness, as in speculum metal, which is thus compounded. In a similar manner does the metal bismuth change its properties and induce a similar alteration in certain other metals. Its point of fusion is 480° Fahr., and yet when melted with other metals, some of them having a melting point far above this, it produces an alloy or metal (in the non-chemical sense) which will quickly melt if placed in hot water. The following formulæ may here be fittingly introduced:—

Lead, five parts; tin, three parts; bismuth, two parts. This alloy will melt in boiling water.—Bismuth, eight parts; lead, five parts; tin, three parts. This is more fusible than the former.—Bismuth, five parts; lead, three parts; tin, two parts. This melts at 15° below the boiling-point of water. If to the last formula be added one part of mercury the point of fusion is reduced to 172° Fahr., the alloy becoming solid at 140° Fahr. The fusible metal employed in the experiment brought before the Society of Arts, and to which we have already referred, was composed of—bismuth, seven parts; lead, four parts; tin, three parts; nickel, one part. The last mentioned is stated to possess properties distinct from the others; but we cannot yet speak of it from our own experience as we can of the others.

Mr. Woodbury has shown that an excellent and sharp impression may be obtained from a gelatine relief by superposing a sheet of tin foil and dabbing it with a brush. This method used in conjunction with gutta-percha and pressure, with plaster of Paris, or with fusible metal, ought to prove of exceptional value.

PERSONAL NEATNESS IN OPERATING.

Though the old public conception of a photographer as a man with a velvet coat, black hands, and linen of doubtful appearance, unjust as it was, has given way to more reasonable ideas before the advancing status of the photographer of today, there still remains a substratum of truth underlying it. Yet in the actual necessities of busy studio work we see little reason why photographic operators, with the exception of an occasional silver stain, should be any different in their appearance from ordinary unprofessional mortals. Being—outside our editorial chair—in some sense part of the "public," we are, perhaps, better able to look at the doings of professional photographers from an outsider's standpoint, and we thus hear and see many things that the photographer himself would be little likely to hear. We are aware that some persons consider that professional peculiarities should manifest themselves by personal eccentricities; but, to pass that point by as beyond our province, we may be allowed to say that there are some points beyond which it would be unwise, for pecuniary reasons, to pass. Thus, very recently, a lady coming out of a photographer's, after an unsuccessful attempt to have baby photographed, and was heard to say, speaking of the operator, who affected the peculiarity of unkempt locks to a monstrous extent—"No wonder baby would keep crying in front of such a head of hair as that!"

Can any reasonable reader question the truth at the bottom of this little speech? If operators will make themselves unlike other men they must expect to be objects of distrust in the minds of tiny sitters. We confess that to keep cool, physically and mentally, in a close studio and amid the continual worry that besets photographic portraiture must be no easy matter, if even it be possible at all; but that a presentable appearance, even on the busiest occasions, may be preserved we have had proof in various studios we have visited. We have been in one where, half an hour after work had begun, the operator was in a mess, and so he continued till the day was over. In fact, it was his normal state. He could not have taken a picture, we verily believe, if he had clean hands and face; his pictures would go all wrong. Something would be the matter without his feeling what it was exactly. Dirt and untidiness were that man's second nature, and he could not fight against it. On the same day on which we saw this gentleman last we walked, later on in the afternoon, into another studio during a momentary lull in work, and found the operator drying his hands on a towel, having taken advantage of the five minutes to wash his hands slightly—"A fellow can work so much better with clean fingers," he said. This was the key to his appearance, which was just as clean and neat as the other was unclean and untidy. As to their work, artistically speaking, there was little to choose between them; but how much more at ease the latter must have felt when he numbered among the clients of the day many lady sitters! and how much more likely they would be to frequent a studio like his rather than the first named! He told us that he found it necessary to be most particular about cleanliness and freedom from dust in the studio. Everything he used he insisted upon being kept scrupulously clean; and he carried out the same system in his dark room, with great advantage to the cleanliness and evenness of his plates.

We have no doubt a hundred voices will be raised to say it is impossible to keep the hands at any rate free from stains, and that cyanide is too dangerous to be always rubbing their fingers with. Before making a few remarks upon the best detersives we would say that such stained hands as are most frequently seen are not by any means a necessity; it is possible to develope a great many plates and yet have but few stains on one's hands. This is our own experience, and it is borne out by many photographers of our acquaintance. But care must be exercised; and it will be found that the photographer with the cleanest hands will most frequently have the cleanest plates. It will be a sign that he frequently washes his hands, and the handling of plates in their various stages by hands only half cleaned of previously-used solutions is a fertile source of stains. A great help to clean hands will be found in the use of developing holders—"old women's dodges," we have heard them called by the untidy men. That one of suitable shape is no hindrance to quick work we are well assured; we have found, with many others, an actual advantage from their use. We have employed one consisting entirely of india-rubber, mounted on a long handle, and after many trials we have arrived at the conclusion that the plate can be taken out of the holder, and held *in situ* to commence development, with greater rapidity than can be obtained without the intervention of any instrumental aid.

We have in our mind as we write a very clever operator who produces exquisite negatives, but whose hands are never fit to look at, and he informs us that latterly he has been subject to an eruption on them every spring. This may or may not be owing to the continued exposure to the action of photographic chemicals; but nothing is more likely than that this should be the cause, for to see him develope is something wonderful. He dexterously poises the plate on the tips of the finger of his left hand (a wise precaution to avoid stain on the plates) and pours the developer on and off from one corner to another as he deems best, and the way he moves and sways the plate about suggests nothing so much as that he is actually fondling the beautiful pictures he is calling into existence. He is absolutely and utterly regardless of his hands. The developer runs down his fingers back and front, all over his wrists, lodges in the palm of his hand; still he goes pouring it on and off, hugging his picture till all is dissipated. Half-a-dozen negatives submitted to this process leave his hands indistinguishable from his coat, save, perhaps, an occasional brilliant streak of white proclaims that still one spot has been untouched by the stain-carrying fluid.

Granting, however, that some stains must be contracted during a busy day's photography, we may pass on to say something about the means of removing them. A reference to previous numbers of this Journal will show that a multitude of plans have been proposed; and yet a reference to our "Answers to Correspondents" columns will also show that either they have proved inefficient or that they have not been seen by some readers. There are few of them that we ourselves have not tried as soon as they were recommended; but most of the new ones have failed. Taking in the first place articles of dress, shirt cuffs, and pocket handkerchiefs, always the first to suffer, nothing possibly can be wanted to improve the processes we already possess. A strong solution of iodine (iodine and iodide of potassium, one drachm of each added to one ounce of water) used first to dress the silver stain, will convert it into iodide of silver, which will entirely be removed upon the application of cyanide of potassium, and leave the fabric as clean as when first it left the loom. Iron spots are removed with greater difficulty by soaking in dilute "muriatic acid" (one of acid to four of water), or hot solution of oxalic acid, same strength, till the stain disappears. The fabric must then be well rinsed in rain or distilled water, as the stains will reappear if washed in spring water.

For cleaning the hands the chief suggestions in another direction have been the use in some form or other of chlorine. We are sorry to say that in our hands they have not by any means borne out the enthusiastic recommendations of their inventors. To such an extent has this been the case—and recommendations have been given by well-known names—that we endeavoured to find out a cause for the discrepancy, and this, we feel sure, we have done. At the close of a day's work an operator finding his hands all over stains puts them down at once to *silver*, and, trying all his known plans to get rid of them, hits upon some chlorine mixture, which has the desired effect, and forthwith he publishes the new means of removing silver stains, when the fact is all the while that it is not a silver stain at all he has made to disappear, but one from pyrogallic acid! This, we are sure, is the whole secret of the matter.

Pyrogallic acid leaves an inky-toned stain quite different from the warm brown that a simple solution of nitrate of silver causes when applied to the skin, and differing also, but less so, from the colder-toned stain given by the iron developer when mixed with silver. Hence we find that for pyro. stains the chlorine mixture answers well, and also the chromic acid. But for silver stains on the hand the same treatment we have just described for articles of dress is all that can be desired. In place of the final cyanide strong ammonia may be used, which destroys the yellow of the iodine, and leaves a mark behind like dirty white paint—undissolved iodide of silver. If even this slight mark be objected to, the ammonia may be replaced by cyanide, which (with its attendant risks) would remove all the iodine and the silver marks.

We find chromic acid very useful in its place as above, and have not felt any unpleasant or injurious effects from its use. It is next to impossible to wash the stain entirely away by simple cold water, but a little of the strong ammonia used causes it to disappear at once when washing under the tap, and it is further calculated to leave the hands free from any trace of the powerful acid—a contingency which might lead to evil results.

RECENT PATENTS.

No. V.—EASEL ALBUMS FOR EXHIBITING PICTURES.

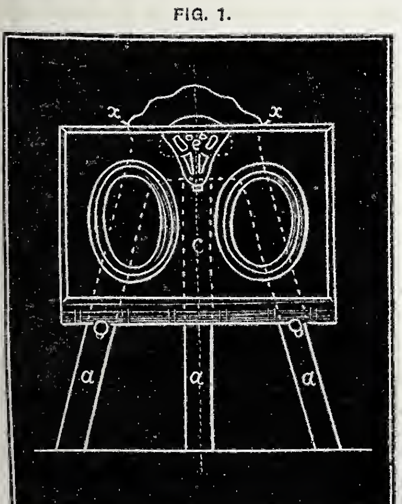
As a fine stone has its beauty enhanced by its setting, so does the method by which a fine photograph is displayed conduce to the effect it produces. For this reason will professional photographers, in particular, look with interest upon every new appliance capable of displaying their pictures in such a manner as to catch the public eye, and thus create a favourable impression.

The following invention, designated "Improvements in Easel Albums for Exhibiting Pictures," has been patented by Mr. John Caspar Koch, of Berlin, and relates to what are known as easel albums for exhibiting a number of photographic or other pictures at once. The invention consists, first, in an assemblage of mounts capable of being displayed in a fan-like form above the album, and of being contracted and slid down into the body of the album, where they are concealed from view. By the adaption of this novel feature to easel albums, their appearance is improved and increased space is obtained for exhibiting the pictures.

The invention also consists in the means hereafter described for operating this fan-like arrangement of mounts, whereby the pictures they contain may be suddenly displayed to view; and it further consists in improved means for facilitating the insertion and withdrawal of pictures, more especially in glazed mounts, to avoid damage to the picture, and in a supporter or leg hinged to the clasps attached to the cover of the album, and which, when the album is opened and the cover turned down, places itself on the table in such a manner that the leaves of the album are supported in a favourable position for inspection.

In order that the invention may be more readily understood, the patentee describes it in detail with reference to the accompanying drawings, in which *fig.* 1 represents a front elevation of the easel album closed; *fig.* 2 a similar view open, and the whole of the pictures displayed; *fig.* 3 represents a vertical section of the same, taken on line *a*, B, *fig.* 2; and *fig.* 4 represents a front elevation, partly in section, the leaves being removed to show the mechanism for operating the fan-shaped mounts at the top.

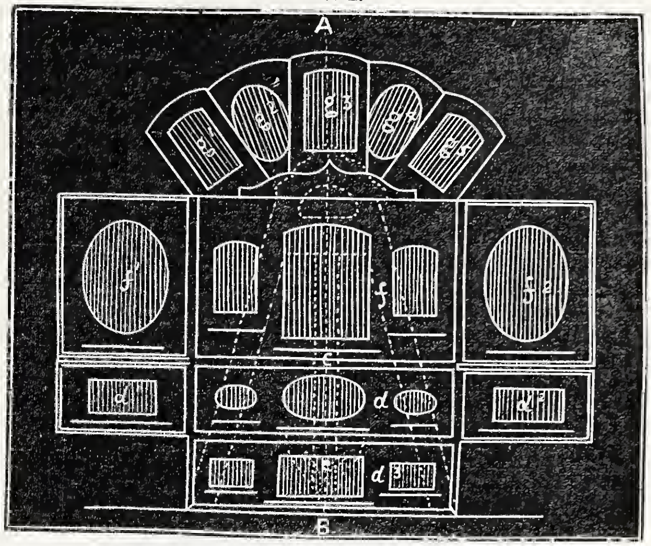
FIG. 1.



The album is of book form, and fixed on an easel *a*, to which the back cover *b* of the album is rivetted or otherwise secured. The front cover *c* drops down in a forward direction to display the pictures contained in the leaves, d^1, d^2, d^3, attached thereto, and in the leaves f, f^1, f^2, all of which open out as shown in *fig.* 2. So far the easel album is much as usual.

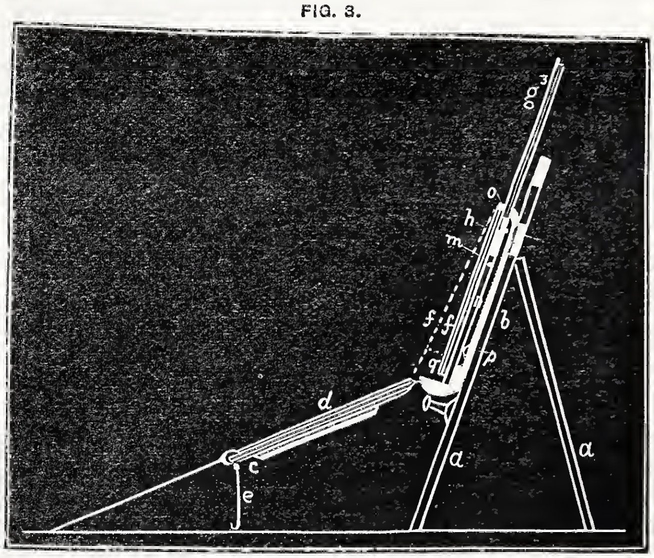
According to my invention the cover *c* is supported in the position represented in *figs.* 2 and 3 by a leg or support *e* in the form of an ornamental plate, which is hinged loosely to the clasp of the album,

FIG. 2.



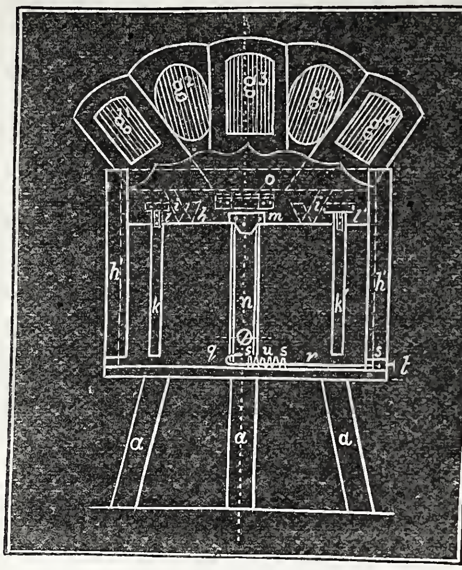
as shown in *fig.* 1, so as to assume a vertical position and stand upon the table, as shown in *fig.* 3, when the cover *c* is dropped down. g^1, g^2, g^3, g^4, g^5, are the mounts arranged in a fan-like form, and projecting above the top of the book portion of the album when in their raised position. These mounts are carried on a horizontal bar *h* fitted to slide up and down between guides h^1 at either side of

FIG. 3.



cover *b*, the said bar being also furnished with studs l, l^1, which work in slots or grooves k, k^1, lined with tin in the cover *b* and serve to retain mounts g^1, g^2, g^3, g^4, g^5, and prevent them rising too high. The middle mounts g^2, g^3, g^4, are in one and are rigidly fixed to the bar *h*, while the side ones g^1, g^5, are capable of swinging inwards towards the central mount g^3, passing in front or behind the intermediate mounts g^2, g^4. The lower edge of the side mounts g^1, g^5, which rest on the bar *h* is oblique, as shown by the dotted lines, in order that the mounts may be inclined at the proper angle, and the inner corners are rounded and roll on the bar, the mounts swinging as on a pivot, or they may be pivotted at this corner. The side mounts when drawn up free from the guides h^1 are caused to spread outwards by elastic bands *i*, by which they are connected at bottom to the bar *h*, and when the fan-shaped mounts are pushed down these side ones, g^1, g^5, are gathered inwards by the guides h^1. The bar *h* is drawn up to the position shown by an elastic band which lies in a vertical groove in the back cover *b* of the album, and is attached thereto at one end by a rivet *p*, the band passing over a pully *o* at the top of the groove, and being connected at the other end to the bar *h* by a U-shaped metal staple *m*. When the mounts *g* and bar *h* are pushed down to their lowest position, a spring bolt at the lower part of the album engages with this staple *m* in order to retain the mounts in the lowered position and keep the elastic band end stretched in readiness to cause the mounts *g* to spring up suddenly immediately the bolt is released. This bolt is a square rod *r* fitted to slide in two fixed guides, *s s*, between which, on the bolt *r*, there is a spiral spring *u* which tends to keep the hooked end *q* of the bolt engaged in the stable *m*. *t* is a knob at the other end of the bolt *r* projecting at one side of the album, as shown, and by pressing which the bolt is disengaged from the staple *m*. The leaves *f*, f^1, f^2, are attached by hinges to a plate behind them,

FIG. 4.



so that they can be raised, as indicated by the dotted lines in *fig.* 3, when photographs are to be inserted. On the outside of the front cover *c* there are glazed frames or mounts for the reception of photographs or other pictures as usual; and to facilitate the insertion of the said pictures and enable them to be readily withdrawn when desired, pockets, sheaths, or envelopes are provided in which to encase the pictures before inserting them through the slit in the frame or mounts, the said pockets having openings corresponding in shape and size to those of the frames or mounts, so as not to interfere with the view of the picture. The said pockets are made of cloth or paper and provided with tabs *x*, *fig.* 1, to facilitate the removal of both pocket and picture.

The special claims consist in the following:—

1st. In an easel album, the assemblage of fan-like mounts constructed to slide up and down in the album, and to be expanded or displayed, as shown and described, together with the means by which they are so raised and displayed, substantially as specified.

2nd. The self-setting hinged rest or support, *e*, in combination with the fall-down front cover of an easel album, substantially as and for the purpose specified.

3rd. The employment of pockets, sheaths, or envelopes provided with tabs and having openings to display the pictures for the purpose of enabling the pictures to be readily inserted in and withdrawn from the glazed frames or mounts of albums, as described.

A SENSITIVE GELATINE EMULSION PROCESS.

To give full particulars of the negatives alluded to by "Franklin" and yourselves is a difficult task, inasmuch as it is not that there is much difference in the emulsion itself as that I have to point out so many items in which great care with the materials and manipulation will, combined, secure the desired effect, viz., a very rapid negative. To such of your readers as will carry out every point faithfully to the letter I can hold out full hope of success. I shall keep nothing back, so that it will lie with them to get the same rapidity. We shall have all the materials in common excepting one, and that is the washing water.

First, then, the light. I have tried "warranted non-actinic" and "tested by spectrum analysis" glass, and can print transparencies through two thicknesses of such in about thirty minutes. Procure therefore, from a glass merchant, some of the *darkest* shade of ruby, and use two thicknesses for daylight and one for lantern. This is positively necessary, as we are to use a very powerful developer upon a very sensitive plate. If gelatine workers were careful on this point I think we should hear less of "organifiers" or "want of density" than at present. I never have any trouble on that score, because no actinic light having touched the emulsion I can apply any amount of development without any danger of fog.

To make "assurance double sure," use a ruby-coloured hock bottle, and with two eight-ounce decanter-shaped bottles made of test tube glass to stand heat—procurable at Rouch's and, doubtless, elsewhere—weigh out for a ten-ounce emulsion—

Bromide of ammonium	7 grains.
Best nitrate of silver	11 ,,
Gelatine	20 ,,
Distilled water	1 ounce.

Use Nelson's "No. 1 photographic gelatine," for with the opaque sixpenny packets you have irregularity, red fog, and frilling. Place aside four ounces of water for the bromide and two ounces for the silver; dissolve the bromide with heat in one of the test bottles in one or one and a-half ounce of water; pour into the hock bottle, swill out the test tube with the remainder of the four ounces set aside for the bromide, and also pour in. I do it by heat to ensure all being dissolved, as it does so very slowly *after* the gelatine is inserted. The four ounces of solution being now almost cold add the gelatine, shake up well, and place in two or three gallons of water at 90°. I use a fish-kettle with lid. In two hours the bromised gelatine will, after well shaking, be quite liquid, and also nearly at 90°. Now dissolve the silver in the other test bottle by heat in one ounce of water, cool to 90°, and pour in; use the remainder of the two ounces set aside for the silver to swill out, heat to 90°, and pour in. By being so particular we get regularity and are able to mix the plates of different batches, which is a great boon. Shake the emulsion very briskly and replace in the kettle for two, four, or seven days, according to rapidity required. The temperature should never be over 90°; if you do not let it exceed that you will not have red fog. "Cosy" it up with flannel, and it will not lower many degrees during the night. I, however, use a stove two feet across and place it on that; a faint gas jet below keeps it always at 90°. I shake up every twelve hours. If washed in two days the emulsion is rapid and dense; in four days more rapid and less dense—quick enough for any drop-shutter known, when developed as below. With some that I kept for seven days, with drop-shutter and dull February morning pebbles close to the camera were perfectly exposed. The negative was thin under ammonia, but bore intensifying to any extent.

Cool the emulsion in a bottle not smaller than a Winchester quart, and wrap it up in brown paper to exclude all light except the lip of the neck. Let an india-rubber tube go quite to the bottom of the bottle to stir away those layers of water which, on account of greater specific gravity by reason of the salts they now contain, would otherwise remain there. Wash for twelve hours; a dribble is sufficient. Upon melting you have eight or nine ounces of emulsion; add three-quarters of an ounce of pure alcohol, heated to 90°; fill up with water (also warm) to ten ounces, and coat. The plates should be only lukewarm, or you will have red fog. Expose a few plates with small stops—instantaneously; gradually increase the size of stop or length of time.

To develope I use for $6\frac{1}{2} \times 4\frac{3}{4}$ one ebonite tray $8\frac{1}{2} \times 6\frac{1}{2}$ for ammonia, one ditto for silver, and one 10×8 to cover over either during development to keep all light off. After soaking a minute pour the following quickly along that side of the tray which is not occupied by the plate, and by rocking the dish suddenly send it sweeping over the plate (it is developed in five to twenty seconds):—

Pyro	1 grain.
Bromide	*none.*
Pure undiluted liquid ammonia	1 to 10 drops.
Water	1 ounce.

Do not flood with pyro. first or you will render the plate slower, nor add more pyro. or you will again slow the plate and, moreover, have it too dense. If the exposure has been sufficiently short you should have a dense negative with bare glass for shadows almost as soon as the developer has covered it. A 10×8 Dallmeyer triplet, with drop-shutter, would require in good light (say) four drops of ammonia; if bad light, eight to ten drops. A six-inch single lens, in good light, would require (say) one drop; in bad light, four drops. If much ammonia be used and the plate be not developed in half-a-minute, make fresh developer and wash the plate.

Being now in possession of some extra sensitive plates, put one in a thick book, and, having placed it five or six inches from your ruby glass window or lantern, draw out the plate one-third for a few minutes; again draw it out further one third more for a short period. You will then have the film in three divisions, as it were—one portion not having been exposed to the red light and the other two portions having had different exposures. Now develope, and use (say) three drops of ammonia. If your light be still at fault the exposed portions of the plate will fog; in that case use another thickness of ruby glass.

Finally: I need scarcely wish success to those readers who desire the same rapidity as my negatives alluded to in your last issue exhibit, because success is certain, provided *no* modifications of the foregoing particulars are made. CHARLES BENNETT.

WHIMS AND FANCIES OF A LANDSCAPE PHOTOGRAPHER.

[A communication to the Bristol and West of England Amateur Photographic Association.]

LIKE all other photographers I have my whims and pet theories, and although many of my ideas may be simply "fancies," the narration of them will perhaps lead us to a discussion during which some useful remarks may be elicited. I should state that the whole of my remarks may be taken as applying to landscape work only, as several of my "whims" as applied to portraiture would need considerable modification.

Many of our members, doubtless, anticipate that my "whims and fancies" will take the form of a recital of certain pet formulæ; this, however, is not my intention, for one of my strongest whims is an utter dislike of anything like a formula. One of the great weaknesses of photographers is a blind adherence to certain formulæ instead of an intelligent appreciation and application of the principles of the photographic art. The conditions under which a landscape photographer works are so varied that the use of fixed formulæ, instead of tending to success, only leads the photographer into difficulties.

One of the most varying influences under which we work is that of temperature. At one time we may be working in an atmosphere of 90°, and at another with the thermometer at freezing point. What can be more absurd than the idea of using the same formulæ under such widely-different conditions? Take, as an example, development under such circumstances, and what would be the result? The developer that with the high temperature would cause the picture to flash out with the rapidity of lightning would under the influence of the lower temperature possibly fail to bring out any of the deep details of the picture. Yet how frequently do we hear that success depends upon using a developer containing just so many grains of iron and so many minims of acetic acid, and that the slightest variation leads to certain failure! *Apropos* of this subject I may give an anecdote which, though rather an old one, is too good an illustration of my meaning to be omitted. A certain photographer—perhaps not one of the most successful—met a brother of the art whose work was always of the highest merit and universally admired. Our unsuccessful friend does all in his power to make the acquaintance of the other, and with note-book in hand inquires how his toning is done, how his enlargements are made, and carefully notes down all particulars, asking so many questions as to become somewhat of an annoyance. At last he comes to the all-important question—"How do you mix your developer?" He receives the answer—"With brains." Out comes the note-book again—"Mem.: developer mixed with brains. Thank you; and how do you make your bath?" "With brains also." Possessing just sufficient brains to see that he was getting the worst of it our friend quietly retires. Let us hope that the lesson was not lost upon him, and that he found out that there was something more to be learned in photography than a blind adherence to a formula.

I think I have said sufficient in support of my first whim to show the necessity of varying our formulæ according to the conditions under which we are working, and that a careful study of the action of the various chemicals and a judicious application of our knowledge is more to be relied upon than a strict adherence to a mere formula.

I will now glance in succession at the various operations in the taking of a negative, giving my whims in connection with each, and attempt to give a good reason in support of each of my fancies.

First, then, let us consider the cleaning of the glass plate. Simple as the operation may seem it is one which is the groundwork of success, for with a dirty plate it is impossible to succeed. For new plates nothing can be better than the application of a mixture of alcohol and ammonia rubbed well over with a tuft of clean rag. New glass should require nothing further than this, the chief impurity which we have to remove being simply the result of greasy finger-marks. For this purpose acid is worse than useless, and instead of removing a grease-mark only makes matters worse by forming a compound more difficult of removal than the grease itself. Acid is undoubtedly useful for cleaning plates previously used; for if by chance a used plate is put aside uncleaned it will be found covered with a metallic scum, which adheres to the glass with the greatest tenacity. For the removal of such stains nothing can be better than the use of either nitric or hydrochloric acid diluted with water. Rouge and tripoli, though useful and effective as plate-cleaners, I object to, for the reason that particles are liable to adhere to the rough edges of the glass and get carried into the bath. The use of a substratum of albumen has been highly recommended, and though, doubtless, efficacious may carry injurious organic matter into the bath. For my part I am inclined to look upon albumen as an apology for cleanliness and a lazy way of getting over the trouble of plate-cleaning. Such expedients are not advisable, and are too much like putting on white gloves to hide dirty fingers, or buttoning up a vest to hide a soiled shirt front. In order to obtain the best results new glass should, as far as possible, be used, well cleaned with alcohol and ammonia, and finally polished with a perfectly clean cloth kept for this purpose only. While on the present point I may say I am particularly whimsical as to the cloth used for this purpose. If we take a cloth or towel white and spotless as it comes from the hands of the laundress, and proceed to polish a plate, we find that each stroke, instead of removing marks and streaks, only adds to the number. We may rub and polish, and polish and rub, till one's arms ache, and our plate only becomes worse and worse; in fact, instead of cleaning our plate with a *clean* cloth, we are using one impregnated with a concentrated essence of soapsuds. For this purpose I always take a so-called clean cloth and for the time being turn laundress, and thoroughly wash in repeated changes of water, finally washing it out in clean water to which is added an ounce or so of liquid ammonia.

As to collodion: there are now so many good collodions in the market that it may seem out of place to name any maker. I have tried most of the makers of repute, and have only on one occasion had a bad sample. Some makes would seem better adapted to one purpose, some to another; but for general landscape work nothing can be better than bromo-iodised collodion—Hardwich's formula. It flows evenly, gives a smooth, textureless film, which bears any amount of washing, gives a fair amount of intensity without forcing, and for half-tone and detail in the shadows nothing can be better. When slightly aged it will bear a long exposure without fogging better than most other makes. Its keeping qualities are certainly unsurpassed; and, taken for all in all, may be considered for landscape work as one of the best, if not the best, collodion in the market. In thus stating my preference for a special make I would not say one word against others; and, considering the competition and outcry for cheapness, the only wonder is that so many good collodions are to be obtained.

For landscape subjects having heavy masses of foliage or any deep shadows the addition of a grain or two of bromide of cadmium to each ounce of collodion is advisable, as it reduces the tendency to hardness in the high lights, gives detail in the shadows, and tends in all cases to give more harmonious and delicate pictures.

In no case is it advisable to use for landscape work a newly-iodised sample of collodion; as a rule, it is better for keeping until it becomes of a deep sherry colour, when it will bear a sufficiently-prolonged exposure to give all the detail, without fogging in the better-lighted portions of the picture. With a newly-iodised collodion it is almost impossible to expose a picture long enough to get *all* details without risking fog in some portion of the plate.

We doubtless lose in rapidity by using an old and ripe collodion; but rapidity is a matter of so little importance that we need not take it into consideration; in fact, unless we can work so rapidly as to get absolutely instantaneous pictures, I am decidedly of opinion that it is better to work so as to give very prolonged exposure. I should prefer an exposure of three or four minutes to three or four seconds. For running water or cascades it is usual to attempt rapid exposure. Such subjects, as a rule, being surrounded with heavy foliage or dark masses of rock, a perfectly instantaneous exposure is rarely admissible, and it is customary, as a compromise, to give an exposure too long for an instantaneous effect with the water, and too short to give proper detail and half-tone in the deeper parts of the picture. The result is usually a failure. Under such conditions I consider it preferable to prolong the exposure so as to obtain all the detail of the deepest shadows; and the running water instead of suffering will really be improved by the long exposure, the effect being more like a correct rendering of the subject than a semi-instantaneous exposure can ever give. At first sight this may appear somewhat strange, yet if we closely examine a running cascade we shall find that, although at first sight it may appear ever changing, yet there is a constant and regular succession of the same motions and the same forms; and as in gazing at a landscape containing such a subject we do not get an instantaneous impression, but an impression as given by such succession of changes, so I conclude the impression on the plate as given by a long exposure is in effect more natural and lifelike than the effect given by a semi-instantaneous exposure.

As an example I may instance the picture of *A Cascade on the East Lynn*, which, I may say, without being egotistical, is a better rendering of running water than nine out of every ten such subjects. The exposure was in this case, as far as my memory serves me, about forty or fifty minutes; yet the result is certainly natural, and gives the impression of life and motion. This picture I have shown to several experienced photographers, and it has more than once been greeted with the remark—"Of course this is instantaneous." You may judge of the surprise caused by my giving the facts of the case.

Having on a previous occasion given a paper on the negative bath, I should be needlessly taking up your time by any repetition. I may, however, state that I have taken to a fancy in discontinuing the use of distilled water for making the bath; for an examination of the distilled water as supplied by the chemists has convinced me that in many cases it contains a large amount of organic matter, and is, in point of fact, less reliable than water as supplied from the company's pipes, which I now always use for making my bath. The company's water, though it contains a considerable amount of chlorides and carbonates, is fairly free from organic matter, and I have succeeded in making a good working bath, without any preparation, by simply adding the requisite quantity of silver to the water and filtering. As a rule I keep a large glass bottle filled with water standing on a greenhouse shelf in the full sunshine; to the water is added a small quantity of nitrate of silver, which, of course, in the light precipitates the organic matter. I have thus at hand a supply of water for making up a reliable bath at a minute's notice. By acting in this way I think I could make a good working bath from ditch water.

We now come to a consideration of the developing solution. For this I prefer the double sulphate of iron and ammonia to the ordinary protosulphate, the resulting picture being richer and warmer in tone than when the latter salt is used. The reason of this is that the ammonia sulphate of iron is a more nearly neutral salt than the ordinary protosulphate, which contains a considerable quantity of free sulphuric acid. Sulphuric acid has a tendency to produce cold, grey images, as may be readily proved by preparing a developer and adding sulphuric acid instead of the acetic acid as usually added.

In practice I prepare my developer by making a strong solution of iron and adding the required quantity of acetic acid, keeping in this state and diluting as required for use. By so doing I find I get better results and richer and warmer tones than by making the developer of the required strength and afterwards adding the acid. I am inclined to think that when the acid is added to the concentrated solution some organic compound is formed which causes the developer to give the rich, warm tones I have named; when the acid is added to the dilute solution the result does not appear to be the same. On adding acid to a saturated solution of the iron small crystals are precipitated. I am not sufficiently versed in chemistry to understand the composition of these crystals, but presume them to be a modified form of acetate of iron; and it is to the substance so formed that I am inclined to ascribe the good results of a developer prepared in this manner. It will, probably, be suggested that the addition of acetate of iron will produce the same results; but, having tried developers containing acetate of iron formed by double decomposition with acetate of lead and also acetate of soda, I find they do not give the same results, being usually accompanied with a trace of fog and deposit in the shadows, whereas clearness in the shadows is one of the great points in a developer prepared as I have described.

Having during our last session given a paper on iron intensification, it will be unnecessary for me to say anything further on this point; but I may add that the past season has more than ever convinced me of the value of iron intensification.

With these few notes, hastily put together, I must close my paper, which I trust may lead to a conversation more profitable than my few remarks. My regret is that I have not been able to offer something more worthy of your consideration; but want of time prevents my devoting so much attention to the study of our art as I could desire. I am, therefore, obliged to play the part of a butterfly photographer, passing from flower to flower, and sipping the pleasures of our beautiful art-science, instead of diving more deeply into its yet untold wonders and untrodden paths. Such a course leads but to "whims and fancies," where—

"Errors, like straws, upon the surface flow;
He who would search for pearls must dive below."

E. Brightman.

THE EDUCATION OF PHOTOGRAPHERS.

Now that the idea has been mooted that the Photographic Society of Great Britain should take the initiative, and become, as it were, the parent of a school for the better education of photographers, I am desirous of adding a few remarks to a paper on this subject contained in a former publication of this Journal.

With the list of names the Society already possesses—many of them, as the outside public as well as the professional world are aware, containing some of the most prominent men in connection with photography—surely they are the best nucleus for the formation of a photographic school without the infusion of fresh blood into its ranks. But the Society states that they are hampered in starting a scheme to better educate the junior members of the art from want of funds.

The question then arises—"How are these necessary funds to be obtained?" I answer, by a general appeal to the profession, and also to amateurs, for subscriptions and donations.

It must be borne in mind that there are at the present time a great number of photographers who are not members of the above Society, yet who are, without doubt, strongly interested in the future supply of photographic labour. A direct appeal to these gentlemen and others would be scarcely fruitless, and they would, as a correspondent in the *News* of the 22nd instant remarks, be much more likely to become members of the Society if they knew that by doing so they were materially assisting in the formation of what ought really to be called a national project. Supposing even if they did not join the Society, but gave a yearly subscription or donation to a school, they would be greatly helping in a matter in which they had large interests.

Now there are several names in the list published by the Society—if the owners of them could only be induced to interest themselves—that might obtain not only the pecuniary aid of noble and distinguished amateurs, but also enlist the sympathies of royalty in behalf of a scheme which has for its main object the better education of a section of society wherein a vast amount of both capital and labour is annually employed, and which is deserving of the mutual support and assistance of the whole nation.

In conclusion: I may say that there ought to be no real difficulty in applying for monetary help from any one who is in the slightest way connected with the art of photography, and that though the formation of a school might not possibly be of any immediate advantage to them in their days, yet when "the time cometh when no man can work" they would have the pleasing recollection that they had been the direct means of assisting the wants and requirements of the new and rising generation of photographers.

George Cecil Hance.

OUR APPARATUS.

No. II.

The shutter of the dark slide should work easily, and in large cameras, more especially, be of the flexible form. This kind of shutter is of great advantage when attached to cameras for outdoor work, offering no resistance to the wind, and is not so likely to admit light or require the protection of a focussing-cloth during exposure, as in the case of the old form of sliding shutter. It is an advantage to have the back of the dark slide free—that is, not attached by hinges to the frame—in all cameras larger than whole-plate size. A 15 × 12 sized slide, for instance, having an attached shutter is an absolute nuisance, the greatest care being required to prevent it falling at unpropitious times and injuring the plate, or inflicting damage of some kind or other in the semi-gloom of the operating chamber.

The arrangement for capping the lens, especially when engaged in portraiture, is more convenient when attached to the interior of the camera than if the usual plan of a cap on the exterior of the lens be adopted. A flap secured to a rod passed through the camera above the lens with a milled-edged button at each end, one end made to screw so as to retain the flap in any position, like the sky-shade of a lens, and constructed of cardboard covered with black cloth or velvet, the weight of which will always cause it to cover the lens unless prevented by the screw-head alluded to, answers admirably, and has the advantage of not attracting attention like manipulation in front of the camera. But to return to the dark slide.

The wells usually made to catch the drainings from the plate are very little use, as the wires upon which the plate rests conducts most of the solution to the outside rebate instead of into the well. These wire supports should be just *inside* the top edges of the well to make them of any real use, as in the hurry of business it is not always possible to drain the plate as thoroughly as is necessary.

With cameras used for copying it is as well to have a few carriers made with rather broad plates at the corners instead of wires to permit odd-sized pieces of glass to be used up. This is a consideration where patent plate is used, and an economical plan. The strap or handle is frequently attached to the upper side of the camera—a bad plan, for if the camera be heavy the strain on this one side will cause it to bow outwards and interfere with the proper working of the slide, besides the danger of letting in the light. It should be carried by straps encircling it or in a case, so that the strain may be equally distributed.

As the user of a camera is supposed to exercise some sort of care over it, it should be made as light as possible consistent with rigidity, and be brass bound, which, although adding very little to the weight, adds considerably to the strength. A light waterproof cloth will be found useful to throw over it in case of sudden showers. I would suggest, when photography is carried on for amusement, that the whole-plate size should be adopted, with an arrangement for taking two cabinets on this sized plate. One lens and a movable front is better than the more cumbersome sliding back. For the professional photographer an arrangement by which any size less than the largest intended to be worked can be made in the same instrument is very convenient. A good camera should possess rigidity, ease, and smoothness in working in all its parts. A dark slide that is given to stick, and then suddenly to go in or out, is a perfect nuisance; yet how many there are of them!

Easy focussing is another matter necessary to ensure sharp pictures, and screws or racks that work steadily and evenly are a necessity. The focussing-glass must occupy exactly the same plane as the sensitive plate, and be very finely ground. Other prepared surfaces, although they may answer pretty well at first or for a special purpose, soon get scratched and stained. The advantages of finely-ground glass are that lines can be ruled upon it and obliterated at pleasure without injuring the surface. A little soap and water and a damp sponge will restore it, however dirty, to its pristine condition. In case of breakage when away from home, or where a new glass cannot be immediately supplied, a couple of pieces of tape or string tightly stretched across the screen in the place lately occupied by the ground glass will act as guides, and permit pieces of the broken glass to be used for focussing until the loss can be repaired. This plan is particularly useful to those who only take dark slides filled with plates and do the development at home, and cannot, of course, use them as temporary focussing-screens. Old screw-holes should be looked after, especially such as are left after altering a flange, and the whole apparatus should be in a sound, light-tight condition and free from dust.

Camera-stands and tripods must, of all things, be firm, and not given to vibrate by gusts of wind or slight blows of any other kind. I have not found any to supersede for real work the old-fashioned tripod with the legs formed of continuous pieces of wood; that is, not hinged or made to double for convenience of carriage. True, it is rather an unwieldy form in comparison to many ingeniously-constructed modern ones; but it has the advantage of superior rigidity and will stand an immense amount of hard work without injury, which are qualities not to be underrated. The very light ones, I have found, require such great care in use that the saving of weight is but a questionable advantage in comparison. This is a matter, however, that will be decided in most cases by the amount of muscle possessed by the photographer using it.

For the studio a heavy table stand is most pleasant to use for 10×8 pictures and upwards, and lighter ones on castors that can be readily wheeled about from place to place as may be required. A fault in many studios is that, when the table is raised to its greatest height, as in photographing a very tall person, the strain on the rack is too great, and it becomes top-heavy and unsteady in consequence. An extra thumb-screw, working in the opposite direction to the one supplied with the stand, will be found useful. A wedge driven down by the side of the rack will sometimes be advisable. A stand, or rather a table, for copying purposes should have a top not less than three feet long by eighteen inches across, with an arrangement for tilting it at either end and for lengthening it as required.

If there be a room specially devoted to copying purposes this stand should be made to travel on rails firmly fixed on the floor, to and fro from a large board or easel accurately adjusted at right angles to it, and upon which the pictures, &c., to be copied can be placed. I had a sliding table for copying purposes constructed, some nine or ten years ago, which answered its purpose admirably, and was fully described in THE BRITISH JOURNAL OF PHOTOGRAPHY at that time. It was specially constructed with regard to economy of space, the studio I then worked in being of very limited area. In copying small things a mirror laid below the picture to be copied is an advantage. A very useful addition to any copying-stand, or to cameras where several are at work simultaneously (as in interior work), is a small dial or clock face with a hand that can be set to any time, so that when the exposure is began the time is registered and there is no fear of forgetting the "how long" of the exposure, which, in protracted cases, frequently happens if other work be gone on with during the interim.

Plate-boxes are always best with V-shaped or semicircular grooves, unless for storing negatives, when very much thinner divisions than those usually made are advantageous in the matter of economy of space. If they are made of soft wood, a coat of varnish inside and out tends to cleanliness and the more easy removal of dust, which generally accumulates to a greater or lesser degree; and dust being one of the photographer's greatest enemies, any means to render it less obnoxious is to be advocated. Draining-racks are all the better for a coat of varnish occasionally applied, continued application of moisture causing the grooving to warp and leave the framework, which, although not absolutely rendering them useless, is still unsightly, and when the remedy is so easily applied should always be done. E. DUNMORE.

ON PERSPECTIVE.

I FEEL impelled to make a few remarks on a subject which has lately occupied the attention of photographers at the meetings of some of the societies—the perspective representation of objects. It is an old hobby of mine, and one which, when an art-student, I studied practically and mathematically with some amount of success. Mr. Cocking read a very interesting paper grounded on thoroughly correct principles; but it is a little unfortunate that in his desire, I dare say, to be understood by all his hearers—even those not hitherto conversant with the subject—he has used his scientific terms rather loosely, and has mixed up perpendiculars, verticals, and horizontals in a rather vague manner.

In perspective representation, as recognised by artists, there are some points which Mr. Cocking also did not make clear—such, for instance, as that in depicting a given view it is assumed not only that all the objects in it are stationary but also that the eye itself is supposed to be rigid and immovable, one only being assumed to be employed. I will now point out some further principles of pictorial representation.

Between the eye and the view a supposititious plane of glass is set up perpendicular to the axis of the eye; and, as nature is generally viewed with the eyes looking straightforward with the body erect, it will follow that this plate of glass would usually be vertical. Upon this glass lines are drawn corresponding with the appearance of lines in the view, so that, in fact, the lines when drawn on glass hide those of nature. This plate is usually termed the "plane of delineation." There are various rules made use of in such drawings by means of which, when we know the distance of objects and their size and the angle their lines make with the plane—if it be possible to make a drawing whose lines would, if transferred to the plane, exactly coincide with those of nature—a modern photographic lens of suitable focus would give an exactly similar picture. Hence I may say that a correct perspective picture is one when placed at a certain distance from the eye, must produce upon the eye exactly the same impression as the original view would, so far as regards form; but the instant it is placed too far from or too near to the eye, or at an angle other than a right angle to the axis of the eye, it ceases to produce a correct impression.

With regard to Mr. Sawyer's contention, which I shrewdly suspect to hide some paradox, it is pure question of observation in the converging or non-converging of certain lines. It has been settled long ago that if the eye be looking straight out—that is, its axis parallel to the earth, the plane of delineation then being vertical—all parallel lines (whether vertical, horizontal, or slanting) which are parallel to the plane—or, in other words, situated in a plane perpendicular to the axis of the eye—will be parallel when drawn on the plane or when photographed in a levelled camera (the axis of the lens being perpendicular to the film). The parallel lines suggested by Mr. Sawyer fall in this category, and must undoubtedly be photographed as parallel lines if, and only if, the camera be levelled and the lens at a true right angle to the ground glass. This has been proved long since by artists and opticians.

I cannot but think Mr. Sawyer has some clever paradox at the bottom of his assertion. Taking him *au serieux*, it would follow that, if in addition to the vertical lines he names he would draw two horizontal lines across them at such a distance as to include a true square, this square, as its sides are stated to narrow as they are removed from the centre, would come out in the photograph as barrel-shaped—the old distortion that opticians have long ago banished. If Mr. Sawyer were to copy a map in (say) such a manner his clients would very soon return it upon his hands.

In connection with this subject it may be very easily confused by reference to the human eye itself, which is not achromatic, and which is subject to errors of spherical aberration; but it must be remembered that whatever effect is produced on the eye by the parallel lines of nature will also be produced by the smaller parallel lines of the reproduction. Hence we cannot be allowed to distort the lines of our pictures on the excuse that that is how they are seen by the eye; for, if we do this, the already-distorted lines would become still more distorted when viewed.

The moment, however, the eye changes its position, and is directed upwards towards the top of the chimney or map, its axis is not at a right angle to the vertical lines of nature, and a tracing upon the plane of delineation of a chimney or tower so seen, or a view from the camera, would give converging vertical parallel lines.

Captain Abney was as lucid as he was brief in his exposition of the relation of focal distance to truthfulness of representation; but he fell into an error (if he be correctly reported) when he said that vertical lines in a picture taken by a short-focus lens would appear parallel at one distance, but converging when seen from the focal distance. Apart from the aberration of the eye I named—and it exists for any distance or focus—such lines would always appear parallel.

Mr. Sawyer, Mr. Woodbury, and Mr. Davis in the discussion all took the same view, viz., that vertical parallel lines would and should converge, on the ground that the angle subtended by a section of their upper part would be less than that subtended by the part opposite the eye. For a moment putting aside the fact that their assertion has been long since proved both in practice and in theory to be incorrect, it can very easily be shown how they have arrived at a wrong conclusion from correct premisses.

It is true that the top of a tower appears to subtend a smaller angle than that part which is opposite the eye; but the draughtsman's or the photographer's copy of it has also exactly the same effect upon the eye when it is drawn parallel. If, to meet these gentlemen's views, we draw the tower with a narrow top, when we look at it from a point relatively the same as the original was viewed from the top of the tower in the drawing being further from the eye will appear still more diminished to an absurd extent. And in the camera it must be remembered that the expanding beam of rays has further to travel from the centre of the lens to the edge of the plate than to the middle, and hence in the former it has the opportunity of spreading out far enough to preserve the parallelism. All such errors as these would be prevented by accepting the definition I ventured to propose—that a linear perspective picture is one which, as regards form or outline, has the same effect upon the eye as the original objects themselves.

G. Watmough Webster, F.C.S.

THE REACTIONS OF CHROMIC ACID AND CHROMATES UPON SUBSTANCES OF ORGANIC ORIGIN, CONSIDERED WITH REFERENCE TO THEIR USES IN PHOTOGRAPHY.

The photographic chromate processes, to which little attention was paid at first, in course of time attained an unexpected importance. From day to day, from year to year, the interest in these processes increased; and as their influence on art and science increased so did the literature devoted to chromate photography—that is, to the chromates regarded as producers of pictures—swell in bulk.

The attention of chemists and of artists having been thus directed to the subject, the difficulty of condensing what is really known began to be experienced; and, though from the fact of several establishments for working the process having been set moving, the difficulty seems to have been more or less solved by the latter class. Still the photochemist has a difficult task in studying how to arrive at a clear view of the subject, owing to the number of branches into which it is split up, and the defective and contradictory opinions expressed on many points.

In the present paper I have tried to map out the fundamental points of photography by means of chromates, both from the theoretical and practical view of the question. Though I have separated the important from the unimportant, still I have had to take note of small, apparently trifling, variations in the behaviour of the reagents, because, in photography, more almost than in any other case, inconsiderable causes produce great results. On the other hand, in treating of cognate circumstances it is not easy to draw the line between fundamental facts in the chemistry of chromate photography and unimportant practical details, which last should find no place in this paper. As I wished to make a critical study of the former, and thus had to take a sort of general standpoint, I held aloof as far as possible from special formulæ, but to facilitate the comparison of the views of different authors I have given exact reference to the passages alluded to, so as to make a study of the details of the subject treated under each head much easier.

Besides independent experiments, it seemed to me that a careful experimental repetition, and a thorough sifting of the materials already accumulated by the observations of others, would be of value in acquiring a rational basis for photography with the chromates. I have repeated the greater part of the experiments cited, even when I do not expressly mention the fact, and have only put the name of the person whose observation agreed with mine in the text.

By a searching investigation of the subject I found myself in a position to get a clear view of the present state of chromate photography, in so far as regards its photo-chemical aspect, and, as I hope also, to impart it to others. I worked out an analysis of the often contradictory opinions of the different experimentalists without suppressing the opposing views, as the only way in which they could be utilised. In doing this I had to try to mould into one well-organised and well-fitting-together whole the more than five hundred original statements made by various authors, and which I had myself verified. In this work I derived considerable assistance from the kindness with which Dr. E. Hornig placed a great quantity of photographic literature at my disposal, while Captain V. Tóth made many of the photographic experiments along with me. The chemical analytical experiments were carried out in the laboratory of Professor J. J. Pohl, in the technical High School of Vienna. I have also the agreeable duty of expressing my thanks here to the gentlemen on the committee which awarded the prize to my essay for the valuable hints they gave me for the better rounding off of the present paper.

Introduction.

The question as to what is the action of chromic acid and its salts upon gelatine, albumen, gum, sugar, and so on, either by themselves or with the combined action of light, heat, or other agents, is very difficult to answer. The difficulty of obtaining chemical control over that action is very much increased by the chemical composition of the above-named organic substances being uncertain; and the products of their decomposition by the less energetic reagents, to the number of which those belong that are treated of in this paper, in consequence of the slightly characterised form in which they appear, are difficult to grasp as chemical individuals. But though no very exact conclusion can be arrived at as to the chemical constitution of the products of these reactions, still from the course of the reaction and the properties of the resulting substances we can give some explanation of the composition, so that from the practical photographer we obtain assistance for the chemist, and the latter, in turn, assists applied photography.

The property of the chromates of being reduced by many organic substances only under the influence of light has attained great importance in practical photography. The methods of producing light pictures by chromates are divided sharply into two groups, when the part played by the different products of the reaction in the formation of the photographic image is used as the cause of separation.

To the *first group* of photographic processes with chromates those pictures belong in which the image is formed by the chromate itself decomposed by light. Ponton* was the first to obtain a negative picture in this way, by exposing to the light, under a drawing, a paper saturated with potassic bichromate. The light picture produced is of a dull pale brown colour, and consists of hydrate of chromous chromic oxide. The paper reduced to ashes contains chromous oxide. The brownish-yellow colour of the image, its subsequent darkening to green when treated with ammonia, which extracts small quantities of chromic hydrate, while chromous oxide is left behind, confirms the assumption that hydrate of chromous chromic oxide is present. Thus the contents of the last-named substance correspond to the existence of such a picture, and so I shall in this place mention the properties—in so far as they concern our purpose—of hydrate of chromous chromic oxide, which plays an important part in all later processes. It is formed as a brown powder, of very little stability, by the de-oxidation of chromic hydrate, by sulphurous acid, by heating, alone or with chromous oxide†, and by the precipitation of chrome alum with potassic bichromate‡. Acids and alkalies decompose it into chromic hydrate and chromous oxide, and even long washing with distilled water is sufficient to cause the gradual but complete removal of the chromic hydrate, leaving the

‡ Elliot and Storer. *Jahrber Chem.*, 1861, p. 251.

chromous oxide behind. Chalky spring water accelerates this separation very much.

The pale colour of the chromium pictures can be deepened by various means. Lead, silver, and mercuric salts give a yellow colour*, and for many dyestuffs hydrate of chromous chromic oxide acts as a mordant†; for example, for alizarine, logwood, and fustic. Coloured pictures‡ belong to this class. According to Hunt§ and Burnett‖ cupric bichromate gives denser pictures upon paper than potassic bichromate, because the picture then consists of a mixture of hydrate of chromous chromic oxide and basic cupric chromate. The presence of the latter is explained by the decomposition of part of the chromic hydrate by light, by which the insoluble basic copper salt is produced.

Such cupric chromate pictures can be coloured a reddish-brown by ferricyanide of potassium.¶ Nickelous bichromate behaves in the same manner; also the Willis'** aniline printing method, which was improved by Vogel,†† may be included here. These methods have neither practical nor theoretical interest; it is sufficient to have named them.

The *second group* of photographic processes in which chromates are used is of far greater importance. These are based upon the property of chromates of rendering certain organic substances insoluble through the action of light, or of wholly transforming them, so that it is no longer the chromous oxide alone, but the organic substance changed by the light, that forms the image.

We have now to find out in what way the action of the chromates proceeds, of what the organic substances changed by the light consist, and how far the chromous oxide produced contributes to the formation of the photographic image. The prevailing idea, which can be traced back to Swan,‡‡ is that the picture-producing organic substance contains chromous oxide as an integral component, and that the picture is first produced by the chromous oxide in a secondary reaction. Whether this view, which is supported by some experiments of Swan's, be correct, or whether the other idea—that the chromate light picture is formed by the oxidised organic substances—as is pronounced by Lemling§§ and Liesegang‖‖ to be the case, was not decided, and upon the basis of existing observations cannot be stated with certainty.

In studying the behaviour of the various organic substances used in chromate photography with the reagents and with light, I have tried to solve the question. J. M. Eder, M.D.

FOREIGN NOTES AND NEWS.

Durable Paper for *Bombé* Pictures.

In the *Photographisches Wochenblatt* Herr Fritz Haugk gives directions how to prepare durable paper for *glacé* or enamelled pictures:—Take some good albumenised paper and float it as usual on a one-to-ten silver bath. When the paper has floated long enough, which will be in about two minutes, lift it slowly up and draw it backwards over the edge of the bath, and lay it between sheets of clean blotting-paper, so that when looked at from the side it will have a perfectly equal but somewhat dull appearance, quite free from any shining, marble-like marks. In this half-dry condition the paper is laid, film side undermost, upon a bath containing—

Water	400 cubic centimetres,
Gelatine	5 or 6 grammes,
Chloride of sodium	5 ,,

and, being repeatedly lifted up and laid down again, it is allowed to float until the gelatine film formed adheres closely and equally to the albumenised silvered film. The paper is then dried at a gentle heat and is ready for use.

Paper prepared in this way, it is said, will keep as long as washed silvered paper. Like the latter also it requires to be fumed with ammonia, after which it is treated like albumenised paper silvered in the ordinary way. Care must be taken not to wash off the gelatine covering, to prevent which it is advisable to keep the pictures printed on gelatine paper separate from the prints on ordinary paper, and to use the chemicals and washing water rather cold. The water used for washing must also be perfectly free from dust or dirt, as the particles would be apt to settle on the softened gelatine.

The proportions given for the gelatine solution should also be adhered to, as, if more gelatine were added, the film would be thicker and would swell up and so be easily injured. The quantity of salt should not be increased either; as, when there is a great amount of salt present—even when the paper is well fumed—the prints are flat; indeed, the quantity of salt might with advantage be lessened. If it be wished to use the same gelatine solution several times it must be stored in the dark after each time of using, because it contains a little chloride of silver in solution.

Prints which do not require to be spotted may be placed upon the collodionised glass immediately after the last washing. A two-per-cent. collodion is used, and when it has dripped sufficiently the plate is laid in a vessel containing water until the water runs clean off. The prints adhere easily, and, with a little care, quite free from air-bubbles, to the collodion film; but, even if a few air-bubbles should be formed, they are easily removed by a slight pressure with the squeegee.

To mount the pictures: let the print dry for five or ten minutes upon the collodionised glass. Then paste the back of it with some fresh paste to which a little gelatine has been added; lay the cardboard (which has previously been moistened for a short time in water and then dried with a towel) upon it, and smooth it down with the wooden back of the squeegee. When the card sticks fast to the print leave the whole to dry spontaneously. When perfectly dry push the point of a knife between one corner of the print and the glass, and the former will spring off.

With regard to pictures which require to be spotted, these should not be placed on the collodionised plate directly they are taken from the last washing water, but must be dried. To dry them Herr Haugk recommends rather a peculiar plan. He sticks them, film side outwards, against a door which has been oil painted, and when they are half dry and fall off he spreads them out on a table to become perfectly dry. The spotting presents no difficulties, as the indian ink adheres well to the gelatine film, and had better be rubbed down in a very thin solution of gelatine. When the ink is dry place the prints in water for a few minutes and then finish as above.

Our Editorial Table.

The Forge and Lathe—The Turner's Manual.

London: F. Offen, 3, York Street, Covent Garden.

Commencing its existence, under the skilful editorial supervision of Mr. D. A. Aird, as the *Turner's Manual*, this favourite fortnightly periodical, which is devoted to the requirements of the engineer, mechanic, and artisan, ere it has completed its first yearly volume has undergone a change of a twofold character, namely, of title (in a modified sense at least) and, what is of more importance to those who will bind the numbers, in dimensions. The numbers already issued prove the work to be one of great value, several of the regular contributors—to wit, Mr. Aird, Mr. J. H. Evans, the author of *The Lathe and its Uses*, and others—being recognised as amateur or professional mechanicians of the highest reputation for theoretical acumen and practical skill. Up to this the last number issued the work has been profusely illustrated by means of wood engraving, lithography, chromo-lithography, and photography. The *Forge and Lathe* is intended for a high class of readers, and there is no doubt it will secure the suffrages of such. We should not omit to state that the reproduction of M. Bergeron's valuable work, translated by Mr. Aird, forms an attractive supplement to each number.

The University Magazine.

London: Hurst and Blackett.

For the "advanced" character of its articles, and the beauty of the illustrative photograph of the new series of contemporary portraits, the *University Magazine* still ably maintains the high position it has taken since the recent change of management. The current number contains a varied series of articles—one of them, "The Other Half," being a contribution of great value and interest to the student of the science of "soul." Not less interesting is the "Home-side of a Scientific Mind," and Mr. Conder's "Religious Imagination in the East." The biographical sketch in this number is that of Professor Owen, C.B., F.R.S., &c., who, it is well-known, is Superintendent of the Department of Natural History in the British Museum. The portrait, which is printed in excellent style by the Woodbury mechanical process, is from a negative by Messrs. Lock and Whitfield, of Regent-street, and is exceedingly characteristic. The keen, thoughtful look of the venerable *savant* (for he is nearly seventy-four years of age) is admirably depicted.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

THIS Society met on the 18th January,—Dr. Vogel occupying the chair as usual. The ordinary routine business having been despatched,

The President read a letter from Herr Strumper, of Hamburg, in which the latter said he thought it quite possible under certain circumstances to get an impression from a lichtdruck. The letter was accompanied by a perfectly-successful print reproduced by Herr Strumper from a linear illustration from a publication.

Herr JACOBI explained that it depended almost entirely on the composition of the ink with which the lichtdruck was printed whether one could get another print from it or not. A lichtdruck might, however, be very well printed with *rather* fatty ink. Pictures in half-tones were not, he thought, very suitable for reproduction in this manner.

Herr Obernetter had sent a series of very successful prints in colours of views of the walls of Nürnberg. The prints in each separate colour, which had served to produce the pictures, were very instructive. In a communication which accompanied the prints Herr Obernetter said he used different reproduced negatives, made by his dusting-on process, for the various colours. The negative for blue is exposed with a weak chromium solution and slightly dusted on. For yellow the same film serves, but long prepared and strongly dusted on. For violet an ordinary negative, in which the green is covered over, is used. The plate for red is also prepared by stopping out. Herr Obernetter likewise uses a print from sepia, which gives power and outline to the whole.

The President then read a letter from Herr Oscar Kramer, in which he said that Winter's imitation Gobelin tapestry is photographed directly upon linen and then painted over, and is not treated in the way mentioned at the meeting of November 16th.

Herr Schaarwächter laid on the table the reply he had received to his petition on the misuse of medals at exhibitions.

Herr Fechner exhibited his design for the diploma of membership of the Association. The design was greatly approved, and it was resolved to have 500 copies printed by lichtdruck.

A communication from Herr Winter, of Flaville, was then read, from which it appeared that, in consequence of an advertisement (a copy of which accompanied the letter) appearing in a technical journal, the writer had been induced to send two negatives to Herr Pfeiffer, of Guben, to be enlarged, and had in return got the two enlargements which he laid upon the table, and for which he had had to pay twelve shillings; but the pictures sent in no way corresponded to the promise made in the advertisement. This view was confirmed by those members of the Society who examined the enlargements.

The President then exhibited a piece of French oiled silk which he used as a dark-room window, and also some plates varnished with chrysoïdine, and announced that he had been astonished to find that the pale yellow oiled silk prevented the chemical action of light much better than the deep red-yellow chrysoïdine varnish. He also showed a one-to-twelve solution of bichromate of potassium which, in a film only one centimetre thick, in spite of its pale colour, kept out blue light excellently.

The following question was then put:—"In speaking of Albert's chromophotographs, the *Mittheilungen* says that Albert works with three plates taken from nature and sensitive to different colours, and the negative upon which *red* has *not* acted furnishes a lichtdruck plate for *red*, and the same in the case of blue and yellow negatives. In the *Photographisches Correspondenz* the contrary is held to be the case. It is there said that the negative *upon which red has acted* furnishes the lichtdruck plate for *red*. And the same holds good for blue and yellow. —Which is right?"

Herr QUIDDE said the *Correspondenz* was wrong, owing, probably, to the accidental omission of the *not*.

The same person asked how Herr Obernetter would prepare a lichtdruck plate for blue from an ordinary negative. The explanation given was that he would cover every part not intended to be blue with a perfectly opaque varnish, beside which the blue parts, which were formerly opaque, would appear comparatively transparent, and with a long exposure would give powerful prints. Another member asked how he was to photograph oil paintings without reflection from the face and other light parts; and Herr Reméle gave an account of his journey to Fez, which was listened to with great attention.

The meeting was immediately afterwards adjourned.

THE PHOTOGRAPHIC SECTION OF THE AMERICAN INSTITUTE.

AT the November meeting of this Section, Mr. H. J. Newton, President, occupied the chair.

Mr. O. G. MASON (Secretary) said that he intended to say something on the new application of carbon; but he saw a gentleman present who was a practical carbon worker, and who also had some specimens of the latest work in that line. He would, therefore, prefer to listen to his views on the subject, and called upon Mr. Bierstadt.

Mr. EDWARD BIERSTADT, in answer, exhibited some specimens of coloured photographs, which he said were made in a peculiar manner. They were printed by the Albertype process, from three different plates of each subject. He had seen published, something like a year ago, an article by an Englishman who proposed to make similar negatives by allowing the light from the object to pass through a prism, by which the light from the object would be analysed; and thus the blue, the yellow, and the red rays would each make a different negative, and by printing the three colours over each other we have the effect here produced. It is a very simple process. Of course, in yellow and red light the exposure would require to be at least one hundred-fold more than in the blue light. Workers in the process wanted to hold it as a secret; and it was only by his reading of it in the foreign journals, and his correspondence with parties in Europe, that he had obtained reliable information upon the subject. M. Albert, of Munich, wrote to him, and gave him a description of the process. He promised him (Mr. Bierstadt) that if he would make three negatives as he should direct, and send them to him, he would return a print from them showing the objects in their natural colours. The print was not made from the original negative. He found it to be necessary to pass the light through some medium to analyse the colour. The light that was not wanted had to be filtered out by some means. The prism had been suggested as the best for the purpose.

The PRESIDENT inquired if coloured glass placed in front of the lens would not have the desired effect, or could it not be secured by using coloured lenses.

Mr. BIERSTADT thought that the use of coloured lenses would be rather an expensive process. Coloured glass seemed to answer well enough. A writer in THE BRITSH JOURNAL OF PHOTOGRAPHY, about a year ago, suggested the use of the prism.

The PRESIDENT remarked that when coloured glass was interposed the light coming from the coloured object was compounded, whereas if a prism were used it would not be.

Mr. BIERSTADT said that scientific men whom he had consulted told him quite differently. He was trying some very interesting experiments in this line which, if successful, he would bring before the Section.

The PRESIDENT stated that in photographing red the image on the glass would be brown, but if blue glass were used it would not present that tint. The subject of photographing in colours was exceedingly interesting, and they would be highly pleased if Mr. Bierstadt would show them something further at the next meeting. He had great faith in Mr. Bierstadt's ingenuity, and had no doubt but that he would succeed.

Mr. BIERSTADT remarked that in the process used for producing the prints exhibited three negatives were used. In one portion of the specimen was shown what was effected by the different lights—yellow, blue, blue and yellow printed together and red, and in the remainder of the strip the effect of the whole three were combined. Those, they were told, were the three primary colours. They had the full force of the three colours printed on each other. The lines were very sharp. Lithographers could not produce so fine lines as those.

The SCRETARY said that according to this system, as they understood it, combined with the Albertype, anything could be photographed and produced in the natural colours by using three negatives. It was not like the chromos. which Prang made, where twenty different stones had to be used upon one print. But here they had the effect of twenty stones with three colours. This was an immense step in the application of photography to the illustration of nature. It would be remembered that at two or three of their recent meetings the subject of blue glass was much spoken of. He incidentally heard Mr. Chisholm make some statements in regard to making pictures with coloured glass. He would like that gentleman to state to the meeting his experience in that line.

Mr. JAMES CHISHOLM said that the idea was suggested to him while crossing the Brooklyn Ferry. He observed, on looking through the blue glass windows of the cabin of the steamboat at a building on which the sun was shining, that the blue glass neutralised the colours of the building; so he procured fine specimens of blue, pink, and other coloured glass, He found that when the glass was put on the outside of the lenses it required very long exposure. He also procured from Mr. Currier some of his more bedaubed coloured lithographs, and found that the blue glass neutralised the colours on them. When he placed the glass between the two lenses it produced the effect in much less time than when placed outside of the lenses. He had the most objectionable colours, and he found they could be photographed much better with than without the glass. He could not do anything with white glass on the different colours; the blue glass neutralised them.

The PRESIDENT remarked that very beautifully-coloured glass could be made with aniline blue in varnish or collodion. Iodine gave an orange colour.

Mr. J. B. Gardner said that he used a method different from any here spoken of, and that was to have a place in the light to open, something like a fan-light window over a door; and the light that came through that was made to pass through coloured glass before reaching the object under treatment. By that plan he would work quicker than by any other he knew.

The President remarked that Mr. Gardner's method would only answer for indoor work; for landscape work, of course, it would not do.

The Secretary stated that in using the microscope he had it so arranged that he could drop into a receptacle in the sub-stage a piece of coloured glass, and he found that by passing the light through that coloured glass he could see objects that were completely invisible without its use. It was extremely interesting to him to examine the effect so produced. He found blue glass to answer his purpose best in a great number of cases.

The proceedings then terminated.

Correspondence.

CHLORIDE OF SILVER.

To the Editors.

Gentlemen,—I notice that Mr. M. Carey Lea, in the third paragraph of his communication of last week, is under the impression that the late Mr. Sutton was able to utilise the developable property of silver chloride by means of the alkaline developer. Now, while Mr. Sutton was certainly a great advocate for the theoretical sensitiveness—if I may so call it—of silver chloride, I am not aware that he ever was able to produce practical images, or that, indeed, his trials resulted in anything more than a mass of fog, the silver being reduced all over the plate.

As far as I remember, Mr. William Robinson was the first to state the possibility of obtaining thin images with silver chloride, which he did in a communication to this Journal on *The Sensitiveness of Iodide of Silver*. I then took up the matter in the autumn of 1874, and now perfectly remember the exultation with which I first looked upon a clean chloride negative of great intensity. The gelatine film, in which was formed the silver chloride by means of the nitrate bath, had become loosened during the final operations; and, as it hung in folds, like a wet blanket, from a corner of the plate (gelatine workers know the appearance only too well), it was no mean type of the failures in store for me in the future.

However, at the time I was sufficiently delighted, and set to work making an emulsion. This I did with gelatine, and I naturally promised myself a high degree of sensitiveness; but, in spite of my "best-laid schemes," "horn silver" refused to lift up its horn and assert its superiority over silver bromide, and to this day something of mystery hangs over the *untheoretical* obtuseness of silver chloride.

Mr. Lea, as the discoverer of so many good things in photography, will naturally understand and, I hope, excuse my desire to retain my claim (if just it be) to at least a share in the practical utilisation of silver chloride with alkaline development.

I also hope that others will not misconstrue my object in writing this letter. It is not for the credit of having suggested the possibility of using silver chloride as a substitute for silver bromide that I contend; but that Mr. William Robinson was the first to publish the practicability of obtaining an image—feeble, no doubt, and somewhat foggy I suppose; and, secondly, that I was the first to publish a means whereby silver chloride, by the use of either bath or emulsion, could be made to produce both dense and clean images.—I am, yours, &c.,

31, *Grove Place, Brompton, S. W.* Herbert B. Berkeley.
March 26, 1878.

VOIGTLANDER'S NEW LENS.

To the Editors.

Gentlemen,—Permit me to trouble you with an extract from a letter I have received from Mr. Voigtlander in reply to that of Messrs. Murray and Heath, which appeared in your Journal of the 8th instant. Mr. Voigtlander writes:—

"Messrs. Murray and Heath use words which approach to a personal injury, and do me an injustice. Should these gentlemen, therefore, continue in the use of the language of invective I say at once that I value myself too much to follow them in such a course, and to attacks and suspicions of that kind I shall merely oppose silence; indeed, the reproach of an *imitation* should be more seriously reflected upon before being made in such a brusque and public way.

"If Messrs. Murray and Heath believe they have found in my euryscopic lens an imitation, in so far as Mr. Steinheil's aplanatic lens (the merits of which are certainly recognised by me as much as they are by all persons occupied with photography) is composed, like the euryscopic lens, of two flint glasses, and that the diaphragms are placed in the middle of both systems—such assertion will at once appear frail and vain to persons acquainted with the laws of optics and the construction of lenses.

"It is certainly no business of mine to explain to a critic the difference of the optical effects of the lenses in question; but if Messrs. Murray and Heath wish to have any information in this respect I beg to draw their attention to tests and trials of Professor Dr. Vogel, President of the Berlin Photographic Society, and of Herren Prümm and Schaarwächter, who made comparative experiments, and whose experiences are published in the *Photographische Mittheilungen* of May and June, 1877. Further information respecting the euryscopic lens may be found in the Vienna *Photographische Correspondez*, No. 159, and the *Revue Photographique*, by Professor De Vylder, Brussels, July, 1877.

"There is still another point to which I do not fail to direct Messrs. Murray and Heath, and that is the long-standing acquaintance with, and respect of, my house for the firm of Mr. Steinheil, which seems to be unknown to them, but which I greatly value; consequently, such an act as that cited by Messrs. Murray and Heath is precluded.

"I deeply regret that Messrs. Murray and Heath—perhaps guided by a natural interest for Mr. Steinheil—have forgotten themselves so far as to be transported to utterances which only give evidence of a superficial knowledge of the matter."

—I am, yours, &c., Richd. W. Thomas,
10, *Pall Mall, March* 25, 1878. *Agent for Voigtlander and Son.*

NON-CONVERGING PERPENDICULARS.

To the Editors.

Gentlemen,—I was much interested in your report of the discussion at the meeting of the Photographic Society of Great Britain in your last number, and I do not think that even Mr. Sawyer can contradict the following mathematical statement:—

In looking at a drawing the eye should be removed from it exactly to a distance equal to the length of the "point of distance," or at a photograph to a distance the same as the focus of the lens by which it was taken.

If this be done objects—such as high buildings—will appear in their correct propertion when represented by non-convergent (parallel) lines; for the relative distance from the camera of any objects in the same plane as the original is directly proportional to the relative distance of their representations in the picture from the eye. Hence pictures taken with long-focus lenses satisfy the eye, while those taken by wide-angle and short-focus lenses often do not.—I am, yours, &c.,

Liverpool, March 27, 1878. W. Horseman Kirkby.

To the Editors.

Gentlemen,—In glancing over your report of the discussion that followed the reading of Mr. E. Cocking's paper on *Non-Converging Perpendiculars in Architectural Photographs*, I was rather amused, nay astonished, at the ideas expressed by some of our "big guns" with respect to this very simple question, and I think I will be able to show wherein they are mistaken; but, in order to do this, I will have to take one by one the arguments of Mr. J. R. Sawyer—one of the chief opponents to Mr. Cocking's theory.

Mr. Sawyer says:—"If you take your stand at the bottom of a street and look down it you notice that the sides gradually approach until they come to converging point." To this I answer—"correct;" and, further on, will show the reason why. The report goes on to say:—"He carried that reasoning further, and held that if you stood at the foot of a tower and looked upwards you saw also the lines of the tower recede from the eye until they also came together." Again I say "correct," and for the same reason as above. But Mr. Sawyer also says:—"Now supposing the tower was 200 feet high, and the camera be placed at such a distance as that the whole be brought into the field of view covered by the lens, he maintained that supposing the lines were vertical, the camera being further from the top than from the bottom, the lines as presented by the camera must necessarily converge." To this I must reply that if the camera be set quite level the lines will *not* converge, and, by a single experiment, which I shall point out, Mr. Sawyer may convince himself of his error; or, if he even take his own, by which he proposed to decide the question (I refer now to the sheet of paper on the wall), if carried out as he stated at the meeting, he will at the end acknowledge his mistake.

There appears to have been several members of opinion that because the top of a tower was farther from the eye than the bottom the vertical lines must necessarily converge; but any one who has had experience in photographing architectural subjects, or copying engravings or plans, knows that this mistake occurs through not having the camera at right angles with the object to be photographed, and that any departure from a right angle gives more or less an oblique view, consequently more or less convergence.

Now for the experiment to prove all this. Get a long, level, and parallel table; at one end place a drawing-board, perpendicular and at right angles with the table top and also with the edges; upon the board draw parallel lines to show the sides of a tower, and of any height that may be convenient so that it represents a high tower; now place the camera on the table anywhere, only let it be sufficiently back from the drawing to show on the focussing-screen the full height of the tower, and note accurately its appearance. No convergence of lines will be seen, and, as we have our apparatus ready, we may carry this experiment further, to prove that it is not lines or objects at a great distance from the lens or eye that causes convergence, but the angle at which an object is viewed.

As we have settled the parallel vertical lines, now let us draw two or more horizontal lines, after which place the camera exactly parallel with the drawing-board, but at one side of the table. You will find no convergence of the horizontal lines—even, in fact, you may move the camera right across the table, and so long as you keep it parallel with the drawing-board no convergence will take place. However, as I said before, any departure from the right angle will cause more or less convergence, for on looking in a natural way at any natural object with vertical lines the eye of necessity forms a right angle with such object; but on looking at a high tower from its base an oblique view only is obtained, which is neither natural or comfortable, however pleasing such views may appear with reference to horizontal lines looked at obliquely.

In carrying out the above experiments it is unnecessary to say that non-distorting lenses only must be used.—I am, yours, &c.,

Barnard Castle, March 26, 1878. J. T. Bainbidrge.

EXCHANGE COLUMN.

I will exchange a Dallmeyer's 15 × 12 rapid rectilinear for a No. 4 or 5 D group lens by the same maker.—Address, G. Hadley, 33, Newland, Lincoln.

I will exchange mahogany repeating-back camera and lens, also walnut half-plate camera, for whole-plate bellows camera.—Address, W. Fisher, 2, Nashville-place, Hanwell, W.

Wanted to exchange, a 12 × 10 Kinnear, with swing-back, focussing-screw, and four carriers, quite new, for a wide-angle rectilinear, or a pair of wide-angle rectilinear stereo. lenses, or sciopticon.—Address, J. Schofield, Heaton Mersey, near Manchester.

Edwards's graphogenic apparatus with dark slide, for plates $6\frac{1}{2} \times 4\frac{3}{4}$, and iron-bound deal box, for packing chemicals when travelling, offered for Dallmeyer's 1B long or Ross's No. 2 *carte* lens, or Cusson's photo-lectern.—Address, A. Davidson, Station-road, Carluke, N.B.

ANSWERS TO CORRESPONDENTS.

Photographs Registered—

☞ *Correspondents should never write on both sides of the paper.*

Juvenis.—Let the mounting-board be slightly damped, and there will be no fear of perfect adhesion.

T. G. A.—1. Any enlarging camera will answer your purpose.—2. Coat the wooden trays with a mixture of wax and paraffine.

Varnish (Belfast).—The alcohol has been rather too weak, but we find that when the negative is heated to a sufficient degree it gives a glossy film.

T. F. Paxton.—We, too, have had the same experience. Gummed paper will not adhere to glass for any length of time. Sooner or later it becomes detached.

H. H.—More depends upon the negative and the paper than upon the formula for the toning bath. However, you may try the effect of increasing the proportion of tungstate.

J. Cockburn.—We regret that we can obtain no information whatever respecting any process in which the sub-nitrate of mercury has been proposed as a substitute for nitrate of silver.

W. T. B. (Bradford).—We are unable at present to give the formula; but we understand that as soon as the best conditions for working it have been ascertained photographers are to be made aware of it.

H. M. C.—You are bound to serve, according to the terms of your indenture, until you are twenty-one years of age. Such, at anyrate, is our opinion; but you should consult some friend in the legal profession.

Geo. W. Brogden.—The enclosure in your letter is an additional instance of a fact of which we have long been aware, namely, that excellent prints may be obtained upon durable sensitised paper over a year after the time of its having been sensitised.

H. Edwards.—Four feet by two and a-half feet will prove suitable dimensions for the window in your laboratory. It would have been better if circumstances had permitted its being made larger, but, from the plan sent, this does not appear to be possible.

R. D. B.—The tone is good enough, but there is a great lack of vigour in the print. The cause of this it is impossible we could tell unless made acquainted with the circumstances under which the paper was prepared. Does the negative possess the requisite degree of intensity?

Auld Reekie.—Having looked over the volume for 1872 (the year indicated by you) we have failed to discover any allusion to the matter of which you speak. Will you obtain further and more definite particulars, and write again? The subject is one possessing much interest.

D. H. W.—You have been quite correctly informed. There *is* a secret in connection with the method of working the process; and, when the whole of the circumstances are taken into consideration, it is scarcely to be wondered at that the firm are somewhat reluctant to divulge more than they can help.

George Ross.—The extreme acidity of the sensitising bath may account for the difficulty experienced in toning. Try a neutral bath of the strength of forty grains. Fume the paper with ammonia through the agency of the pads in the printing-frame; wash after printing in three changes of water, and then transfer to the toning bath. By adopting this course you will have no cause of complaint as to bad toning of your prints, presuming that you make use of the same toning bath hitherto employed.

A. M. A.—While the placing of a ground plate of glass behind stereoscopic transparencies is the most ready method of mounting them, it is not the best. A much better system to adopt is to apply a coating of fine matt varnish to the picture.

Obliged Reader.—There is a great difference between decomposing by means of heat the chlorate of potash and nitrate of ammonia. In the former case pure oxygen is liberated; in the latter the gaseous emanation is not oxygen, as you imagine, but nitrous oxide, which is, in fact, the "laughing gas" of the popular chemical lecturers in Mechanics' Institutes and at "Polytechnic" gatherings.

Georgius.—We think that under the existing arrangement you cannot make any claim upon your employer for travelling expenses. It was somewhat unwise in you to sign such an agreement; but, having done so, nothing remains but to submit to the terms therein imposed. It does not appear to us that you have so much cause for complaint as, in your estimation, appears to exist. There is scarcely any business extant in which one can have everything he would desire. Consult some clear-headed friend who is better acquainted with the circumstances than we possibly can be, notwithstanding your intelligent letter.

J. Ekralc.—Seeing that the lens at one time produced pictures possessing great brilliancy, its present fogging propensities are clearly traceable to some defect in the mounting. It is very possible, for example, that the black varnish by which the cells or other portions of the mount have been protected has, owing to being rubbed, ceased to have a thoroughly dead, matt surface; and, as a surface covered with a shining black varnish reflects much light, that may be sufficient to account for the fogging. To discover this proceed as follows:—Mount the camera on its stand, directing the lens to a portion of the landscape above which are very bright clouds. Now cover the camera and your head with a large focussing-cloth, and, having removed the ground focussing-screen, examine the lens under these conditions. The result of the examination will probably prove our surmise to be correct.

Medicus.—In stating that an eighth of an inch foreign microscopic power was not better than an English quarter-inch we did not refer to its magnifying power, but to its capability of affording a knowledge of structural detail. What we meant in this statement by a "foreign" power was the achromatic triplets—all the lenses of which are alike—supplied with cheap microscopes. Perhaps it might be more accurate if we distinguished them as "Bavarian powers." Observe that we are very far indeed from speaking disrespectfully of such objectives, for many of them are excellent glasses and define well, having good penetrative qualities; but, from the very nature of their construction, they cannot be employed in resolving difficult test objects. If a quarter-inch object glass of this kind show the markings in *P. Formosum* we should unhesitatingly characterise it as an excellent glass of its kind, although a good English two-thirds will show these markings with great facility.

South London Photographic Society.—The next meeting of this Society will take place on Thursday next, April 4th, at the Rooms of the Society of Arts, Adelphi, when a paper will be read by Mr. E. W. Foxlee, entitled *Hints on the Gelatino-Bromide Process.*

Photographic Society of Great Britain.—This Society will meet on Tuesday next, April 2nd, at 5a, Pall Mall East, when the discussion on Dr. Monckhoven's paper, read at the last meeting, will be resumed; and Mr. England will read a paper entitled *Dry Plate Photography: a Few Remarks on the Various Processes from Practical Experience; with Copies from Negatives Taken by the Different Methods.*

Trade Catalogues.—It is a healthy sign of vitality when new editions of trade catalogues are being issued. We have this week to acknowledge the receipt of two such works—one from Mr. Morley, of Islington (one of our best-known dealers in new and second-hand appliances for photography), and the other from Messrs. George Mason and Co., of Glasgow. It is exceedingly difficult to mention any optical or mechanical piece of photographic apparatus which is not represented in the goodly array of second-hand goods described in Mr. Morley's catalogue. But in addition to the various and numerous second-hand articles are many others quite new, some of the cameras being, apparently, specialities manufactured by Mr. Morley. The catalogue of Messrs. Mason and Co. is merely a "Supplemental Trade Price List" of the photographic apparatus, chemicals, and materials manufactured or supplied by this firm; but this supplement forms a goodly work of 108 pages. It contains numerous illustrations, and a brief account of the nature and composition of most of the chemicals used in photography. It also embraces numerous hints in connection with photographic practice, including the posing and lighting of the sitter.

JOURNAL OF PHOTOGRAPHY.

No. 935. Vol. XXV.—APRIL 5, 1878.

THE PRIZE DRY PROCESS.

At the meeting of the Photographic Society of Great Britain, held on Tuesday evening last, the conditions under which Mr. Joseph Paget offered his prize of £50 for the best dry-plate process were stated. They were drawn up by a small committee, who embodied in them Mr. Paget's ideas respecting the requirements of a good dry process. These conditions we shall publish *in extenso* on another occasion—probably next week; but in the meantime we shall give a digest of them.

Each process entered in competition must be described with so much fulness and in such detail as to enable any ordinary photographer to secure results which shall equal those obtained by wet collodion, whilst it must yield plates that will keep good for four months previous to exposure and three months after exposure. Both exposed and unexposed plates (three $8\frac{1}{2} \times 6\frac{1}{2}$ of the latter) must be lodged with the committee before a certain day in March, 1879, accompanied by the detailed description already alluded to; and provision is made for respecting the privacy of all communications save that having reference to the process to which the jurors shall award the prize, which is to be done without their being aware of the identity of the fortunate competitor. It is scarcely necessary to add that the prize process is to be published for the benefit of the world, there being no restriction as to its being practised by all.

It will be seen that the property of sensitiveness is not imported into the conditions mentioned, *certainty* (irrespective of duration of exposure) being what is chiefly sought to be realised. In one of the conditions, however, there is a proviso to the effect that if two or more of the competing processes shall equally satisfy the requirements as to quality and keeping properties that which is found to be most rapid shall have the preference.

That the process to which shall be awarded the prize will be a slow one—slow, we mean, as regards the great sensitiveness that has now been reached with dry plates—may, we think, be accepted as a foregone conclusion. One reason for thinking so is that in all the dry processes known to yield plates that will keep after exposure albumen is found to be an ingredient in the preparation, and no process associated with that substance is recognised as possessing great rapidity. This, we think, is a matter that falls within the experience of every worker with the collodio-albumen process, no matter in what guise or under what name that process is presented. Gelatine, when used not as a preservative for collodionised plates but as a substitute for the collodion itself, affords the means of making a bromised emulsion by which an exalted degree of sensitiveness may be obtained; but while the excellent quality of the negatives secured by this process are well known, together with the admirable keeping properties of the plates *previous* to exposure, we are not aware of anything having been placed on record by which we may predicate with certainty the enduring properties of the latent image impressed upon such plates. It may be that they will keep for as long a period after exposure as those prepared by albumen, but we are not aware of the data for forming such a belief having been published.

What, we wonder, would be the consequence if the process which was proved most completely to fulfil the conditions attached to the prize turned out to be some old and well-recognised one of days long gone by—say the Taupenôt, Ryley, Fothergill, England, Gordon, or other methods of preparing plates with or without albumen? There being no stipulation that the competing process must be a new one, and there being much evidence to prove that even when adhering strictly to the letter of description of a process the experience or skill of one worker will enable him to obtain by such a process results vastly superior to those secured by a competitor less fortunate in these respects, it is not impossible the award may, after all, turn out to have been given for experience and dexterity in the manipulation of a process long pre-existing. This will, doubtless, have received attention from the committee (Messrs. T. S. Davis, W. England, and W. Bedford) appointed by the Society to aid Mr. Paget in placing the conditions of the award on a satisfactory basis.

Had time permitted Mr. England was to have read a paper on dry processes at the meeting on Tuesday evening; but, owing to the length of the discussion on the fading of carbon prints, the paper was postponed till the next meeting, which is to take place on the 14th May. We are quite uncertain in what way Mr. England will treat his subject; but, on the possibly mistaken assumption that he will confine himself in the main to giving a detailed account of the process by which he produced those admirable landscapes for which he was awarded a medal at the last Photographic Exhibition, we shall in our next number give the first of a brief series of articles on certain dry processes of the present and past time, those of a previous period being confined to processes that have stood the test of time, and which, in many important respects, are worthy of the highest consideration from the most advanced workers of the present day. Quality of negative, keeping properties before and after exposure, and rapidity have already been secured, although not all by means of one process. The efforts of the experimentalist should be directed towards combining in one process all these desirable features.

APPARATUS FOR THE PRECIPITATION OF EMULSIONS.

The description of Professor Stebbing's apparatus for the precipitation of collodion emulsions, given in our last Almanac and also, more recently, in a letter from our Paris correspondent, raises a question as to the benefit derivable from the general adoption of that or similar contrivances for the purpose. Independently of any special form of apparatus, however, the subject presents itself in two distinct phases. We may consider it in an economical light—that is, as a means of economically recovering the waste material—and also as a mechanical aid to the physical perfection of the product with a minimum amount of trouble.

The first is a matter which more closely affects manufacturers, or those who prepare the emulsion upon a commercial scale, for we think there can be no two opinions as to its practical economy to the amateur or to those who only manipulate small quantities occasionally. In comparison with the saving of silver residues, we must bear in mind the lower cost of the materials it is sought to save, and also the greater difficulty of the operations involved, when we think it will be agreed that on a small scale the trouble will more than counterbalance the advantage. Even in working upon commercial qualities it is questionable whether the trouble involved in the fractional distillation of the semi-volatile liquid resulting from the precipitation of the emulsion does not more than compensate for the economy of material secured, and it may be doubted whether the product so obtained in the hands of comparatively inexperienced persons would be of such a character as regards uniformity as to conduce to perfection in the properties of the emulsion in which it is subsequently employed.

We have convinced ourselves by experiment on a small scale that a large proportion of the volatile solvents may be recovered by fractional distillation in a state of purity quite sufficient for all emulsion purposes, but it is at the expense of such an amount of trouble and care as we do not suppose any manufacturer of emulsions could afford to devote to the operation, to say nothing of the hazardous nature of the operation unless special apparatus be erected for the purpose; while the material recovered is so cheap, and the supply from ordinary sources so plentiful, that it is doubtful whether its actual money value would compensate for the mere expenditure of time. We are, of course, assuming the use of methylated solvents; if it were necessary to employ the pure products possibly the increased expense might render their recovery on a large scale remunerative.

On the ground of utility as a labour-saver, however, we are inclined to believe that the adoption of a simple form of apparatus might be beneficial both to the manufacturer and to the amateur, its special character being of course dependent upon the quantity of material to be operated upon, as well as upon other conditions. The ingenious but complicated apparatus of Professor Stebbing, it is scarcely necessary to say, is more suited to the requirements of the wholesale manufacturer than to the amateur, in whose hands it would partake very much of the character of the proverbial "white elephant."

Since the popularisation of the method of precipitating emulsions in place of the original plan of washing, much has been written regarding the conditions necessary to complete success; but it is doubtful whether any of the rules laid down will prove equally effective under all circumstances. Very much, of course, depends upon the nature of the pyroxyline used in the formation of the emulsion, and if the highest degree of success is to be obtained with certainty a special sort is necessary. Still with inferior samples—that is, samples which do not possess to the fullest extent the necessary power of withstanding the effects of precipitation, though otherwise well adapted to emulsion purposes—it is possible by the exercise of care to produce a satisfactory result; while, on the other hand, the most perfect sample of cotton does not free us from the responsibility of the exercise of ordinary precautions.

The operation of precipitating an emulsion when performed upon a small scale—say one or two ounces—presents no special difficulty if the pyroxyline be of a character in any way adapted to the purpose; but in proportion as the quantity is increased so do we find the difficulties make their appearance, and this is equally true whether the emulsion be poured into the organifier, or *vice versâ*. Let us watch closely the operation as it proceeds. We commence by pouring a few drops of emulsion into pure water or an organifier, stirring the while. Presuming the emulsion to be of fair quality it is at once precipitated in fine clots perfectly distinct and with no tendency to coalesce; as we proceed, however, a point is reached at which the proportion of ether and alcohol present is sufficiently large to exercise a partial solvent effect upon the precipitate, which, if the stirring be discontinued, is found to mass together in a pasty lump. So long as no further change in the conditions occurs this solid mass is easily broken up by stirring, and if more water be gradually added it at last loses its coherence and settles to the bottom in small, distinct fragments, and may be easily collected.

If, however, while the precipitate is in the sticky condition the diluted solvents are poured off and replaced by fresh water (which is done with the greatest ease at this stage without any loss of the solid matter), the whole mass solidifies into a tough, leathery condition, and becomes almost impermeable to water and most difficult of management. A somewhat similar result occurs when the mode of precipitation is reversed, and it may be generally traced to the use of too small a quantity of water in proportion to the bulk of emulsion. It is usually recommended to employ three or four times the quantity of water as compared with emulsion; but no reliance can be placed upon such a rule, as we have found some emulsions precipitate satisfactorily with less than their own bulk of water, while others refuse to do so however large a proportion may be used.

It is in overcoming this uncertainty that the employment of hot water recommends itself, as, owing to the volatile character of the solvents, they are in great part driven off in vapour the instant the emulsion comes in contact with the heat. In addition to this, by the sudden volatilisation of the ether the emulsion is precipitated in a spongy, porous state particularly favourable to the subsequent removal of soluble matter. But, as we have before pointed out, the use of hot water has the disadvantage of seriously affecting the working qualities of the emulsion; hence we cannot recommend its adoption except when it is found by experiment to produce no ill effect.

But to return to the subject of apparatus. We require some means by which the emulsion may be brought rapidly and effectively into contact with the water or organifier, so as to instantly deprive it of its ether and alcohol, and, in operating upon considerable quantities, to prevent the subsequent massing together of the precipitate as the emulsion continues to be added. We have attained the first end by the adoption of a simple contrivance on the principle of the chemist's washing bottle. A wide-mouthed bottle of suitable capacity is accurately fitted with a good soft cork, through which are bored two holes to take a couple of glass tubes. One of the latter is drawn to a capillary point and bent in the form of a syphon, the open end of which must pass through the cork and reach to the bottom of the bottle; the second tube is bent at right angles, and merely passes through the cork to form a mouthpiece by which air may be forced into the bottle. The joints must be made as airtight as possible by means of wax or otherwise.

To use this arrangement the emulsion previously filtered is poured into the bottle, and the cork carrying the two tubes inserted as tightly as possible. If, now, air be forced in through the mouthpiece the emulsion will be ejected in an extremely fine stream from the capillary opening of the syphon; and if it be directed into a vessel of water, or of some organifying solution, it is precipitated in the state of fine shreds or strings, which, if kept well stirred for a short time, show little tendency to conglomerate. The operation of precipitating a given quantity of emulsion by this plan is necessarily slower than if it be merely poured from a bottle or through a funnel, but it is much more complete. A quantity of ten ounces may be precipitated in three or four minutes, using the lungs as the source of pressure, the exertion being no greater than in using the blowpipe. As a further refinement a continuous blast from a foot blower might be employed.

With a difficult sample of pyroxyline we have found no necessity for any further appliance when working with eight ounces of emulsion, but with larger quantities it is desirable to arrange for the gradual removal of the spent solvents as they accumulate. This we effect as follows:—A tall jar (a pint jam pot answers well) has its bottom removed, and a piece of muslin or canvas stretched securely over it so as to form a sort of sieve. This is suspended or fixed in a second jar or vessel in such a manner that the canvas diaphragm is at least an inch from the bottom of the outer vessel, which must be shorter than the first-named, in order to allow the excess of water to flow over its edges and escape before the internal vessel becomes full.

If this arrangement be placed in the sink or in a large basin, and a stream of water from the tap turned into the central compartment, it is evident that it will pass through the canvas diaphragm and fill both the compartments to a certain height; but as soon as it reaches the upper edge of the outer jar it begins to escape into the sink and can rise no higher in the "sieve." It is also plain that if the emulsion be poured into the inner compartment simultaneously with the stream of water the ether and alcohol will escape with the surplus water, while the diaphragm effectually retains the solid portions of the emulsion, which are rapidly and certainly precipitated without the slightest loss.

This arrangement may seem complicated upon paper, but is not so in fact. The whole affair, including syphon bottle, was "rigged up" and got into working order in less than half-an-hour (with the exception of knocking out the bottom of the jam pot, which had been previously done for another purpose) at the cost of a few pence, and is as effective as if it had cost two or three times as many shillings. It may be used with hot or cold water and upon any quantity of material; for as the precipitate accumulates it may be removed into clean water without any fear of its becoming massed together, owing to the entire absence of ether or alcohol. Lastly: either portion of the apparatus may be employed separately when such a course seems desirable—in fact, the one last described will, in many cases, do away with the necessity for the wash-bottle.

AMMONIA.

Holding a position of corresponding importance in dry-plate development to that of acetic acid (to which we recently devoted an article) in wet-plate work, a companion article may suitably be presented upon this substance. Whether it is in the form of solution of caustic ammonia or the solid sesquicarbonate is of equal relevancy. It has, in conjunction with pyrogallic acid and bromide of potassium, been the means of revolutionising the practice of dry-plate work, and it is essential that the photographer engaged in experimenting with its aid should be able to obtain it of uniform strength and purity, and be further able to test it in some simple manner; for both liquid and solid are liable to considerable fluctuations in strength.

At the present day its main sources are the ammoniacal liquor produced in the manufacture of gas—a source which is so polluted that it is next to impossible to obtain pure products from it. Formerly the ammonia found in commerce could be obtained sufficiently pure, the manufacture for a long period having been conducted on the same principle and originally produced from the soot collected from the burning of one form of animal excreta—camel's dung—in Egypt near the temple of Jupiter Ammon (whence we get its name). It was afterwards obtained from putrid urine, and also by the destructive distillation of animal substances. At the present time we may be said to depend entirely upon three sources for our supply—the gas liquor already pointed out, the boracic acid layers of Tuscany, and such animal matter as bones, hartshorn, &c.

The ammonia from gas liquor, which forms the largest portion of our supply, is, perhaps, the most impure, being contaminated with many of what are termed the compound ammonias, together with other matters of an empyreumatic nature.

The dry distillation of animal matter yields a product more easily purified, its main impurities being empyreumatic.

The finest and purest kind of ammonia is, however, that obtained as a by-product in the manufacture of borax. When soda is added to the boracic acid, ammonia in a state of great purity is evolved, and is made use of for the production of ammonia solution and ammonia carbonate, which are met with in commerce under the name of "volcanic ammonia." This is the purest obtainable in the usual way, and is what we would always recommend our readers to employ for all delicate work.

Solution of ammonia is most commonly met with in an almost saturated form of specific gravity ·88, a fluid drachm containing 15 88 grains of pure ammonia. It is liable to become contaminated with carbonate, lime, metals, sulphates, chlorides, and sulphides, its freedom from which would be shown by the absence of precipitate or turbidity upon the addition of solution of lime, oxalate or hydrosulphuret of ammonia, or ammonio-sulphate of copper, and, when treated by excess of nitric acid, by the absence of turbidity upon addition of nitrate of silver or chloride of barium. The solution should further be free from colour, which, in conjunction with a peculiar smell, indicates the presence of empyreumatic oil.

A well-known quality of the solution is its power of dissolving many salts and oxides insoluble in water—notably silver oxide and bromide.

The carbonate of ammonia, so called, is, in its parent form, perhaps more correctly called the "sesquicarbonate," there being other carbonates containing less and more acid. It is obtained by sublimation in cakes about two inches or more thick, which, when quite fresh, have a clear, translucent appearance, rather fibrous than crystalline in texture. Exposed to the air the pieces decompose rapidly, ammonia being evolved and the acid carbonate left behind. This decomposition is shown by the change in appearance of the carbonate; it becomes quite opaque, a few minutes' exposure to air being sufficient to produce a visible alteration. Even when kept in well-stoppered bottles it will gradually alter, and, in consequence, it is always necessary when making a solution to remove all the opaque crust, and use only the clear, transparent inner portions of the lumps.

The composition of the sesquicarbonate is open to considerable doubt, authorities differing very considerably from one another; the opinion of Rose, that it varies according to its mode of preparation, seems most likely. It is stated that repeated sublimation diminishes the proportion of the sesquicarbonate in the condensed product. However, by the authority referred to by us recently in our article on standard solutions, &c., it is required that fifty-nine grains dissolved in an ounce of distilled water should be exactly neutralised by the 1000-grain measure of the oxalic acid solution; 1·5 grain of it is also dissolved by seventeen grains of citric acid.

It is soluble in water at 13° C., in the proportion of twenty-five parts to one hundred; at 17° thirty parts; at 32° thirty-seven parts; at 41° forty parts; and at 49° fifty parts. At a higher temperature than the latter the salt is decomposed, carbonic acid being evolved, and a solution of the normal carbonate being left behind. Hence it is obvious that the solution kept for developing should not be made by boiling water. This solution when exposed to air gradually decomposes, the acid carbonate being produced; it should be kept in tightly-stoppered bottles, a little wax or paraffine melted over the stopper being a good safeguard for either the cakes or the solution if they are to be kept any length of time. We repeat it is most desirable to use only the clear, unchangable pieces for solution, and if possible always to obtain the "volcanic ammonia."

The ammonia more commonly sold is liable to an impurity which is especially obnoxious to photographers—nothing less than hyposulphite of ammonia. When the sesquicarbonate is prepared from either a sulphate or a chloride containing a sulphate this impurity is most likely to be met with, and it is not always entirely got rid of by resublimation. It may be detected by the addition of nitrate of silver to a solution of the carbonate neutralised by acetic acid, the well-known white precipitate turning to black even in the dark easily showing the presence of the sulphuric acid. Such samples should be rejected entirely.

RECENT PATENTS.

No. VI.—TINTED CHROMOTYPES.

When speaking of the pictures that were displayed at the last exhibition of the Photographic Society of Great Britain, we drew particular attention to a number of exhibits by Sir Thomas Parkyns, which, from the colour of the picture, suggested various effects, such as moonlight, summer, winter, and soforth. We hazarded a guess as to the method by which they might have been produced, and promised to give further details as soon as the specification of the patent was published. This promise we now redeem. The provisional specification is brief, and is as follows:—

This invention relates to improvements in the process of printing chromotype and autotype photographic pictures so as to tint or colour the same. For this purpose, according to my invention, I employ two methods of producing coloured effects in chromotype or autotype prints.

First. In place of applying plain collodion on the waxed glass previous to applying the pigmented tissue (supplied by the Autotype Company), I use collodion, coloured according to taste or fancy or the requirements of the particular case or subject.

Second. I proceed with the process of printing according to the usual practice in chromotype, but before transferring the gelatine pigment from the glass to the transfer paper, which constitutes the finished print, I flow the gelatine alum-fixed picture with coloured collodion, by which a coloured print is imparted to the picture.

The tints produced and imparted to photographic prints in the process of printing, as previously described in accordance with my invention, may be greatly varied, depending upon the character and proportions of the permanent colours or pigments and chemicals used, and in the manipulation thereof.

More complete details are given in the following completed specification:—

My invention is an addition or improvement to the autotype and chromotype processes. It consists in the fact of my being enabled to colour prints so as to produce a pleasing relief as to tint from the ordinary monotone, or white and black, or one shade of colour. I therefore designate it "bichrome."

I adopt the autotype system exactly, with modifications or additions, and for this purpose I use a coloured medium. These mediums are various, but some of them are difficult to manipulate, and none of them so good, practically, as collodion, seeing that they must be applied with water, which requires a considerable time to dry, and is more difficult to manage, whereas collodion flows regularly on the plate and dries immediately. I treat, therefore, of collodion only, reserving the right as to other mediums which might be applied to the principle of my invention.

I prefer to use no fugitive dyes or any colours which are likely to fade or change; nevertheless, it is at the option of anyone working under this patent to use any means or colours, or kinds of colours, he may choose, but he cannot in such case guarantee his productions to be permanent unless his dyes or pigments be so accredited by the profession.

I use no colours except dry pigments. These are principally earths or pigments known from long experience to be absolutely permanent, such as the madders; but I can use any colours. These colours I mix in various proportions and thoroughly grind and levigate them in a mortar, adding more or less of the various colours until the desired shade or tint is obtained.

When the proposed colour is arrived at, or supposed to be, I add a very small quantity to a very small quantity of collodion (as described hereafter), and having allowed it to thoroughly dry on white paper, it (after having been well shaken) gives the permanent colour of the medium. The pigments not being all of the same weight I use a small measure, about as large as a small thimble, to which a handle has been attached, and of a size suitable for the necks of my pigment bottles. With this I take so many parts of one colour, and so many parts of others, carefully registering the various proportions, so that there may be no uncertainty afterwards. I find that about half a measure is sufficient to colour one ounce of plain collodion, because the tint should generally be arrived at by the mixing of the pigments to the proper shade, and not by adding pigment to the collodion. If too much pigment be added the result will be that in the final operation the transfer paper will not have the power to "pick up" the first collodion, the result being unsatisfactory. Neither must the collodion be of a horny nature, or made with too much pyroxyline.

For the collodion (normal) I take about one hundred grains of a medium pyroxyline (which must not be powdery, nor too tough), and having put it into a bottle I add ten ounces of the strongest ether (methylated will do). I then add five ounces of the strongest methylated alcohol. This nearly dissolves the pyroxyline. I then either add a portion of another five ounces of alcohol to the pigment in the mortar, and grind it again for a minute or so, and pour it into the collodion (washing out the mortar with the remainder of the alcohol); or I put the whole of the alcohol into the collodion and add the pigment in powder. In either case the whole must be thoroughly well shaken, when it may be immediately used.

The above is the formula, which may be increased or diminished to any extent.

The measure for the pigments which I use is about five-eighths of an inch deep and half-an-inch in diameter, three or four of which I find about sufficient for six ounces of the collodion.

I now proceed to describe the way in which I utilise my invention:—So far as the autotype procedure goes I follow it up to the point when the tissue-developed picture has been fixed with the alum water, washed, and allowed to dry. This may be gradually hastened. The preliminary wax had better not be rubbed off too much so long as it is smooth. The alum-fixed picture having been washed and dried, is flowed with the coloured collodion, as above described, and having been allowed fairly to set (which takes a very short time), the plate is plunged into cold water, where I leave it for a few minutes. Meantime the transfer paper (white) is prepared, and when ready the treatment proceeds as usual. It is preferable to allow the picture to dry spontaneously in a warm room, and it should be put under a moderately heavy pressure, as usual, previous to drying. The proceedings are, in fact, precisely similar to the autotype double transfer processes, with the exception of the flowing the alum-fixed picture with the coloured medium previous to transfer.

I proceed to add some ideas which have arisen in the course of my experiments:—As above stated there are other mediums which may be used in the processes, but they are aqueous, and as such I do not recommend them; for instance, albumen, gum, gelatine, &c. They take long to dry, and the after-washing removes part of the colour, the consequence being that they dry very unevenly. They do not properly hold pigments in the same manner that the cotton in collodion does, and I therefore prefer the latter for the purpose required.

I have found that dyes cannot be depended upon, as they change colour in the process of washing to a great extent. According to my process the dry colour thoroughly amalgamated with the film of the pyroxyline is held by it, so that it can be put into water, and kept there for any reasonable time, without any change of tint. If, therefore, ordinary care be taken in the original preparation there ought to be no variation in the final results. I do not doubt but that those using the patent may find it capable of considerable modifications as regards the variations of colours in the same picture by means of masks, &c.; but as I do not believe that this can be done to advantage I refrain from recommending it.

In the mixing of some colours I use large quantities of white (principally zinc), thereby producing a body colour, and enabling me to produce any tint required. Some colours I use pure—green oxide of chromium, umber, siennas, and others; but all may be mixed with white, except when used with the first, or, rather, only collodion. Black I do not use to any great extent, and principally for moonlight or mourning colours. It may, however, be used for other shades of other colours.

The numerous shades of tissue paper, purples, red, brown, black, &c., to be procured in the market enable, or may enable, the artist to combine almost any two colours, the one representing the image of the picture and the other the background, either in harmony or contrast. There is an unlimited field for a display of taste. I generally filter my plain collodion through a proper filter, and then add the pigment. After standing I stir up the deposit of pigment, should there be any, with a glass rod and thoroughly shake before use. I find no loss in proceeding thus. If the collodion is too thick I add ether and alcohol; if too thin, more pyroxyline; if the colour is too pale, more pigment.

I sometimes, though rarely, pour coloured collodion on the waxed surface of the plate instead of plain collodion, but I find this a very delicate operation. The plain collodion must be only slightly tinted with a few drops of the coloured collodion above described, otherwise there will be a veil over the image, and those colours known as transparent are only used, and in small quantities, but great care and judgment are required. No body colour—that is, colour mixed with white—can be used. Prints thus treated should be permanent, which is not the case with dyes, neither will the pigment be washed out in the course of manipulation, so that the tint remains as intended. I find all aqueous solutions used as mediums uncertain, and the colour added to them is more or less washed out in the various operations. I believe that the fibrous pyroxyline with collodion, if allowed to dry sufficiently, holds the dry pigments, the same having been thoroughly incorporated with it, and that to a great extent the coloured film so formed is uninjured by water. This, so far as my experience goes, is not the case as regards fluid dyes, or any mode of colouring soluble in water. After the print has been allowed to dry, and has been stripped from the glass, it may be at once plunged into cold water and left there for a few minutes. It can then be nearly dried between blotting-paper, and while still damp at once be mounted. The wetting of the print reduces the high gloss and produces a semi-matt surface.

Having now particularly described and ascertained the nature and objects of my invention, and in what manner the same is to be performed or carried out in practice, I hereby declare that I claim the said invention of "Improvements in Chromotype and Autotype Photographic Printing, and Colouring or Tinting the same," substantially as hereinbefore set forth and described, consisting in the manner of mixing pigments thoroughly levigated with a collodion, such collodion, so coloured, according to taste or requirement, to be applied as an addition or improvement to the autotype or chromotype process, according to the double transfer system, the coloured collodion being poured on the developed, alum-fixed, washed, and dried plate previous to transfer, my principle being that the collodion cotton film impregnated with dry pigment and properly set will retain the desired colour notwithstanding the requisite washings, whereas aqueous solutions of any kind will not do so, as far as my experience extends.

From the foregoing specification of Sir Thomas Parkyns' patent it will be seen that we shall be justified if we indulge in a little gratification at our having made so lucky a surmise as to its nature when, in an article on *Effects in Photographs*, at page 518 of our last volume, we gave it as our opinion that, "by imparting a tint to the collodion forming the substratum upon which the carbon print is transferred and developed, it will be evident that this tint will affect the appearance of the print after it has been attached to its final support, and the collodion film which was formerly the substratum has assumed the position of the superstratum or external covering of the image." Having already, in the article from which we have just quoted, given our ideas respecting the various effects that may be obtained by adopting such a method as that here described with so much detail by Sir Thomas Parkyns, we may now leave the matter in the hands of our readers.

There is one point upon which Mr. Charles Bennett lays particular stress in his article in our last number which, in its bearing upon the sensitiveness of dry plates, deserves considerably more attention than it receives at the hands of the majority of photographers; we allude to the employment of a thoroughly non-actinic light in the preparation and development of the plates. It is now some years since it was first demonstrated that in this respect dry bromide films are more *exigeant* than even wet plates; and, as at the time when notice was first called to the fact dry plates were not found, in practice, to be more generally sensitive than wet ones, the difference was attributed to a greater sensitiveness on the part of silver bromide to particular rays of the spectrum. But, taking into consideration the whole of the facts connected with the behaviour of wet and dry plates respectively, we have always found some difficulty in accepting this theory, and a simple experiment performed during last summer convinced us that the difference is due entirely to other conditions, and that wet plates may be made to exhibit extra sensibility and to require greater care in the selection of the light. It has been pointed out, over and over again, that the greater liability to fog which a dry plate exhibits when prepared and developed in a light which may be sufficiently non-actinic for a wet plate arises from the much longer period during which the former description of plate is exposed to the feeble amount of actinism that may be present. This may be true enough, but there is still more to be said. If, employing the same light, the development of the dry plate be so modified as to be completed as rapidly as the wet plate, the tendency to fog will still be as great, if not greater. Now to bring about such rapid development we must have recourse to one or other of what we may, for argument's sake, term the abnormally strong developers now in vogue with rapid emulsion plates; plainly, the more energetic developer will bring out the fogging effect in a much shorter time than the weaker one, and hence little or no advantage is gained. Anyone accustomed to the deep ruby glass of the dry-plate developing room cannot fail to be struck by the contrast presented by the "dark rooms" of many professional portraitists; but it must be borne in mind that in such rooms rarely is any great departure made from the normal strength of developer. The exposure is made to suit the development, and not the development to suit the exposure. Adopting this train of thought, the experiment to which we have alluded above suggested itself. We had been attempting to develope dry plates in the ordinary light of a wet-plate room with the inevitable result of fog, though wet plates, much more sensitive than our dry ones, developed perfectly clear. We induced our "host" to mix a more energetic iron developer, and, after exposing for a shorter time than usual, his wet plate was, as we fully anticipated, hopelessly fogged. We now covered the window with an additional thickness of deep orange-red tissue-paper, when, upon repeating the experiment, the wet plate under strong development came out perfectly clear. This experiment, we think, distinctly proves not only that the quality of the light exercises a powerful effect upon the *practical* sensitiveness of the plate, but that that effect is not confined to bromide films, as is generally supposed, but applies equally to bromo-iodised wet plates.

A DEMONSTRATION OF THE PREPARATION AND DEVELOPMENT OF "PALMER" FILMS.

[A communication to the Liverpool Amateur Photographic Association.]

The recent publication of a new film process of exceeding simplicity, and one which may be readily accomplished in all its operations by every amateur who pleases to make the attempt, has elicited so much notice in many directions that I have ventured once more to trespass upon your time and patience, in the hope that I may augment the interest of our meeting tonight by enabling you to witness all the details of this process from beginning to end, and also that I may convey additional information to the many who are seeking it on this subject.

My first proceeding is to take a clean glass of quarter-plate size, and, having placed it upon a level surface, I pour upon it three drachms of a thirty-grain solution of gelatine in dilute ox-gall. I distribute the pool from the centre to the edges of the plate, with the help of the tip of the forefinger, which answers better for the purpose than a glass rod, and then remove possible bubbles with the point of a penknife. For this preliminary film, as well as for the emulsion itself, I find that Nelson's opaque is better adapted than the clear photographic gelatine. The latter does not leave the glass so readily, and the opacity of the former effectually prevents blurring, and, at the same time, does not affect materially the printing capacity of the negative.

The remarks on the subject of halation made at the last meeting of the Edinburgh Photographic Society had reference, I imagine, to gelatine negatives on glass, and not to these film pictures. I have never met with the slightest tendency to blurring in my films, and the entire absence of it when opaque gelatine is employed enables me to give up the plan I had first adopted, namely, of backing up each film with a glass coated with coloured gelatine and sugar. In the film negative of the *Interior of Wallasey Church* the large east window is as clear and sharp in all its detail as would be the case with a wet plate. I have exposed dry plates of all kinds upon this subject, and, in spite of a backing of colour, blurring invariably takes place at this point in the picture.

We now sensitise our dried film by pouring upon it a pool of emulsion, and distribute the latter over the surface with the tip of a *clean* finger. To avoid waste of emulsion, this operation is better conducted upon a dish or tray, and any spilt gelatine may be restored to the vessel of emulsion for further use. It is important that the proportion of gelatine per ounce be the same in both the preliminary and the sensitive coating. If this be not the case, the film will curl and give trouble under the developer. Some gelatines which I have been using lately manifest a tendency persistently repellent of the emulsion. When this is the case it is better to add a few drops of ox-gall to the latter. It will now flow better over the surface; but will still require to be humoured a little by tilting the glass towards each side in succession, so that the surplus emulsion may run round the edges of the plate two or three times.

When thoroughly dry, the film is readily stripped from the glass, and may be exposed in the camera. The best method of securing a sufficiently "taut" surface in the dark slide is, in the first instance, to make the sheet slightly longer than the required size. It is then laid face down upon a sheet of blotting-paper; a glass is pressed into close contact with it, the two ends are moistened with the tongue, folded over, and so fastened to the back of the glass support. In changing the film, a knife readily effects the separation, and the glass is ready for a fresh sheet.

Mr. Kirkby has suggested that these films should be prepared upon ferrotype plates of the larger size, so that a perfectly rigid support may be provided for use in the dark slide. I have tried this plan, and find that the plate will take the gelatine as readily as glass. It will be necessary to secure perfect flatness of the plate during the coating, and the film will strip off for development and printing with perfect ease.

Of the requisite exposure I need say little. It will suffice to mention that the films I am about to develope were exposed in bright sun, at 8-30 a.m. yesterday, with Dallmeyer's rapid rectilinear, stop No. 2, for twenty seconds. I place the film in a dish of water for a few moments, pour this off, flow over a ten-grain solution of bromide of potassium and then follow with the ordinary alkaline developer. When detail is fully out, if necessary, I apply an acid silver intensifier, and then fix with hypo., washing copiously before and after each operation. The negative is conveniently kept from slipping into the sink by the assistance of a camel's-hair brush, and the latter useful little accessory helps me to draw the finished film on to a glass plate, and also to sweep out any air-bubbles which may have interposed between the surfaces.

The films must be allowed to dry spontaneously, or inevitable cockling or splitting will be the result. When desiccation is complete, a knife is inserted under one corner, and then swept rapidly beneath the edge of the film. A pause in this operation will sometimes cause a sudden crack across the negative, so also will the temperature of a hot room. It is essential that no attempt be made to remove the negative from the glass upon which it has dried until all tackiness of surface has disappeared. If this be neglected the resulting negative will be useless until it has been wetted and redried, like the specimen I have here.

One word of caution is necessary with regard to density. What would be considered a decidedly weak negative in any other dry process, will be found to possess sufficient printing vigour in the case of a gelatine film. H. J. Palmer, M.A.

NOTES ON PASSING EVENTS.

By a Peripatetic Photographer.

As I have occasionally to produce reversed negatives, I read with some degree of interest the account of Derogy's aplanatic lens described by your French correspondent as being intended for the production of negatives of the kind to which I have alluded. I have been wondering if I should be considered hypercritical in making an observation as to a defect existing in it, and which must mar its excellence for the purpose for which it is intended, which is the production of reversed negatives for the photolithographic and single transfer carbon processes. Photolithography, somehow or other, "smacks" of negatives of engravings, maps, and similar work in which no distortion or want of sharpness is admissible. Judging by the diagram given the lens is symmetrical, and the rectangular prism situated equidistant between the front and back lenses, the tube being, of course, constructed in a rectangular form and the reflecting surface of the prism equidistant from the lenses. In short, mechanical and optical symmetry prevail. Such being the case, where is the diaphragm to be placed? If it be either in front of or behind the prism one of the conditions of freedom from distortion will have been ignored, for as the position of the diaphragm determines the nature and amount of, or freedom from, distortion, that position which is known to secure immunity from this evil cannot here be obtained—always supposing, as I do, that the diagram is correct, which I see no reason for doubting. From this I deduce the fact that with a symmetrical combination like the one in question, and a prism placed in the described position, entire freedom from distortion will not be possible. In order to secure this freedom the back lens must be brought tolerably close up against the posterior face of the prism, and the front lens must be removed a corresponding distance from it in order to admit of the diaphragm being placed as it ought to be—that is, close to the anterior surface of the prism. A copying lens of this kind might with great advantage have one of its lenses of a focus so much longer than its companion as to admit of the diaphragm being placed near to the lens having the shorter focus of the two. Mechanical symmetry would not here be present, but optical symmetry and freedom from distortion would; and these, after all, are the main points to be secured. If instead of a prism a silvered reflector be employed, the matter is one of great simplicity; a diaphragm with an aperture *oval* in its horizontal direction, and placed in the same plane as the silvered reflector, and of course close to it, will yield perfect freedom from distortion coupled with flatness of field and marginal definition *ad libitum*. But "is the game worth the candle?" I think not; for while a mirror may be attached to the front of a lens by means of the mechanical contrivance of a bit of wood and a strip or two of tin, it can only be inserted between the lenses at the cost of an entirely new rectangular tube for the combination. I have given my reasons for my conservatism in this matter, feeling assured that they will be appreciated by every one who has bestowed even a passing thought upon optics as connected with distortion.

In the course of my wanderings I, accompanied by two friends, one day found myself in the editorial office of this Journal, examining, with others, the gelatino-bromide negatives of Mr. Charles Bennett, which are still there, I believe, on exhibition. Of course, the first to be subjected to critical examination was the interior of the room in which the supper table forms a conspicuous object. It was taken on a dry gelatino-bromide plate, by gas and lamp light, with an exposure of one hour, landscape single combination lenses (it is a stereograph) being employed. Here, sure enough, is ample food for thought. Of course the "regulation" thing to do was to hint that possibly daylight may have had something to do in the way of aiding the exposure, or, failing that, the services of oxygen or magnesium may have been secured in connection with the illumination. Both surmises, we were assured, were wrong; the picture was obtained under precisely the circumstances described. If there should happen to be an unusual development of gelatinomania before long Mr. Bennett will have to be held to a large extent responsible. I am aware of several gentlemen having already avowed their determination to "go in" for the gelatine process as described by him. A point worthy of noticing in Mr. Bennett's description of the process is that the longer the time (calculated by days) allowed for the silver-bromide-forming ingredients to digest in the gelatine the greater is the sensitiveness of the resulting emulsion. At first sight one would think that if gelatine were kept in a fluid state for the number of days mentioned by Mr. Bennett it would become decomposed; such, however, is not the fact. Heat, in this case, seems to act as an antiseptic.

(To be continued.)

NOTES FROM AMERICA.

Stability of Pigments in Carbon Tissue.—Reducing Prices.—The Fading of Carbon Prints.

There is much that is commendable in certain observations offered (in *Anthony's Photographic Bulletin*) in the course of a few *Scattered Thoughts*, by Mr. F. M. Spencer. The lowering of prices by professional photographers has been recognised as an unwise step by those who in this country have given the subject their attention. In America there also seems to be a good deal of talk about the inexpediency or folly of reducing prices. Mr. Spencer says:—

It is an expedient that I am convinced will not pay as a rule. It is easier to get down than up, and does not seem to galvanise trade in any ratio commensurate with the sacrifice; for the nearer we get to cost of production the more must be done to realise a living profit, and I do not believe any of us are anxious to work any harder than we have been doing for our money.

No good photographer is overpaid. The nearer we get down to Cheap John prices the closer will the public associate us with a class now too large, who are disgracing a profession they have no fitness to follow. Last spring I advanced prices, and I have had no reason to regret it. I believe my business is better than any of my cheaper competitors; but every man ought to be his own judge as to the standard of prices he can maintain. Expenses are greater in some localities than in others, and in some the people are better able to pay high prices than in others. I do know that in many parts of the country five and six dollars per dozen for cards would amount to prohibition; the people have never paid it, and in these dull times would not, and generally could not, pay it; but for a photographer to throw away the best prices he can get is sheer madness—it does not create a demand, and hurts trade. Once begin reducing and the people will begin to wait for the next reduction, and the next, instead of going in a rush for pictures. Every trade is demoralised in that way—ours already enough so, without committing the most fatal act of all. Let photographers heroically "hold the fort" until other branches of business revive, and we shall see good times once more. There is a rich mine for pictures accumulating—the population of the country is increasing in numbers and growing in size, and a harvest awaits him who preserves his reputation, and is awake for business when the flow of trade sets in.

Mr. Wenderoth has evidently been making a study of the permanence of the various pigments capable of being used in the preparation of carbon tissue, for in the same journal we find him saying:—

Carbon photographs made with the proper materials are *absolutely permanent* in regard to tint, and, under ordinary circumstances, likewise so in regard to materials, but I do not say indestructible; neither are silver prints. In an article of mine published about twelve years ago, on the *Merits of Carbon* versus *Silver*, in regard to the cost of production I said that carbon prints of a reddish-purple tint, resembling photographs, could only be made permanent by the use of one of the most expensive colouring matters, madder lake, and which would raise the cost of production considerably, and that by employing the cheaper kinds of crimson lakes the prints would soon not only lose their purplish tone but depth also. In a rejoinder to this article, I have forgotten by whom, I was called an ignoramus to call crimson lakes unstable. I thought then to argue with one who had so little knowledge of colouring matter as that person would be useless, and therefore passed his assault with silence.

Before I made photography a study I had practised painting for about fifteen years, but being careful in selecting my materials I would never employ a colour without having tried it for a permanency. The mode adopted was to mix some of the colouring matter with silver white, and smear it on a pane of glass in a window facing south, and some on a piece of glass for comparison kept in a room in the shade, and generally a few days of sunshine would be sufficient to prove the worth or worthlessness of any colour so treated. Now any careful painter knows that there is only one kind of this beautiful transparent red colour which is permanent, and which in English is called "madder lake," "crapp lack" in German, and "laqu egaranee de Smyrna" in French.

When I commenced carbon photography I thought it more desirable to imitate the tone of mezzotint engravings, which, in my judgment, is more artistic than the red-brown photograph, and therefore made all my tissue of pure india-ink and the finest ivory or grape blacks. Such carbon prints can never fade, and then there is nothing more permanent than carbon. The red oxides of iron, which are permanent, might be substituted for the madder lakes, but being opaque the tone of the print will be lowered.

In regard to the cracking of the prints: it is a sign of carelessness or faulty manipulation, and if the transfer has been made on a paper thinly gelatinised, and afterwards passed (after the transfer has been effected) through a solution of alum, such a print can only be detached from its support by force, and will not crack. If M. Lambert is unable to work his process during hot weather, it would only show that he is not master of a matter he is pretending to know all about, but it does not prove that carbon cannot be worked successfuly in the hottest weather.

Upon this the editor remarks—

What Mr. Wenderoth states as to the fading of coloured tissues is true. M. Lambert warmly advocates warm-coloured tissues as a great step forward in "Lambertypy," and hence the great wrong practised upon the public, because it is notoriously true that all such carbon tissues fade, as described by Mr. Webster. Therefore if all Lambertypes are made on such tissue they will sooner or later *all fade.*

"W. B. C.," in the same periodical, assumes an air of virtuous indignation against those who speak of the superior stability of carbon over silver prints. But we allow him to speak for himself:—

I have wondered if those photographers knew they were injuring themselves in the eyes of sensible people. How do *they* know carbon prints will not fade? The assertion is only supposition, when, in fact, they *do not know.* I have silver prints that have been made for fifteen years, and to all appearances they are just as good as ever. I have also some ferrotypes I made eighteen years ago that are *just* as good as the day they were made.

We all know that gelatine is affected by the weather, and I have the first enamelled picture (for they are gelatine finish) but checked, and was full of fine cracks in time. True, they look nice when first made, but I think they will *not* wear. Besides, I never knew a patent in my life (that was peddled out as they do the carbon process) that was of any account; and when I see one selling patents I just set him down at once as a travelling humbug.

My worthy competitor here invested in the carbon swindle some months ago, but I have never heard of his making a single picture. I did hear of him, however, rushing frantically round town, the next day after he returned, showing his deed for the *exclusive right* to make carbon pictures, and how he had the world (this part of it) by the tail. But of late I never hear him say carbon. I think it is about the same as the celebrated *souvenir*, and will play out about the same. I think it is only got up by a few to grow rich, if possible, from the photographers of our country.

We have entirely too many travelling about peddling this, that, and the other, and too many photographers are always ready to bite at the bait; and after they have, they applaud it in order that others may also bite, simply because they want to see others equally swindled with themselves, when they should come out and condemn it at once. And our journals are too apt to recommend things for a few dollars that often prove detrimental to the craft.

We do not think that among our readers there are many who share these opinions, which are inserted in our contemporary without any editorial comment; but in case there be a single such one we take this opportunity of showing the fallacy of the reasoning implied in the above, which, if placed in the form of a syllogism, would be as follows:—Gelatine is affected by the weather, and prints which were faced with gelatine have become full of cracks (major premiss); carbon prints are composed of gelatine (minor premiss); *therefore*, carbon prints will become affected by the weather, and become full of cracks. Q.E.D. This logic is undoubtedly sound but for one or two slight fundamental errors. First of all, prints that have been enamelled with gelatine do not crack; and, secondly, a carbon print is not composed of gelatine. This second statement may possibly at first prove surprising to a few; but we must inform them that although a carbon print is made out of a gelatine pellicle, that gelatine is converted into vellum by the action of the light by which the print is formed, the "gelatine" being all washed away by the operation of developing the print, which is now composed of vellum of a varying degree of thickness, having imprisoned in its substance certain pigmented matter, such as carbon. We know that carbon prints will *not fade*, because both vellum and carbon are well known for their durability.

THE REACTIONS OF CHROMIC ACID AND CHROMATES UPON SUBSTANCES OF ORGANIC ORIGIN, CONSIDERED WITH REFERENCE TO THEIR USES IN PHOTOGRAPHY.*

General Properties of Gelatines.

I commence with the most important organic substance of which chromate photography makes use, namely, gelatine. Under this designation are comprised pure glues, without specifying the particular sort. Glues are distinguished as glutin (bone glue from leather, parchment, bones, and isinglass), and chondrin (cartilaginous glue from the side bones and joint cartilages). The properties of the glue vary very much according to whether glutin or chondrin predominates in it. In a pure form neither the one nor the other is a commercial article, but almost without exception all the ordinary commercial and most of the photographic gelatines consist really of glutin. I found very few samples of gelatine rich in chondrin, and these were all photographic. I shall hereafter speak of the composition of the different commercial sorts and of their suitableness for photographic operations.

Though chondrin and glutin generally behave in much the same way, still they can be distinguished by reagents. Alum, sugar of lead, ferric sulphate, chrome alum, and acetic acid precipitate chondrin, but not glutin. Thus one has at hand a means of distinguishing gelatines rich in glutin from those rich in chondrin, by making a ten-per-cent. solution of gelatine in hot water to which a concentrated solution of chrome alum (or a solution of alum) is added. If chondrin be present in considerable quantity the gelatine solution, while still hot, will stiffen in a few seconds, so that one can soon turn the test tube, in which the experiment is made, upside down without being obliged to take care not to spill the contents.

In the following remarks I shall speak especially of gelatine proper, since common sorts of glue are not at all suitable for use in chromate photography. When the contrary is not expressly mentioned the statements apply to gelatines rich in glutin as well as in chrondin.

Gelatine is very hygroscopic, and when dried in air contains, according to my calculations, from fifteen to twenty per cent. of water, which it only gives up completely at a temperature of 120° C. Ordinary sorts, which generally find their way into the market as thick cakes, contain, to follow Heinze's experiments,[1] about nine to sixteen per cent. of water. In cold water they swell out to an elastic transparent mass, which occupies from six to eight times the volume of the dry mass. The quantity of water taken up stands in a certain relation to the goodness of the glue, as Schattenmann[2] first showed. But that this view does not apply to all sorts of glue Weidenbusch[3] showed. He found that the inferior sorts of glue became decomposed after standing twenty-four hours in water of 15° C. With the exception of some bad sorts of lightdruck gelatine, I found that photographic gelatines took up from five to ten times their weight in water of 15° C. Water of from 2° to 5° C. is taken up more slowly by the gelatine, on which account Talbot[4], Sawyer[5], Liesegang[6], Vogel[7], Liébert[8], Voigt[9], and Edwards[10] recommend the cooling down of the chromate bath for pigment pictures with ice, if the too high temperature of the atmosphere would cause the gelatine to swell too much while being sensitised, which produces flaws, and sometimes may have for consequence the solution of the gelatine film in the bath. The chromate bath, therefore, if one wish to guard against disturbances, should not be warmer than from 10° to 18° C.

Gelatine dissolves more or less easily in hot water. The solution is particularly easy when the gelatine has been previously soaked in water. In this last case it will have absorbed so much water that heat is all that is required to dissolve it. Heating in a water bath of 30° to 35° C. will then melt the thoroughly swollen mass. Good gelatine, after its saturation with water of 15° C., does not melt at 25° C., and indeed the kinds of gelatine well adapted to photographic work can be warmed even up to 30° C. without melting. The ordinary sorts of glue and inferior qualities of gelatine melt at about 20° C. Only bad sorts will, under the conditions mentioned, long remain undissolved in the water bath, though some will resist even if the temperature be raised to 60° and 100° C., and such sorts are not at all usable in chromate photography.

These observations are of importance to the photographer, because the sorts of gelatine that become fluid very easily are apt to run off when paper coated with it (as carbon tissue) is being dried at an increased temperature, which a good gelatine dried at a moderate temperature will not do.

[10] *Phot. Archiv*, vol. x., p. 193.

From the above-mentioned melting points of the swelled gelatine it follows in drying pigment tissue, even when the gelatine of which it is made is good, that one should never exceed 25° C. of heat if one wish all to go well. Geymet and Alker,[1] who fixed the maximum drying temperature at 20° C., because they found that the gelatine often became fluid at 25° C., and Vogel,[2] Swan,[3] and Monckhoven,[4] who do not use a higher temperature in drying than from 20° to 25° C., confirm the correctness of the numbers I have found; so does Rodrigues,[5] who says that good photographic gelatine should become a jelly at 20° or 25° C., or, as he says later,[6] the best kinds of jelly already stiffen at 35° C. Vidal[7] requires of pigment gelatine that it should not yet dissolve or melt in water at 20° or 30° C. If a gelatine film which has soaked until it is quite full of water be freed by pressure from superfluous water it will require a higher temperature to melt it than it would have done while it still contained the latter. For this reason many persons squeegee the superfluous moisture of the chromate bath out of their sensitised pigment paper, so that it may remain[8] undisturbed by a higher temperature than would otherwise be the case.

Most persons agree with Bostock,[9] who found that good gelatine imparts to water containing one per cent. of it the property of becoming gelatinous when cold. I found that it went even further, and that of some sorts of gelatine, which, by Lipowitz's method,[10] are capable of bearing a strain of from 700 to 1000 grammes, only from 0·5 to 0·8 per cent. was required to stiffen the watery solution. Concentrated solutions stiffen much quicker than dilute solutions. This fact is of importance when one coats paper or glass with glue and then wishes to dry it *after* it has set. For photographic purposes (pigment printing, lichtdruck, photogalvanography, &c.), as a rule just so much water should be used for the solution of the glue as it can absorb at an ordinary temperature.

By long-continued boiling with water glue loses the property of jellying when cold. This is a frequent cause of defects in the manufacture of glue, as the manufacturer has the alternative of either by boiling for a short time scarcely getting the good of all his material, or by simmering for a long time extracting the full benefit of it, but in the mean time getting inferior glue. Such glue, boiled for hours, never again jellies so firmly; it melts at a lower temperature than if it had never been subjected to such treatment, and it dissolves more quickly in water. The diminished stability renders such gelatine little suitable for lichtdruck plates, and its low melting-point would stand in the way of its employment for pigment tissue. In fact, Blair[11] lays the greatest stress upon never letting gelatine solutions intended to be used in the carbon process be heated to boiling point, nor be kept for a long time in a melted condition. For Woodburytype and photogalvanography, &c., I believe it may be very useful, and perhaps not without preference over a lichtdruck gelatine, more difficult to dissolve. The glue changed by long boiling with water has almost entirely retained its composition. Goudoever's[12] theory, that in four molecules of gelatine (glutin) one molecule of water is combined, as according to his and Mulder's analyses,[13] seems very probable. Also the addition of acetic acid, dilute nitrate acid, and chloride of zinc hinders the gelatinising of concentrated solutions of glue. Such mixtures of acetic acid and glue are used to produce glue which remains fluid when cold.[14] Dumoulin[15] uses for the same purpose nitric acid, but Balland[16] prefers acetic acid, which preserves the adhesive power better. J. M. Eder, M.D.

(To be continued.)

FOREIGN NOTES AND NEWS.

Dr. Richard on Fog in the Negative Bath.—A New Sort of Charcoal Pencil.—Upon Photographic Irradiation.

In the *Monatsblätter* Dr. Richard has something to say about a simple means of curing the fogging in the silver bath when the fogging is not caused by badly-polished plates. It sometimes happens that the bath begins to fog when sitters have come to be taken, and there is no time to try to doctor it nor to prepare a fresh bath. Such an accident happened some years ago to Dr. Richard, and he was able to get the better of it—not, indeed, by curing the bath at the instant, but by removing the fog from the negatives. He placed the developed but fogged negatives, after they had been well washed, in a place where they were protected from the light, and left them there to dry, which required from thirty minutes to three hours at a temperature not over 15° R. In this way in a single afternoon he has had over a dozen developed plates in the plate-box at a time; these he would develope one after the other, and find that there was no longer a trace of fog remaining that could be attributed to the bath, or, indeed, to anything but badly-cleaned plates.

Dr. Richard's explanation of the sort of fogging which was so easily removed is as follows:—The negative bath may have become saturated with ether and alcohol in consequence of the great number of plates sensitised in it, and then perhaps rather much alcohol may have been in the developer, and thus rendered it impossible to develope the picture fully without fogging. Then by placing the plates, sensitisedi n a bath which thus produces fog, after being developed, to dry in a dark place, they have the chance of giving off the superfluous ether and alcohol to the air—or, in other words, of getting rid of the fog before they are fixed—so that an operator is enabled to get pictures perfectly free from fog with a fogging bath, and to go on working with his old bath until a new one is prepared. The old bath may then be diluted with distilled water and brought up to the proper strength by the addition of the necessary silver. Dr. Richard's explanation and remedy have at least the merit of being simple and easily tried by anyone who is "tried" in the same way.

The *Correspondenz* extracts from the *Papier-Zeitung* a description of a new sort of charcoal for drawing with. The ordinary drawing charcoal is made by charring pieces of wood so that every knot in the wood remains, and there are often scratchy pieces and bits of unequal softness. The new pencils, which have been patented by Herr Heilmann, are made as follows:—Sawdust of wood taken from lime, willow, or even poplar trees, is pressed between wooden moulds having grooves about the size of those made for lead in lead pencils; it is then dried in air and charred in a retort. The hardened sticks are now rubbed smooth, cased in paper, and packed in bundles of twenty-five. The fibres of the wood having been freed from every foreign substance, the charcoal made from it can be moistened with any sort of liquid. Thus moistened with gelatine it can be used instead of black chalk, or it may be moistened with linseed oil, or with lime water. The charcoal is also prepared of a catechu-brown.

It is well known that pictures of intensely-bright subjects are often too broad. This is frequently observable in connection with light hair in enlargements made in the camera. It is also remarkable in the case of astronomical views of the sun, in which the apparent size of the sun varies according to the length of the exposure. The *Mittheilungen* says that M. Angot has made some precise experiments on the origin of this fault, from which it is supposed that it is possible to calculate the amount of the error. M. Angot took several photographs of an object consisting of two right angles separated by a dark space. Exact measurement of the various images taken under different circumstances furnished the following results:—The intensity of the light increases the size of the photographic image. When, however, the light is weaker the image is rather within the geometrical size. Duration of exposure has a similar effect as intensity of light, but there is no proportion between the degree of increase. The irradiation increases also with the sensitiveness of the plate. On removing the stops from the lens, and at the same time considerably increasing the light, it was seen that the images decreased in size as the diameter of the lens increased. Also, pre-exposing the plate exercised an influence on the size of the image. Upon a pre-lighted plate the image is smaller than on a fresh plate. M. Angot finds the explanation of all these appearances in the curvature of the rays of light at the edge of the lens; and, according to this hypothesis, a plate of a certain sensitiveness, and taken with a certain exposure, remains unaffected so long as the strength of the light does not exceed a certain degree.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

The usual monthly meeting of this Society was held on Tuesday evening last, the 2nd instant, —Mr. James Glaisher, F.R.S., President, occupying the chair.

The following gentlemen were admitted as new members, viz., Messrs. Charles Harris, H. N. White, F. Wratten, Joseph Webster, William Mansell, Payne Jennings, Newland, W. Field, Nelson, Dale, and Henry Sampson.

Mr. T. Sebastian Davis, on behalf of his fellow-members of committee and himself, read the conditions upon which the prize of fifty pounds offered by Mr. Joseph Paget for the best dry process was to be awarded. A statement of these conditions will be found in an article in another page.

It will be remembered that at a previous meeting the silver "progress medal" of the Society was awarded to Captain Abney for having made the most valuable communications to the Society during the past year. This medal was presented to that gentleman by the President, who spoke in terms of great admiration of the value of the various papers contributed by Captain Abney, who, on receipt of the medal, expressed his sense of the honour conferred upon him.

The Chairman then announced the subject for the evening's discussion to be the paper by Dr. van Monckhoven read at the previous meeting. Before calling upon the gentleman who was to open the discussion he stated that he had received a letter from Mrs. J. A. Spencer expressive of the regret of her husband (who was incapacitated from serious illness from being present) at not being able to take part in the discussion on a subject in which he had ever felt the liveliest interest. He (the Chairman) hoped that Mr. Spencer's illness would speedily pass away, and thus be enabled to meet with them all again.

A paper by Mr. W. S. Bird was then read, in the course of which he reviewed the whole question of the fading of the pigments that had been mixed with carbon in tissue for the purpose of modifying its colour.

Mr. J. R. Sawyer read a paper on the same subject by Mr. J. W. Swan, of Newcastle-on-Tyne, and also made some lengthened remarks in the same direction. But, however, until the publication of Mr. Bird's paper and that of Mr. Swan the various remarks which followed would not be understood; hence we defer this portion of our report for a week. Those who made observations on the matter were Mr. Samuel Fry (who announced his intention of using silver printing for all small work in preference to carbon); Colonel Stuart Wortley (who combated some of Mr. Fry's ideas); Mr. Bolas (who spoke of certain experiments made by him with the oxides of iron); and Mr. Spiller (who alluded to the fact of there being six shades of alizarine now prepared).

The Chairman proposed the thanks of the meeting to the various gentlemen who had contributed to the information of the members on this subject.

A paper on *Dry Processes* was to have been read by Mr. William England; but, owing to the lateness of the hour to which the previous discussion extended, the Chairman announced that it would be deferred till next meeting, which will take place on the 14th prox.

The walls of the gallery were adorned by a very large and choice collection of works executed and exhibited by the Autotype Company, and a special vote of thanks to this Company was proposed by the Chairman. After the exhibition of some of Mr. Dallas's most recent works in Dallastint the meeting was adjourned.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

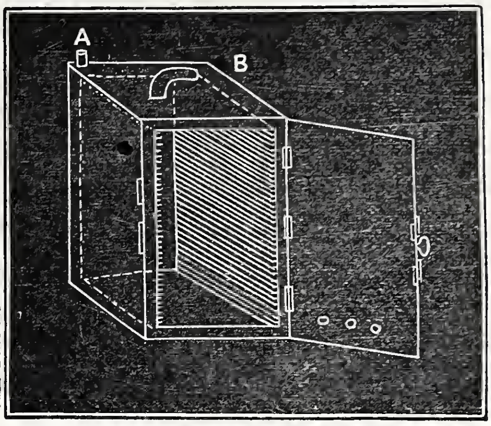
The monthly meeting of this Association was held on Thursday evening, the 28th ult., at the Free Public Library, William Brown-street,—Mr. H. A. Wharmby, President, in the chair.

The minutes of the previous meeting having been read and confirmed, Mr. J. C. Forrest was elected a member of the Association.

A communication was read from Mr. J. A. Forrest stating that, as this was an age for exhuming old photographic ideas and dressing them up to the times, he had sent some pictures treated in the following manner:—Take a strongly-printed photograph on paper and saturate it from the back with a rag dipped in castor oil. Carefully rub off all excess from the surface after obtaining thorough transparency. Take a piece of glass an inch larger all round than the print, pour upon it dilute Russian glue, and then squeegee the print and glass together. Allow it to dry, and then work in artist's oil colours from the back until you get the proper effect from the front. The examples sent showed that both landscapes and portrait could be effectively coloured by the above method without any great skill being required.

The exhibition of Mr. J. H. T. Ellerbeck's drying-box excited considerable discussion as to which was the best form and mode of heating drying-boxes. Mr. Ellerbeck described his drying-box as follows:—In a chemical laboratory is used a water oven for drying precipitates, &c., at a certain temperature. Finding a want for drying plates quickly, and at the same time away from light and the action of deleterious fumes, I have made on the same principle a water oven for this purpose, differing only in having in the inside, instead of one shelf, a number of ledges for the reception of the emulsionised plates. As this apparatus may not be much known a slight description may be serviceable to some. A Milner's safe is a good model. It consists of a double box of metal, with an open tube at top for the admittance of water, which surrounds on all sides, except the front, the inner case, the sides of which are shelved or grooved the same as an upright plate-box. From the top of the inner chamber is a pipe leading to the outer atmosphere for the escape of fumes and to cause a current of warm air throughout. To effect this more advantageously I have made the box two or three inches deeper than the plate itself, so that when this latter is inserted it will be that distance away from the entrance. If the next plate be placed flush with the door, and each alternately in and out, the hot air is made to pass over each plate to its full length. The drying thus takes place in a few minutes. I have made mine for thirty-two plates, but this is hardly necessary, for amateurs do not usually make this quantity in a night. Still it is best to be on the safe side, and the extra space allows all to be left till the evening's work is done, and you need not stop in the middle to put away those already finished. The whole had better

Hot Water Oven for Drying Plates.



A—Inlet for water. B—Outlet for vapour or hot air.

be of copper, when it will last a lifetime. Tin is, of course, cheaper at the first but dearer in the end, as being liable to rust and wear out. The diagram will show better than any description the plan. The distance between the inner and outer metal need not be an inch, and a thermometer can be fixed with the register outside for any delicate work. Gelatine workers will find this oven of value if the shelves are properly levelled, and it will be found useful for many other purposes, such as drying chemicals, evaporations, &c. The heat can best be kept up by a gas boiler to any required temperature.

The Rev. H. J. Palmer then gave a practical demonstration of his method of preparing and developing the "Palmer" films, which was watched with the greatest interest by the members. [See page 159.]

The demonstration was also illustrated by a number of film negatives, showing conclusively their excellence and portability.

The receipt of the *Bulletin Belge* and the *St. Louis Practical Photographer* was announced by the Secretary.

After votes of thanks had been cordially given to the different exhibitors, a large number of transparencies were shown by the aid of the Society's lantern. Some from albumen plates by Mr. Lund, of Manchester, and some of animals taken on Kennett's gelatine plates by Mr. L. W. Weber, were greatly admired.

The meeting was afterwards adjourned until the 25th instant.

PHOTOGRAPHIC SOCIETY OF VIENNA.

A meeting of this Society was held on the 5th February,—Dr. Hornig occupying the chair. The usual routine business having been despatched,

The Chairman read a communication from the Lower Austrian Industrial Association, in which it was stated that that Association had supported by a memorial the Photographic Society's application to the Minister of Commerce for a revision of the regulations affecting the transport of collodion; at the same time he mentioned that the Austrian Engineers' and Architects' Association had not complied with his request for similar support. He (the Chairman) also said that by the intervention of the President a committee of the Chamber of Commerce was appointed to consider the question, and it was decided that collodion cotton might be sent by rail. He had also received a letter from the Minister of Commerce in which he promises to bear the point in mind at the forthcoming readjustment of regulations for railway traffic.

The first number of a new technical journal, the *Oesterreichischen Gewerkzeitung*, was laid on the table by Dr. Hornig, along with a proof sheet of Herr Bolhoever's *Münicher Renaissance.*

Some of Herr Wilde's emulsion plates were then shown, and the Chairman asked if any member would try them and report to the Society the degree of success he had met with. Dr. Eder and Captain Tóth undertook to make the requisite experiments, the former at the same time calling attention to the article on Wilde's emulsion process which appeared lately in the *Mittheilungen.*

Herr Oscar Kramer gave an account of the progress made during the last two years in the *lichtpaus* process in his establishment. During the last eight months the Salz-kammergut-Bahn has used about 10,000 *lichtpaus* pictures, principally as a quick means of multiplying plans for carriages, locomotives, &c. Paper for *lichtpaus* is sensitised by the cyanotype process, by a machine, in rolls of from 100 to 200 metres long, and sold in rolls ten metres long, and sixty-five, seventy, and seventy-five centimetres wide. In many parts of Germany a sensitive fluid is sold which is applied to paper with a sponge or a brush; but, as some difficulty is experienced in applying it, the rolls are more convenient, being equally sensitised, and it not being necessary to unroll more than the quantity it is desired to cut off.

By request, for the last nine months Herr Oscar Kramer has produced, from direct prints, pictures with dark lines on white ground by Willis's aniline process. The pictures are very successful; but paper prepared for the purpose cannot be sent into the market, as it only keeps for a few hours, while that prepared by the cyanotype process, besides being easily used, keeps for half-a-year. Herr Kramer showed, from a single original, prints upon paper and upon cotton both by the cyanotype and aniline processes, and also very good prints upon cotton from photographic negatives.

Dr. Eder asked whether cyanotypes did not always fade with exposure to light.

Baron Schwarz-Senborn, Dr. Böhm, and Herr Kramer replied that, on the contrary, they had observed an increase of density in the blue tones, which, after some discussion, was attributed to a residuum of the chemicals which had not been washed out.

Herr Kramer also said that a great deal depended on the proper choice and mixture of chemicals. The raw paper he used was the same as that on which the Austrian bank notes were printed.

After a little more discussion the matter of *lichtpaus* processes was dropped.

Herr Fritz Luckhardt showed a box or bath for acids made of pressed glass, in which there were grooves, so that the plates, when being treated with acids, could not be shifted about. This bath is only made in one size at present, but Herr Luckhardt supposed it could be made to order in larger sizes.

The following question, taken from the question-box, was then brought under the consideration of the meeting:—"In order to avoid the wearisome labour of polishing glass when on a journey, and also to cause the dry collodion to adhere better to the glass, I albumenised my previously carefully-polished glass plates before I set out for my summer tour. The plates when exposed were in the dark tent developed with iron, intensified with pyro. and silver, and after being washed with a four-per-cent. solution of potassic iodide, in order to prevent the further action of the intensifier, they were rinsed with water and dried. After a stay of about a fortnight I returned home and fixed the plates with hyposulphite of soda, which made the black parts somewhat lighter, and the dark parts were then seen to be sown, as it were, with minute dark blue spots. These spots showed most in lights of the sky when the light fell directly upon the plate, and I thought it would be necessary to stop out the whole of the skies of all the plates. Happily, however, I found by the prints that the actinic action of these dark blue spots was exactly the same as that of the surrounding black parts, and that they did not show at all in the positive picture. My question is, therefore, are these dark blue spots a peculiarity of previously-albumenised plates, which I have not seen described in any work on photography, or should the cause of their appearance be looked for somewhere else? Perhaps the sulphur contained in the albumen is to blame."

It was regretted that the question was not accompanied by a specimen negative, and a member remarked that the spots were most likely caused by the plates not being properly polished at first, or from some particles of dust having adhered to the coating albumen.

Herr Luckhardt took the opportunity of observing that nowadays the photographer had often to contend against bad glass as well as against bad albumenised paper and mounts.

The business of the meeting was shortly after brought to a close by the Chairman handing over his office for a time to Herren von Melingo and Luckhardt, and bidding the Society good-bye, previous to his departure for Paris, where he is one of the Exhibition Commissioners for Austria.

THE PHOTOGRAPHIC SECTION OF THE AMERICAN INSTITUTE.

The December meeting of this Society was presided over by Mr. H. J. Newton.

Mr. O. G. Mason (the Secretary) remarked that his attention had been called within the past few days to a chemical fact that might be classed as a discovery. They had always been told in books on chemistry that chloride of gold contained in its pure state forty-nine per cent. of metallic gold—they had it as a terchloride of gold—and that it always contained three atoms or molecules of water. But it had lately been found that pure chloride of gold contained but forty-five per cent. of metallic gold, and instead of three molecules of water it contained forty; consequently when they estimated the cost of prints they found that they could make more prints with $10 00 worth of metallic gold than they could with the estimated quantity as sold. That is, the best chloride of gold contained less metallic gold; and if the water of crystallisation were driven off to the fullest extent without decomposition, it still contained four elements of water. This, he thought, an interesting fact for photographers. Gold, as they bought it, was usually warranted to contain seven and a-half grains of metallic gold in fifteen grains of the compounded salts.

Mr. D. C. Chapman stated that at the last meeting there was much said on the subject of coloured light. It was stated that one member said he made a picture with blue glass much quicker than without it. Now he doubted that statement. The only effect the blue glass produced was to absorb some of the light from the picture, and the contrast of some portions was thus rendered greater; the outlines were stronger, and therefore a contrast was got which was not found without the glass. There was no such thing as primary colour. It was one continuous stream of wave lengths for the space of an octave. There was no such thing as a fixed colour. Every different length of vibration of light gave a different colour. He had been all over the ground, and knew what coloured light would do. When light passed through blue glass some of the rays of light were stopped. What they called white light was nothing but a confusion of all the wave lengths, which pressed on the optic nerve. For instance, if the waves were waves of 300,000, the eye was acted upon by waves of that length. Light passing through blue glass was not changed, and acted on the chemical substances the same.

The President remarked that colour was purely a sensation. The varying colours were the result of the peculiar excitation of the optic nerve by different wave lengths, which were conveyed to the sensorium or perceptive faculties. The result of that excitation and perception was what they called colour. The position assumed, as he understood it, was that the light from the subject to be photographed, having a variety of colours, was modified or changed in its passage through a coloured medium to the ground glass; that yellow appeared green, &c. The question was, whether the eye was a correct interpreter of the different wave lengths or not; and if the yellow were actually changed to green, or simply if it were an illusion. He (the President) could not adopt the idea that blue light would photograph quicker than white light, unless it could be shown that the white light, in passing through a blue medium, had some retarding agent filtered from it in the passage. All the blue rays being contained in white light, such a proposition would be equivalent to saying that a part was equal to the whole.

Mr. Chapman said that when a camera focussed on a yellow light behind blue glass it was focussed on the yellow light that came through the glass. It was a yellow image just as it was before. Now if they interposed a prism, they separated the yellow and the blue. The camera was not deceived by the coloured glass. The image was not composed of green light. All light except that which came from the sun was reflected light, and no matter what was interposed between the light was reduced in power.

The Secretary remarked that he had green and orange, and green and ruby, in his dark-room windows. The ruby glass would stop all the actinic light. A piece of ruby-coloured glass might be placed over photographic paper and put in the sun for a week, and the paper would be white still. By blue light he produced more harmonious pictures than he had been able to do by the use of any other tints.

Mr. Chapman said the only advantage blue light had was that it was more comfortable to the sitter, and a more composed, natural, expressive picture was the result.

Mr. J. Chisholm remarked that with blue light and a long exposure he thought he got a better picture.

The President said that his impression was, from the experience of others, that for copying oil paintings the blue light possessed an advantage.

The Secretary claimed that blue light would make a more harmonious picture than could be had without it, for the reason that the chemicals recognised a difference and worked under more favourable conditions. But one great trouble encountered in the use of blue light was that too great a quantity was used. The proper shade was of much importance. By looking at a yellow object through blue glass it looked green, and red seen through blue would appear purple. The question was—Did they, by interposing the blue, change the red into a purple, which was a more actinic colour? There seemed to be no doubt, in his mind, that the interposition of blue glass of the proper tint did accelerate the work and add to its intrinsic value. He was aware that he stood alone on that ground, yet he proposed to hold his position until driven off by clear demonstration of its no longer being tenable.

The meeting was then adjourned.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

A meeting of the above Society was held on the 1st February,—Dr. Vogel in the chair. Four new members having been admitted,

The Chairman placed on the table some portraits by Rocher, of Chicago.

Herr Hartmann called attention to their remarkable sharpness, saying that he believed them to have been taken with a Dallmeyer's rapid rectilinear lens.

A reclamation on behalf of Mr. Walter Woodbury was then lodged, in which it was stated that the dark slide for emulsion paper exhibited to the Society by Mr. Warnerke was constructed on a principle previously published by the reclaimant, Mr. Woodbury. The communication also contained the description of a process for obtaining bird's-eye photographic views by means of a camera fixed to a captive balloon, and furnished with a dark slide containing a roll of emulsion paper. This roll is moved by means of machinery worked by an electric current from the earth. It is not necessary for anyone to go up in the balloon.

The CHAIRMAN remarked that however chimerical this idea might appear, it contained nothing impossible, he himself having already seen in America views taken from a balloon. Mr. Black, of Boston, took a view of that city from a balloon upon a wet plate, which was sufficiently sharp to allow of the principal buildings in the town being recognised. According to recent experiments it would appear that they need not despair of getting similar instantaneous views upon dry plates under favourable circumstances.

Herr ZIPSER gave an account of his experiments with Husnik's dusting-on solution. The solution was diluted with three times its volume of water, then poured upon a clean glass plate, dried with heat, and placed while still warm in the printing-frame with the negative to be reproduced. In the printing-frame it received an exposure sufficient to get a good carbon print from the negative used. The picture was then developed by having the prepared graphite dusted upon it. The process was very similar to that of Herr Obernetter. Herr Zisper showed the results he had obtained by the process, but he was not very well satisfied with them, and he said it was less trouble to reproduce the negative by the carbon process than by Husnik's process. Herr Husnik, he might mention, recommended that the plate be rubbed with a dilute solution of water-glass, and that one should breathe upon it before pouring on the dusting-on solution.

Herr JOOP had also tried Husnik's solution, and expressed himself pleased with the results. Instead of water-glass he had treated the plates with alcohol and glacial acetic acid, and did not breathe upon them, as he found that it changed the temperature of certain parts. He also remarked that, when drying, the plates should not be placed in a draught.

Herr BECKER said the negatives so obtained were reversed, and he had not been able to draw them off and turn them over. He had coated the picture with raw collodion, let it become perfectly dry, then laid it in acidulated water, and when he tried to draw off the picture half of it stuck to the plate while the other half came off with the collodion.

The CHAIRMAN had never found any difficulty in drawing off the negative, but he thought the collodion should not be allowed to become dry, but only to stiffen, and should then be placed at once in the water.

Herr JOOP described his present manner of developing carbon prints. When the pictures were removed from the pressure-frame they were first dipped into cold water and then squeegeed, being then placed for about a minute in a two-per-cent. alcoholic solution of white shellac. Afterwards they were again squeegeed in the usual manner on a glass plate, and about a quarter of an hour after they were developed.

Herr LIEBMANN worked on the same plan, but used a shellac solution at least one-per-cent. stronger.

The CHAIRMAN pointed out that the *New Lichtpaus Process* described in a Swiss technical journal is merely Willis's well-known aniline printing process. He (the Chairman) took this opportunity of pointing out that when an application for a patent was received and taken into consideration at the patent *bureau* that was by no means, as some people seemed to suppose, the same thing as granting the patent. It merely meant that the application and specifications were to lie in the patent office for eight weeks until inquiry could be made as to the real novelty of the invention, after which, if the results were satisfactory, a protection would be granted for five years. Some other people in describing an invention did not merely patent the new part, but included parts of the process in common use before. Thus, in the specifications of a process for producing photographs on textile fabrics by electric light, a deseription is given of the method of salting and silvering the fabric and of toning and fixing the pictures, though these last processes are not new and have often been employed, so that the labours of the testing commission are by no means light.

The question-box contained but one query. A member wished to know whether there was any truth in the paragraphs going the rounds of the papers as to the remarkable influence of coloured light upon lunatics.

The CHAIRMAN said, in reply, on the authority of Dr. Levinstein, director of the *Maison de Santé*, at Schöneberg, that the plan of acting on the minds of lunatics by means of coloured light had never been tried in earnest by medical men who made madness their study, and that the *whole* thing was *humbug*. He (the Chairman) then reported that Dr. Eder and Captain Tóth's report on chrysoïdine in the last number of the *Archiv* was less unfavourable than that in the former number; but their experiments were made with bromide of silver emulsion, which differs in sensibility to violet and dark blue light from ordinary iodide of silver wet plates. He (the Chairman) had made his own experiments with the latter, and found the action of the chrysoïdine upon it much less favourable.

The conversation next turned upon disturbances in Eder and Tóth's intensification with lead.

The CHAIRMAN remarked that when plates intensified unequally it would often be seen that the cause lay in their having been allowed to become dry, or half dry, before being laid in the lead bath. The plates ought to be placed in the lead bath wet, immediately after being fixed and carefully washed.

Herr SCHAARWÄCHTER stated that his plates intensified in the lead bath often sprung off the glass during the drying.

The CHAIRMAN said that had only happened once to him. For a year back he had intensified with lead almost daily, and got the best results.

Herr JACOBI remarked that by intensification with lead the fine lines were easily veiled.

The CHAIRMAN said that that could easily be prevented if the shadows were kept clear, for which end a drop of nitric acid should be added to fifty centimetres of collodion. He (the Chairman) then intimated that on January 22nd a meeting had been held of those persons interested in the proposed exhibition to be held at Berlin in 1879. A committee had been chosen, of which he was a member, and they might rest assured that he would do all in his power to further the interests of the Society. At the exhibition photography is to be classed with prints. The exhibitors will be limited to Berliners.

Dr. Weissenborn read an extract from the annual financial statement of the "Dresden United Manufacturers of Photographic Papers," from which it appears that the company will pay its shareholders a dividend of ten per cent,, making, with that already paid, sixteen per cent. for last year, as against seventeen and two-thirds, fifteen and a-half, and twelve and a-half per cent. in previous years.

On the motion of Herr Leibmann it was resolved to hold a second social meeting in March. The meeting was then adjourned.

Correspondence.

PHOTOGRAPHY IN CEYLON.

To the EDITORS.

GENTLEMEN,—Enclosed I beg to hand you some photographs of sunset effects, also some of the burst of the south-west monsoon in May of last year.

I have had two or three "goes-in" at carbon, but except once I have not done much at it as a rule. I sensitise a batch of tissue at night, and on the following day, if I have no appointments, I can get through all right; but I am sure to be called away at some point or another, or else get an order to go out somewhere, and there you are!—the tissue is spoilt.

I am still using the collocine, and have tried it several times against glacial acetic acid, the result being always the same, viz., the collocine gives a quicker and better image. You remember how I use it, namely, one ounce of collocine to seventy-five ounces of water. I use this exactly as I would acetic acid.

I often wish that you could have twenty-four hours of our sun once a week in exchange for a like period of cold weather; but really, as a fact, the heat here is not oppressive unless you are sitting down indoors, or standing in the sun in dark clothes without an umbrella. For myself I have plenty to do, and although life here is monotonous it is very pleasant, and time flies very rapidly.

We had a rather curious phenomenon here last week. At about three o'clock the sky was overcast, the sun shone through the clouds, and was of an orange colour. Although the light was almost as bright as before, the exposure required for a plate was about five times more than it ought to have been.

With kind regards to all my old friends,—I am, yours, &c.,

Colombo, Ceylon, March 4, 1878. W. T. WILKINSON.

[The prints sent by Mr. Wilkinson are singularly fine, the combinations of sea and sky being most attractive. In the "monsoon" views the sea is seen in the picture dashing over a pier as a cloud of spray.—EDS.]

NON-CONVERGING PERPENDICULARS.

To the EDITORS.

GENTLEMEN,—Will you kindly inform me, and probably many other readers, if the nature of the perpendiculars in a photograph is affected by the kind of lens that is employed in the production of a picture, and, if so, to what extent.

It has been clearly shown by those who have so recently written on this subject that distortion ensues if the camera be pointed upwards, causing the convergence of the perpendiculars. Now what I wish to know is this—is this the case with *all* lenses, or only with those known as distorting or single lenses?—I am, yours, &c., MEDICUS.

Hornsey Rise, April 3, 1878.

[No matter what kind of lens is employed the perpendiculars will converge if the camera be tilted, the amount of convergence corresponding with the extent to which the tilting takes place. In the case of a non-distorting lens the lines of the perpendiculars (whether converging or not) will be straight; with a single lens they will be slightly curved.—EDS.

EXCHANGE COLUMN.

No charge is made for inserting these announcements; but in no case do we insert any article merely *offered for sale*, that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a *nom de plume* be thought desirable), otherwise the notice will not appear.

Wanted to exchange, a skylight and dark room, for *Bigelow's Album* in good condition.—Address, G. Brown, 8, Madelaine-street, Prince's Park, Liverpool.

Ross's No. 3 symmetrical, 5 inches focus, will be exchanged for a ditto an inch longer in focus; value adjusted.—Address, S. S. Crewdson, Union-street, Ulverston.

I will exchange a folding-tent, and wheels for moving it, for two or three good posing chairs or useful accessories for studio.—Address, Geo. Collins, 130, Culford-road, N., Kingsland, London.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

*** Reviews, &c., in our next.

Robert Whitehouse.—By "sal soda" is meant common washing soda.

W. S. Barker.—The tone of the transparency can still be modified and improved by placing it in a weak gold toning bath.

Rev. T. P.—The credit of the discovery or invention (whichever you like) is due exclusively to Mr. M. Noton, of Manchester.

Engraver.—While it is our intention to give full working directions for the process, some time will yet necessarily elapse before it can be done.

Obliged Reader.—Nos. 1 and 2 in your list, although by different makers and bearing different names, are in reality alike both in principle and construction.

M. E. E.—Either your light is too concentrated or you under-expose the picture. Try a longer exposure and a developer that is more diluted before deciding upon altering the roof of your studio.

L. G. B. (Gray's Inn).—The streaks on the negative are caused by the bath being out of order—probably from the presence of organic matter. The remedy in such a case will consist in neutralising and sunning.

Oxon.—If you are again so unfortunate as to stain your coat by means of acid lose no time in pouring a little ammonia upon the red stain, by which it will, in most cases, be reconverted into its original black colour.

Australia.—The photographic trade is said to be no better in Australia than it is in this country. We would not risk offering you advice under the circumstances. There are no local photographic journals published in Australia; we, at anyrate, are not aware of any.

T. O. B.—Seeing that (contrary to the experience of others) the use of French chalk does not facilitate the transfer of the collodion film, you may try the effect of giving the plate a coating of a weak solution of wax. Describe to us in what manner you proceed, and we may then be able to help you.

J. M.—By increasing the strength of the sensitising bath till it contains not under forty grains to the ounce, and by then adding a few drops of nitric acid, the evil of which you complain will be remedied. From the offensive smell of the paper we infer that it must have been prepared with very old albumen.

W. W. W.—The bronzing in the shadows may be got rid of by reducing the strength of the exciting bath; but the bronze that appears in patches on the plain piece of paper is owing to some surface defect. The paper has, perhaps, been handled by some one whose fingers were dirty. Try the effect of using another sample of paper.

P. S. J.—1. You will obtain all that is required by purchasing an ordnance survey map of the locality, and photographing just so much of it as serves to illustrate your lecture.—2. The lantern transparency ought to be produced on a plate exactly three and a-quarter inches square. Cushion-shaped mats will best suit your purpose.

S. Y. L. L.—While the portraits, as photographs, are well executed and technically perfect, there is a very unpleasant expression in most of them. This is somewhat difficult to account for, unless on the supposition of your being somewhat "grumpy" when posing your clients, the expression upon your own face influencing those of the sitters. Can *you* account for this peculiarity otherwise?

G. S. Smith.—First of all produce an over-intensified transparency, then, after fixing, tone throughout its entire substance with a weak solution of chloride of gold, wash, transfer to the porcelain plate, and place it in the muffle. This will yield a picture of the kind desired; but you may modify the process by toning the image in chloride of platinum or of iridium, or of a mixture of either of these with gold.

L'Etude.—Let the interior be painted a pale blue colour, and avoid thick window bars. Let the latter be thin and deep rather than thick. For the rest see that your assistant is supplied with a lens of large aperture and short focus, and you may commence as soon afterwards as you choose to issue the proposed advertisement. You will, of course, have carefully considered the wisdom of making a speciality of photographing children.

Capt. Young.—Among the useful tables given in each issue of our Almanac you will find one devoted to the subject about which you write. The table—that having reference to the production of enlargements—is so constructed as to afford all the explanation required. If after perusing it you should find your proposed course still "misty," write again and give full details. This we think, however, you will not require to do.

Atelier.—1. A collodion transparency may very easily be transferred to canvas, and it is occasionally done by specialists in the transfer process. The method you propose for doing so will answer quite well, but the squeegee will not be required.—2. We think that the roller-and-cord system will prove most convenient. If properly fitted up it need not prove inelegant.

G. B. Hudson.—Procure, or make, a small view-meter, and let it be your companion when out for a walk. If it be adjusted to embrace precisely the amount of subject included on the ground glass of your camera you will soon acquire facility in estimating with considerable accuracy, and, eventually, *without its aid*, the extent of any subject or landscape which can be photographed from any particular standpoint.

Amateur.—The Dry-Plate Club has ceased to exist. So far as we are aware the Amateur Field Club is the only one of the kind devoted to outdoor photography in a social capacity. The Solar Club was organised and continues as a social dining club. If you call at our office we can give you the address of several amateurs who will be glad to accompany you on your proposed Saturday excursions "out and about" with the camera.

J. F. F.—Having made a strong solution of soda or potash in boiling water, immerse therein the brass mounts from which you wish the lacquer removed. If the solution be hot and strong an immersion of about a minute ought to prove quite sufficient. If you have access to a turning-lathe "chuck" the mount, and give it a final polish with rotten stone and oil, using a woollen cloth for the purpose. This will impart a beautiful finish.

A. Conlon (Lincoln) says he is about to proceed to the continent, and wishes to take with him a camera and a few dry plates. He wishes to know how he can best pass his plates scatheless through the Custom House. He proposes going *via* Newhaven and Dieppe to Paris, and from thence to Nancy, Meurthe, Moselle. If any reader happen to know any places of interest within easy reach of that town he should feel obliged by being informed of them.

Old Professional.—The yellow, or even orange, glass at one time so commonly made use of in glazing the windows of the dark room of the professional photographer will prove quite inadequate to the requirements of the bromide emulsionist. Read what Mr Bennett said on this subject in our last number, and accept our assurance that he has not overrated the importance of working with a minimum of a strong ruby-coloured light. Begin the study of sensitive bromide emulsions by discarding the preconceptions derived from your wet collodion experience.

Orion (Blackheath).—When we stated that triplets were usually constructed with larger apertures than doublets we merely stated a fact that was generally recognised at that time. The term "doublet" in that assertion did not apply generically, but had reference to a certain article of manufacture bearing that as a trade designation. Since that time the term is recognised in a broader sense, and cemented doublets have undergone a great change. The manufacture of the triplets there referred to has also been discontinued. Many improvements in lenses have been effected within the last thirteen years.

Fusible Metal.—In our article last week *On Blocks for Woodbury-type Printing* we gave several formulæ for the compounding of fusible alloys. In the one made use of by Mr. Thomas Bolas in his lecture at the Society of Arts we gave as an ingredient "one part of nickel." This is an error; it ought to have been one part of *cadmium*.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician.
For the two Weeks ending April 3, 1878.
These Observations are Taken at 8.30 a.m.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 936. Vol. XXV.—APRIL 12, 1878.

THE FERROUS OXALATE DEVELOPER.

Since our last reference to this subject we have had ample opportunity of trying the new developer under almost every variety of circumstances, and are now in a position to speak more decidedly of its capabilities than was the case when we last mentioned it. We have placed it in direct competition with alkaline pyro., and are able to confirm all that has been previously said with regard to the remarkable energy of its action. A variety of experiments have also been made with a view of finding a suitable restrainer to be used under circumstances which render the solution in its normal state too powerful; but, in this direction we have not been able to attain complete success.

The most noticeable feature in connection with this developer is the extraordinary rapidity with which it performs its work. Whatever may be the exposure the plate has received the full effect of the developer appears to be produced at once; that is to say, the time occupied in bringing out the whole of the detail it is possible to secure with a given exposure is as short, or shorter, than would be necessary with a wet plate and iron development. In this respect it offers a marked contrast to most other developers, strongly alkaline pyro. presenting the nearest approach to similarity. Under-exposure does not, as in other cases, produce a slow and gradual development; but, though the characteristics of the finished negative may resemble closely those of an under-exposed plate developed by other means, the development is as rapid as if a full exposure had been given, and no continuation of the action of the solution appears to be capable of bringing out further details.

This peculiarity in its action may possibly in many cases lead to the formation of an exaggerated idea of its power; for rapidity of action and energy have hitherto been so closely allied that it is not improbable the *searching* power of a prolonged development under favourable circumstances may be overlooked. For practical purposes we take it that the energy of a particular form of development is represented by the amount of detail it is capable of producing with a given exposure, and irrespective of the time occupied in the developing operation. Of course, other things being equal, we should give the preference to that solution which produced a given result in the shortest time; but, however rapid its action, we should hold it inferior to a slower developer capable of rendering a fuller amount of detail. Viewing ferrous oxalate from this point, we were at first inclined to believe that its powers had been overrated; but, after a number of careful comparative trials, we have been forced to the conclusion that it does undoubtedly shorten the exposure, though, perhaps, not to the extent which some claim for it.

Owing to the unfitness of the weather for outdoor work many of our early experiments were made upon transparencies, in which branch the extra sensitiveness arising from the use of the new developer is not very apparent; it may be noticed, indeed, that the gain in that direction only becomes evident when the solution is tested to its utmost by extremely short exposure. For instance: if we expose a plate sufficiently long to give a good result with alkaline pyro., it will be found that a similar plate exposed for the same length of time, but developed by means of ferrous oxalate, will exhibit no trace of over-action; in fact, the exposure may be considerably increased without producing such an effect, which argues greatly in favour of the elasticity of its powers. The absence of any fogging tendency no doubt contributes to this result, as, unlike alkaline pyro., especially when used strong, the new developer is not liable to veil the transparent parts or render heavy the shadows of a transparency if the exposure be a little overdone.

Thus with a certain negative we found that an exposure of ten seconds to a gas flame sufficed to give a fully-printed transparency when a moderately strong developer of pyro. and ammonia was employed. Under similar circumstances, but substituting for the pyro. a mixture of one part of saturated solution of ferrous oxalate to two parts of water, the resulting image differed only in colour, though it perhaps exhibited a generally softer appearance without showing any increase of detail. Up to twenty seconds' exposure the results obtained were satisfactory, but beyond that point gave strong evidence of over-action. Upon gradually reducing the exposure we found that no detail was lost until it had been reduced to two seconds. With three seconds' exposure all the detail exhibited by the alkaline developed plate with ten seconds was present; the general appearance of the image was cleaner and more crisp without showing any sign of under-exposure. A nearly similar result as regards the amount of detail brought out was given by alkaline pyro. in five seconds; but the finer detail in this case was extremely feeble, and the general appearance of the picture crude and incomplete.

These experiments were, so far, decidedly in favour of the new developer; but as we can scarcely accept transparency printing as a fair test of the power of a developer for landscape work, we seized the first opportunity of applying a more complete test. A dry emulsion plate was exposed for three minutes upon a bright clear day about the middle of February, the subject being houses and broken ground in the foreground, with a background of trees. Developed with pyro. and strong ammonia a vigorous and well-exposed negative was the result, the naked branches of the trees forming the background being perfectly rendered, though with little strength. With two-thirds of the exposure ferrous oxalate gave a better result—better inasmuch as the fainter portions possessed greater vigour—and produced a more harmonious negative.

A wet emulsion plate was then exposed for thirty seconds upon the same subject, the resulting picture, under alkaline development, being a decided improvement upon the similarly-treated dry plate. With twenty seconds' exposure ferrous oxalate produced but a feeble and apparently fogged picture, and it was only by reducing the time to *five seconds* that a clean and passable result was obtained; but even then it was inferior to the image secured with alkaline pyro. This difference in the behaviour of the developer upon wet and dry plates appears rather remarkable, and would seem to lead to the idea that in the open and permeable state of the wet film its reducing action, at least at the strength we employed it, is too powerful. We may remark that there was nothing in the preparation of the wet plates which would interfere in any way with the working of the ferrous oxalate. The same emulsion was employed as in the preparation of the dry plates, and after coating the plate it was merely washed under the tap to remove the ether and alcohol, no preservative of any sort being used.

Another peculiarity in the behaviour of the ferrous oxalate may be mentioned, namely, that it appears to act less favourably in a strong light, or when the subject offers little contrast, than when the opposite conditions prevail. Thus for cloud subjects we have found it wholly useless, as, however short the exposure, a general veiling of the whole plate occurs, as if from the action of diffused light in the camera, and no variation in the strength of the solution appears to materially affect the result.

This leads us to the subject of restrainers, and we are compelled to confess that, so far as the addition of any extraneous matter to the solution is concerned, we have been wholly unsuccessful in this direction. Large additions of sulphuric, citric, or oxalic acids, or of solution of bromide of potassium produce no effect beyond slightly retarding the *commencement* of the development; once commenced it proceeds as rapidly and produces as full an effect as when no restraining agent is employed. The only means which have proved at all successful in modifying the action of the solution consists in using it in a state of considerable dilution, when the effect is, as might be anticipated, much less energetic and more easily controlled, without any apparent diminution in the developing power. It is to be remarked, however, that as the strength of the solution is diminished so does the density of the image become less; and, though the same amount of detail may be brought out, it is proportionately weaker and more difficult to work up to printing density. The strength we have generally employed is one part of the saturated solution to two of water; but the quantity of the latter may be increased to eight, or even ten, parts without losing working properties.

We have so far spoken only of development proper, and we may now say that, so far as our experiments have gone, we have been unable to trust entirely to ferrous oxalate for the production of printing density. For transparencies a sufficiently strong image is easily obtained, though the colour is not generally satisfactory; but for negative work we have found silver intensification a necessity. With a film of pure bromide the silver appears to deposit with greater difficulty when ferrous oxalate is used than when the preliminary development is performed with pyro.; but the presence of a very small proportion of iodide in the film entirely removes this difficulty. The iodide does not seem to alter the characteristics of the image produced by the iron salt, but when the intensifying solution is applied it appears to attract the deposited silver more readily.

In a future article we shall have something to say on the effects produced by variations in the strength and mode of preparing the solution.

DRY PROCESSES—ANCIENT AND MODERN.

I.—COLLODION WITH ALBUMEN.

It is now ten years since we, in the course of a few chapters entitled *Dry Processes for the Approaching Season*, and in which we described a few of the many processes then practised, said:—"It is unquestionably a fact that the majority of our best dry-plate workers prefer those processes in which albumen is united with the collodion film." But since that period dry-plate photography has made great progress, and the unquestionable "fact" of April, 1868, has ceased to be a fact in 1878; for which we are in no small degree indebted to Mr. W. B. Bolton, who, by the introduction of his washed emulsion process, has raised to a position of great popularity this the simplest of all processes.

Nevertheless, there is a well-marked predilection shown by many for processes in which albumen is called to play a part; and, although it is true that not one of the somewhat extensive family of collodio-albumen processes can for a moment compare with washed emulsion in its general convenience and facility of utilising, yet, yielding plates possessing such special points of excellence, they must always be held to occupy an important place among dry processes. The great fault attributed to collodio-albumen plates is their slowness, an exposure of twenty minutes being sometimes required under circumstances of lighting which, in the case of the modern rapid processes, would not necessitate an exposure of twice as many seconds.

Previous to describing in what manner this stigma of slowness may in a great degree be removed from collodio-albumen plates, it is fitting that we give a brief outline of the various methods by which such plates have been prepared by those who have most successfully worked this process; and, to prevent misunderstanding, we shall include under the generic designation of collodio-albumen all those processes in which albumen is called to enact the part of a preservative or organifier.

The original process, introduced by Dr. Taupenôt, differs from all others in being to a large extent an albumen process upon a collodion substratum; that is to say, the albumen was iodised and sensitised *per se*, its function not being confined to the *rôle* of a mere protective varnish to the stratum of collodion underneath. The plates are prepared by coating them with a bromo-iodised collodion giving a short or "rotten" film; they are then excited in a negative silver bath of the kind commonly made use of by wet collodion workers, and after remaining in this bath for the usual time the plates are taken out and washed, then transferred to a weak bath of iodide of potassium and thoroughly washed. This, be it understood, is merely a preparatory coating of the plate to act as a substratum for the iodised albumen, which is applied before the collodion is allowed to dry. The iodised albumen is prepared according to the following formula, which was published in our Almanac for 1866, and which is believed to give the best proportions that can be adopted:—

The white of	1 egg.
Distilled water	½ ounce.
Iodide of ammonium	4½ grains.
Bromide of ammonium	2 ,,
Ammonia	10 drops.

Before adding the water to the albumen dissolve in it the salts and sufficient iodine to make it of a pale sherry colour, then add the ammonia. Beat up the whole to a froth, allow to stand for a few hours, and pour off the clear portion, which is ready for use. Apply this to the plate by pouring it on and off at different corners, and rear up the plate to dry for half an-hour, after which subject it to the action of heat before a hot fire. All this may be done in not over strong daylight. The plates may now be stored away, for months if required, until it is convenient to excite them, which is done by immersion for three minutes in a forty-grain silver bath, to which has been added half-a-drachm of glacial acetic acid for each ounce of the solution. Next wash thoroughly, and if the plates are to be kept for any length of time apply sufficient of a saturated solution of gallic acid to flow over the surface, after which allow them to dry.

The process of preparing plates here given is an improvement upon that of Dr. Taupenôt, from which, however, it differs only in matters of detail, being similar to his in its leading features.

The Fothergill process has produced negatives of equal excellence as the foregoing, and possesses the merit of being somewhat less complex in the manipulations required. A plate is coated with an old and porous collodion, and sensitised in a thirty-five-grain bath. It is then removed to a flat vessel containing distilled water, and is allowed to remain there *not* so long as to be thoroughly washed, but only for about a minute, the water being agitated by rocking the vessel. It is then removed, and receives an application of a preservative composed of the white of one egg mixed with two ounces of distilled water and ten drops of ammonia. This is allowed to remain on the surface for about two minutes, during which time an action is taking place between the residuum of nitrate of silver left in the film from the slight washing it received and the albumen. It is now *thoroughly* washed, and dried without heat. If the plates are to be kept for a long time a final application of a solution of gallic acid, as in the former process, is desirable.

It was found by Dr. Ryley that the coagulation of the albumenous organifier of a collodion film might be otherwise advantageously effected than by means of nitrate of silver, and his experiments culminated in a process which, either for the beauty of its principle or the excellence of its results, has never been surpassed. When a collodionised plate has been sensitised as usual, and then thoroughly washed, a small quantity of diluted albumen, similar to that made use of in the Fothergill process already described, is poured on and off the plate, taking care that every part is covered. The best results we have obtained were with the white of one egg to three ounces of water and ten minims of ammonia. After allowing a little time—say two minutes—for the albumen to permeate the film, the plate is suddenly immersed in a vessel of boiling, or, at anyrate, very hot, water, which must be conveniently at hand. A tin tray placed over a Bunsen gas stove is very handy for this purpose, although when we prepare a few plates by this process, as we frequently do, we keep a kettle of boiling water close at hand, and, holding the plate in the left hand and the kettle in the right, we pour into the tray sufficient water to well cover the plate, which is then immediately immersed. In half-a-minute it is removed and reared up to dry, which it does with a hard and glassy film not easily injured.

A process by which Mr. W. England has produced many charming pictures—presumably those for which he obtained the medal in connection with the last exhibition—consists in collodionising and sensitising as before, then partially washing, and applying albumen with a final washing, as in the Fothergill process, to which he adds another application, namely, that of a little of a thirty-grain solution of nitrate of silver, each ounce of which is acidulated with a few drops of glacial acetic acid. A thorough washing completes the preparation of the plate.

The processes here described comprise the best and most reliable of those in which albumen takes part; but, as we have said, they are all more or less slow, mainly owing to the mode of development employed, which is that of acid pyro. In proportion as the alkaline system of development is applied to these processes so is the rapidity increased.

REMARKS ON DR. MONCKHOVEN'S PAPER.

[A communication to the Photographic Society of Great Britain.]

In commenting on the paper contributed to our last meeting by Dr. Monckhoven one may for the present dismiss the question of the suppression of bichromates in carbon printing, and proceed to his suggestions for a more perfect fixation of the pigment image, and the introduction of ferric oxide as a brilliant pigment absolutely inalterable by the solar rays.

Before doing so I wish to express a certain diffidence that I experience, due to the fact that, being commercially interested in all that pertains to carbon printing, I stand before a Society like this, not only with the fear of being credited with "talking shop," but with the dread that the bias of a trade interest may really obscure the judgment and indispose me for the judicial investigation of a new fact. I shall endeavour to avoid any such bias as far as possible, and I feel my position somewhat easier in the present case, as the author of the paper which is to be considered is not only a distinguished *savant*, but has thrown his resources and energy into the manufacture of carbon tissue as a trade. You, therefore, gentlemen, outside the disturbing influences of any commercial rivalry, may maintain evenly-balanced minds, and can discount, to any extent found desirable, the statements put before you. In the paper to be considered it is evident that Dr. Monckhoven comes before the Photographic Society of Great Britain not as a manufacturer but as a *savant;* that, as such, he prefers the honourable reputation of the discoverer to the profits of the patentee, and therefore places the results of his chemical researches freely before the public. This Society cannot but feel honoured to be the recipient of original papers offered in such a spirit.

This premised, I feel bound to object to the first part of the title of the paper, *On the Fading of Carbon Prints*, as unwarranted by facts, and consequently misleading, The experiments detailed and the arguments adduced by Dr. Monckhoven are intended to prove that in the ordinary production of a pigment print the bichromate of potash is not fully deoxidised, that the print leaves the alum bath with a tinge of yellow, which, upon after-exposure for a considerable time to the direct solar rays, changes to a greenish hue; with this change of colour the chromic salt present in the pigmented film has reached the stage of sesquioxide of chromium, when any further change is not to be apprehended.

Ignoring experience, and for the sake of argument granting all this to be true, this is not fading of the picture; at the worst it is only an alteration of tint—one that does not disturb the relation of light and shade, or impair those subtle half-tones on which its photographic excellence depends. To say that carbon prints fade in the sense with which we apply that term to their silver prototypes is to belie common experience and the whole history of the process. Such an assertion is sufficiently contradicted by the myriads of prints spread over Europe the last ten years by the indefatigable enterprise of the late Adolphe Braun. Judged by the practical experience of fourteen years, one may fairly say that carbon printing has removed the one reproach of the photographic art—the fugitive nature of its beauty. From my own experience in dealing with large numbers of pigment pictures, and from my position as a natural recipient for complaints of fading, if such existed, I can honestly declare (postulating the avoidance of known fugitive colours in the tissue, and proper care in the production of the prints) my belief to be that, for all the purposes of use and ornament to which they can be applied, carbon pictures are absolutely permanent.

If for the ends of use or beauty it were essential to expose photographic pictures for months to the direct rays of the sun, my conviction might possibly have to be modified to the extent indicated by Dr. Monckhoven, namely, that a yellow tint not discernible by ordinary vision when the print is produced changes to an almost equally invisible green after long exposure to sunlight.

I have made an extensive search through a great variety of prints in various colours to discover any traces of that congenital yellow predicted by Dr. Monckhoven. I place a series of such pictures before the Society this evening. As you may observe in many cases the half-tones denote an incredibly thin film of the pigmented gelatine, and in others the high lights are denoted principally by the white surface of the paper support, where, if visible at all, the yellowness of the chromic salt should be descernible. Upon the walls you will see examples of duplicate and similar prints in frames that have been subjected to abundant daylight in a lofty gallery with glass roof for from three to eight years. These prints are the productions of Braun and of the Autotype Company. The loose prints are from stock kept in portfolios or drawers, and can be compared with those in frames after years of daylight.

I do not produce these specimens and make these statements as arguments against the theory advanced by Dr. Monckhoven of the changes produced by light on the chromic salt; but rather to show that the *Fading of Carbon Prints* is not a judicious title for the paper, and is calculated to convey an erroneous impression as to their real and relative permanency. The so-called "fading," if it exist at all, is only a minute change of *nuance* in these pictures, and that change can only be expected under conditions of exposure to light which, in the same conduct of human affairs, do not usually occur.

With regard to this theory of imperfect oxidisation of the chromic salt in the ordinary process of carbon printing, the experiments detailed are interesting, and may probably suggest a method of perfect fixation. While contending that experience proves that carbon prints, after ten years' exposure to the ordinary influences of light and atmosphere, are as perfect as on the day of their production, I will cheerfully admit that any new light thrown upon the chemical changes involved, and affording the means to ensure more perfect stability, is a boon to be thankfully acknowledged. Although roasting our photographs in the sun is not a human need at present, yet the knowledge that they will pass triumphantly through such an ordeal renders our interest in them more secure.

The experiment of immersing a sheet of plain paper in the bichromate bath, exposing to light, washing in boiling water, and fixing with alum is not by itself conclusive. The bichromate penetrates the fibrous nature of the paper more intimately than it does the pigmented film of gelatine; the paper does not supply the same organifier and is less accessible to the impact of the light. The experiment is not parallel with the production of a pigmented print, and might be dismissed had not Dr. Monckhoven, since the presentation of the paper to the Society, published an experiment more to the purpose. He prepares a gelatine film with sulphate of baryta, exposes to light, developes on a glass plate, and finds the resultant colour to be yellowish and convertible into green by continued insolation. This is an experiment largely supporting the Doctor's theory of the chemical changes involved, and of the value of his suggestion to add to the alum bath a proportion of bisulphite of lime. If no drawbacks shall be found to the employment of the lime the comfort of a theoretical security will be added to the practical immunity from change enjoyed.

For all practical purposes, it may be said, the fading of carbon prints is simply a question of the pigments employed. Lampblack, Indian ink, red chalk, and the various earthy colouring matters employed on the bases of carbon pictures, can be relied on with absolute confidence; but as more brilliant effects are demanded, and as it is sought to emulate the beautiful tones obtained in silver printing, it becomes quite possible to fall under suspicion. The seductive beauty of the cochineal lakes has been dallied with by most tissue makers. Carmine has not only added bloom to the cheek of Phyllis, but has imparted lustre to a good many gelatine pictures. In pigment printing, however, this delicate colour was used very sparingly, until M. Lambert, of chromotype renown, demonstrated the latent capabilities of carbon to rival, and perhaps to surpass, the finest picture obtainable by the older method. This gentleman possessed an admirable tact of manipulation, and had so deftly combined all previous experience as to produce from portrait negatives more beautiful pigment pictures than had been known before his time. His results were almost unique, the labours gave a decided impetus to carbon printing, and although the preference for a roseate hue (at that time only obtainable by cochineal) led to a temporary vitiation of the standard of permanency, yet this was counterbalanced by the incentive it gave, in various directions, to provide substitutes for the cochineal lakes, and to the production of permanent tissues of finer structure and more variety and brilliance of tone. I have placed on the wall a frame of twelve cabinets, the work of Mr. Ferranti, of Liverpool, produced while M. Lambert was in England, and with the tissue he recommended. These pictures were printed nearly three years ago, and after exhibition at Edinburgh have hung in the Autotype Gallery. If compared with a card of nine *cartes de visite* adjoining, recently produced with the same tissue, the members will be able to discern the minute loss of bloom from two years' exposure. It will be observed that the delicate half-tones of the picture are perfectly preserved, and fifty years hence, although the tone will be still cooler, there is no reason to fear but that they will remain charming photographs, creditable to the artist, and evidencing a high degree of mechanical perfection in the tissue employed.

In the paper before us we find a statement that the vitiating action of light upon colour is interfered with by the presence of the chromate salts, and that while alizarine pigment by itself will slowly change under the influence of the sun's rays, if the alizarine be in combination with gelatine in the form of a carbon print, the change will be greatly accelerated. This is singularly opposite to the fact with regard to carmine, which, employed in carbon tissue, manifests a power of resistance to light immensely superior to that possessed when uncombined. If any one spread cochineal lake in a thin layer on paper, he will not wait long before perceiving a change under the influence of light. Despite the theory that the ordinary washing and fixing of a pigment print leaves an imperfectly deoxidised chromic salt to facilitate decomposition of the colour, it does not apply in the case of so delicate a pigment as carmine. Probably the antiseptic property of carbon in contact with a pigment of animal origin has something to do with it. Anyhow, it indicates that further experiment is desirable to avoid the danger of adopting hasty conclusions.

It has been long felt by the company with which I am connected to be exceedingly desirable to abandon the employment of cochineal lakes, and my friend, Mr. Sawyer, has given much attention to substitute the products of alizarine. The alizarine colours appear to me to afford not only great beauty and variety of tone in combination with carbon, but to be free from objection on the score of want of permanency. They afford, as is well known, some of the most durable dyes known to commerce, and as far as careful tests, and a not inconsiderable experience goes, they can be enlisted in the service of the pigment printer with perfect safety. There is no difficulty in utilising aluminate of alizarine in a manner to give the tone required, without either rendering the tissue insoluble or staining single transfer paper; but it requires very careful management and combination so to prepare it as to avoid staining the picture when developed on a collodion film. Since the hitherto high reputation for permanency possessed by the alizarine colours is called in question by the experiments of Dr. Monckhoven, it has been deemed expedient to recommence testing in a critical manner the pigmented prints in which such colours are employed. As these tests have been continued for barely three weeks, and not the slightest change is discernible at present between the masked portion and that exposed to the sun, it would be futile to bring them before you this evening. Three months hence the evidence will be worth recording, and I can promise that the Autotype Company will place the results before the Society. It is, of course, perfectly easy for any member to test the matter himself.

Dr. Monckhoven has produced a very rich brown tissue with a peroxide of iron pigment, but although he was careful to give your Society his method of preparing alizarine aluminate, the indications he afforded for the preparation of his new peroxide of iron are too indefinite to be of practical use. There is no novelty whatever in the production of aluminate of alizarine; but the modification of an oxide of iron in such a manner as to convert it from a dull and opaque to a lustrous and transparent pigment is an achievement worth being recorded in detail. Whatever may be the mode of its preparation it yields a fine colour; but it appears to be limited entirely to the brown shades, whilst the alizarine products readily lend themselves to combinations with permanent blue for attaining the purple tones.

In conclusion: I may be permitted the expression of my belief that, but for the existence of Swan's patent, neither in England nor on the continent would carbon printing have reached its present stage of importance. Without the probability of ultimate reward held out by patent, the capital and energy necessary to overcome the many practical difficulties would not have been overcome; but now that commercial success is shown to be possible, the lapse of the patent stimulates research, attracts fresh talent, and, by the exertions of new workers, will render the transition from a fugitive to a permanent process of printing more rapid and easy. The field is large, and by no means wholly won. Although for artistic purposes pigment printing offers a wide range of monochromic effect and a special expression not competent to silver, and although for enlargements it affords features of decisive superiority, yet for the facile and certain production of small work of high excellence there is still much to be desired. From my personal knowledge of the energy, ability, and scientific attainments of Dr. Monckhoven, I anticipate that his concurrence will be of great advantage to the cause of permanent photography.

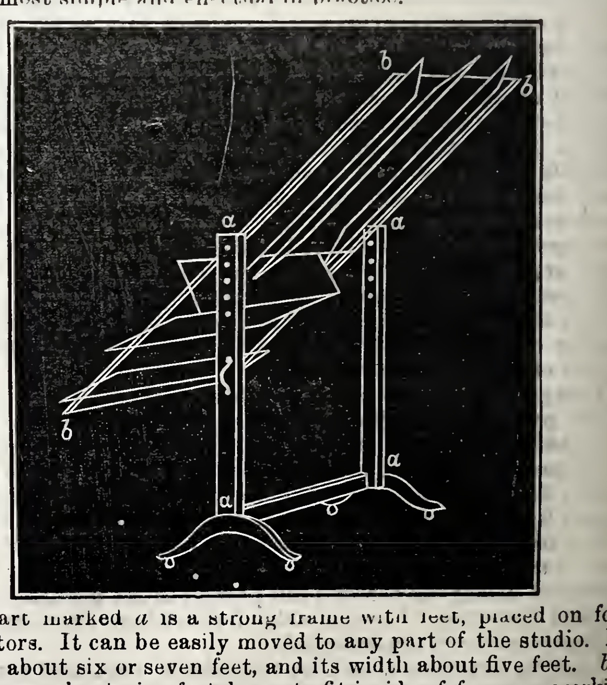
It will be very interesting to receive the further details promised of his experiments for the suppression of bichromates in carbon printing, but in the present stage of the subject it would be difficult to discuss them with advantage. W. S. Bird.

AN IMPROVED MOVABLE SCREEN.

As the use of movable screens to control the light is of great importance to photographers, I will endeavour to describe one that will be found most useful both by professionals and amateurs.

To give a description of every form of head-screen, side-screen, reflector, &c., that I have seen or used would be of no service, as they number many dozens, all of more or less service, but most of them with many disadvantages.

The head-screen (as it is named) which has been so often described, is one of the best forms; but occasionally it will be found necessary to use two or three, which makes it rather complicated. After carefully studying the different advantages and disadvantages of the screens in present use, and bestowing a little thought on what is required, I am convinced that the screen described here will be found most simple and effectual in practice.



The part marked a is a strong frame with feet, placed on four good castors. It can be easily moved to any part of the studio. Its height is about six or seven feet, and its width about five feet. b is a light frame about nine feet long, to fit inside of frame a, working on a bolt and thumb-screw, and, as will be seen, it can readily be adjusted at any desired angle. Inside frame b are a number of smaller very light frames, width from sixteen to twenty-four inches. These work on a pin or bolt in the centre of each end, and are fitted either vertically or horizontally. On the smaller frames is stretched any material, either opaque or transparent, according to effect designed. Tissue-paper might be used, but it would be easily injured. A very simple way to make tracing cloth or calico more transparent is to thoroughly wax it all over. It gives a beautiful, soft effect.

In describing this frame I do not give any definite proportions as being best, but simply give the principle; and as it is not patented it can be modified to suit any studio or purpose by the judicious use of a little *brains*. By the use of two, covered with an opaque material, it would be an easy matter to light a sitter out in the "open," as the sun could be kept off at any part of the day.

The most important points are not to have frame *a* too low; to have frame *b* long enough to come well over the sitter; and not to have the inner frame too wide, about twenty inches being the best width.

To give a full description of the many uses to which it can be applied would take up too much space; but on any point that may not seem quite clear it will be a pleasure to me to give a more definite description. J. Cowell.

LANDSCAPE WORK AND ITS RELATION TO ART.

[A communication to the Edinburgh Photographic Society.]

In noting down a few thoughts in connection with landscape photography I do so with the hope of encouraging my brother workers in the same field to aim at the highest possible excellence, and to always go *forward* with the work so that, ultimately, we shall compel even the most obstinate enemies of Photography to admit that she *has* art claims, and will *assert* them; that, no matter *what* the means, the result must be looked at as the production of the *mind*. What we want is not *technical* but *art* education, and this, I maintain, we must use all our energies to develope. We have, alas! too few eminent artists either in portraiture or landscape; but I am sure you will agree with me in saying that the works of all these men will be found to be stamped with an individuality which it will be found impossible to deny, showing clearly that the brain has been at work in a predominant degree, and that lenses, cameras, and other materials have only been what brushes and colours are to the painter. I do not mean to convey that we should not take care to provide ourselves with good materials—the best we can get by all means. Will you not find the painter equally careful that his brushes are of the required quality, also that his colours possess the necessary purity? But all these are eminently subservient to the brain, which conceives the work, and are only as a means to carry it out. It does not matter to an artist what collodion or other matter he uses, so that it be good; it will not influence the result. It may give him a little more trouble in some cases, but the effect will be the same; he has made up his mind to produce a certain result, and he will *do* it.

Suppose, for the sake of illustration, that two or three photographers are requested to make a negative, the subject being a cottage, immediately at the back of which is a hill. They are to treat the subject *pictorially*, and are left to themselves as to the means they shall employ. We will take it for granted that, technically speaking, they are all equal.

Photographer No. 1 will probably go to the place, and it being a fine clear day and wind steady—the sun, we may add, is shining almost vertically on the scene—he will immediately conclude that nothing could be more favourable; he "will show every stone in the cottage, and, for that matter, every stone on the hill, too, if there be any." The camera is arranged, best lens fitted and carefully stopped down to give extreme sharpness, the plate is exposed and developed, and "Oh! joy! the negative is a beauty—sharp as a needle; let them beat that if they can!"

Photographer No. 2 will go about his work after another fashion; *he* will turn out something different to that other fellow. He has been told that it is best to have the light strike the subject at an angle of about forty-five degrees, and he selects the time of day accordingly. It is true the image on the ground glass does not strike him as being particularly beautiful; but has he not gone strictly according to his instructions? *He* will not have the cottage in the centre of the plate as No. 1 has shown it; but, still following his instructions, he puts the principal object to the right or left. He must now have a foreground to complete matters, and what could be better than Mr. and Mrs. Rustic, the occupiers of the building, who are straightway induced to "stand as if they are talking to each other?" He has been told that figures *judiciously* introduced are a great help, and "what could be more natural than this arrangement?" The figures look toward each other as if they were striving to stare each other out of countenance; however, the instructions have been strictly adhered to, and so all *must* be right. The negative is taken, and although the result, in comparison with No. 1, is very different, still, judged pictorially, they are about equal.

Photographer No. 3, whom we will suppose to be an artist of cultivated taste and feeling, goes to look at the cottage; but gentlemen Nos. 1 and 2 chuckle as they see him going, for how can he possibly improve upon their productions? Arrived at the spot the artist is disappointed—the ugliest portion of the cottage is in strong sunlight; and he feels that he is helpless to produce a picture under that condition. He considers the subject, and calculates that in the very early morning the opposite, and very picturesque, gable will receive the light, and he determines to be up betimes to see the effect, and seize it if it be satisfactory. The next morning is fine, but hazy; however, he does not mind the haze. Perhaps he says to himself as he is dressing—"The effect will be prettier, as it will throw the cottage into bolder relief, and assist photography in separating it from the adjoining hill." Arrived at the scene, he is charmed beyond measure at his little cottage in its new garb. The sun, as he predicted, though shining faintly, is tipping the gable he so much admired. The housewife, just up, is evidently starting the fire, as the smoke is lazily pouring from the chimney; the hill behind is slightly obscured by the haze, but looms up grandly, and the picture is complete. And now, to make the most of it, no time is to be lost, as the effect may soon be gone. Care is taken to have the smoke from the chimney relieved by the dark fir which is near to it, and the camera is moved up as near as possible to the creepers which hang over the wall in front; no other foreground is required. He asks permission to have the rustic door partly open, as he is greatly in want of a little intense shadow. And now a last look at the ground glass. He breaks away a twig that will *not* come into focus, but pokes itself provokingly in front of that cluster of roses. "Ah! what is that?" A gleam of light of greater intensity now steals across the screen—not altering the effect, but heightening it, the sun seeming to say, "Well done, old fellow! I'll help you; but come on now quickly with your plate or I may not be able to keep it up." The negative is taken and developed, and I tell you that man carried home a picture; he carried home a result produced by true art feeling and careful study. He saw a beautiful effect, and his artistic mind grasped it at once, and determined him to secure it. Had the early morning effect not pleased him he would have secured it under some other aspect; but you may rest assured he would have made a *picture* of it—nothing else would satisfy him. He had become accustomed to work up to a certain standard and he could not go below it.

I am sorry the limited time at my disposal will not allow me to enter more fully into this subject; but I shall be amply repaid for the little trouble I have taken in writing this short paper should it be the means of increasing the love, which I am sure all of you have, for our beautiful art.

I have sent for your inspection a few of my studies of English and Irish scenery, which may be of interest to you. I have also forwarded a few smaller views which require some explanation. I have been commissioned to illustrate several of the poets with photographs from nature, and my people are at present busily engaged in printing four or five thousand of these little views. Nos. 1 to 18 are specimens of these studies. I send you them because I know the interest we all have in looking at actual productions; and I know no better means of advancing our art and mutually improving ourselves than the system of exhibiting the results of our labours, so that we may see where we are at fault and where improvement is needed. We can all learn something, and should not be ashamed to do so even from the humblest of our brethren.

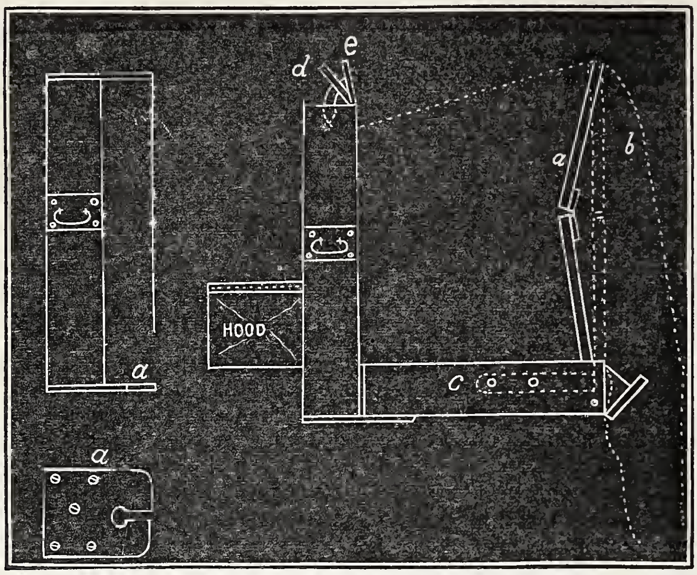
Payne Jennings.

A PORTABLE TENT AND CAMERA COMBINED,

As Exhibited and Described at the Meeting of the Edinburgh Photographic Society, 3rd April, 1878.

This is a simple means of preparing, exposing, and developing a wet collodion plate in the field. As a dark tent it can be rapidly constructed and removed *without a single detached screw, bolt, or spar*. The woodwork, of half-inch yellow pine, is divided into two portions—the back 24 × 20 × 4 inches; the front 24 × 24 × 4 inches. It is fixed in the usual way to the tripod by means of a bolt, which in this case need never be unscrewed from the triangle. A cloven foot at the bottom of the front portion, *a*, *fig.* 1, is slipped under the bolt head and screwed tight. The back portion, being hinged four inches from the bottom of the front portion, folds down and rests firmly and securely on the cloven foot (see *fig.* 2). There is now a cover of two plies of black twilled linen tacked round the inside of the front portion and along the bottom, and is raised by a wooden frame or stretcher (*a*, *fig.* 2) which folds up, and is held in position

FIG. 1. FIG. 2.

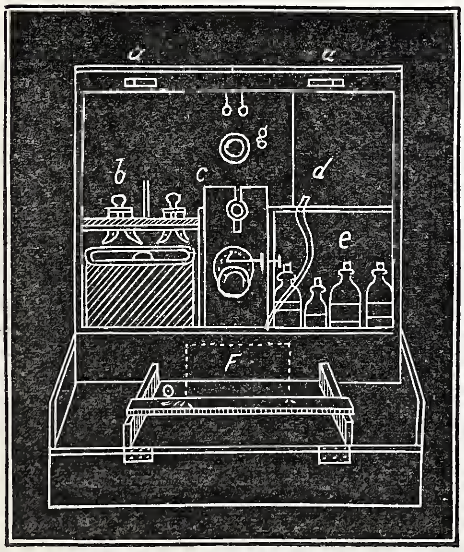


CLOSED. OPEN.

by the tension of the cloth cover *b* and by two springs *c*, which are self-acting when the stretcher is raised to the proper height (see dotted lines). It is illuminated from a window at the top covered with yellow calico. The light passing, as it were, down the inside wall of the tent, which is covered with yellow paper, is reflected inwards and can be moderated according to the intensity of the light outside by means of a shutter, which may be raised and lowered at pleasure from the inside by means of a wire, *d*. Another shutter, *e*, of similar construction, is for the admission of white light and water when wanted. A ventilator, *a*, *fig.* 3, under each shutter keeps the air pure and pleasant.

To use this tent as a camera: having fixed upon the point of view a shutter 8 × 6 inches is raised, and a hood of black cloth folds out and uncovers and shades the lens, as in *fig.* 2. *b*, *fig.* 3, is a water-tight bath. The india-rubber top is held in close contact, by an elastic band, with the two pinching screws, which are permanently fixed in their places, so that, when unscrewed, the bath falls forward and lies at a proper angle for use. When done it is raised to the perpendicular, and with a few turns of the screw it is water-tight. *C* is a swing front, with raising and lowering motion and lens. The swing is effected by means of a frame of wood about 8 × 4 inches, balanced on either side by screws—one for pinching it at the required angle. The raising and lowering motion is on much the same principle as the usual camera fronts. The lens is screwed to the sliding front inside or outside, although I prefer it to be so arranged that the stops may be introduced from the inside of the tent. To do so the lens must be reversed in its jacket. *d* is a water tank; *e* a recess for chemicals; *f* a bridge across the developing tray, with ground glass in position for focussing—an arrangement whereby dark slides, plate carriers, &c., are abandoned. The bridge, moving backwards, forwards, and horizontally, suits any size of plate. An American spring clip fastened to the top of the bridge holds the plate by the left hand bottom corner quite steadily and perpendicularly. *g* is a small pane of ruby glass, not necessary for light, but as an outlook through which, when about to expose, you may watch the happy moment when the foliage is at rest, &c.

FIG. 3.



INTERIOR.

The whole arrangement has given me great satisfaction, and I have much pleasure in recommending it to my brother photographers.

JOHN MCKEAN.

ON THE USE OF ALCOHOL IN GELATINO-BROMIDE EMULSIONS.

[A communication to the South London Photographic Society.]

AT our last meeting I was asked by Mr. J. T. Taylor to elaborate the article *On the Use of Alcohol in the Gelatino-Bromide Process* that I had the honour of contributing to THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for the present year. This I have endeavoured to do. I wish it, however, to be clearly understood that I am not putting myself forward as so old and experienced a worker in the process as many of our members, such as Messrs. Kennett, Taylor, Nesbitt, Wratten, and others; but, having had much experience during the last few years in the use of gelatine for another branch of photography, I may perhaps be able to say sufficient to open a discussion on the subject.

Now it is impossible to work much with gelatine without being struck with the great difference in the various samples to be found in commerce, no two kinds being alike, and rarely indeed are any two samples even by the same maker identical. Some will require as much as fifty per cent. more chrome alum to bring about insolubility, while others, again, will become absolutely insoluble upon being treated with bichromate of potash or ammonia. So variable, indeed, are the reactions of this material with the salts of chromium, that it is now the practice at the Autotype Company's works to submit each fresh supply to a chemical examination before taking it into use, so that it may be modified to suit the different purposes to which it may be applied.

Happily the gelatino-bromide emulsion worker is exempt from these perplexing reactions, as all he requires is that the gelatine should be of good quality *as* gelatine, and free from any impurity likely to act on the silver bromide. These conditions may be relied upon in Messrs. Nelson, Dale and Co.'s photographic gelatines, and also in their opaque gelatine, one or other of which, I believe, is generally employed in this process. We all know that gelatine in a dry state will keep for any length of time free from decomposition, as witness the glue joints of old furniture, violins, &c., many of which are as sound now as they were when first made a century or more ago. And we must all admit the judgment and ingenuity of Mr. Kennett when he introduced his pellicle in the dried form, the keeping quality of which is now beyond question.

Although gelatine will keep indefinitely in its dried state, it is quite the reverse when in a jellied form—in fact, I scarcely know a substance so liable to decomposition as this. The more aqueous to solution the more liable is it to decomposition. The manufacturers even tell us that, if a thunderstorm occur during the time a batch is in a heated or fluid condition, it generally sets up decomposition or putrefaction, which renders it useless as a first-class gelatine. This has been borne out in my own practice; for, during the autumn of last year, when I was daily preparing between two and three hundredweight of jelly for tissue making, I was surprised on one occasion to find that a batch had become decomposed, showing beads of gas studded throughout its bulk, although some prepared in precisely the same manner some days before and some after were quite perfect, all being from the same batch of gelatine, the only difference being that during the time it was in a fluid state a rather severe thunderstorm passed over the neighbourhood. When this decomposition is set up in it the only course to adopt is to throw it away; for, if it be used for any purpose in photography, it is sure to bring trouble to the operator.

Although Mr. Kennett's pellicle is very convenient, still an emulsion that will keep for a reasonable time in the jellied form, so as only to require warming when a few plates are required, is a desideratum; and to secure this end various antiseptics have been suggested, such as carbolic acid, salicylic acid, and also various essential oils, such as oil of cloves, &c. Carbolic acid will, undoubtedly, prevent putrefaction if added in sufficient quantity; and I am not aware that *pure* carbolic acid will exercise any deleterious effect on the silver bromide. Salicylic acid I have not tried, but its price is, I think, a great bar to its use. I believe that few will care to use essential oils, owing to the reducing action most of them have on the salts of silver. The antiseptic I am about to advocate is alcohol (methylated will do), which prevents decomposition of gelatine—I had almost said indefinitely, but I have not tested it to *that* extent.

Here, however, is a bottle of solution containing about one-fourth its bulk of alcohol which has been made over eight years, and you will see that it is quite as good now as when first prepared.

Not only does the alcohol act as an antiseptic and has no action on the silver bromide, but it assists in other ways, causing the emulsion to flow more freely over the plate like collodion, and to set quicker, and also to dry in much less time than when water alone is the solvent. The quantity that may be added depends very much on the kind of gelatine used. *This* flask contains one part of gelatine to three of water and three of spirit; you will notice by its opalescent appearance that part of the gelatine is precipitated. *This* flask has one part of gelatine to four of water and two of spirit, and is only slightly precipitated. If either of these samples be liquefied the solution will be transparent, and a plate coated with it will become opalescent as soon as the gelatine has set; but it will be quite transparent when dry. Here is a plate coated from the flask containing the larger proportion of alcohol, which shows that a large proportion of spirit may be added without injury.

I may here remind the members that the more frequently a solution of gelatine is heated and the longer it is kept in a fluid state the sooner it loses its property of gelatinising or setting, so that I advise that the stock of emulsion should be kept in several small bottles in preference to one larger one, so as to avoid having to melt the whole bulk each time that a few plates are required. And for this reason I should avoid the elimination of the haloid salts by dialysis whilst the emulsion is in a fluid state; but I think that few will require this advice after seeing Mr. Wratten's very simple method of effecting this, as shown by him at our last meeting.

There is another use to which alcohol may be put in this process, namely, in abstracting the water from the plate so as to allow of its being dried by heat; for, if after the gelatine has set, the plate be immersed in alcohol for a minute or two, it may be placed on a hot-water bath without fear of its running off the plate, seeing that gelatine is insoluble in strong alcohol. By this means I have coated a plate, dried it, printed a transparency, developed, fixed, and again dried it, in little over a quarter of an hour.

For coating the plate I always use a Crookes' albumen pourer, which I cannot too strongly recommend for the purpose, as not only is the emulsion filtered immediately before pouring on the plate, but the air-bubbles—always so troublesome in gelatinous solutions—are prevented from getting on to the plate. Of course the instrument must be placed in a vessel of warm water when in use.

At the last meeting one of our members raised the question of the inequality of the film if the plate were not perfectly flat. This was disposed of by Mr. Kennett, as far as fairly flat plates are concerned; but not in the case of curved ones, such as those used in the late Mr. Sutton's panoramic camera. Such plates, I find, may easily be coated with gelatine emulsion by adopting the plan employed in coating albumen plates, namely, to first coat the plate with a porous collodion, and, after washing out the ether and alcohol, to pour on the emulsion, and allow it to soak well into the film. It is not then necessary to place it horizontally to set, but it may be reared on end to dry. This will be found very advantageous in exceedingly hot weather. Of course the plate should be rinsed with warm water to slightly heat it before applying the emulsion.

E. W. Foxlee.

THE VOLUMETRIC ESTIMATION OF THE STRENGTH OF SOLUTIONS OF SILVER NITRATE, AND THE RECOVERY OF SILVER FROM WASTES.

[A communication to the West Riding of Yorkshire Photographic Society.]

Before entering into the details of my subject it will perhaps be best to commence by a few remarks illustrative of the principles on which the various reactions are founded, which will help us not only to a better understanding of the subject in hand, but of many other chemical changes in connection with photography.

Up to the present time the chemist is acquainted with sixty-two elements. Many of these, in some form or other, are in daily use by the photographer. It would be difficult to find another business where more of the elements are brought into use and in proportion as our knowledge of these substances increases so will the science be advanced.

It is found that each element has a definite combining proportion by weight and volume, and possesses in and out of combination with other elements such proportionate weight and no other quantity. Hence, if the combining weights of the elements in a compound be summed up such sum will be the comparing weight of the compound.

For the better understanding of our subject I will put on the black board the relative combining weights (hydrogen taken as unity) of the various elements we have to do with tonight:—

	Combining wts.	Symbol.
Silver	108	Ag.
Nitrogen	14	N.
Oxygen	16	O.
Chlorine	35·5	Cl.
Sodium	23	Na.

Silver nitrate is a combination of silver, oxygen, and nitrogen, and is the result of the action of nitric acid ($H\ NO_3$) combined with silver, and may be put down in chemical formula thus:—

$$\begin{array}{ccccccc} \text{Silver.} & & \text{Nitrogen.} & & \text{Oxygen.} & & \text{Silver Nitrate.} \\ Ag. & & N. & & O_3. & & \\ 108 & + & 14 & + & 48 & = & 170. \end{array}$$

Chloride of sodium (common salt) is a combination of sodium and chlorine, and is represented thus:—

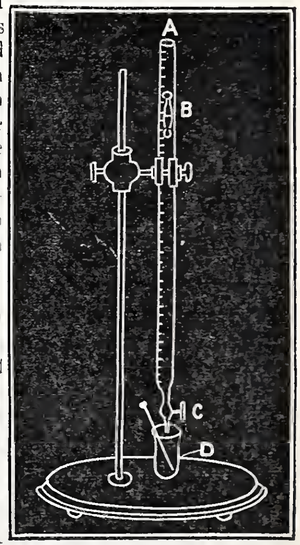
$$\overset{Na.}{23} + \overset{Cl.}{35{\cdot}5} = 58{\cdot}5.$$

This invariable combining proportion of the elements is one of the most beautiful subjects that the human intellect can study or contemplate; and it will be easy now to show how they can be used as an infallible measure one for the other.

If we take a solution of chloride of sodium and add it to a solution of nitrate of silver a mutual exchange takes place, whereby we obtain a precipitate of chloride of silver and a solution of nitrate of sodium. The exchange is thus rendered:—

$$\begin{array}{ccccccc} \text{Silver Nitrate.} & & \text{Salt.} & & \text{Silver Chloride.} & & \text{Sodium Nitrate.} \\ Ag\ No_3 & + & Na\ Cl & = & Ag\ Cl & + & Na\ NO_3 \\ 108 + 14 + 48 & & 23 + 35{\cdot}5 & & 108 + 35{\cdot}5 & & \\ 170 & + & 58\ 5 & = & 143{\cdot}5 & + & \frac{23 + 14 + 48}{85} \\ \hline & 228{\cdot}5 & & = & & 228{\cdot}5 & \end{array}$$

It will now be easily seen how the salt can be taken as a measure for the silver, or *vice versâ*. It only remains to apply the principles I have endeavoured to elucidate. I shall use for the purpose a Mohr's burette, A, graduated in grains and parts of a grain, into which I pour a portion of the solution of silver I wish to test, and by turning the tap C at the bottom I can regulate or measure the quantity of the solution run off with great nicety. The small tube B you see floating inside has a mark round it, and is known as an Erdman's float. With this float we can tell with great exactness the amount of solution run out.



I have here a solution of common salt in water. The solution is of such strength that one cubic centimetre of the solution will exactly precipitate one grain of nitrate of silver, and is prepared in accordance with the formulæ given above. We will take a quantity in this pipette—say five cubic centimetres—and put it into the beaker D, and place it under the burette. We will dilute the salt solution with a little distilled water and add a few drops of a saturated solution of chromate of potash, which will serve as an indicator.

The use of the chromium salt is, I hope, obvious; its affinity for silver being less than that of chlorine it forms a very accurate indicator of the exact point when the quantity of silver present is precipitated by the chloride of sodium—another formation of chromate of silver. This reaction is thus represented:—

$$\begin{array}{ccccccc} \text{Silver Nitrate} & + & \text{Potassium Chromate.} & \times & \text{Silver Chromate} & & \text{Potassium Chromate.} \\ 2\ Ag\ NO_3 & + & K_2\ Cr\ O_4 & = & Ag_2\ Cr\ O_4 & + & 2\ K\ NO_3. \end{array}$$

If we run in the silver solution slowly it is converted into chloride as long as there is any chloride of sodium in the beaker. As soon, however, as all the chlorine is combined the precipitate instantly ceases to be the well-known white, curdy one, and the liquid is turned a deep red, chromate of silver being formed. It requires some little practice to stop the flow of the solution into the beaker, but you will find that when you have just got the number of grains to run into the test the result is invariably the same. This process, the explanation of which may to some seem tedious, it will be seen can be performed in a few minutes, and it is I believe one of the best methods of estimating the strength of silver solutions. JOHN GARBUTT.

[We are compelled to defer till next week the portions of Mr. Garbutt's paper connected with the recovery of silver from wastes.—EDS.]

NOTES ON PASSING EVENTS.*

BY A PERIPATETIC PHOTOGRAPHER.

A FEW years ago, when I was making a three months' tour in Spain and the South of France, I became acquainted with a skilful stereotyper in a village where I was staying for a week, and observed very carefully his method of prosecuting his business. His process of casting stereotypes was by the French system, in which layers of paper and paste are hammered or pressed into contact with the type to be reproduced, a sharp mould being thus obtained from which a metallic counterpart is secured. Now, when reading a recent article in this Journal on obtaining casts for the Woodburytype process it occurred to me that stereotype casts ought to be very easily taken from a gelatine relief by means of the ordinary stereotype process of casting. Flatness, I am aware, is an essential requisite in a Woodburytype printing surface, and so is exquisite perfection of detail. The former can be ensured by attaching the pellicular relief to a flat plate of metal; the latter is always obtained in great perfection, as every one acquainted with practical stereotype casting is well aware. It may be this method has been suggested or even practised before now; but I have not seen it alluded to in the course of my reading.

I do not clearly apprehend why, as suggested by a recent writer in these pages, the education of photographers should be taken in hand by either the Photographic Society of Great Britain or by any other Society. Education is doubtless an excellent thing, but why a body of men meeting together to further their knowledge in the technics of a particular art should go out of their way to impart a knowledge of the three R's to any, merely because they are in some sense or other *attachés* to that art, it is not easy to perceive. The school board will see to it that embryotic photographers, while in their state of juvenility, shall not be allowed to rise to the state of manhood without receiving an elementary education, and what other kind of education does Mr. Hance advocate? A technical education is imparted by the master to whom the boy is apprenticed, and I am not aware of any other. It is well known that in point of education many of the photographic juniors can already vie with their seniors, some of whom are reputed to be scarcely able to write their own names. Education is already within the reach of every boy and girl connected with photography or any other branch of trade; and of those whose aspirations are so low as not to lead them to acquire education all I have to say is—let them revel in their social degradation, and remain hewers of wood and drawers of water in the photographic trade. It is not of such that either gentlemen or artists will be made.

The mere term "the fading of carbon prints," of which we have heard so much during the past month, seems to be a contradiction in terms. During the past week I was subjecting to a careful examination several portraits which were printed in carbon by Mr. J. W. Swan in 1864, and I affirm most positively that they are quite as good as the day—now nearly fourteen years ago—when I first saw them. Why, then, raise up a foolish clamour about "the fading of carbon prints?" No carbon print ever did, ever *can*, fade. *Pigments*, I grant, may, and often do, change their colour, but carbon never. Let the young photographer, whose mind is apt to get perplexed with "things that are not what they seem," allow himself to become well grounded in what I have just said as a sound basis for his faith in the permanence of the prints of the future. It may, after all, be well that so many photographs have faded when we consider the number of artistic atrocities that have been palmed off upon the public during the last twenty or thirty years.

In his paper on the *Elimination of the Nitrate Salts from Gelatine Emulsion*, read before the South London Photographic Society, Mr. F. Wratten somewhat over-estimates the difficulty of, or, more correctly, the time required, for effecting this end by means of dialysis. He objects to it on the ground that the material may decompose and become useless during the process of dialysing. This surmise is not borne out by the facts; for, whereas the operation of removing the soluble salts by dialysis need not occupy more than three or four hours, it has been shown by Mr. Bennett that the emulsified gelatine may, with advantage, be retained by means of heat in a fluid condition for several *days*. I have dialysed gelatine emulsion many a time, but I never had a batch spoilt from this cause; and, what is more, I have never yet heard of any who have had such an experience. Mr. Wratten is quite right in saying that it is "theoretically perfect," but wrong in asserting that it is "practically useless."

* Continued from page 160.

Meetings of Societies.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

ACCORDING to promise we now publish [see page 169] Mr. W. S. Bird's communication on Dr. Monckhoven's paper read at the March meeting of this Society. We also now give, from the official organ of the Society, the letter of Mr. J. W. Swan, and the remarks that were made on the subject.

Mr. SAWYER: Before proceeding on the discussion, it may be convenient if I state that, acting upon our request, Mr. Swan, of Newcastle-on-Tyne, has been kind enough to send a letter, expressing his opinions on the subject. I venture to interfere now, in order that Mr. Swan's letter may be before the meeting, as well as the communication just read. We considered it would be of advantage to the Society to have all the light that could be thrown upon the subject, and more especially from the introducer of the carbon process. Mr. Sawyer then read the following letter:—

DEAR MR. BIRD,—Remembering the wish which you lately expressed to me that I should contribute somewhat to the discussion on Dr. Monckhoven's paper tomorrow, I take the opportunity of saying that I have read the paper with great interest, and that in the main I am inclined to accept without dispute Dr. Monckhoven's statements with regard to the tendency of carbon prints containing cochineal, or even madder colour, to change colour under the influence of light; and I heartily agree with him that it is most desirable, if possible, to get rid of them altogether. The ephemeral character of the carmines of cochineal should be proclaimed as loudly and as widely as possible in the interest both of carbon printing and of painting, for it is lamentable to think that even first-rate artists still use it in their most valuable works. To ascertain exactly the effect of light upon it, I produced prints coloured only with this beautiful but frail pigment, and exposed these, half covered up, to brilliant sunlight. I expected to find evidence of fading in the parts exposed to light, but I was astonished to find it so quickly; even twelve hours' exposure was sufficient to produce a marked lightening of the colour in the more delicately-tinted portions of the picture. After this experience it is scarcely necessary to say I discarded the use of carmine, but I confess I found great difficulty in finding a perfect substitute for it, in so far as regards the brilliancy of colour. The best substitute that I could find at the time (I am referring to twelve years ago) was purpurine, one of the derivatives of madder. I found I could get very bright purples with this, and tested it in the same isolated way in which, as I have already described, I tested carmine. I found that it was incomparably more resistant to the action of sunlight than carmine; still it was not absolutely stable, and I felt that there was a want in this respect. Alizarine was just then beginning to be an article of commerce, and, as you know, I proposed its aid should be sought to overcome the difficulty. I see that Mr. Johnson and your firm, as well as Dr. Monckhoven, have all been working in this direction, and I believe a decided advance has been made by the employment of lakes, which are obtainable by means of alizarine, and a nearer approach has been made to permanence by their use as tinting pigments; for it must never be forgotten that that is the only function they perform, and that the basis—the solid ground, as it were—of carbon always holds good.

With regard to the iron pigments to which Dr. Monckhoven refers as efficient substitutes for vegetable reds, of course no one will dispute the advantage of discarding *totally* the use of the vegetable reds, *if* you can get all you want by means of oxide of iron. But is it possible? If Dr. Monckhoven has succeeded I congratulate him. I tried hard, but found, after I had done my best with it, a certain lack of brilliancy which the public would not put up with.

Dr. Monckhoven is right when he says that the iron red is only transparent whilst it is in a hydrated state; in that state, moreover, it is a foxy red with no purple shade in it. Dry and heat in order to bring out the purple tint as in Indian red, and immediately you have an opaque and heavy colour, not well suited for the photographic purple (which is the only case in which there is the least occasion to use a colour of a questionable kind); then it does not, or rather did not in my hands, quite fulfil all the requirements of the case. Dr. Monckhoven speaks of the variety of reds obtainable from iron. The tints vary from yellow ochre to Indian red, and all sorts of rich *browns* are producible by means of them; but photographic purple! Well, as I have said, I shall believe it when I see it. As to the chemical part of the paper, I will only remark that, according to my experience, it only needed a very thorough washing to eliminate completely all the chromium compounds acted on by light, and that the only tint remaining is a very faint green. This tint is producible, as I have proved, by light alone, without any washing of the composition, if the gelatine mixture is suitable, as it may be, for the production of this complete action. I have observed that under the action of light a film of gelatine containing, besides the bichromate, sugar of milk and glycerine, has the yellow colour completely discharged, and a chromium green is exchanged for it. The *rationale* of this change of colour is evidently in favour of the generally-accepted theory of the chemistry of carbon printing, which, I believe, I was the first to propound.—Believe me, dear Mr. Bird, very truly yours, JOSEPH W. SWAN.

Mr. SAMUEL FRY thought a little too much importance had been attributed to the conclusion arrived at by Dr. Monckhoven in regard to want of permanence. The conditions under which the specimens exhibited at the last meeting were prepared were such as could never be present under ordinary circumstances, in addition to which it was evident that the prints shown were imperfectly washed. At the same time he thought there were difficulties attendant upon the use of carbon prints in ordinary photographic work. For such purposes as enlargements, reproductions, work on porcelain, ivory, &c., nothing could be better; but when it was remembered that a photographic printer had to deal with a number of negatives, each requiring a different printing, it was evident that the carbon process as at present used could not be conveniently adopted, owing to the drawback that the picture could not be watched during the process of printing. When one looked at the works of the best known photographers it must be owned that carbon was still very little used in ordinary portrait and landscape work. Even Mr. Ferranti, whose carbon pictures were exhibited in the room that evening, used silver as well as carbon; and he (Mr. Fry), in determining some time ago what kind of printing he should adopt, after travelling hundreds of miles, and consulting a number of photographers, had come to the conclusion to issue his pictures in silver. At the same time he firmly believed that the general use of carbon, when the process was perfected, was but a question of time. Silver prints were very evanescent—far more so, he thought, now than they used to be; and although the public did not complain, they were certainly entitled to have their photographs as permanent as any other form of pictorial art.

Mr. Woodbury, in reply to the Chairman, stated that he had had very little to do with autotype printing. His prints were mostly kept in books, and certainly had no bichromate in them, being simply pigment and gelatine.

Mr. Bolas observed that with regard to the oxide of iron giving a purple tint, as stated by Dr. Monckhoven, he must confess that after a variety of experiments he had not been able to verify this.

The Chairman: Does Dr. Monckhoven state that in his paper?

Captain Abney: I think not; he rather advocates the discarding of the purple tints, and using those produced by iron.

Mr. Bolas, in continuation, said he had tried the oxide of iron, but he could only get a brick yellow colour—nothing approaching brilliant reds and violets obtainable by other means. Dr. Monckhoven recommended these oxides to tissue makers, but he hardly gave sufficient working directions to enable them to try them. Moreover, he said he used the oxides of other metals, but did not say what these metals were. With regard to the hydrated oxide of iron, he very much questioned whether this oxide was not as liable to undergo change as any other pigment. It was certainly liable to change under the influence of heat, and it was worth while experimenting to see whether it was not also affected by light, especially when in contact with organic matter. This was a point which he (Mr. Bolas) hoped before long to be able to try, and it might be as well also to try the oxide of the other metals in the same way. With regard to the slight change of colour which alizarine is said to undergo, the change was exceedingly small—certainly not more than was seen in other materials, and even in wood, leather, or paper.

Colonel Wortley observed that he had printed a large number of carbon transparencies, but had not noticed any sign of fading. Some of these had been exposed for more than eighteen months, and had had their due share of sunlight, but he could not see any change. Of course no portions had been covered up. He did not know what was in the tissue, because he only used that prepared by the Autotype Company, and which was prepared specially for him, giving the most beautiful effect. With regard to Mr. Fry's remarks as to watching the picture during the progress of printing, he very much preferred when a printer could not do so. If he gave a printer twenty sea and sky negatives he simply gave him the letter of the actinometer for each, and was absolutely certain (if the tissue had been properly prepared) of the prints being alike month after month and year after year. This certainly was not the case with albumenised prints.

Mr. Sawyer, in referring to the paper of Dr. Monckhoven, said that it had been long known that preparations of cochineal, when introduced into pigment and exposed to light, showed a difference of tone; and the letter he read from Mr. Swan quite bore out the idea, although he must say in a somewhat exaggerated form. It was, however, just possible that the cochineal with which Mr. Swan experimented was not the preparation that was common to the best colour makers of the present day. It was, he might say, the practice of the Autotype Company, until two years ago, to employ cochineal in small quantities. They had had practical proof of its permanence, as prolonged exposure did not produce any perceptible change, although Mr. Swan had stated that twelve hours' exposure was enough to effect it. He might, perhaps, briefly state what it was that caused him to abandon cochineal entirely, and to try and find out some other substance in its place for combining with carbon pictures. When he introduced a mechanical printing process with colours he used the purple colour ordinarily used by lithographers, in ignorance of its peculiarly fugitive character. On one occasion he happened to see a mechanical print in Paris, and, to his amazement, the crimson tint had vanished, and the picture looked like a simple black engraving. He considered that if the colour behaved in this way it was time to seek out some other pigment. He made many experiments, and tried many colours of the metallic oxides, and at last fixed upon alizarine, which had already been tried at the Autotype works, but not with success. With the assistance, however, of Mr. Perkins, a method was indicated by which the alizarine could be introduced into the tissue. Before doing so, some alizarine was introduced into lithographic ink and used in mechanical printing, and the result was that it was found to be a permanent colour. He (Mr. Sawyer) then considered that if alizarine under such circumstances behaved so, under the protecting influence of gelatine it was likely to be still more permanent; he therefore thought it would be perfectly safe to use it. Dr. Monckhoven stated in his paper that if alizarine, prepared as he prepares it, was exposed to sunlight a few hours sufficed to cause a slight change. Since the last meeting, however, he (Mr. Sawyer) had prepared some alizarine prints, and had exposed them, a portion being covered, in the tower of the Autotype works, through a clear glass window with a southern aspect. These pictures he would now exhibit, to show that no change had taken place. He quite agreed that a trial like this could not be accepted as final, as the exposure was not of a very long duration. Dr. Monckhoven also recommended purple tints to be abandoned; but if we were confined to the brown colours the range would be very limited. Practically, in carbon printing, there were but three primary colours—black (which is the foundation), red, and blue, and to discard the latter would be to take away at least one-third of our power at once. Again: Dr. Monckhoven told us very specifically how to prepare alizarine according to *his* method; but in regard to the hydrated oxide of iron no information whatever was given that was of the slightest use. However, as the researches were to be continued, possibly Dr. Monckhoven may tell us more at a future time. If anyone would take the trouble to go through experiments with peroxide of iron it would be seen that the colour, in the ordinary way of using it, was of no use so far as the manufacture of tissue was concerned. No doubt Dr. Monckhoven would supplement what he had stated by giving the exact process; but all he (Mr. Sawyer) could now say was that the alizarine colours, which were known in dyeing as permanent, had resisting powers which entitled them to be classed among permanent pigments. Now that the manufacture of tissue had been thrown open, a great advance might be anticipated from the chemical knowledge which would be brought to bear upon it. At the same time it should be borne in mind that no one was more entitled to honour than the first introducer, Mr. Swan. The reproach to photography was its want of permanency, and he (Mr. Sawyer) maintained that the carbon process of Mr. Swan had done more to raise photography to a high level than almost anything else.

Mr. Spiller wished to know from Mr. Sawyer whether he had made any experiments with an extra scarlet shade of alizarine prepared by Mr. Perkins. This preparation gave a brilliancy almost equal to cochineal.

Mr. Sawyer was not aware that there was any special scarlet shade made. When he first became acquainted with alizarine there were two kinds made—the blue shade and the red. He tried the blue, but he found that it certainly did not stand exposure to light. He then turned his attention to the scarlet, and found that satisfactory. What they now used was, he believed, the ordinary commercial product.

Mr. Spiller observed that there were now six shades of alizarine.

The Chairman was glad that so much time had been devoted to the discussion of Dr. Monckhoven's paper. The information afforded in Mr. Swan's letter, in Mr. Bird's communication, and in Mr. Sawyer's remarks, was most valuable, and he hoped that the discussion would be resumed at some future time, and that Dr. Monckhoven would give a second paper on the subject.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

The usual monthly meeting of this Society was held on Thursday, the 4th inst.,—Mr. Frank Howard, Vice-President, in the chair. Mr. George Maitland having been elected a member,

Mr. E. W. Foxlee read a paper *On the Use of Alcohol in Gelatino-Bromide Emulsions.* [See page 172.] During the reading of the paper Mr. Foxlee submitted for examination a number of bottles containing the gelatine preparations to which he had alluded.

Mr. W. Wainwright, after referring to the addition of oil of cloves to gelatine, inquired if the presence of alcohol affected the sensitiveness of an emulsion.

Mr. Foxlee said that he had been unable to discover any diminution of sensitiveness.

Mr. Mawdsley stated that it appeared to him that Mr. Bennett's remarks at the previous meeting had been imperfectly understood by some of the members. The view of the interior of an artificially-lighted room then exhibited had been obtained in the camera on a dry gelatine plate. He had been present when Mr. Bennett was operating, and could testify to the extreme sensitiveness of his plates. In further proof of this he (Mr. Mawdsley) submitted for examination several negatives of interiors lighted by means of common gas, and taken at night, the exposure of one of these having been twenty minutes.

Mr. Kennett observed that gelatine varied very much in quality, no two samples being quite alike. The addition of alcohol to gelatine, in his experience, prevented the negatives from being of a fine quality. It was always best to use gelatine fresh; he invariably preferred to do so within five hours after its preparation.

The Chairman, alluding to the tendency of advocates of processes to claim for them a great degree of sensitiveness, observed that the time of exposure required for some of the slow processes might be materially reduced by the adoption of a proper alkaline developer.

After some remarks by Mr. Pearsall, a number of negatives and prints were exhibited by Messrs. Brooks, Nesbitt, and others. Those by Mr.

Brooks were enlarged by collodion emulsion; they were of great dimensions, and quite free from texture. Mr. Nesbitt's pictures indicated a high degree of sensitiveness, and this may also be said of some by Lieut. Lysaght exhibited by Messrs. Wratten and Wainwright.

Mr. W. M. Ayres exhibited an appliance, moved by clockwork, for ventilating a studio. It consisted of a wide strip or flange of tin wrapped spirally round a central rod which was geared into the clockwork. This rotated in a cylinder up through which the heated air was drawn and emitted. Mr. Ayres also exhibited several vessels of glass for dissolving crystals.

The thanks of the Society having been tendered to Mr. Foxlee for his paper, it was intimated that at the next meeting a paper would be read by Mr. W. Brooks *On the Enlargement and Multiplication of Negatives by Emulsion Processes.*

The proceedings then terminated.

EDINBURGH PHOTOGRAPHIC SOCIETY.

The sixth ordinary meeting of the above Society was held in 5, St. Andrew-square, on Wednesday, the 3rd inst.,—Dr. Thompson in the chair.

The following gentlemen were unanimously elected ordinary members of the Society:—Messrs. T. N. Christie, Francis Briglemen, W. Maule Borley, F. Moore, W. Iveson Macadam, and James Lyle.

Mr. W. T. Bashford then read a paper contributed by Mr. Payne Jennings—*Remarks on Landscape Work and its Relation to Art.* [See page 171.] The paper was illustrated by a large number of exquisite landscape studies, which excited the enthusiastic admiration of all present.

The Chairman, referring to Mr. Jennings' contributions, remarked that he had heard many papers read on artistic matters, but none with more practical value. The author had illustrated his remarks by works of his own production, showing that the writer had much more than theoretical ideas to treat upon, having reduced all he had to say to practice, as shown by the very numerous art-productions exhibited.

Mr. W. Nelson said that while on a visit to Pitlochrie, he had, of course, admired the beautiful scenery; but, when he desired to take photographs of some of the views, he found the greatest difficulty in selecting a scene that would be harmonious as a photograph.

Dr. Hunter had experienced great difficulty in selecting a point of sight that would render within the bounds of one negative a harmonious composition which might justly be called a picture, and congratulated Mr. Jennings on his great success in this particular. The difficulties surmounted greatly enhanced the value of such renderings of nature as Mr. Jennings had submitted to them.

Mr. Mickie was greatly impressed with the peculiar picturesque beauty of some of the illustrations, and knew that such results could only be obtained by one possessing high art-feeling, being at the same time one who could "bide his time" till nature was in a favourable mood to assist him in rendering his conception of the scene, and who, when the right moment arrived, also possessed the necessary ability to seize and perpetuate it. From his own profession as an artist he knew some of the difficulties a photographer laboured under, as to a very large extent he must render forms exactly as they are, and he is not at all times able to control or modify repeating lines and objectionable features, though they could be altered to any extent if rendered by hand. Bearing these difficulties in mind, he was much impressed with the triumphant vindication of the art possibilities of photography as exhibited in some of the pictures by Mr. Payne Jennings.

Mr. M. G. Dobbie remarked that numerous papers had been read to the Society bearing more or less directly on the relation of art to the science of photography, and requests had been made over and over again to our artist members to accompany the Society on its outdoor excursions, and practically instruct the members in really artistic work. In more instances than one this had been done advantageously. Now in this paper of Mr. Jennings' we had the result of that gentleman's experience in a practical shape, and when combined with such an authority it was of the highest value. There could be no doubt about the fact that one of the essential requisites—indeed, the leading element in the production of a good photographic landscape picture—was artistic knowledge on the part of the operator; in fact, it required brain work, and a correct idea of the beautiful in nature in order to stamp the picture with a true sense of individuality and excellence. No amount of mechanical skill, without the element just referred to, would or could produce a landscape picture in an artistic sense. Mr. Jennings had demonstrated the truth of this in such a way that no one could contradict; not only so, but the very beautiful examples of his own work which accompanied his paper gave practical illustrations of the fact. Mr. Jennings, judged by his pictures alone, was an artist possessed of fine discriminating taste and judgment, and he combined with that an enthusiastic love of the photographic art; hence his success—a success which has gained for him a world-wide renown. He (Mr. Dobbie) concluded by proposing a vote of thanks to Mr. Jennings.

The motion was carried unanimously.

Mr. John M'Kean then exhibited a new camera and tent combined. This was a very ingenious apparatus, being a perfect dark tent for wet-plate photography in the field, and, at the same time, a camera, enabling the operator, if desired, to watch and modify the negative while being exposed, so that various times could be given to different parts of the view, allowing a harsh, badly-lit foreground to receive sufficient exposure without overdoing the delicate distance, and also securing on the one plate an instantaneous cloud effect. A yellow window facing the scene enables the operator to select the most favourable time to impress the plate, and several original and ingenious appliances are introduced to facilitate operations and reduce to a minimum the troubles and somewhat bulky *impedimenta* that the ardent wet-plate worker has to contend against compared with his dry-plate brother. The whole is intended to stand on a very rigid form of tripod. The apparatus in all its details was examined with much interest, and a vote of thanks was heartily accorded to Mr. M'Kean.

The Chairman next submitted a proof impression of the presentation print for the current year. It is a beautiful reproduction of Sir Noel Paton's well-known picture, *I Wonder Who Lived in There,* and all members who have paid their annual subscription of five shillings will be entitled to a copy of it. The picture is of large size, beautifully printed in pigmented gelatine by Mr. W. H. Davies. It is mounted on cardboard with a tint, and has a suitable engraved title. Of course it is worth in itself far more than the annual subscription to the Society, and it is recommended that all persons who wish to become possessors of this really fine work should send in their subscriptions at once, as only the exact number of copies absolutely required will be printed, this being one of the conditions attached to the artist's generous permission to reproduce the picture.

In the question box was found an inquiry as to the manufacture of collodio-bromide emulsion used by many members of the Society.

Mr. A. Mathieson said the details had been so often explained to the Society, and published in its reports, that any one could by referring to The British Journal of Photography find all the working particulars with formulæ; still, as a good many inquiries had been made since the last meeting of the Society, he would again give the formulæ. The collodion is what is known as Mr. Aird's, and is almost identical with that published by Messrs. Sayce and Bolton about twelve years ago:—

Ether (methylated)	6	drachms.
Alcohol (pure)	2	,,
Pyroxyline	6	grains.
Bromide of cadmium (anhydrous)	6	,,
Bromide of ammonium	3	,,

The sensitising solution for one ounce of salted collodion is composed of—

Alcohol (pure)	2	drachms.
Nitrate of silver	12	grains.

Place the silver in a test tube, and add a few drops of distilled water. Apply heat until the silver is dissolved; now add the above alcohol. Shake, and re-heat in order to redissolve the silver which, most probably, has been thrown down in a fine powder when the cold alcohol was added. Now add this alcoholic solution of nitrate of silver, a drop or two at a time, to the salted collodion, shaking vigorously after each addition. Let the test tube rest in a cup of hot water while shaking the collodion, in order to keep the nitrate of silver dissolved. Test the emulsion thus prepared, and see that there be a very slight excess of bromide; it will then be found neutral on the following day. When the emulsion has been made about two days it is better than when quite new, and if neutral it will keep indefinitely. Coat the albumenised plates with the emulsion, and wash under the tap till all greasiness disappears; then apply the preservative:—

Tannin	10	grains.
Sugar	5	,,
Water	1	ounce.

This makes a hard, sensitive film; or common bitter beer may be used instead, when the plates are less sensitive. The plates require to be "backed." The tannin-preserved plates necessitate bromide to prevent fogging, and also require that the plates be flooded with alcohol previous to development in order to soften the film. The beer plates do not need bromide, and only require the backing to be removed with a damp sponge and to be simply washed under the tap prior to development, which is, of course, the ordinary alkaline pyro.

Votes of thanks brought a most enjoyable meeting to a close.

WEST RIDING OF YORKSHIRE PHOTOGRAPHIC SOCIETY.

The ordinary meeting of this Society was held on Monday, the 4th ult., at the Oddfellows' Hall, Bradford, at 7.30 p.m.,—Mr. E. Greaves, the President, in the chair.

The minutes of the previous meeting having been read and confirmed, Mr. John Garbutt read a paper on *The Volumetric Estimation of the Strength of Solutions of Silver Nitrate, and the Recovery of Silver from Wastes.* [See page 173.] In reply to a question,

Mr. Garbutt said that caustic potash would do as well as caustic soda. The actions of the two compounds were very similar; there being a very beautiful analogy between the two substances. The only difference was that chloride of sodium was easier to eliminate than chloride of potash, and that an oxide of silver was produced when potash was used, which could readily be detected by the neutrality of the solution. If oxide of silver were not present the solution would be alkaline. In reply to another question as to the method of treating developer waste containing citric acid, he (Mr. Garbutt) said that owing to the strong affinity of chlorine for silver the action of the citric acid might be overlooked; the addition of chloride of sodium would precipitate all the silver; and the other products would be very soluble and easily washed away. Hyposulphite of soda solutions were not worth the trouble of saving.

The question of the best method of dealing with paper-waste being introduced,

Mr. Garbutt said the matter was such a lengthy one that he could not deal with it that evening, but promised on some future occasion to read a paper on that particular subject.

The discussion was then dropped, and a hearty vote of thanks was passed to Mr. Garbutt, and by him suitably acknowledged.

The meeting was then adjourned.

Correspondence.

IMPROVEMENT TO THE FERROUS OXALATE DEVELOPER.

To the Editors.

Gentlemen,—I have obtained a marked improvement in the use of the ferrous oxalate developer by the addition of *gallic acid.* The image is richer and brighter, and comes out more rapidly. If the materials are good, and are properly used, fogging seems to be almost impossible.

For this purpose gallic acid may be kept in alcoholic solution. Sixty grains to the ounce is a convenient strength. The alcoholic solution does not, as in the case of pyrogallol, deteriorate by keeping. I have now a bottle of solution, made a year ago, which is in excellent order.

The solution of ferrous oxalate in potassic oxalate does not keep so well, and is best made fresh at shorter intervals.

A peculiarity resulting from the addition of gallic acid is that the development extends much farther down through the film than when the oxalate is used without it. Intensity comes more readily than with the plain oxalate, and much more readily than with the alkaline pyrogallol development.

The proper proportion is from four to six drops of the sixty-grain solution to the ounce of developing liquid. It should be added after the strong solution of oxalate has been diluted to the strength intended to be used. Generally this addition somewhat blackens the solution; but this does not affect the development, which is a particularly clean one.

In a letter from Mr. Alexander Henderson, of Montreal, that gentleman mentions that he finds the use of the oxalate developer with gelatine plates removes all the difficulties usually encountered in that branch of dry-plate work.—I am, yours, &c., M. Carey Lea.

Philadelphia, March 25, 1878.

VERTICAL AND HORIZONTAL LINES.

To the Editors.

Gentlemen,—Amidst the war of words about vertical and horizontal lines it strikes me that no appeal has been made, on either side, to the inexorable logic of figures. The most irrelevant assertions have been made; and, in more than one instance, repeating a statement appears to have been thought equivalent to proving it. A little calculation would be of more value than pages of unsupported talk. Let us suppose an outsider, with no bias either way, to inquire for some actual data on which to form an opinion. I propose to offer him a few for his guidance. If their evidence be disputed, it may be refuted, in like manner, by figures.

I shall take a tower 40 feet square, 165 in height, viewed by an observer 300 feet distant from its base, with his eye five feet from the ground. How far is the top of the tower from his eye? Any one accustomed to similar calculations will in a few minutes satisfy himself (*Euclid* I., 47) that the answer is 340 feet; that is, the top of the tower is 40 feet further from the observer's eye than the base, or about one-tenth part of the whole distance.

I next turn to the law of vision, which makes the relative size of objects depend on the angle any object subtends (or is opposite to) at the observer's eye. The nearer it is the larger it looks; the further off the smaller. I am not speaking now of surfaces, which, for an obvious reason, founded on the law just mentioned, vary as the squares of the distances. Linear dimensions appear to vary as the distance. A line twenty feet off will seem twice as long as the same line viewed from a distance of forty feet, and so on.

Well, then, applying this to our tower, we first remark that the top and bottom of one side of it are in reality the same length (forty feet); but the top is observed from a point one-tenth part farther off than the bottom. It will therefore appear less; but how much less? Why, also one-tenth part, or some four feet less. Each apparently vertical side of the tower, therefore, inclines towards the other, two feet in 160, or one in eighty; and if we suppose a photographic print to represent the tower as six inches in length, the base line would then be an inch and a-half long, and the top one-tenth less, or about one-eighth of an inch. Here, then, is a demonstration that really vertical lines are not seen parallel in certain given conditions. The camera swing-back would, of course, put all to rights; or, if possible, a more distant point of view be selected.

How important this may be appears if we assume the distance of the observer from the base of the tower to be 500 feet instead of 300. In this case the top of the tower is only twenty-five feet further from the point of view than the bottom is, or one-twentieth the whole distance. Everything is, of course, diminished in size, but the top in a smaller ratio to the bottom than before; so that if (say) an inch and a-half represents the bottom of the tower in a photographic print, a little more than one-sixteenth of an inch would represent the difference of length between top and bottom, the image of the tower being supposed six inches in height.

Thus much regarding vertical lines. As I have already, I fear, trespassed too seriously on your space, I reserve my remarks on horizontal lines till another opportunity, if you are favourably disposed to receive them also.—I am, yours, &c., J. Stothert.

Clapham, April 8, 1878.

TINTED CHROMOTYPES.

To the Editors.

Gentlemen,—I, and I am sure the majority of the profession will do the same, emphatically protest against the claims of Sir Thos. Parkyns.

The adding of pigments to collodion for several purposes has been known and practised for years, and unless the applying of two known processes together entitles a person to the protection of a patent, I cannot see the right of Sir Thos. Parkyns to monopolise this idea.—I am, yours, &c., T. S. Hicks.

April 6, 1878.

[It is a very well-recognised fact that a valid patent can be made by the combining of two or more previously well-known processes.—Eds.]

"VOIGTLANDER'S NEW LENS."

To the Editors.

Gentlemen,—Circumstances have prevented our seeing till this morning Herr Voigtlander's reply to our letter respecting the above lens, which reply was communicated to you by Mr. R. W. Thomas on the 25th March.

Will you allow us now simply to remark that we can fully justify all we stated in our former letter, and, would time permit, should be pleased to do so at once; but as such will not, and as Herr Voigtlander chooses to infer that ours is only a "superficial knowledge of the matter," we shall communicate with Herren Steinheil, and ask you to be good enough to insert their opinion in a future letter upon this subject.—We are, yours, &c., Murray and Heath,

Agents for C. A. Steinheil Söhne.

69, *Jermyn-street, S. W., April* 10, 1878.

Photography in Court.—At the Bloomsbury County Court, on Monday, the 25th ult., the case of Nicholl *v.* Sagers was heard before Mr. Judge Russell. The plaintiff, a photographer in Grafton-street, sued the defendants—two ladies having a ladies' boarding school in Camden-road—to recover the sum of five guineas, being for the value of a quarter-plate negative and twenty proofs from the same, ordered on stated terms and at the plaintiff's request.—The plaintiff stated that in October last one of the defendants requested him to arrange for taking a photographic group of the young ladies attending the school. He found that the group would consist of eighteen pupils, exclusive of the defendants. He mentioned the price at the time, which not being objected to he completed the work and forwarded his account, but in consequence of non-payment he brought the present action.—The plaintiff's assistant, who was present when the order was given and who assisted in the operation, was called in support of the plaintiff's case.—Mr. Lewis, who appeared as solicitor for the defence, urged that the price was an excessive one, and his clients would state that they were generally dissatisfied with the plaintiff's work.—Both defendants denied that any sum was agreed to at the time the order was given, and they had told the plaintiff that they were not pleased with the pictures. The plaintiff had taken four large negatives before he was pleased with the result, it being a difficult task to get eighteen school girls to be perfectly steady while the group was being taken.—The Judge said he could well imagine that, and then asked the plaintiff if he was quite sure the sum for which he sued was mentioned at the time the order was given.—The plaintiff said it was, and that the amount and character of the work were never objected to till he pressed for payment. One of the proofs was produced by the defendants, who complained of the indistinctness of part of the group. The plaintiff replied that although he had a very quick lens it was impossible that all the group would remain steady.—The Judge: exactly so. I suppose the eighteen young ladies are not in Court?—As none were present, his honour, in giving judgment, said that considering the picture represented eighteen young girls he thought that under the difficulty in which the artist was placed he had executed the task in a very creditable manner, and that if the defendants had any cause of complaint at all they should have made it before proceedings had been instituted against them.—Judgment was then entered in favour of the plaintiff for the full amount claimed, with the costs of one witness.

EXCHANGE COLUMN.

No charge is made for inserting these announcements; but in no case do we insert any article merely *offered for sale*, that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a *nom de plume* be thought desirable), otherwise the notice will not appear.

A prism for taking reversed pictures will be exchanged for repeating-back *carte* camera or burnisher, or anything useful.—Address, Photo., Alexandra-cottage, Christ-road, Bournemouth.

Grubb's C 2 portrait lens for plates 10 × 8 (nearly new), with diaphragms, will be given in exchange for Ross' No. 3 or 4 rapid symmetrical or triplet.—Address, Geo. Duncan, Tanfield, Edinburgh.

Whole-plate camera and Ross' doublet, Howard tent (home-made), tripod, 5 × 4 dish, air-tight bath, printing-frames, half-plate French portrait lens, chemicals, &c., will be given in exchange for gentleman's gold watch.—Address, J. W. Danter, Avenham-villa, Llandudno.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

North Star.—The copyright in the picture will expire in 1882.

F. Prince.—There is no necessity for undue haste in returning the prints.

Pylos.—Instead of replying directly to your questions we prefer referring you to a very complete series of articles on the reduction of residues by Mr. E. W. Foxlee, which we published in this Journal a few years ago. You will there obtain all the desired information.

E. D. (Weymouth).—There is a collodion in the market well known for possessing qualities diametrically opposite to that about which you write. We recommend that a mixture be made of the two. Yours will also be improved by the addition of a little "tough" cotton.

Bothered Photo.—From the graphic description given by you of the evil doings of the negative bath it seems to be high time that it was reduced and sent to the refiner. After a bath has been in use for five years it may certainly be allowed to retire in favour of a successor.

E. H. E.—When the iodide of silver formed by the immersion of a collodionised plate in the nitrate bath falls away from the surface it is an indication that the collodion is over-iodised. To rectify this add to it a small proportion of plain collodion. This will prove an infallible remedy.

J. O'B.—If you put your query in a more definite form we may offer an opinion as to the patent. At present we cannot quite perceive your drift, nor can we clearly understand the nature of the information you wish to obtain. When you write again number your questions, and enclose an envelope for a private reply.

P. O. J.—Achromatism in a lens has nothing to do with curvilinear distortion—a fact that may be practically tested by mounting two meniscus spectacle glasses a little distance apart from each other and placing a diaphragm between them. Mount the objective thus formed in a camera, and you will find the marginal lines to be quite straight.

Chromotype.—The minute specks on your carbon prints are caused by "particles" of air imprisoned by the action of the squeegee instead of being expelled by it. If you *pat* a globule of mercury lying on a flat table by means of the side of a knife the globule, instead of flying off, becomes broken up into innumerable particles; so with the action of the squeegee in your case.

Rev. J. McD.—The effect you describe is easily explained. The binocular picture is *pseudoscopic;* that is, its foreground and distance have changed positions with each other in respect of the relative degrees of convergence caused to the optic axes when examining them. Remove them from the mount and transpose them; all will then be right and the picture will be stereoscopic.

M. A. (Oxon).—The following method of preventing the formation of blisters in albumenised paper prints has been recommended:—Soak the prints, after toning, for ten minutes in a solution composed of an ounce of alum to two pints of water; they must then be transferred to the fixing bath. Give this method a trial, and if it prove the means of ridding you of the annoyance complained of so much the better.

Theta.—A simple method of washing collodionised plates is to put a number of them in a flat tray of large dimensions, and place a small rod of wood, the thickness of the finger, under and across the bottom, so that an oscillatory motion may be imparted to the tray. In this manner a dozen of Fothergill plates may be washed with great evenness. The sensitising may be effected in a similar manner.

X. Y. Z.—To blacken brass by staining it, first make it quite clean and apply a solution of chloride of platinum. Another method consists in mixing together solutions of nitrate of copper and nitrate of silver, applying this to the brass by means of a camel's-hair brush, and then submitting it to considerable heat. This latter method is objectionable in the case of articles that have been put together by the aid of "soft solder."

Geo. Tanner.—Do not give yourself any annoyance concerning the diaphragms; they are all right enough. You may study with advantage any elementary chapter on the construction and uses of diaphragms, such as that which was published in our Almanac for 1870. So far as we recollect no treatise on this subject has been published since that date. You may also consult Dr. Monckhoven's treatise on *Photographic Optics*, in which he deals with this subject in a very able manner.

Poco.—To alter the name under which the business has so long been carried on would be a very unwise proceeding on your part. Continue to carry it on as at present, until you have had at least six months' experience of its working, after which you may introduce changes in its designation should you then consider it wise to do so. Lose no time, however, in introducing as many photographic novelties as you can, and let the public discover from the style of the work that a new hand is at the helm.

F. W. T.—It has been found that glacial acetic acid exercises a solvent action upon some of the resinous constituents of gutta-percha. This is precipitated as a white mass when water is added. A strong solution of nitrate of silver also acts upon gutta-percha; but while we are only too well aware of the fact that a nitrate bath becomes spoilt from the absorption of organic matter by being kept in a gutta-percha receptacle, we are not in a position to indicate in accurate terms the precise action that takes place. Ebonite not being open to the same objection as gutta-percha, we recommend its adoption in preference to the other.

Rapidity (Bolton).—Certainly an "ordinary" dry process would be too slow for your purpose; but if you consult our advertising pages you will find that processes and plates that will prove suitable for instantaneous work are accessible to all. It is only three weeks ago since we described dry-plate negatives some of which had been obtained by an exposure estimated at the one-twentieth of a second, followed in the next number by a detailed account of the process employed. The kind of lens that we recommend you to employ is a half-plate portrait lens corrected for flatness of field and worked with full aperture, or nearly so, upon a 5 × 4 plate.

☞ Editorial Communications should be addressed to "THE EDITORS"—Advertisements and Business Letters to "THE PUBLISHER"—at the Offices, 2, York Street, Covent Garden, London, W.C.

Collodion Transfers.—From Mr. R. Stuart, of Chiswick, we have received two excellent enlarged collodion transfers. The whites are pure and the tone is good. Specimens of this kind amply bear out all that was said with respect to this process of producing enlargements in the editorial chapters on the subject in our Almanac for the current year.

GOOD FRIDAY.

Owing to our usual day of publication next week falling on Good Friday we shall go to press a day ealier than usual, and publish on Thursday, the 18th instant. Advertisers and correspondents will please bear this in mind.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician.
For the Week ending April 10, 1878.
These Observations are Taken at 8.30 a.m.

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 937. Vol. XXV.—APRIL 19, 1878.

THE FERROUS OXALATE DEVELOPER.

It now remains to fulfil the promise we made last week to add to our remarks upon this subject by narrating our experience with different methods of compounding the developing solution, and the various effects produced by using it in a more or less concentrated state. Nearly all previous writers on the subject have confined their remarks to the behaviour of a concentrated, if not saturated, solution, having been led thereto, no doubt, by a desire to ascertain to the fullest extent the capabilities of the new developer. But though, as we have already pointed out, the energy as well as the relative density of the image are dependent to a great extent upon the degree of concentration, we are far from believing that it is either necessary or desirable to so employ it upon all occasions, though for special purposes it will be found highly useful.

The solution we have chiefly employed has been made as follows, and we lay particular stress on the method of preparing it, as some uncertainty will be thereby avoided:—One ounce of neutral potassic oxalate is dissolved in water to form a saturated solution, which will necessitate the employment of about three ounces of water. If the latter be used *hot* (which may be considered desirable in order to facilitate the solution) *it should be allowed to cool before proceeding further.* We lay this down as one of the requirements, because the hot solution dissolves a larger quantity of ferrous oxalate than when cold, though, as we employ a limited quantity of the latter salt, this would not be of much consequence. A more serious objection is found in the fact that the hot solution does not appear to keep so well as one made cold, depositing, after a day or two, a considerable crop of crystals which do not redissolve unless fresh water be added. This does not occur with the cold solution; hence we think the latter offers the greatest chance of uniformity of action. To the above quantity of cold saturated solution of potassic oxalate we add one hundred and twenty grains of ferrous oxalate, and allow it to stand for three or four hours with an occasional shaking, after which it is filtered. This forms, we think, the most concentrated form of the solution consistent with stability.

For very rapid exposures, or for subjects comprising harsh contrasts, the solution may be employed at this strength with advantage. In printing transparencies it may also be employed in conjunction with a short exposure, in order to obtain depth and brilliancy without having recourse to pyro. and silver. For general landscape work, however, it will be better to employ it in a state of dilution, the strength we have found to answer best being one part of saturated solution to two of water, though we have used it as weak as one in ten with the only difference that the action was slower and the density less, especially in the feebler portions of the picture. With an ordinary exposure—that is to say, such an exposure as we should give when not striving after extreme rapidity—there does not seem to be any falling off in the power of bringing out detail when the solution is as weak as one in six, though beyond that a longer exposure becomes necessary to produce a similar result. With the weaker solution, however, much more is left to the action of the intensifier. It is impossible to give any very definite instructions as to strength, so much depending upon other conditions; but we have said sufficient to show that a pretty wide margin exists, and, on the whole, we see no necessity, except upon economical grounds, to carry the dilution further than we have stated above.

On the score of economy—though we should be unwilling to reject the strong solution on that ground solely—it will be found, at the present market price of the ingredients, to be considerably more costly than the old method with pyro. and ammonia. This will be easily recognised when we state that the potassic oxalate is soluble in about three parts of water, and that each ounce of this saturated solution is capable of dissolving, as far as our experience goes, between thirty and forty grains of ferrous oxalate. If we set one ounce of potassic oxalate and (say) forty grains of the ferrous salt dissolved in three ounces of water against an equal bulk of a three-grain solution of pyro. at ordinary commercial prices we shall find there is a very considerable margin in favour of the latter. Against this, however, it is only fair to say that the ferrous-potassic oxalate solution presents a power which alkaline pyro. does not possess in common with it, namely, the capability of being used repeatedly without material loss of energy.

We are not yet in a position to speak decidedly as to the full limit of this power, not having made it the subject of any strictly comparative tests; but we are able to state that three or four plates which have received ordinary exposures—that is, which require no forcing in development—may be brought out successively with the same quantity of solution. Further than this the solution, after being once used, has been allowed to stand exposed to the atmosphere in an uncorked bottle for several days, and was then found to exhibit no noticeable difference in action as compared with a fresh and unused solution of the same strength. Unlike alkaline pyro., the solution of ferrous oxalate undergoes no *apparent* change during development. This is, no doubt, partially explained by the depth of its original colour, which would render any slight alteration in that respect indistinguishable; but no deposit occurs in the solution, at least for some considerable time after its use, and, as far as we can judge, not at all if precautions be taken to preserve it as far as possible from contact with the atmosphere. The solution, whether used or unused, if exposed to the air gradually deposits a rusty, yellowish-brown sediment, and if in a concentrated state crystals also.

It will be interesting to ascertain by careful comparative trials to what extent the solution loses in energy by contact with an exposed film and with the atmosphere during development, as, if we are correct in the estimate we have formed of this phase of the subject, it appears to involve a principle which will add greatly to the facilities this agent affords to the travelling photographer. This principle was shadowed forth in the suggestion of Mr. J. W. Swan as to the employment of a dipping-bath for the development. Now that, of course, necessitates the use of a considerable bulk of solution, and consequently its re-utilisation for a number of plates—a method which has been tried, but not with the most satisfactory results with the ordinary iron developer. To a slight extent it has been practised with alkaline pyro., successive plates being developed in a dish, the same solution being employed; but the chemical conditions involved in the use of the new developer are so entirely different that we may fairly expect to find it succeed under circumstances where the other two have failed.

In the case of the ordinary iron solution, for instance, which requires the co-operation of free silver nitrate, a very rapid loss of power ensues from the introduction with each successive plate of a quantity of silver much in excess of what is actually required for the formation of the image; so great is this loss that no two plates are developed alike, while the possibility of obtaining the best results by such a mode of treatment is more than doubtful. If we turn to alkaline pyro. the prospect is but little improved, as, after the addition of the alkali, the pyro. is oxidised so rapidly even without atmospheric contact that it soon loses its power of development. Certainly it may be renovated by fresh additions of the ingredients; but this does away at once with any possible advantage which might accrue from the re-use of a quantity of solution, besides introducing considerable uncertainty.

Ferrous oxalate, on the other hand, presents in itself a perfect developer requiring no further addition to render it active. It is free, then, from the rapid deteriorating action of the large excess of silver, as in the case of ferrous sulphate, while being comparatively permanent in itself, and but slowly acted upon by the atmosphere, it is not liable to the same spontaneous decomposition as alkaline pyro. If we add to this the fact that the presence of a soluble bromide does not appear to act injuriously upon its developing power, it will be evident that any accumulation of bromine or soluble bromide derived from the film itself during development is not likely to interfere with the results obtained. The deterioration in its power appears, then, to be narrowed down to the comparatively small effect produced by the reaction of the developer upon the exposed portions of the plate, and, having cleared the ground thus far, we have a better chance of success in employing ferrous oxalate for repeated development than is offered by any other developer in ordinary use. This view is strengthened if we look at the theory of the action of ferrous oxalate. Presuming that the production of an image is accompanied by the conversion of the ferrous into ferr*ic* oxalate, we have the formation of a salt which is freely soluble in water without the aid of potassic oxalate. A portion of the latter contained in the developer is thus set free to dissolve a fresh quantity of ferrous oxalate. The ferric salt exercises no developing action, nor, so far as we can ascertain, does it exert any restraining power, whence we may legitimately assume that the change which takes place is merely a diminution in the active power of the solution. If the correctness of our ideas be borne out by more crucial experiments it will be possible for a dry-plate photographer, when travelling, to develope his plates *en route*, using for the purpose a dipping-bath or dish and a solution of suitable strength of ferrous oxalate. In preparing the latter an excess of oxalate of iron might be used, and the clear solution poured off from the sediment for use. After developing the day's plates the solution would be poured back into the bottle, well shaken, and would again saturate itself with ferrous oxalate, and become clear for next day's use, or, if needful, could be filtered.

For the benefit of many of our provincial readers who may be unable to obtain the ferrous and potassic oxalates without sending to London we append brief directions by which the developer may be prepared from materials obtainable in any country town. If the proportions which we give be adhered to the result will be, for all practical purposes, equivalent to the saturated solution we have given above. Dissolve 1,000 grains of ferrous sulphate in a sufficiency of hot water, and add half that quantity of oxalic acid, also dissolved in boiling or very hot water. The first addition will, in all probability, not cause a precipitate, but only a yellow colouration of the solution, and several hours should be allowed for the completion of the interchange of elements. If mixed over night the oxalate of iron will be found in the morning to have subsided in the form of a bright yellow powder, which may be purified by repeatedly changing the water, and then, if desired, it may be dried upon a plate or dish in the oven. The potassic oxalate is formed by dissolving three ounces of oxalic acid in twelve ounces of hot water, and neutralising by stirring in, gradually, four ounces of dry carbonate of potash. Strictly speaking, this quantity of carbonate is insufficient to quite neutralise the acid, being about sixty grains short of the theoretical quantity; it is desirable, however, that the alkali be not in excess, and as a slight excess of acid is of little consequence it is better to err on that side. When the solution has become cold it is poured on to the precipitated ferrous salt and allowed to stand for an hour or two, with frequent stirring, when, after filtration, it is ready for use. The above quantities may, of course, be reduced if it be desired to work upon a smaller scale.

DRY PROCESSES—ANCIENT AND MODERN.

II.—A HYBRID PROCESS.

The washed emulsion process possesses qualities so exceptionally its own, and of such recognised value, as to render it undoubtedly *the* process of the future. Contrast its simplicity with any other existing process: a plate having been properly cleaned is coated with an emulsified collodio-bromide, and by that one act everything is accomplished. No sensitising bath, no washing, no preservative. The plate is ready for immediate exposure, or it will remain good for months. Can we conceive of greater simplicity? That is impossible. But has the process no drawback to counterbalance such exceedingly great advantages? We reply—*None.* Plates are prepared with an ease undreamt of in earlier times; they are, as respects sensitiveness, on a near equality with wet collodion, and may be rendered even more sensitive; they are developed with great ease; and, lastly, they yield pictures of exquisite quality.

Why, then, it may be inquired, not stop here and ignore entirely the cumbrous bath process with its long train of other manipulations? We reply—One, at least, of these bath processes possesses a particular feature more pronounced than any emulsion method, and there are circumstances under which that feature may prove to be invaluable; we allude to the plates retaining the latent image for a long period after exposure. There is, of course, a limit to all things—even to the keeping properties of a photographic plate—and that limit was exceeded when an attempt was made a few weeks ago to develope a successful negative upon plates exposed in Central Africa by Mr. Stanley about three years since, the plates in the meantime having been subjected to violent alternations of heat, moisture, and dryness.

Readers of this Journal are well aware how we have thoroughly appreciated and practised the "hot water" collodio-albumen process of Dr. Ryley. A few years ago we placed on record the fact that we had applied this method of organifying a film to a purely-bromised pellicle as well as to the stratum of iodised collodion hitherto made use of in connection with this preservative. In what follows we shall explain in detail the method we adopted in a very successful attempt to combine the post-exposure keeping qualities so associated with albumen with the other excellent properties inherent in washed emulsion. We, first of all, prepared an albumen preservative as follows:—To the white of each egg we added an equal portion of water and ten drops of strong liquor ammonia. These were placed in a cylindrical glass jar, and the whole was beaten into a stiff froth by means of a piece of apparatus which, although we described it some years back, is still not known so well as it should be, for of all the egg-whisking appliances hitherto introduced we have found it to be the best. It consists of a cylinder, made of any dimensions, of perforated zinc. We have found, for experimental purposes, the most convenient dimensions to be those which will enable the cylinder to stand easily inside of a wide glass tumbler, its height being about an inch in excess of that of the tumbler. It is fitted with a modern top, in the centre of which is a hole slightly under half-an-inch in diameter, through which passes a wooden rod attached to a piston of solid wood which works freely up and down the perforated cylinder. The action is as follows:—The white of egg and other ingredients having been placed in the tumbler, the cylindrical albumen beater is introduced, and the piston rod (which terminates in a handle at the upper end) is quickly pushed down. This causes the albumen to be forced out through the holes in the cylinder, a return of this being effected by the same means when the piston is drawn up. By continuing this upward and downward motion of the cylinder for about a quarter of a minute the whole mass will be converted into a stiff froth. The beater is now washed, wrapped in paper, and put away for future use, while the glass tumbler or jar is covered for one or more hours, or until the froth has subsided into a pure limpid liquid requiring no filtration, and which will remain good and fit for use for several months.

The albumen being now in a state of readiness, we shall indicate the method of using it which we have adopted:—A plate is coated with collodion emulsion. We have not found a substratum necessary, as the albumen to be subsequently applied seems to bind the collodion film to the surface of the glass. When set the film is rinsed, perfect washing not appearing to be necessary. A small quantity of the albumen solution having been placed in a glass, it is poured over the surface and allowed to flow to each corner; it is a good plan to allow it to run off from each corner in rotation back into the vessel. The appearance of a half-rinsed collodion surface is familiar to most readers, the antipathy of the water to "take kindly" to an undried collodion pellicle causing a greasy appearance. In the process we are now describing this is not of the slightest consequence, as the alkaline albumen flows over the surface with an oily kind of smoothness.

While all this is being done, a flat, empty bath must have been placed in front of the manipulator, and a kettle of boiling water within reach of his right hand. Allowing the albumen to drip off from one corner a little fresh albumen is poured upon the surface, and as soon as it has been allowed to spread the boiling water is poured into the bath and the sensitive plate is gently slipped into it. The albumen is, of course, coagulated in a few seconds both on the surface and throughout the pores of the collodion—wherever, in short, it has happened to penetrate. The plate is now removed and is reared up to dry. Previous to its drying an application of a three-grain solution of gallic acid is found to be an improvement.

In the manner just described was prepared the plates which we subjected to a thorough trial both against some prepared by totally different processes and against others prepared with the collodion emulsion alone.

Bearing in mind certain statements made some years ago relative to the destruction of sensitiveness of bromised films by means of heat, we are now in a position to state that the sensitiveness is not affected by the amount of heat to which we subjected these plates in the course of their preparation.

In speaking of the quality of the negatives produced we may, first of all, premise that in a definite series of comparative trials we have recently brought to a termination we never exposed a hot-water emulsion plate without at the same time exposing, and for the same length of time, a plate prepared with the simple emulsion. The exposure we gave, with a lens having an aperture of $\frac{f}{15}$, was respectively ten and fifteen seconds in sunshine, and thirty seconds when the sky was overcast with gloomy clouds. When making use of an alkaline pyro. developer—a mixture of "sal." soda and liquor ammonia forming the alkaline agent present—both sets of plates showed the same amount of detail, proving that neither by the immersion in hot water nor by the albumen preservative was the sensitiveness of the bromised film diminished.

When making use of the ferrous oxalate developer the results were not quite equal to those obtained by the alkaline pyro.; but we do not regard our experiments in this direction as yet completed.

We close by giving in a few words the conclusions at which we have arrived as the result of our experiments. The emulsion employed was a commercial sample we have very often used with uniform satisfaction; it may be accepted as a typical preparation. If the plates are intended to be kept for a moderate period only after preparation previous to being exposed, and if they are to be developed very soon—that is, within a few days—after exposure, we see no advantage that can be gained by the subsequent treatment with albumen. It entails a little more trouble in the preparation of the plate, but does not produce a better negative. The film, however, is rendered much harder by the albumen preservative—so hard, indeed, that it may be briskly rubbed whilst wet without being torn. If the plates are intended to be kept for a long time both before and after exposure the albumen will be found of much service. The image is a little thinner, and of a browner colour, with the albumen than without it when the development has been carried out in a similar manner in both cases; but by treatment with acid pyro. and silver the density may be increased to an almost unprintable extent.

CITRIC ACID IN THE DEVELOPER.

It is not the least remarkable of the many strange facts of photographic practice that the solution used for developing a wet collodion plate is, in the vast majority of instances, identical in composition with that first recommended when the introduction of bromo-iodised collodion into studio practice became general. As a matter of course various nostrums and complications of formulæ arose, too numerous to mention, some being accepted as improvements in the first blush of publicity, others rejected without trying (such is photographic logic!), and others yet enjoying a popularity of greater or less duration, but still to be followed by their gradual disuse.

The changes have been rung upon all the available acids, mineral and vegetable, here and there an artist less conservative than his brethren finally adopting one of the novelties without any perceptible alteration in the character or quality of his work. Thus, we know of one celebrated photographer who for a considerable period made up his iron developer by the aid of sulphuric acid with a little acetic, with which heterodox mixture he used to produce marvellous effects—unsurpassable, in fact, by any method. We are not aware whether he still continues to make use of the same formula, though it is highly probable he does not.

All these facts conclusively prove that, vast as is the number of experiments that have been tried with various modifications, they have been of so inexact and unsystematic a nature that no trustworthy comparison can be made (at anyrate without an immense amount of labour), from published data, of the action of the various additions to the plain solution of sulphate of iron. We have of late been accurately testing the effect of different acids upon the appearance of the deposit and the peculiarities of their working; and, as a contribution to the subject, we shall proceed to point out the usefulness of one particular acid which has more than once of late had its praises sounded—citric acid.

Naturally, the first step that would occur to the mind in instituting such experiments would be to try the action of the proposed addition in a test glass by means of solutions of suitable strength, to which would be added small quantities of nitrate of silver solution. We have, of course, tried this plan, but upon rigidly comparing it with the effect of the same solution used upon the exposed plate we cannot conscientiously say that we have found anything like that entire accordance, either in the colour of the deposit or rapidity of precipitation, between the two processes which the common reputation of this method of trial would have led us to expect; and hence we made little or no use of it in finding out the value of each particular acid with which we experimented.

Rapidity being the great aim of all changes—its discovery being to investigators as the search for the philosopher's stone to the alchemist of old—our first experiments were to test the powers of citric acid in that direction, one of the claims made for it being that on account of the length of time it could be kept on the film without fogging a practical increase of sensitiveness followed. We repeated our experiments many times, but, so far from finding any decrease of exposure with its aid, we unhesitatingly condemn it as slow; in fact, it causes a most material increase in the time of exposure when tried against iron with acetic acid.

The most marked feature of its use is the very remarkable colour of the deposit as compared with that given by the familiar acetic acid and iron developer. With the latter the tone of a good, correctly-timed negative is a peculiar rich greyish-brown of good printing character; but the substitution of citric acid causes a great change, an equally well-timed negative being of a dense indigo-purple or ink-like colour, which, however, prints well enough. Further: the density of the deposit is so great with citric acid that no intensification with pyro. need ever be resorted to when the bath is in fair order.

It is evident from these statements that, for portraiture, citric acid is in every way inferior to acetic; but for copying engravings, maps, &c., it possesses characteristics which would seem to point it out as being especially useful.

We have also been able to make it very useful in another direction. A point in the development of dry plates upon which great stress has been laid is the power, by altering the proportion of the ingredients of the developer, of being able to get good negatives with a very wide latitude of exposure. So much has been made of this point that it might be supposed that with wet-plate development no such latitude could be allowed. This is so far from being really the case that, by the aid of citric acid, we do not hesitate to say we could make a good negative with an exposure much more than double that needed by an acetic acid developer. We do not mean that that is the usual ratio, but that it is possible to have the development under control to that extent—a power of no mean value on occasions. It is evident that it must be just as useful to have this command with wet-plate work as with dry. To obtain this effect all that would be necessary would be to make the developer of about nine or ten grains of iron to the ounce with a due proportion of citric acid, increasing its quantity according to the slowness desired.

We have in our wet-plate work been able to avail ourselves of this property of citric acid to some advantage. We always have at hand a supply of citric acid solution (if this be well boiled it will keep for a considerable time without becoming thick or "ropy"), and, when we find the image to flash up too quickly, we at once flood with water to arrest the development, if possible, before it is completed, and then, adding a few drops of citric acid and a good supply of silver solution to the same developer weakened by water to one-half of its strength, we find ourselves able to produce a negative perfect in gradation and with sufficient contrast; whereas without this aid nothing but a flat, grey, worthless result would have been obtained We need scarcely say that if we had from any cause good reason to suspect at first that the negative was much over-exposed, we should use citric acid in a weak iron solution in the first development, without waiting to see from the acetic developer whether the timing had been correct.

We may conclude our notice by stating that in practice we find one grain of citric acid to be equal to from twenty to thirty minims of glacial acetic acid. Their effects are so different in iron solutions that it is difficult to form a closer estimate than this. With pyrogallic acid we find the lower estimate to be about the due equivalent.

WOODBURYTYPE BLOCKS.

We are enabled to supplement our article on this subject, which appeared four weeks ago, by giving the text of a patent obtained by Mr. W. B. Woodbury for a similar purpose. Taken in connection with our recent article, it will prove a valuable contribution to our knowledge of this most important subject.

The title of Mr. Woodbury's specification is "Improvements in Photo-mechanical Printing, and in Apparatus and Appliances therefor." These improvements, he says, relate—

Firstly. To a method of obtaining by photography blocks suitable for employing with type in the ordinary method of typographic printing, either from a subject represented by lines, as an engraving or woodcut, or from a photograph containing only half-tones, as a portrait or landscape from nature, or a painting.

Secondly. To improvements in the process known and termed in the trade "Woodburytype," by which that process is rendered much simpler.

Thirdly. To an improved method of producing the same by machinery.

To accomplish the first part of my invention I proceed as follows:—Where the subject is in line I make a positive photograph of it (*i.e.*, positive by transmitted light), and from this I obtain a relief in gelatine by the ordinary method, the result being that the hollows of the relief will all be of one uniform depth, this characteristic producing a level or uniform surface in the resulting mould, which I make by impressing this relief into metal by hydraulic or other pressure, or by the method stated in the second part of this invention. Where the subject is in half-tone, as in a photograph from nature, I proceed as follows:—In printing on the gelatine film I interpose between it and the negative a photograph on mica or transparent collodion of what is known as musquito netting, or Brussels net, which breaks up the resulting relief into a multitude of fine square or hexagonal lines. To obtain from this a printing block I employ the means already described, the resulting block in soft metal being capable of giving from one hundred to two hundred impressions; but where large numbers are wanted I electrotype this block in the ordinary way. I use diffused light to produce the block from half-tone negatives, as in that case the light in the parts that represent the whites creeps around the lines, thus obliterating them in that part, and leaving them strongest only in the parts printing dark. I sometimes adopt another method. I take a negative of the network by transmitted light, and copy this together with the negative, thus producing a positive with the lines already thereon, from which I proceed to make a relief as stated.

To accomplish the second part of my invention I proceed as follows:—In place of using a thin film of collodion (as is generally used in the process called "Woodburytype") to hold the gelatine of the relief I proceed as follows:—I first rub over a sheet of plate glass with French chalk or ox-gall, and then coat with the bichromatised gelatine solution as now used. When this is dried and ready for use I expose the side that was next to the glass for a few seconds to daylight before exposing it under the negative. This has the effect of causing a thin film of the gelatine to become insoluble, which after subsequent exposure under the negative will not wash away but form a support for the photographic image afterwards impressed, thus doing away with the expense and trouble of the double coatings as now practised. When the gelatine relief is dried in the ordinary way I take a thin sheet of tinfoil (same size as the gelatine relief), and attach it by gum or other adhesive substance round the edges to the gelatine relief. I now lay on the back of this a stout sheet of plate paper, and pass the whole through an ordinary rolling-press. The tinfoil is by this means impressed into all the details of the relief; but in that state it would be useless to print from. I then proceed as follows:—A shallow metal box is filled with a composition of shellac and asphalte, which, on warming, becomes soft, but hardens on cooling. This box is placed on a hot plate until the composition it contains softens; it is then placed on the lower plate of the ordinary Woodbury printing press, the foil and relief laid on it, the press closed, and the pressure applied by the under screw. When the composition has hardened the tinfoil adheres to it. I remove the gelatine relief from the foil, and use the foil-backed mould to print from. In place of fixing the proofs by alum or other substance of a like nature I varnish the proofs with an ordinary varnish composed of shellac and alcohol, which gives the print the effect of a photograph on albumenised paper, at the same time protecting the surface from moisture. I also sometimes use the composition melted in boxes without the foil as a printing mould direct, and when sufficient numbers have been printed the box holding the composition is again heated, and can be used over and over again.

The third part of my invention consists in an improved method of printing "Woodburytype" by machinery. This I accomplish as follows:—Out of a solid block of iron I have turned a cylindrical hole, in which is made to fit very loosely a cylinder of soft metal having a taper or conical hole through it lengthwise. Between the interior of the steel block and the soft metal cylinder I insert the gelatine reliefs; then, by means of a taper or wedge-shaped spindle (roughened), I drive by hammering or by pressure the soft metal against the iron cylinder, thus impressing the relief on the outside of the metal cylinder, the taper spindle at the same time forming a shaft for the cylinder to be used in the process of printing. I then mount this roller bearing the relief in vertical slots in a frame having a bed of plate glass on which the paper rests, the roller resting on the glass by its own weight and being dragged round by the paper itself; or in place of the glass plate I allow the soft metal cylinder to lie on another fixed or movable roller of metal or glass. The latter may be hollow so as to reduce its temperature in hot weather by a stream of cold water running through it.

Although the foregoing specification is not quite new, there can be no doubt as to its suggestiveness and value at the present time.

In the course of some recent experiments with ammonio-nitrate of silver we encountered a rather curious experience which we are at a loss to explain, though possibly some of our readers may be able to throw light upon the matter. Having met with a difficulty in evaporating a solution of the double salt without decomposition from disengagement of a portion of the ammonia and consequent deposition of oxide of silver, we endeavoured to obtain the crystals by exposing a concentrated solution to the desiccating action of sulphuric acid under a bell glass. Accordingly two porcelain capsules—one containing the ammonio-nitrate solution, the other strong sulphuric acid—were placed under a bell glass and left for several days. At the end of that time the solution had become much discoloured from the formation of a dirty deposit, presumably of oxide of silver, together with a quantity of small crystals of the same colour. At a little distance above the level of the solution, however, a ring of efflorescent matter had formed on the sides of the capsule of a snowy white appearance, and on the side nearest to the sulphuric acid this white formation extended right up to the edge of the capsule, as if a portion of the contents had been poured out at that point. This, however, could not possibly have occurred, as the bell glass had never been removed during the interval. Upon the upper edge of the other capsule (which was about half-an-inch distant), and immediately opposite the nearest portion of the one containing the silver, a thick incrustation of the same white substance was found; it formed a sort of crown upon the extreme edge of the vessel, and did not extend downwards to the surface of the acid. We at first supposed it to consist of sulphate of ammonia, but upon second thoughts that appeared scarcely possible. Upon testing it was found to consist, as far as our means of analysis enabled us to judge, of *pure nitrate of silver;* it was neutral to test paper, and certainly contained no sulphuric acid. We could readily understand the possibility of the combined ammonia going over to the sulphuric acid, but how had the silver nitrate passed from one capsule to the other and across the intervening space? Is it possible for a salt of silver in the presence of or in combination with ammonia to assume the form of vapour? or does the ammonia in combination with aqueous vapour act as the vehicle for removing the silver in a state of minute division or possible solution?

NOTES ON PHOTOGRAPHIC SUBJECTS.

Sensitiveness of Silver Haloids.—It has seemed to me that in all cases silver bromide gained in sensitiveness by being placed in contact with silver iodide. This conviction was expressed by me in your columns two or three years ago. It seems to make its way but slowly, and yet I am confident that the opinion is correct. Recently I have had a proof of the high sensitiveness that can be given even to negative paper by the use of all three of the silver haloids, the chloride being added to increase the clearness, not, of course, the sensitiveness.

Some paper was soaked in a solution of alkaline bromide, iodide, and chloride, was blotted off well, and then immersed in a twenty-grain bath of silver nitrate, acidulated with a drop of nitric acid, sp. gr. 1·28, to each ounce. It was then washed for over an hour in running water not wholly free from chlorides. This acid bath, long washing, and the presence of chlorides in the wash water tended, of course, to reduce the sensitiveness, yet this was so great as to afford the following proof:—The paper was placed under a negative, and was exposed for one second at a window to a clear blue sky, with a total absence of cloud to reflect light, at nine a.m. in March. The paper was so completely over-exposed that it developed on the back nearly as strong an image as on the front. I conclude that a quarter of a second, or less, would have been right. The light was certainly not one-tenth as strong as direct sunlight, therefore one-fortieth of a second of sunshine would have been sufficient. This indicates a high degree of sensitiveness for paper, especially as it was intentionally placed under certain disadvantages. Besides those already mentioned of an acid bath, long washing, &c., this paper had no accelerating substance such as should always be used when high sensitiveness is an object. Had the alkaline haloids, instead of being dissolved in water, been dissolved and used in an infusion of *cocculus indicus* (which is what I have found best for the purpose), the exposure might have been reduced one-half.

The haloids used were—

Potassium bromide	8 grains,
Potassium iodide	2 „
Ammonium chloride	1½ grain,

to the ounce of water. The same proportions answer very well for collodion emulsions, and might very likely for gelatine.

Carbon Prints.—Dr. van Monckhoven's remarks on carbon printing constitute the most important contribution made to that subject for a long time. There can be no doubt that he is correct in his view that in bichromate printing the chromic acid is not reduced immediately to chromic oxide. There exist three or four compounds between chromic acid (or anhydride) and chromic oxide whose exact constitution is perhaps not definitely settled; they resemble each other in this—that they are brown in colour and insoluble in water. Doubtless they constitute the intermediate step between the acid and the green oxide under reduction by light. These brown oxides of chromium, or chromates of chromium, are capable, of course, of further reduction, and the reduction goes on, as I have noticed, spontaneously and in the dark, even after everything soluble is washed out of the paper, though this takes place but very slowly. I have a collection of prints of ferns and dried plants made about forty years ago, soon after Mr. Ponton first published his discovery, by exposing under them letter paper soaked in bichromate solution and dried—after exposure simply washed in water. Shortly after these prints were made they were bound into a volume, and this volume was kept rolled in thick paper and in a dark drawer. Nevertheless, in a few years the ground changed from a rich dark brown to dark green; it was then permanent, and has so remained ever since.

The method proposed by Dr. van Monckhoven of converting the brown oxide formed into the green by sodium bisulphite is, of course, correct in principle. It is probable that sodium hyposulphite would answer equally well. The substitution of iron oxide as a colouring matter is also a step in the right direction. There is no known colouring substance equal in permanency to ferric oxide. The drawings in red crayon made three and a-half centuries ago by the artists of the renaissance period are as bright as if made today. The suggestion to substitute ferric citrate in the print and to apply the bichromate afterwards is most ingenious.

For this purpose I would, however, suggest that ammonia-ferric oxalate might give far better results than ferric citrate. In 1873-1875 I made hundreds, I might almost say thousands, of experiments with the iron salts; and though this work was with quite different objects from those that Dr. van Monckhoven has pursued, I think I can say that the oxalate would be found preferable to the citrate. Dr. van Monckhoven is much to be praised for not fettering these valuable novelties with patents.

Architectural Perspective.—In the discussion on this subject, reported in The British Journal of Photography for March 22nd, some of the opinions offered seem to overlook the fact that in observing either a photograph or a perspective drawing of an architectural subject the eye is not supposed to be opposite the centre of the drawing, as in observing a portrait. In the former case the photograph or drawing is supposed to be held up vertically in front of the observer, whose eye is opposite to, and on a level with, the horizon line. In all views of architectural subjects the horizon line is placed below the middle of the picture, and in views (or drawings) of high buildings very much below. Therefore, when the view is held up vertically in front of the observer, with his eye opposite the horizon line, the upper part of a high building *is much farther from the eye* than the lower, and, therefore, when (correctly) made of equal breadth the upper part subtends a materially smaller angle at the eye than the lower. In both these particulars, viz., greater distance and subtending a smaller angle, the representation corresponds with the object itself. This is, perhaps, the simplest explanation of the fact that vertical lines in nature must be rendered by vertical lines in every correct representation—photograph, drawing, or painting.

Gallic Acid in the Oxalate Development.—Next week I shall have some further remarks to contribute on the employment of gallic acid, the usefulness of which becomes more apparent with every trial.

M. Carey Lea.

THE VOLUMETRIC ESTIMATION OF THE STRENGTH OF SOLUTIONS OF SILVER NITRATE, AND THE RECOVERY OF SILVER FROM WASTES.*

In the short time at my disposal I shall only be enabled to give you an outline of a process for the recovery of silver from wastes.

There are two general methods of dealing with this subject, namely, the dry and wet processes. The one I wish to bring before you is the wet process, which I have found in many respects to have an advantage over the dry.

We will suppose that you have a solution containing silver nitrate—say an old bath, or any other kind of liquid waste. The best thing to precipitate it is hydrochloric acid, or you can use common salt. It will be well not to add too much of either of these substances. It can be easily ascertained when the proper

* Concluded from page 174.

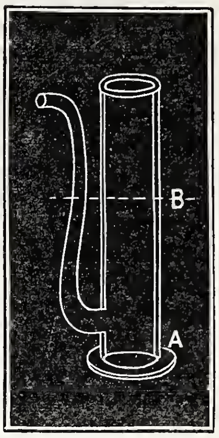
quantity has been put in. Use a large glass beaker, and in adding the precipitant let it mix thoroughly with the waste. The silver will quickly combine with the chlorine and form silver chloride. This reaction is represented thus:—

$$Ag\,NO_3 + H\,Cl = Ag\,Cl + H\,NO_3.$$

Or with common salt—

$$Ag\,NO_3 + Na\,Cl = Na\,NO_3 + Ag\,Cl.$$

If the quantity be small it can easily be perceived when enough of the precipitant has been added by its no longer affecting the solution. It frequently happens when the solution is contaminated with many impurities, or when large quantities are operated upon, that it is best to have recourse to an ingenious contrivance known as "Beal's quick filter," which is a small cylinder about three inches long, with a spout out of the bottom end (or you can use a test tube that has the bottom end broken off). By tying a piece of filter paper over the end A and immersing it in the liquid—say as far as B—the liquid will filter through and can then be transferred to a small test tube. If one drop of hydrochloric acid be put into it and no precipitate be obtained sufficient has been added, and it must be left for some little time to settle. If possible now pour the liquid on to a filter, leaving the chloride behind in the beaker. The filter will retain any that might be floating about. No precipitate separates more readily than Ag Cl, and it can very easily be washed. Repeat this washing until the last washing water is neutral to test paper, and now drain off all the water. Then to every three and a-half ounces of the chloride so obtained add at once one ounce of caustic soda and a quarter of an ounce of lump sugar. Now add a little water and boil, stirring it constantly; it will be found that the silver has been reduced to the metallic state in a fine greyish-black powder. This result is brought about by the joint action of the sugar and caustic soda upon the silver chloride.



After thoroughly washing the silver precipitate drain off the water and add pure nitric acid until it is all dissolved; then evaporate it to dryness, add distilled water, and evaporate to dryness again. What is now left is lunar caustic, or, as it is known to photographers, fused nitrate of silver—the best possible form of silver nitrate of which to make a bath. Weigh it, and make a solution of (say) one hundred grains per ounce of distilled water, keeping it so as to use for either paper or silver bath. Bath solutions can now be made up without the trouble of weighing; you need simply measure the quantity of your one-hundred-grain solution that will give the proper strength. I have done so, and found the negative bath so made to work immediately it is mixed, and to give the best possible results.

It may occur to some one that other chlorides might be thrown down and militate against the ultimate purity of the result. This is possible only in the case of lead or mercury, as silver, lead, and mercury are the only elements that give insoluble chlorides as far as water is concerned. It can easily be ascertained if these are present in the washed chloride by taking a small portion and boiling it with distilled water in a test tube, and filter while hot. To the filtrate add a little sulphuric acid; if there be no precipitate lead is not present. Now pour over the portion left on the filter paper a little strong ammonia, warm; if mercury be present it will be blackened, and the ammonia will take up the silver, leaving the mercury behind on the filter paper.

On examining these reactions it will be found that lead chloride is soluble in hot water, and the other two are not; also that silver chloride is dissolved by ammonia, mercurous chloride remaining undissolved, but being blackened by this reagent, a method of separation being thus easily formed. JOHN GARBUTT.

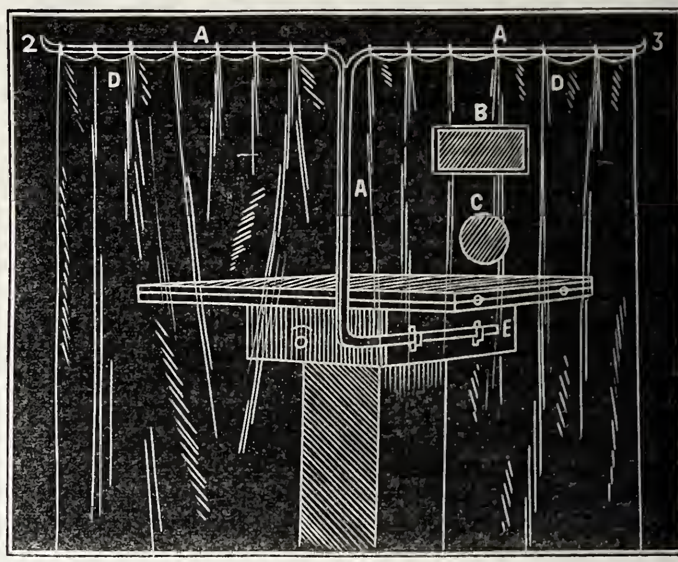
OUR APPARATUS.

No. III.

SCREENS AND CURTAINS.

SOME persons have a great antipathy to be looked at during an exposure, and invariably protest against it; but as the operator will gain considerable advantage if he does watch his sitter carefully, these conflicting wishes must be compromised if possible. By keeping a watchful eye on the sitter a sharp picture may more often be secured than if such surveillance is neglected. This is especially the case with children, who need the most careful, unostentatious watching to obtain a fairly successful picture. A natural expression is the *sine quâ non* of a good portrait of a child. The cross, formal, or constrained expression usually seen must not be laid to the fault of the child, who is often very shy and uncomfortable with such unusual surroundings as a photographic *atelier* and its accessories; but more to the fault of the operator, who fails to use the means he has to the best advantage. But I am digressing.

There is much advantage gained if the operator remain out of sight during exposure, and to effect this nothing is better than a curtain attached to a light iron rod, bent twice as in the diagram,



A A A, iron rod attached by sockets to front of camera stand; B, yellow glass window; C, hole in curtain for lens to look through; D, curtain; E, short arm fitted into sockets.

and attached to the front of the camera stand, which is sufficiently large to hide both operator and apparatus from view. A hole is made to allow the lens an uninterrupted view of the sitter, and a small yellow or blue glass window three or four inches square for the operator to obtain his view, the coloured glass preventing observation in return. The short arm E in diagram fits into sockets in front of the framework supporting the table, the upright portion of the bend 2 is sufficiently long to hide the head of the operator, and 3 is the arm to which a curtain reaching nearly to the ground is attached. As it can be either used or not as may be required, it is, I can say from experience, an exceedingly useful screen. Those used for reflectors I have found more useful and manageable if *not* attached to stands. A light frame covered with white glazed calico can be placed anywhere, and takes up little room when not in use. Not having, however, tried the more elaborate arrangements, I can say nothing for their superior convenience. The light detached screens answer every purpose, and for efficiency and economy I scarcely think will be superseded.

With regard to curtains for modifying the light: much depends on the quantity and quality of light peculiar to the studio, as in this respect most differ. Use can be found for white muslin curtains in almost every glass room. As far as actual use is concerned, black, opaque, and white blinds are all that are required for this purpose; but, owing to the gloomy and funereal appearance of black, good stout green ones are usually substituted as less likely to give a false impression of shade than any other colour. All curtains should be frequently shaken, to dislodge the dust, which is very apt to accumulate and become a nuisance, and, to those who take a pride in the neat appearance of their glass rooms, also an eyesore.

LENSES.

With respect to this very important portion of our apparatus, the difficulty is how to choose amongst so many good ones. Where expense is no object lenses of every form may be part of the stock, and be found useful; but with the majority of photographers half-a-dozen form the assortment from which to choose. Good pictures may be obtained with almost any, if good of their kind. Two qualities are needful for almost all purposes, *i.e.*, crispness or definition of the image, and that the visual and chemical foci shall be coincident. Whether it shall include a large or small angle depends on the purpose for which it is required.

For portraiture in the studio we are limited to a kind that will admit as much light as possible, and act rapidly, but for outdoor work almost all kinds *can* be used. Many eminent photographers prefer the single lens for ordinary landscape work as giving a brighter picture than the compound form. I must, for my own part, confess a partiality for a good medium-angle doublet for landscape or architectural subjects, using a larger lens than is generally considered necessary and working with the largest aperture—say a 12 × 10 lens for an 8 × 6 picture. This plan ensures absolute sharpness over the whole field, straight lines in architectural subjects, and no deficiency of atmosphere, which is often induced by stopping the lens down to ensure sharpness to the edges of a plate of the size the lens is advertised to cover. I, however, merely state my preference, under the impression that I have obtained better photographs when working in this way; but, as I have already said, the lens must be adapted to the subject, and no hard and fast rule can be laid down.

With regard to the storage of lenses: they should be carefully kept in a dry place. Photographic premises are, unfortunately, frequently damp, necessitating much care in this respect. A suitable cupboard or box lined with baize may be devoted to them at home, containing divisions for each lens; and as they of all our apparatus contain the most value in the least space, it is as well to keep them under lock and key when not in use. A sling case is very convenient for carrying them when engaged in outdoor work. The glasses should be carefully wiped with a soft silk handkerchief before use. Never set to work in a warm atmosphere directly after removal from a colder one without gently warming them first, or they will in all probability condense moisture on their surfaces and cause some trouble. This is particularly the case in cold spring months. The mounts also get corroded and unsightly if they are put away in a damp state. Judging by the number of dilapidated-looking lens mounts one sees in use this oversight must be of very frequent occurrence.

If lenses are removed from their mounts for any purpose care must be taken to replace them in their original order, and no force should be used in screwing them together; for if the screws are accurately placed with regard to each other no force is required, and if it be used it will be to the damage of the thread. A little of this injudicious screwing every time a lens is taken to pieces and put together again will soon render the screws useless. If delicate, uninjured screws, such as those attached to our instruments, refuse to work easily, it is an invariable fact that they are wrongly adjusted with regard to each other, and the use of force is a sure way to spoil them. A little knack and gentle treatment will manage a screw that would defy the power of an athlete to turn if set wrong at the commencement.

Metal caps are seldom seen now on modern lenses, the leather and velvet entirely superseding them. Any photographer using the old-fashioned metal ones would do well to discard them for the lighter and easier-fitting make. In the earlier days of photography a ricketty stand and tight-fitting metal cap were a very usual combination of troubles, and even now they occasionally may be found with the village photographer or the less successful town practitioner, whose stock-in-trade consists of a second-hand French combination lens, or maybe with the young amateur, who has had no experience as to the advantages or disadvantages of one kind or the other.

Pneumatic Holders

are, preferably, those consisting of an india-rubber ball enclosed in a case, communicating with an india-rubber disc to support the plate. This form is easily manipulated with one hand, and less liable to get out of order than other kinds; if it do it is more easily repaired. A little strong solution of rubber poured round the screw in the disc will usually set all right, for this is the place where in all probability it will give way first. Lever and half-screw holders are more or less troublesome and continually getting out of order, besides being of a more expensive make. For development the gridiron form of holder is, to my thinking, most convenient. It consists of a stout wire, bent like the frame of a gridiron, the bars of which are supplied by india-rubber bands placed at right angles to each other, forming a sort of lattice upon which the plate to be developed securely rests, with a handle at one corner. This form was described at the last technical meeting of the South London Photographic Society. It allows the plate to be easily manipulated, and keeps the hands clean. E. Dunmore.

NOTES FROM THE NORTH.

The lapse of Swan's patent for the manufacture of pigment tissue will doubtless give an impetus to carbon printing, bringing it into more general use, and probably leading to many improvements both in the *modus operandi* and in the finished result. I do not, of course, mean to imply that the company who have hitherto held the patent acted in anything like an illiberal spirit, as I believe it is mainly to the zeal and business tact which they brought to bear on it that carbon printing has attained its present satisfactory position; but there are many who have such an inveterate dislike to patents—especially patents connected with photography—that they will have nothing to do with them, however liberal the terms may be. But now that the manufacture of tissue is open to all, and with the exquisite results got by single transfer, I have no doubt the ranks of successful carbon printers will be largely increased.

I am glad to say that Scotland is likely to take a fair share of the work, and have pleasure in publishing a few notes of a late visit to the carbon printing establishment of Mr. Annan, of Glasgow, recently erected at Lenzie. I dare say most of my readers will remember an account of the establishment of Messrs. G. W. Wilson and Co., of Aberdeen, which I wrote about a year ago; and as the process and apparatus of Mr. Annan are very similar to those of Messrs. Wilson and Co., I need not take up space in repeating those details.

Lenzie is a village some six or eight miles to the east of Glasgow, and from the absence of smoke and freedom from fog, &c., is better suited for such work than the smoky city. With a view to future expansion Mr. Annan wisely resolved to secure a large plot of land, and this he fortunately found in the shape of a garden attached to a somewhat antiquated dwelling-house. Here he proceeded to erect buildings large enough for present purposes, but in such a way that necessary additions can be made from time to time as the exigencies of business may require. The establishment, as at present in full operation, stands on a pretty high elevation about five minutes' walk from Lenzie station. On entering the gate leading from the public road one sees in front a large two-story building in the form of the letter L, and on the right the dwelling-house already mentioned. Fortunately I found Mr. Annan at home, and received the genial welcome so generally given and received amongst the photographic fraternity, and to my request to be shown over the premises he at once gave a hearty acquiescence and tendered his services as guide and instructor. We first visited the old dwelling-house, thus commencing at the end rather than at the beginning, as the first room we entered was that devoted to mounting, rolling, &c., and in which we saw a rolling-press made by Messrs. Greig, of Edinburgh, more like a huge mangle than anything for photographic purposes. Two other rooms on the ground floor were devoted to enlarging purposes, the one being the dark room and the other the camera. The latter we did not examine particularly, as there was a plate being exposed, and we could not turn on the gas in consequence; but the arrangements generally are very much like those I described as having been seen at Aberdeen. Some idea of the exposures, however, may be obtained from the fact that the operator had gone to dinner, leaving the work to proceed during his absence. The floor above was devoted to the manufacture of tissue, one room being used for the mixing of gelatine and pigments, another devoted to coating, and two others to drying, the temperature being kept at a suitable degree by a stove and plenty of piping. This, I may say, was the only part in which the arrangements seemed to me to be defective, as I believe that the quality of the tissue is influenced by the temperature, and think the drying-rooms should be so arranged that a current of dry air at any desired degree of temperature may easily be sent through them.

Much has been written regarding the necessity for permanency in the coloured pigments used to warm the carbon, and that Mr. Annan is fully alive to such necessity may be known from the fact that I saw a series of reds and browns which had been exposed to light for months before they were admitted into the list of those suitable for the purpose.

The machine for coating the tissue is extremely simple, and, so far as I can learn, has not been improved upon since its invention by Mr. Swan, of Newcastle-on-Tyne—indeed the one in ordinary use by Mr. Annan is the identical machine the inventor employed; but, as I am not quite certain that I got permission to describe it, I shall postpone a description of it till a future occasion, when I may be allowed to furnish a drawing of the machine. I may, however, say that it is so simple that an amateur desiring to coat small bands of tissue for his own use might easily construct one for himself at a trifling cost.

Crossing the well-kept grounds we come to the building described as erected in the form of the letter L. The lower part of the longer portion of this is devoted to printing. The tables, running on rails, may be brought into the open air, kept under glass, or run quite under the upper floor, where the frames are filled and emptied. The lower part of the shorter portion is the developing-room, and contains seven tanks or trays, two of them measuring seven by five feet each. Here also is a boiler for the supply of cold water, both that and hot being laid on to each tank. "What do you mean by a large picture?" is frequently asked, and I suppose the answer must always be a somewhat negative one; but here I saw what most photographers would admit was a large negative, being a copy of a picture on a plate seven feet by three and a-half feet.

The floor above the printing-room is a large glass house glazed on the top and both sides, and fitted throughout with louvre boards. This is used for copying purposes, and contains an enormous camera on rails, with a triplet of some eight inches diameter. The camera was not, as in ordinary circumstances, pointed to the picture about to be copied, but turned so as to look out at the side of the house; and on the lens was placed a kind of cap carrying a plate of silvered glass, so as to give a reversed negative. A door leading out of the studio gave entrance to another laboratory and enlarging-room, both of which were in constant use.

In a long and pleasant chat with Mr. Annan I learned that they were doing a large amount of work for the trade, but he did not, on the whole, consider that a satisfactory branch of the business. Many of the negatives sent were poor and not well adapted for enlarging, while some of those who sent them seemed to expect results quite equal to that of the best-selected specimens. Work for the "trade" must, however, be always a trifling matter compared with the expensiveness of other branches, and an examination of the work in progress of even such a young establishment as that of which I am writing shows, with tolerable certainty, the line in which profitable employment is to be found.

In reply to a question as to the work actually in hand, Mr. Annan, with his well-known characteristic modesty, said they had "a few little jobs;" and taking me over to his private residence—a portion of which, for lack of room elsewhere, had been converted for the nonce into a packing-room—showed me a finished set of 13,000 prints from one hundred negatives, for a second edition of a book about to be published in Glasgow. Another order in the course of execution consisted of 3,000 prints from thirty negatives of the old closes and other interesting portions of Glasgow now removed by the Improvement Trust to make way for more modern erections. A third order consisted of copying four pictures by Herdman, for reproduction in carbon for the Glasgow Art Union, 2000 copies being ordered to begin with.

Altogether Mr. Annan's establishment gives a fair idea of the importance of carbon printing, and I shall rejoice to hear that there are many such both here and in England, as I believe that, at the present time at least, the ordinary course of cause and effect will be reversed, and that the supply will produce the demand.

While carbon printing is thus brisk in some quarters there is still heard the general complaint that photographic business is dull; but it would seem that there are those who think Edinburgh an exception to the rule. For some years the impression has been that of professional photographers we have had "enough and to spare;" but they will require to "put their best foot foremost" if they wish to retain anything like a premier position, as, if report is to be credited, their numbers are to be considerably increased by some well-known men from various parts of the country. Between this and the Whitsuntide term I understand that Mr. Marshall Wane, from the Isle of Man, Mr. Mackenzie, from Paisley, Messrs. Taylor Brothers, of London, and Mr. Thompson, of Kirkcaldy, will throw in their lot amongst us. I hope they will all succeed as well as they can wish, and have no doubt they will get a hearty welcome from their professional brethren, the only rivalry being as to who shall turn out the best work.

The exhibition of the Royal Scottish Academy is now in full swing, and is well worth a visit by all who have an interest in art, and especially of all interested in photography. To the thoughtful photographer such a visit will forcibly suggest two things—first, the great influence that photography has exercised on art; and, second, the great benefit that art may confer on photography. That artists—or at least very many of them—turn up their noses at photography is, for them, a sad fact; but it is, nevertheless, true that a careful study of a majority of even the best pictures on the walls will show that the artists have been more indebted to the art which they affect to despise than they would care to acknowledge; while, on the other hand, the photographer who will carefully examine the composition and method of treatment adopted by the leading painters of the day, and will apply the knowledge thus gained to his work during the approaching season, will, I am quite certain, have no cause to regret his visit to the exhibition.

Does anybody want a hint of something new, and that would be sure to take? Here it is—in the form of a lamp shade I saw in the house of an amateur friend a few days ago. The shade was one of the conical cardboard kind, both cheap and pretty, and which, when laid over the ordinary lamp globe, throws the light down on the table, and is really ornamental. Around the shade at equal distances there were ovals cut out and filled up with silver prints which had been made semi-transparent by paraffine, and when in use the effect was charming. Photographers who adorn their reception-rooms with frames and photographic knick-knacks generally should try something of this sort, and I am persuaded that there would be little difficulty, when taking orders for *carte* and cabinet pictures, to get a commission for a few such shades with portraits of the various members of the family inserted in the openings. If the manufacturers of mounts, &c., are not above taking a hint, I would suggest the propriety of their getting up such shades with the ovals cut out ready for the pictures. The inside should, of course, be white, and the outside of any tint they like; but secondary colours are more chaste and in better taste than primaries. A narrow band of gold might be put at the top and bottom and also round the oval. Of course the price charged for these articles would depend on the work put upon the shades; but I know that a really beautiful article could be produced for a few shillings per dozen. Who will be first in the field, and not only make a good thing for himself but help others to do likewise?

JOHN NICOL, Ph.D.

WASHED FILMS.

In November, 1869, I published an article in the *Photographisches Archiv*, in which I stated that silvered and washed albumenised paper remained white for a long period, and when fumed with ammonia that it gave good prints. The idea made a considerable noise at the time, but it has not been adopted in practice, though scarcely anyone will deny that the process is a good one if it be completely carried out. I, myself, latterly gave up the practice of fuming with ammonia, and substituted a second silver bath having about five per cent. of the nitrate, and by this process, with the exception of a few waste sheets at the commencement, obtained results satisfactory in every respect.

To many it may appear a useless operation, first to wash the paper after having been silvered, and then to silver it again. But one should remember that in washing the silver the nitrate salt will be washed out, which always forms during the sensitising of the paper, and not only appears to be the cause of the rapid deterioration of prepared paper, but also interferes with its sensitiveness and toning.

A short recapitulation of the process may not be out of place here:—On the first (eight per cent.) silver bath the paper should not float longer than is required to change the chlorine salt into chloride of silver, and the albumen into albuminate. The time will vary, with the sort of paper, from twenty-five to forty seconds. I use Höffert's (of Dresden) ten kilo double albumenised paper, and silver exactly thirty seconds. If the paper roll up on the bath then it is too dry. After being silvered the paper should immediately be washed four or five times in clean distilled water, laid between blotting-paper, and finally, while still wet, placed on the second bath. Here, if it float twenty seconds, it will be found sufficient. If one be willing to put up with the loss of a few trial pieces, it is most convenient to dry the second time also between so-called chemically-clean filtering paper; but it is to be feared that occasionally the chemical purity of the paper will be ocularly demonstrated in the form of very annoying spots of reduced silver. The paper improves with constant use.

There remains but one thing more to mention, namely, that I add to the silver bath about five per cent. of alcohol, and to the last washing water, before toning, a little common salt; and that I always fix in a fresh five-per-cent. soda bath. I am seldom troubled with blisters, and it appears to me that they only make their appearance when the paper has been too long silvered.

What has been said of the paper really applies also to the negative process. If it be wished to retain the greatest possible degree of sensitiveness got by the silver bath for the longest possible time the bath is iodised by adding a solution of iodine in alcohol without further acidification; and in the same bath the same collodion is always used, and, if one prepare it oneself, only such as supplies the bath with a single base, and through that with but one nitric salt. Almost all collodions contain the iodine combined with two, and some with even three, different bases; it is only occasionally that we come across one in which only a single base is prescribed (Vogel's bromo-iodised cadmium collodion), and these last base their claim to general use on the fact that only one nitrate is produced in the bath, and thus they retain their sensitiveness longest. Some photographers use in the same bath any collodion that may be at hand, or which may be best suited for some special purpose; they, however, do not think, or do not know, that with every new collodion they add a few new salts, or double salts, to the silver bath, which by no means increase its sensitiveness. But in order to get the greatest possible sensitiveness and fineness with one collodion and silver bath it is necessary to wash out the nitric bases.

Carefully-cleaned and polished plate glass, without any coating of albumen, being used for the picture support, wash the sensitised plate in pure distilled water to which about one per cent. of nitrate of silver had been previously added, and which had been sunned for some hours. If this purifying of the water be omitted, and the water be not perfectly clean, the plates blacken under the developer. The washing is best done in a large dipping vessel, in which the plate, laid upon the dipper, may be moved up and down and backwards and forwards until the water runs smoothly off. Now let the plate drip, and then place it in a third dipping-bath containing a five- or six-per-cent. silver solution saturated with iodide of silver and slightly acidulated with pure nitric acid. The iodising is here most simply accomplished by leaving the previously-washed plate for a long time in the bath; but the acidification should only be done with so-called pure nitric acid from which the cloudiness caused by its addition to the nitrate of silver solution has been removed. In this last bath the plate should remain at least one minute. From the rather powerful fresh developer the alcohol is best left out altogether, and for its acidification I prefer sulphuric acid to the organic acetic acid (Vogel).

The washing of negative wet plates, in order to be able to keep them longer before developing, is not new. In 1869 Mr. Jabez Hughes, of

Ryde (as stated in the *Archiv*), thought so highly of the process that in summer he used it for studio work. However, by his plan the principal advantages of increased sensitiveness and fineness of the negative are lost by washing the plates with distilled water purified, or rather dirtied, with potassic permanganate, and, before developing, the plate is brought back into the original silver bath, which is impregnated with nitric acid, in order to supply it with the necessary silver. THEODOR BADEN.
—*Photographische Correspondenz.*

ON THINGS IN GENERAL.

IN connection with art and art canons there has been much loose writing and talk lately. Naturally I do not class every photographer alike. There have been (alas! poor Rejlander!) and are men of large culture and artistic feeling, but they only show by contrast the shortcomings of the rest. Thus we had recently a paper, by Mr. Payne Jennings, on taste in landscape composition, showing a considerable amount of true artistic insight; but it is very evident that his Nos. 1 and 2 photographers form a large majority, and his No. 3 is almost a *lusus naturæ*. Imagine his No. 2 man reading of Mr. Jennings' imaginary artist dealing with atmosphere in the manner indicated, taking a view in a hazy morning with a lot of smoke tumbling out of a chimney! Even Mr. Jennings will admit that this was very accommodating smoke. My experience of smoke early on a hazy morning is, that it too often hangs about the premises in a manner that would make a photographer as suspicious as a policeman of a man "without visible means of employment;" yet my knowledge has not been obtained by the experience gained from my bedroom window over the housetops.

A great deal has been said about the higher education of photographers and the establishment of some kind of a college giving certificates of competency in photography, and the question arises whether with the rudimentary acquaintance with anything but manipulation—matters which could be learnt by a child in half-an-hour—such an institution might not be productive of great good. On the other side, here we have Mr. Hance suggesting, in effect, that they should first be taught to write and to spell. What unconscious sarcasm!

Dr. Monckhoven's paper seems to have fallen like a bombshell into the middle of a calm, placid sheet of water, and the waves and wavelets have not yet subsided. I feel sure his communication will be the means of great good. It will teach us all to think more about what we do and what we use, and not accept too blindly tradition or present practice as being established facts beyond cavil or discussion; for, be the verdict what it may about the permanency or non-permanency of pigment pictures, there are few photographers who are not now a great deal more competent than they were to pass an opinion on the subject. But it is useless to shut our eyes to the fact that, though now it is possible to produce unalterable pictures, there yet are many pictures produced which will fade into very wretched-looking things after a few years' trial. Further: the present advanced state of really trustworthy pictures has been built upon experiments made at the public expense, for there must be thousands of pictures in existence at the present day in which have been used, to modify the tone, not only cochineal colours but magenta dye. No one can deny that these will fade. I am thoroughly of opinion that all the tissue now sent out by the Autotype Company as permanent can be utterly relied on.

We have not had much process-mongering of late. I wonder whether the something I read the other day was the first symptoms of the exploitation of "a new and valuable process." Some one in France has discovered a new "instantaneous process" which was not to be divulged till a number of *savants* had passed judgment upon it. Last Sunday they were to meet, and a crowd was expected in a Parisian studio. We shall see what we shall see.

Among the new things I have jotted down is a very strong statement that daguerreotypes will not fade when exposed to the air, and that, indeed, they form the most permanent of all kinds of photographic work.

I have also seen recommended that a picture to be photographed should be covered with a layer of soap and then washed off, and finally rubbed over with olive oil, followed by a quick-drying varnish. What a delightful state the picture would be in if the apparent intention of these instructions were followed, and how pleased its owner would be when he saw the effect! The mixture of olive oil and varnish so naïvely suggested is too rich! FREE LANCE.

Our Editorial Table.

THE PSYCHOLOGICAL REVIEW.
London: E. W. ALLEN.

THE public is not supposed to know it, but we happen to be aware that this new quarterly is brought out under the editorial supervision of Mr. William White—a name well and favourably known to the readers of our ALMANAC, as well as to every one who takes an interest in the new processes of producing sodium and magnesium. The editor has gathered round him a host of contributors who are recognised in the psychological world as being clear thinkers and facile writers; and it is scarcely necessary to say that under the supervision of an accomplished *litterateur* like Mr. White, who himself contributes an important article *On the Ethics of the New Age*, the new quarterly is in no danger of sinking to the level of commonplace.

INSKIPP'S RAPID DRY PLATES.

MR. INSKIPP has sent us a sample of his rapid dry plates with a request that we should speak of them as we find them. These plates are of excellent quality, possessing a high degree of sensitiveness. The following are the directions given by Mr. Inskipp for developing the image:—

"Flow over the plate a mixture of methylated spirit three parts, water one part (this may be used over and over again); let it soak into the film for a minute, then well wash under the tap or from a jug, and pour over the following developer:—

Common washing soda	1 ounce.
Bromide of ammonia	25 grains.
Strong liquor ammonia	¼ ounce.
Water	10 ounces.

Take enough in the developing cup to cover the plate, flow over two or three times and back into the cup, then with a strip of thin glass, or card about a quarter of an inch wide, take up a little dry pyrogallic acid on the tip, about the bulk of a pea for a half-plate, stir into the developer, and apply again; the image will speedily appear and gradually gain strength. Should the detail be slow in coming out or lack density, add a little more pyro. *As soon as the detail is all out wash off and fix* in weak hypo. After well washing *let it dry.* If not then intense enough moisten it again (with water only this time) and proceed to intensify with the ordinary pyro. and silver intensifier, when any amount of density can easily be obtained."

In a note appended to these directions Mr. Inskipp says:—

"The quantity of dry pyrogallic acid may seem rather indefinite, but considerable latitude is allowable. Increasing the quantity quickens the development and produces density, and *vice versâ*. Except for instantaneous exposures it is better to add it gradually."

Having given the above formula a thorough trial we can recommend it as a good one. In some instances we found it necessary to slightly increase the proportion of bromide of ammonia.

THE UNIVERSITY MAGAZINE.
London: HURST AND BLACKETT.

THE name of the Earl of Rosebery having recently been brought prominently before the public, it is not to be wondered at that the enterprising conductors of *The University Magazine* should have made choice of his lordship as a fit and proper subject for the fourth number of the new series of "Contemporary Portraits." The photograph is from a negative by Messrs. Lombardi and Co., the printing being effected by the Woodburytype process. The articles in this (the April) number are as varied and interesting as usual, Professor Ruskin leading off with an autobiographical reminiscence—*My First Editor.* Mabel Collins, Karl Blind, F. R. Conder, and others contribute articles which are well worthy of thoughtful perusal.

DESIGN AND WORK. VOL. III.
London: PURKESS, 286, Strand.

LIKE the previous volume of this work, which we noticed last year, this contains much that is calculated to be of both use and interest to the mechanic and amateur, especially to the youthful artisan. There are numerous hints on photography scattered through the pages of the work, those which have been selected from contemporary pages being good and reliable. We cannot speak in the same terms of some contributed articles, entitled *Photography for Beginners*, the author of which adopts the unwise policy of recommending, with numerous illustrations, his readers to manufacture for themselves makeshift apparatus, in which single non-achromatic lenses of the spectacle glass family, pasteboard tubes, and other parts *en suite*, are the appliances. It is true, however, that he informs them that a flint concave lens to achromatise the biconvex may be made out of the bottom of a glass tumbler, provided the class for whom he writes these articles (and whom he apparently assumes to be impecunious) are able to do so. In contradistinction to such teaching we would recommend the photographic aspirant to *purchase* a properly-constructed achromatic lens and camera, which, to be effective, need not necessarily be expensive. "Makeshifts" usually prove as expensive in the end as proper appliances, while they are unsatisfactory throughout. It is proper we should add that some of the correspondents of *Design and Work* are also of the opinion we have here expressed.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
April 25	Liverpool Amateur	Free Library, William Brown-st.
„ 25	Oldham	Hare and Hounds, Yorkshire-st.

MANCHESTER PHOTOGRAPHIC SOCIETY.

The usual monthly meeting of this Society was held at the Memorial Hall, on Thursday evening, the 11th instant,—Mr. Alfred Brothers, F.R.A.S., President, in the chair.

After the minutes had been read and confirmed,

The Chairman showed some mechanical autotypes representing old and new Manchester, from wet-plate negatives by himself, and also some interiors from wet-plate negatives by Mr. J. Pollitt.

Mr. Schofield exhibited a camera-tripod by Mr. Ross, a wood and glass tray, some prints from Mr. Inskipp's dry plates, and a bromide-of-zinc emulsion transparency developed with Newton's developer.

Mr. Wigglesworth showed some results of his experience with Liverpool dry plates.

Mr. J. W. Leigh introduced a camera-tripod made of bamboo canes, and explained how one of the legs could be utilised as a fishing-rod. This tripod was both light and firm.

Mr. J. Holding again alluded to burnt-in pictures on wood, but nothing new was elicited.

A vote of thanks was passed to the exhibitors, and the meeting was adjourned.

PHOTOGRAPHIC SOCIETY OF PHILADELPHIA.

A regular meeting of this Society was held on Thursday evening, February 21st,—Mr. Joseph W. Bates, Vice-President, in the chair.

The minutes of the previous meeting were read and approved.

At the suggestion of Mr. Browne it was resolved to ask the members to bring lantern slides to the next meeting of the Society, from which a selection could be made for another exhibition.

Mr. Thos. H. McCollin exhibited a new form of manipulator, made of wire, and intended for holding plates while developing.

Mr. Browne raised a question regarding the possibility of photographing a building or view illuminated by a flash of lightning.

The matter was discussed at some length, the general impression seeming to be that such a feat was impossible.

Mr. McCollin laid upon the table a portrait, by Messrs. Broadbent and Taylor, thought to be the first ever made in America by the dynamo-electric light. This picture, which was very successful, had an exposure of one and a-half minute.

Mr. Sartain exhibited the apparatus used by Dr. Goddard and Mr. Cornelius in their early photographic experiments. This collection was examined with great interest by the members, and a vote of thanks given to the exhibitor.

The meeting was then adjourned.

Another meeting of the above Society was held on Thursday, March 7th,—Mr. Ellerslie Wallace, Jun., President, in the chair.

After the minutes of the previous meeting had been read,

Mr. Barrington, on behalf of the committee on excursions, proposed the following route for the spring trip:—The party to start from Philadelphia on May 15th or 22nd, and go by rail to Nanticoke, then take the canal boat for Northumberland, which will occupy about three days. After remaining over Sunday at Northumberland the party will start for Harrisburg on Monday morning, arriving there about Wednesday, thence by rail to Philadelphia.

The proposed route was favourably received by the members, and the committee was requested to give a detailed report at the first meeting in April. A short trip by tugboat was also discussed, and the committee was requested to include this in their report.

Following a motion by Mr. Bates, the Room Committee was authorised to select a room more suitable for the Society in the vicinity of Broad-street and Chestnut-street.

Mr. Browne moved that an exhibition of lantern slides, selected from the work of the members, be arranged.—The motion was carried.

The Chairman appointed Messrs. Browne, Dixon, and McCollin as the committee.

The meeting was then adjourned to permit the members to exhibit the slides intended for the forthcoming exhibition.

PENNSYLVANIA PHOTOGRAPHIC ASSOCIATION.

The usual meeting of this Association was held on February 12th, at the studio of Messrs. Mahan and Keller, 1427, Ridge-avenue, Philadelphia,—Mr. J. C. Steinman, President, in the chair.

The minutes of the previous meeting were read and approved.

The Auditing Committee reported that they found the books of the Treasurer correct. The report was accepted and filed as usual, and the Committee discharged. The balance in hand was $\$62\frac{31}{100}$.

The questions of the last meeting were then read and disposed of. It was asked what was the best toning bath to produce a rich purple colour.

Mr. John R. Clemmons stated that the borax bath was the best, such as he gave at the previous meeting.

Mr. Davis Mahan, of Pittsburg, Pennsylvania, being present, was called on, and said he thought that in his hands the purple tones were best procured with phosphate of soda. He also gave his formula for the paper silver bath as worked successfully by him for several years, viz., using glycerine about one ounce to ten ounces of bath; but he varied it a little, as some albumenised papers required less, and others more, than the above. In drying it left the paper soft and pliable, and entirely overcame the cracking of the albumen, as was so often the case with heavily-albumenised papers. It toned with less gold and with great brilliancy, and obviated the use of soap or anything else in burnishing.

The thanks of the meeting were tendered to Mr. Mahan.

The meeting was then adjourned.

Another meeting of the above Association was held on the evening of March 12th, at the studio of Messrs. Mahan and Keller, 1427, Ridge-avenue,—Mr. J. C. Steinman, President, in the chair.

The minutes of the last meeting were read and approved.

Mr. Thos. H. McCollin stated that Professor Charles Potts had lately called his attention to an interesting scientific phenomenon, which, although not particularly connected with photography, might be of interest to the members as such. By placing a piece of sheet metal or opaque cardboard, having a small pinhole through it, before the eye and looking at a white object that was illuminated—such as a white glass gas shade—moving it sideways, backwards, and forwards quickly, and but twice the diameter of the pinhole, one was enabled to see the network of veins and arteries of the eye.

Although it might not be new to scientists, still it was so to the members, who were much interested.

After a few matters of private business and the thanks of the President to the few members who had braved the storm (it being an unusually stormy evening) to attend, the meeting was adjourned.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

This Society met on the 15th February,—Dr. Vogel occupying the chair.

The Chairman mentioned that Herr Brandt, of Bayreuth, was about to publish his glass printing process in the *Correspondenz.*

Dr. Weissenborn stated that Herr Kampf, of Berlin, had applied for a patent for a new dipper for the silver bath, furnished with a clamp to keep the plate from slipping.

A letter from Herr Schoene, San Francisco, was then read, in which he mentioned that rain having fallen the former scarcity of water no longer prevailed, and trade was consequently reviving. He also said that a telescope was being constructed at Paris, for the new Californian observatory.

The Chairman said that was a mistake, as the telescope was being constructed by Herr Schröder, of Hamburg.

Herr Cochius showed a sample of "Thompson's fluid enamel" for glazing photographs, and a few pictures polished with it. The fluid is mixed with a little oil (any oil except linseed will do), and rubbed on the surface of the print just as the French polisher polishes furniture. The polish was also said to act upon wood or metal.

Herr Hoppe, Jun., showed a few *lichtpaus* pictures produced by Willis's aniline process, as slightly modified by Herr Hoppe. A discussion followed on the cost of production of photographs, but no decision could be arrived at, the cost being so variable.

The Chairman said it would be seen by the list just published that their Society was the photographic society having the largest membership in Germany, the number of members being 348.

Herr Schahl showed a number of negative films which had been drawn off with gelatine. These films were covered with spots, which could be seen when the negative was held between the eye and the light, and which produced flaws in the print. These spots only made their appearance after the gelatine had been poured on and allowed to dry. On being asked whether the spots might not have made their appearance in the negatives in the absence of the gelatine, Herr Schahl replied that he had never seen such spots on ungelatinised films.

Herr Hummel, and others of those present, said they had met with the same measly-looking spots, but could neither suggest a cause nor a cure for them. The hindrances to the transmission of collodion cotton were then discussed.

The question-box was opened and found to contain only the following question:—"Are very good results got from Husnik's dusting-on solution?" The questioner was referred to Herren Zipser and Joops's remarks at the previous meeting; and, on the opinion of the meeting being taken, it appeared to be that a longer experience and greater fidelity to routine was required to work the dusting-on process than to reproduce negatives by the carbon process.

The meeting was then adjourned.

Correspondence.

ALCOHOLISED GELATINE.—CURVED PLATES.

To the Editors.

Gentlemen,—As Mr. E. W. Foxlee has succeeded in forming workable gelatine emulsions containing a large proportion of methylated spirit, may I inquire whether he has ever met with failures with some samples of gelatine?

I have always used Nelson's opaque gelatine, as sold in sixpenny packets, for my experiments, and have found that not only would the emulsion not bear the addition of much spirit—especially if prepared with excess of silver nitrate—but also that the presence of small proportions of spirit prevented the homogeneous setting of the film, the bromide gathering into wavy striæ, apparently the result of a repellent action caused possibly by unequal evaporation.

I published some of my experiments at the time they were made; but no one came forward with an explanation of the cause of my failures. I have, however, inclined to the belief that some gelatines are more suited for the addition of alcohol than others. Mr. Foxlee will, therefore, confer a favour by letting us know whether he has tried many samples of gelatine—even of the same manufacture—for making alcoholic emulsions. I shall be much surprised if, in the absence of an invariable manufacture, those who follow up Mr. Foxlee's suggestion succeed to their entire satisfaction.

The method given by Mr. Foxlee for coating curved plates is, doubtless, practicable; but I think that that method will require the emulsion to be of a kind giving a dense image. This quality zinc bromide and excess of silver nitrate will give to an eminent extent; but the emulsion is rather given to red fog *as well.*

From experiments I made some time ago I could perceive that it would be for some purposes a distinct gain to coat the plate with a porous collodion, and sensitise in a bath. An emulsion is hardly admissible on account of the difficulty of making a good washed emulsion with "porous" collodion. An unwashed emulsion might, perhaps, be used; but it should be of a kind giving fair density, and must contain but little free bromide. In any case the plate should be washed in warm water, and then coated with warm gelatine emulsion, which must be allowed to soak well into the film; after which the excess is drawn off, and the plate is dried in a horizontal position. The gelatine emulsion should, in this case, be the most sensitive obtainable, density being conferred by the collodion film. The gelatine emulsion should not form a thick film on the surface of the collodion, otherwise the developer will hardly penetrate so as to act upon the parts which form the denser tones of the negative.

If the collodion film be prepared in the nitrate bath it should be allowed to remain there for some time, in order to convert as much soluble bromide as possible. Fifteen minutes in an eighty- or ninety-grain bath would, probably, be found sufficient.—I am, yours, &c.,

31, *Grove Place, Brompton, S. W.* Herbert B. Berkeley.

RE COLOURED CHROMOTYPES.

To the Editors.

Gentlemen,—I observe in your issue, received today, a letter from Mr. Hicks respecting my patent. Speaking for himself and the majority of the profession—I have not heard a word except from him, and do not know of whom and how many his majority consists—Mr. Hicks says that "the adding of pigments to collodion for several purposes has been known and practised for years." Doubtless such is the case "for several purposes;" but it has never been used for the especial purpose or in the manner in question. I have the written testimony of the Autotype Company that they, the legal patentees of the processes to which my patent is applicable, knew nothing of the means by which I obtained my results.

You and many others have tried to guess how the operation, simple as it is, is performed, and you were the nearest the mark of anyone, though as regards the way in which the exhibited examples were done you were in error. You said by collodion. Right; but you said by preliminary coloured collodion. So far as the specimens in question are concerned you were absolutely *wrong.* They were treated according to my *special* invention, viz., *after* the chromotype print had been developed and fixed with alum water and dried the plate was flowed with coloured collodion prepared specially and carefully for the purpose, and then, as soon as the collodion was set, the print was transferred in the usual way.

This coating of the untransferred picture with coloured collodion is the innovation on, or addition to, the chromotype process which is the subject of my patent; and Mr. Hicks may protest a thousand times, but unless he can prove that he or any one else has ever used anything in the special way in which I use my coloured medium he had better save his time and trouble and the valuable space he occupies in your Journal.

I made my specification as clear and concise as I could, and endeavoured to describe some of the failures which arose during the numerous experiments I was obliged to make, especially as regards aqueous solutions.

I must add a few lines which might have been made the subject of another letter. I have reason to believe that prints produced according to my system will be absolutely as permanent as oil paintings. There *ought* to be nothing to fade or change colour. Referring to the fading of chromotypes now under discussion (not to mention silver prints) there should be nothing of the sort. For this reason: nothing which can be changed by light ought to be exposed, as, for instance, gelatine, albumen, &c. These turn yellow. My principle is, supposing the pigments in the carbon tissue (the image) to be permanent as regards colour, that the *background* shall be equally so; and this I produce by a thin film of cotton (pyroxyline) charged with colours acknowledged to be permanent. Any colours can be used, the only point being to have the collodion film properly charged with *permanent* pigments, so as to form a shield for the possibly changed gelatine, &c., at the back.

If you want a nearly white background use *zinc* white (*not* flake white, or white lead) with a *trace* of black, rose madder, or blue, &c. Prussian blue is apt to turn green. Indigo, I am told, will not stand. Vermilion is very doubtful except it be of the finest quality. The blue which I have used is an earth named here "blue ochre," and is used by the farmers for marking sheep. I have exposed it to light for many weeks and do not find it change. It is an earth.

As sold the price is one shilling per pound, but I sent a pound to Messrs. Winsor and Newton to levigate it for me, and they charged me sixteen shillings for so doing. It was passed through five processes; but I do not think this necessary, as previously I had ground it myself in a mortar with good results, nevertheless it goes a long way.

I need not say anything more as to the best permanent colours, as there are many works on the subject. I believe all the earth colours and some of the chemicals are reliable; but I do not believe in vegetable colours (except the madders) or aniline dyes. Of course, a six months' experience cannot render my opinion of much value, but I give it for what it may be worth. Some pigments are permanent, some are not; and it remains with others as well as myself, from time to time, to enlighten our brethren as to results well ascertained. I try the colours in the way which has been suggested—exposing half the picture to full light and masking the remainder.

Apologising for having drawn out this letter to so great a length,—I am, yours, &c., Thos. Parkyns.
Harnham Cliff, Salisbury, April 12, 1878.

To the Editors.

Gentlemen,—Your correspondent "T. S. Hicks" complains about a patent being taken out for tinting chromotypes by using tinted collodion.

I can tell your correspondent how to produce a similar effect by a process that is not patented. It consists simply in tinting the transfer paper.—I am, yours, &c., A. Whitham.
192, *Yorkshire-street, Rochdale, April* 13, 1878.

Converging Perpendiculars.—We recommend the following elementary experiment to those of our readers who are in doubt as to the effect of tilting the camera without using the swing-back when taking an architectural subject:—Take out the front board of the camera and substitute a thin piece of blackened cardboard for it. In the centre of this substituted front pierce a small hole by a darning needle. Now place the camera in front of a well-lighted architectural subject and view it on the lowering screen. Tilt the camera, and it will be found that the perpendiculars will converge; bring the swing-back vertical and the perpendiculars will be parallel lines. Level the camera, cover up the hole made, and pierce another higher up in the cardboard front, and it will be found that, if the hole be pierced at the right height, the same amount of view is included as when the camera is tilted; and that if the swing-back be vertical the perpendiculars are still parallel. Now a lens is simply a substitute for the pinhole, and is an optical artifice for increasing the illumination of the view. Both the pinhole and the lens will give correctly the projection of the view on any plane on which it is thrown, whatever its inclination, for perspective is merely a matter of angles and not of absolute heights. The optical centre of a lens occupies the position of the pinhole in the foregoing experiment; and, broadly it may be stated, that a knowledge of the position of the axis is only useful to know for focussing purposes. One quality of a theoretically perfect lens is that when it is rotated in any direction round its optical centre every emergent ray should continue its path in the same direction that it had where incident. There is no lens of any use which answers absolutely to this condition, but the existence of the pantascopic camera is a proof that, for small angular rotation round the optical centre, it is nearly fulfilled.—*Photo. Journal.*

Photography in Court.—In the Shoreditch County Court, on Thursday, the 11th inst., the case of Ross *v.* the Great Eastern Railway Company was heard. The plaintiff, a licensed hawker, sued the defendant company for £3 16s., being the value of eight dozen photographic pictures, together with loss of anticipatory profits.—Plaintiff said in the end of January last he had a parcel containing the goods forwarded by the company to Cambridge, whither he was proceeding the same day.

The photographs contained a coloured portrait of His Royal Highness the Prince of Wales, who was then about to visit Cambridge. Plaintiff called for the parcel at the railway station early on the morning of the Prince's visit, but was told it had not arrived. He called twice afterwards, and could gain no tidings of the parcel. Plaintiff reckoned on disposing of the whole of the photographs (the ordinary price of which was twopence each) in consequence of His Royal Highness's visit to the town. The photographs frequently fetched higher prices, especially in places where the inhabitants were very loyal.—A witness on behalf of plaintiff said he had often sold these photographs at sixpence, and even half-a-crown, each. He had followed His Royal Highness through India, and sold the photographs at two and three rupees. His profits were upwards of £700 by the Indian tour. He had also "accompanied" the Prince "all over Europe," and made large sums through the sale of the same pictures. Witness's occupation, as well as that of plaintiff's, sometimes consisted in following the members of the Royal Family, and selling their photographs.—For the defence it was alleged that the plaintiff had never called for the parcel, which had arrived at the office and was ready for delivery, and that, in respect to anticipatory profits, he had no right to sue. The first part of the defence having been substantiated by witnesses, a long argument ensued as to the claim in respect to prospective profits.—In the result, his Honour gave judgment for the defendants, principally on the ground that plaintiff had concealed the fact of the company tendering the goods subsequently.

EXCHANGE COLUMN.

Wanted, Solomon's No. 7, Dallmeyer's 1B long, or good half-plate lens, in exchange for other apparatus.—Address, A. K. S., Whitley-brow, Melksham.

Wanted, a good posing chair, in exchange for first-class saloon rifle; cost four guineas a short time since.—Address, JOSEPH NICKLIN, Dresden, Staffordshire.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

NOTICE.—Each correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a *nom de plume* as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

J. S. R. S.—A solution of the neutral oxalate of potash will not precipitate iron persalts, but this is not the case with respect to the protosalts.

H. B.—1. In your case the convergence is owing solely to the camera not having been carefully levelled.—2. Thanks.—3. The focus of the lens need not exceed twenty-five inches.

GEORGE WOOD.—There is no definite rule, but the following hint will suffice in practice:—If there be a well-pronounced object in the foreground do not keep the lenses so wide apart as when the principal foreground object is farther away.

AN AMATEUR.—You may reproduce any of the articles or jokes appearing in *Punch* provided you make the usual acknowledgment; but, while this is legal, permission is not granted to take a similar liberty with any of the cartoons, even by making the fullest acknowledgment. In this latter case special authority must be obtained from the publisher.

A. & S. (Edinburgh).—The patent for the aniline process of printing has not yet expired; but, if we recollect aright, its term of fourteen years' duration comes to an end about the close of the present year. This will be glad news to many; for it is pretty generally understood that the holder of the patent has declined to grant licenses, or to allow any other than his own firm to practise it.

A NEW SUBSCRIBER.—You have quite correctly estimated the facts—full details were published three months prior to the date mentioned. On application to the Publisher, any of the numbers of this Journal issued within the past three years can be obtained; there are, of course, numbers in stock of previous dates, but the last three years' issues will amply cover all the ground referred to in your letter.

MAUD BROWN.—The difficulties you experience appear to be mainly owing to the use of a glutinous collodion. This may, perhaps, be accounted for by your having allowed the stopper to remain out of the bottle for such a period as permitted the ether to escape by evaporation. Thin the collodion by adding ether alone, avoiding the addition of alcohol. Collodion that has been bromo-iodised with cadmium salts is much more liable to become glutinous than when ammonium salts are used for this purpose.

D. T. O.—The tone of prints is so much a matter of individual taste that we should hesitate in advising you to adopt that of any of the prints enclosed. For our own part we prefer No. 3, but others might like a colder tone. The better system to adopt would be one in which the tone is such as to afford a slight indication of the complexion—a fair complexion, with red, auburn, or light hair receiving toning of a corresponding character.

J. (Kensington).—About ten or twelve years ago several printing-frames specially designed for printing opalotypes were introduced. While it would be impossible for us to describe the construction of any of them in this column, we know that in our volumes of that period all, or nearly all, of them have been described or alluded to, and hence we must refer you to the volumes in question. They may be seen on application at our publishing office if you have not the volumes upon your own shelves.

D. H. B.—You have not been misinformed; there did exist, several years since, a serial named the *Illustrated Photographer*. It was published weekly, price threepence, but after a period of somewhat over two years its demise took place.

S. N.—Although almost any kind of spirit varnish may be employed for freshening up your decayed leather miniature cases, yet the best kind for this purpose, and that which is for the most part used by bookbinders, consists of three ounces of sandarac dissolved in a pint of alcohol. Before making a special varnish for the intended purpose try the effect of ordinary negative varnish applied by means of a soft brush, the case being then held before the fire until it has become quite dry. This treatment will scarcely fail to restore the leather to its original freshness.

T. O. B.—We note in your specimen the presence of numerous minute air-bubbles, indicating defective manipulation. So *very* much has been written on the details of enamelling paper prints that we must request you to institute a close comparison between your method of working and those adopted by others who have been more successful. You may mount such pictures either direct on the card or previously on a stouter paper of a degree of thickness similar to good cartridge paper. The air-bubbles to which we have referred as existing in your print are between the collodion and the paper.

INTENDING TOURIST.—Do not proceed on your tour without a wide-angle lens, and, for your size of camera, one having a focus of seven inches will produce a picture including 90° on the base line, which is quite enough. But let it be understood that we do not recommend you to make constant or even frequent use of such a lens; indeed, in the course of your peregrinations you will meet with very few subjects upon which it could be fittingly used. Still, there are buildings, lake scenes, mountain ranges, and other similar subjects in photography for which a wide-angle lens will prove invaluable. For *ordinary* work we advise you to select lenses of twelve, sixteen, and twenty inches in focus. These, with the wide-angle combination of which we have spoken, will prove a useful and complete outfit of lenses.

GEORGE J. KENNEDY.—To produce a "ghost" in a stereoscopic picture, arrange all the sitters so as to be looking at the place where the ghost is supposed to be, their attitudes and expressions conveying the idea of awe, fear, or any other kindred emotion. Now photograph them; but when the exposure has been two-thirds completed let the lens be capped for a few seconds, during which interval the individual who enacts the part of the ghost enters suitably attired, and takes his place in the circle, the sitters all the time being motionless. The remaining third of the exposure is now given and the picture developed. When completed the "ghost" will appear quite sharp, yet misty and transparent; and altogether the effect will be somewhat startling, especially to those who are ignorant of the method by which the result was produced.

SEVERAL CORRESPONDENTS.—An unusual number of letters have this week been received from correspondents who have neglected to comply with our rule (so frequently printed at the head of this page) requiring the name of every correspondent, although not for publication. The respective writers of these letters will therefore know the reason why their queries remain unanswered.

VARIATIONS IN THE IRON DEVELOPER.

Last week we called attention to certain effects which could be obtained by a slight departure from the usual routine of iron development with wet plates, and we gave full details of the peculiarities of citric acid when employed as a restrainer in conjunction with acetic acid. We have made very many experiments with it, and our trials, tentative at first, have led to our adopting it as a stock dark-room solution for regular use, and under such contingencies as we have fully dwelt upon in the article to which we have referred.

We pointed out how the greater degree of intensity conferred upon the negative was accompanied by a corresponding decrease of the sensitiveness, and we feel almost justified in saying that a special gain in intensity in wet-plate development, whether caused by peculiarities of the bath or the collodion, or by additions to the developer, is invariably accompanied by a loss of sensitiveness. This rule scarcely admits of an exception, though the degree of extra intensity is not always a guide to the extent to which the sensitiveness may be diminished. It is of such universal application as to lead us to expect that its converse would hold good, and that a thinner deposit would be accompanied by a gain in the exposure. We have, however, not found this to be the case, though it may have been observed that, whenever a variation of the developer to increase sensitiveness has been brought before photographers, it has more frequently happened than not that the resulting negatives have been weak and feeble. And, *en passant*, we may observe that it is very easy to fall into an error in this direction. The result of over-exposure, under ordinary conditions, being the production of a weak and flat negative, it is easy to imagine that when a negative is weak and flat it is over-exposed, and, as a consequence, that a gain in sensitiveness has been obtained in any experiment in hand.

Our present remarks will be directed to the effects of *gelatine* in the iron developer, which, in the form of collocine, has again attracted considerable attention. There will be many of our readers who will remember the great excitement caused a number of years ago by the publication of Mr. M. Carey Lea's method of preparing a developer to which had been added the compound obtained by acting upon iron by mineral acids in the presence of solution of gelatine. The product obtained possessed some very remarkable and exceptional qualities; but, owing to the troublesomeness of preparing the liquid, and the strange discrepancies in the published accounts of experiments made with it, the compound, notwithstanding its many valuable qualities, fell almost into entire disuse. A modification of the principle led to an easier method of obtaining a gelatine compound, and, again, many took up the new developer, and on all sides we heard well of it. Nevertheless, after many inquiries, we still do not find that it has obtained any great hold on the photographic fraternity, who, though willing enough to try experiments, are frequently found lacking in either energy or belief to carry out in practice the indications their experiments point out if there be much *extra* trouble in connection therewith.

We have tried most of these additions and pointed out their advantages, and we can readily understand any objection to the extra labour involved, slight though it is, in their preparation. We have, therefore, endeavoured to simplify still further a process in which gelatine should play a prominent part, and after a number of experiments, which need not be detailed, we have found by successive eliminations that a pure solution of gelatine alone added to the developer confers on it exceptional and remarkable powers, a most minute quantity being sufficient to entirely change the character of the solution.

A twenty-grain solution of protosulphate of iron, with eight or ten drops of glacial acetic acid, may, by the addition of a tenth part of a grain of gelatine to the ounce, be kept on the film without fogging the shadows till every trace possible of the most under-exposed image is brought out. It would be a long time before it became muddy, and the density and character of the deposit would be more like that from pyrogallic. It is almost impossible when it is used to fog the plate; and for copying oil paintings and other objects from which it is difficult, by reason of their low illuminating power, to obtain dense negatives the addition of the gelatine enables any amount of intensity to be obtained with little trouble.

Used as an intensifier, where density of deposit is the chief aim, it would quite enable us to dispense with the use of pyrogallic acid. There is not, of course, an entire similarity in the action of the two, but in a large number of cases the gelatino-iron developer or intensifier would answer all purposes to which pyro. could be applied. With regard to rapidity, we are compelled to say that this developer, like all others, follows the rule we have enunciated above, and that, consequently, when used as a developer, in the first instance, a close comparison will show it to be inferior in this respect to ordinary iron developer; but the difference is not great, and when a small quantity of the gelatine is used it would require a very close comparison between a pair of trial negatives to discern which was the more exposed.

We have only observed one drawback to its use, and that is very insignificant: it is that more than usual care is needed to avoid the formation of air-bubbles when pouring on and off the plate; for when once they are formed it is next to impossible to make them coalesce or disappear till the development is complete. With regard to the amount to be added a very wide latitude is permissible, increase of density following upon increase in the amount of gelatine.

Finally, as to the method of adding the gelatine: we find it will keep dissolved in acetic acid almost indefinitely. A standard solution of a definite strength should be made, and one or more drops per ounce added to the iron solution either at the moment of using or to a quantity in bulk. We have sometimes thought, but have not yet positively determined, that, when kept in contact with the iron solution, its density-imparting powers have been intensified.

DRY PROCESSES—ANCIENT AND MODERN.

III.—TANNIN, COFFEE, GUM-GALLIC, AND BEER AND ALBUMEN PROCESSES.

It was Dr. Hill Norris, of Birmingham, who first laid the foundation and practically worked out the principles upon which dry collodion plates should be prepared. The pores of the collodion must, he said, be charged with a material that would prevent their being closed permanently, but which would allow of the permeation of the developer, and also act the part of a varnish to prevent the atmosphere from having access to the atoms of iodide of silver upon which the sensitiveness depended.

Based upon these principles a considerable number of dry processes have been brought into existence, the chief difference between them consisting in the special kind of preservative determined by experimental research or whim. It would be quite foreign to our purpose to describe even in outline those processes which have flashed across the photographic empyrean and, after making a bright but momentary appearance, have sunk into obscurity, no more to be resuscitated; but to those which have been recognised as undoubtedly meritorious we shall make an exception.

Occupying a foremost position among these is the tannin process. In this a plate is collodionised and sensitised as for wet collodion practice; it is then thoroughly washed, and a ten-grain solution of tannin applied. This process is very simple, very certain, and the results obtained are excellent. The plates keep well, but they must be developed within a few days after exposure—the sooner the better. The development may be effected by either alkaline or acid pyrogallol; in the latter case a longer exposure is required than in the former. Plates may be prepared by this process having sensitiveness quite equal to wet collodion, but in this case the collodion should be salted with a bromide (eight grains to the ounce), and the sensitising bath must rather exceed than be under the strength of sixty grains. Alkaline development is here imperatively necessary. The plate must be kept in the silver bath from ten to fifteen minutes, and the tannin may be washed off by a gentle stream of distilled water. Instead of employing a solution of tannin alone an infusion of malt may advantageously be mixed with it.

A strong infusion of coffee (a dessert spoonful to a cup of water) may be used instead of tannin, and, in this case, the process derives its name from the fragrant Mocha berry. The details of the "coffee process," however, are so similar in every respect to that in which tannin is the preservative as to require no distinction in the description of the method of treatment. If any young photographer is at a loss which dry process to try his "'prentice hand" upon let him begin with the simple and excellent coffee process.

With greater detail we shall describe two other bath processes of more recent introduction than those just mentioned, and by means of which high-class results have been obtained. We allude to those in which a preservative of gum and gallic acid and of beer and albumen are respectively employed.

The former of these is well known by the name of the "gum gallic process," which designation was given to it by Mr. R. M. Gordon, by whom it was introduced. An ordinary good commercial bromo-iodised collodion should have two grains more of a bromide, such as that of ammonium or cadmium, added to it, and the bath must be one not under thirty-five grains of silver per ounce. When the plate has been excited it must be thoroughly washed and then coated with a three-grain solution of gallic acid. The readiest manner of preparing this is to make a strong solution of the acid in *hot* water; as the water cools the superflous acid is precipitated until, when it has become quite cold, no more than three grains per ounce have been retained in solution. After draining the plate to which this solution has been applied coat it with the following:—

Gum arabic	20 grains.
Sugar candy	5 „
Water	1 ounce.

These plates, after being dried, keep well for a considerable period, and if the developer (an alkaline one) be strong the exposure required need not much exceed that given to wet collodion plates.

A mixture of beer and albumen as a preservative for dry plates was first proposed by Mr. W. H. Davies, but the details now to be given are those which have been adopted by Captain Abney, who has modified and employed this process with great advantage. Beat to a froth the whites of any desired number of eggs, having previously added a drachm of ammonia for each egg. To half a glass of bitter or mild ale are added ten grains of pyrogallic acid. The plate is collodionised and excited as in the process previously described, and it is then washed very thoroughly to get rid of the free nitrate of silver. A mixture of equal parts of the albumen and plain beer is now applied to the film, and after being allowed to remain on the surface for half-a-minute is poured off. The plate is once more washed thoroughly, and then receives an application of the beer containing the pyrogallic acid, after which it is reared upon end to dry spontaneously. Plates thus prepared will keep a month after exposure, and possess a degree of sensitiveness nearly equal to that of wet collodion, alkaline development being presupposed.

PHOTOGRAPHING BY THE ELECTRIC LIGHT.

Our readers are all aware that portraits are at present being taken by means of the electric light, but we have now to record a much more extended application of the illuminating power of the carbon points.

From Mr. J. R. Prophet, of Dundee, we have received an excellent 10 × 8 print of an architectural view taken within an hour of midnight under circumstances which will be ascertained from the following extracts from a letter that accompanied the picture:—

"This photograph was taken on the 13th inst., about eleven o clock at night, during a drenching rain and in a crowded thoroughfare, with a Dallmeyer's 4a 10 × 8 portrait lens, having a diaphragm two and a-quarter inches in diameter. I exposed for a quarter of an hour and developed with iron. The electric light was about eighty feet distant, and was given by the electro-dynamic machine, producing a light equal to 800 candles. The machine was one of the Gramme order, driven by a small steam engine. With light from the sun it would have been impossible to have taken the picture—first, because sunlight would have shown the falling rain and so obscured the view; and, secondly, because of the dense crowds which thronged this street, and which, upon this occasion, stood to gaze upon the building lighted, thus covering the lower portion of my subject and the pavement with a mass of umbrellas. The crowd being compelled by the heavy rain continuously to move off before the black mass could be photographed, they do not appear in the picture, and with the movements of the figure and the long exposure the reflection on the wet street had, as you see, an occasional chance of being produced in the picture. An 800-candle light is a comparatively weak light to what can be produced, and yet the satisfactory result obtained under such unfavourable circumstances proves that the time is nigh at hand when, to a great extent, we will be independent of sunlight for photographic purposes. The result also illustrates the close relation of our art with mechanics and the sciences."

The resulting picture shows in what an excellent manner a photograph may be produced by artificial light. Several years ago we recorded the fact of the interior of caves and mines having been photographed by means of the magnesium light; but this is the first time, so far as we are aware, that the electric or any other kind of artificial light has been employed to illuminate architectural structures for photographic purposes.

RECENT PATENTS.

No. VII.—EDWARDS'S ENLARGING AND COPYING CAMERA.

Very numerous indeed are the appliances, mechanical as well as chemical, which have been imported into photographic service in producing copies and enlargements of pictures. Among the cameras expressly constructed for this purpose is one by Mr. B. J. Edwards, of Hackney, which contains several features tending to facilitate the purposes above expressed. For this camera with its adjuncts Mr. Edwards has obtained a patent, and from the following summary of the specification an adequate idea of its points will be obtained:—

This apparatus consists of a board or frame, of convenient length and width, arranged to carry or support another frame or board sliding upon or under and parallel to the same, this sliding board being worked by an extending screw fixed to the other or principal frame and worked by a handle, the nut of the screw being fixed to the sliding board or frame, which carries an upright piece, frame, or board, to which is affixed the picture or drawing to be copied.

When the picture to be copied consists of a transparent positive or negative photograph, the patentee uses a reflector of white paper, glass, or other suitable material, placed at an angle a few inches behind the transparent picture, and he also uses an adjustable hood or shade to cut off all light from between the transparency and lens of the camera.

The camera may be a separate instrument, or the necessary parts thereof may be attached or fitted to the principal frame, but not so as to interfere with the working of the screw or the sliding frame which carries the object to be copied, and which object is brought into the focus of the lens, and adjustable by means of the screw before described.

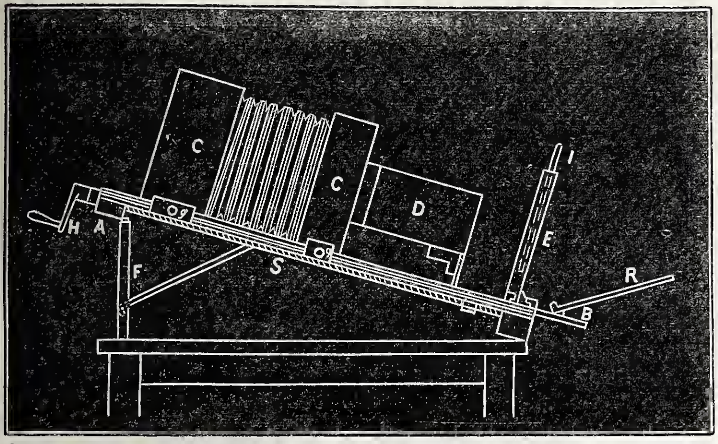
The upright frame or board carrying the drawing to be copied is made to slide both vertically and horizontally at right angles to the sliding frame, in order that it may easily be adjusted to the proper position.

In order to allow a large amount of light from the sky to fall upon the picture to be copied, or upon the reflector, Mr. Edwards raises one end of the apparatus and supports it by a foot or strut at a suitable angle; by this means he considerably reduces or shortens the time of exposure necessary to produce the photographic impression.

By means of the apparatus above described, and especially by means of the screw which adjusts the position or focus of the object to be copied, great facility and accuracy with economy is claimed to be obtained in the photographic reproduction or enlargement of drawings, photographs, or designs.

The invention is more fully explained by the following diagram, in

FIG. 1.



which *fig.* 1 shows a side view of an apparatus for copying or reproducing by means of photography pictures, drawings, photographs, or designs specially intended to facilitate the production and ensure the accuracy of such copies or reproduction, whether they are required enlarged or reduced in size, or of the same dimensions as the originals.

A is a base board or frame of convenient length and width, arranged to carry a movable frame or board B sliding upon or under and parallel to frame A. This sliding board is moved by means of an extending screw S fixed to the frame A, and worked by a handle H. The end of the said screw is fixed to the board B, which carries an adjustable upright frame or board E, on which is affixed the picture or drawing to be copied.

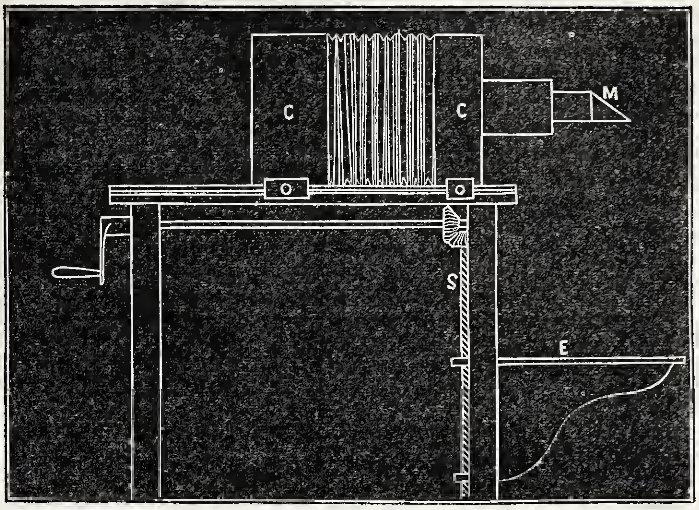
When the picture consists of a transparent positive or negative photograph the board E is replaced by the sliding frame or frames I, which carry the transparency; and a reflector R of white paper, glass, or other suitable material, placed at an angle a few inches behind the transparent picture, is also made use of, an adjustable hood or shade D being also employed to cut off all the light between the transparency and the lens of the camera C. The camera is attached to the base board A by means of the clamps *g*, which slide in grooves, so that the said camera may be drawn out to the required length, when it is kept in position by means of the screws attached to the clamps *g*, the whole being arranged not to interfere with the working of the screw S on the sliding frame E, which carries the object to be copied, and which is brought into the focus of the lens by means of the adjusting screw S.

The frame is made to slide vertically and parallel to the sliding frame E, which is also made to slide across the board or frame B, in order that the object to be copied may be easily adjusted to the proper position.

In order to allow a strong light to fall upon the picture to be copied, or upon the reflector R, one end of the above-described apparatus is raised by means of a support F so as to place it at a suitable angle. By this means the time of exposure necessary to produce the photographic impression is reduced.

When it is desired to make reversed negatives, as used for various photo-mechanical printing, an apparatus similar to the one above

FIG. 2.



described is employed, but arranged as shown in *fig.* 2. In this case the sliding board E carrying the drawing is made to move vertically by means of the screw S worked from the side by bevelled wheels or other suitable mechanical arrangements—a reversing prism or mirror M, the camera C being at right angle to the drawing, being also used.

By the use of the apparatus above described, and especially of the screw S, which adjusts the position or focus of the object to be copied, greater facility, accuracy, and economy are obtained than heretofore.

The special claims in this patent are two:—Firstly. A bed or frame capable of being placed at an angle, and on which is made to slide (by means of a screw) a movable upright frame, which carries the object to be copied, and having at the back a reflector—the above parts being, in combination with a camera, furnished with a hood or shade to cut off all light between the transparency and the lens of the said camera for the purpose set forth, substantially as described and represented in *fig.* 1.

Secondly. The movable frame, sliding vertically, and adjusted by means of a screw in combination with a camera and lens fitted with a reversing prism or mirror, for the purpose set forth, substantially as described and represented in *fig.* 2.

Of the great convenience of the adjustments which have been described there will doubtless be only one opinion.

OXALATE DEVELOPMENT: IMPROVED METHODS.

A fortnight since I sent to The British Journal of Photography a method of improving the action of the oxalate developer by the aid of gallic acid. I propose here to describe the proper mode of applying the gallic treatment, as since ascertained, and also to mention another method of modifying the action which has, perhaps, advantages over the gallic.

Use of Gallic Acid.

The essential point with gallic acid is *not to use too much*, otherwise its action is altered, almost reversed. With a proper dose of gallic acid there is a marked increase of brightness and cleanness, and an increased intensity. The whole action of the developer is better, and more pleasant and manageable. To an ounce of developer I would recommend three, four, or five drops of a sixty-grain solution of gallic acid in alcohol. In saying this I mean, of course, to an ounce of diluted developer ready for immediate application.

The addition of gallic acid to the oxalate solution causes a decided darkening, owing to the fact that the ferrous oxalate always contains more or less ferric oxalate. This darkening is without importance; it does not stain in the least, but every trace of it washes out with the utmost ease. In fact, this dark solution gives a cleaner and purer development than a colourless alkaline pyrogallol solution.

Application of the Collo-Restrainer.

Gelatine, modified by boiling with sulphuric acid in the manner which I have described for the wet development, gives most excellent results with the oxalate. This collo-developer, or collo-restrainer, is prepared precisely as already directed, and is used in the same way, except that, as the oxalate development is far more powerful than the ferrous sulphate development used in the wet process, the collo-restrainer may be employed in larger proportion. Instead of one drop to three ounces, I use in the oxalate development from one to six drops per ounce, graduating the proportion according to circumstances, which scarcely need to be explained. If there has been over-exposure, or the object has presented a lack of contrast, I use five or six drops; for an exposure which has been too short, a single drop. In ordinary cases, with fair exposure, about two drops will be sufficient. Something will also depend on the strength of the oxalate solution, relative to which see below.

The mode of operating is, on the whole, perhaps preferable to the gallic acid treatment. Both are very decided improvements on the oxalate development—so much so that I am very sure that no one who tries them will ever use the plain oxalate afterwards. The collo-restrainer has the advantage that it does not in the least discolour the developing solutions. For those who like to use the oxalate as a bath, and to make several successive developments in the same liquid, it is certainly better. A solution containing ferrous oxalate and gallic acid must tend to continually darken by exposure to air. Of course, any solution of a ferrous salt must deteriorate by exposure to the air, but an exposure of an hour or two would not destroy the developing power of an oxalate bath. If, however, it contained gallic acid it would, probably, be much darkened.

This modified gelatine has no developing power. I have tried it in connection with solution of potash and did not obtain any image. Consequently to call it a "collo-developer" would seem to be inappropriate. I, therefore, speak of it as a "collo-restrainer," which name seems to describe its function better, though not completely; for it not only restrains but intensifies. When it is employed—especially when in the quantity of five or six drops to the ounce of developer—a much intenser, stronger, and blacker image is obtained than without it.

General Remarks on the Oxalate Development.

Several questions have presented themselves for solution in connection with this development. And, first, as to the best condition of the solution, whether it should be *alkaline*, *neutral*, or *acid*. Potassio-ferrous oxalate is perfectly neutral. It can be acidified without decomposition; it can also be rendered alkaline up to a certain point. Enough sodic carbonate can be added to it to render it slightly alkaline without causing a precipitate.

In my work last spring I used a slightly alkaline solution of potassic oxalate for dissolving the ferrous oxalate; but a careful comparative trial now satisfies me that the oxalate developer ought to be neutral, for the very sufficient reason that the image so obtained resists the action of the fixing solution much better. The slightly alkaline solution developes equally fast and may seem to do equally well; but when the developed image is removed from the hyposulphite solution it is found to have much deteriorated. The neutral and acid oxalate do not present this inconvenience, but resist very satisfactorily.

But an acid solution of potassio-ferrous oxalate developes much more slowly than one that is neutral. Contrary to what might be expected, the acidity does not give any additional clearness or brightness. For that effect we must depend upon the collo-restrainer, or upon gallic acid. Acidifying the oxalate simply checks its action disadvantageously, and produces a poor, flat, and thin image. *Therefore, the solution should be neutral.*

Another point suggested itself. Ferrous oxalate forms soluble double salts with soda and with ammonia oxalate, as well as with potash oxalate, and the question arose whether either of these others would have an advantage over the potash salt. Solutions of all three were prepared, using the same ferrous oxalate for all, and on comparative trial it appeared that not only the ammonia and the soda salts offered no advantage, but they proved distinctly inferior to the potash salt.

As to the strength of the developer: this is not easy to describe, as the double oxalate will be usually prepared in solution, and each person will be apt to prepare his solution of different strength. Equality of result is, perhaps, best obtained by preparing a solution saturated in the cold, and this may be done by dissolving neutral potash oxalate in thrice its weight of very hot water, and adding immediately ferrous oxalate as long as it will dissolve. The dark red solution deposits in cooling a little of the double oxalate in reddish-yellow grains, leaving a saturated solution behind. Except as one way of obtaining a definite strength it is not necessary to make the solution so strong. Potassic oxalate may be dissolved in water, 100 grains to the ounce, and this solution may be saturated with the ferrous oxalate. Perhaps this is as good a means as any for obtaining a preparation of a regular strength. In this case no heat is necessary. The neutral potassic oxalate is simply put into a bottle with the requisite proportion of cold water, and ferric oxalate added as long as by shaking and standing it continues to dissolve. The bottle will not need any protection from light, but should be kept well corked, and not more than enough for a month or so should be made at once.

If the saturated solution is made it should be diluted for use with twenty to forty parts of water. With the less strong—that prepared with 100 grains' solution of potassic oxalate—I would take from ten to thirty parts of water. Circumstances may arise in which stronger developers may be desirable, especially in case of under-exposure; but my preference is for the weaker treatment, and I would recommend its trial. No one on taking up a totally new form of development, such as this is, can expect to pass from the alkaline pyrogallol to it instantly, and to get its very best results at the first effort; and the best way to become skilful with it is to work from weak solutions up to stronger. If on the application of the developer the image comes out rapidly but flat and of a cold slate colour, assuming as the action continues a sort of blurred look before any sufficient density comes, it may be accepted that the oxalate solution has been used about five times too strong for the case in hand; and then no amount of restrainer will do any good or give brilliancy—not half-a-drachm to the ounce. With the oxalate development it is never desirable to make the image flash out, but rather to bring it out in an orderly and regular way, that its character may be watched as it appears.

As has been explained in previous communications, I obtain ferrous oxalate by adding a hot solution of oxalic acid to one of ordinary ferrous sulphate, such as is used for wet development. The precipitate goes on forming for some time. At the end of two or three hours the supernatant liquid is to be poured off, fresh water added and well stirred up, and poured off after subsiding. Two portions of fresh water will be a sufficient washing.

As it is desirable to avoid the presence of the ferric salt, one should choose a clean, bright green specimen of green vitriol, the best quality of what is made for photographers' use. When it is intended to use gallic acid we can get a particularly good product by acidulating the solution of green vitriol with sulphuric acid, dropping in some clean nails, tacks, or piano wire, and letting it stand over night. By this treatment all ferric salt present is deoxidised. This, however, is not a necessary precaution, but rather a little nicety for those who like to have their chemicals in the best possible condition. M. Carey Lea.

THE LATE MR. J. A. SPENCER.

With much regret we have to record the death of Mr. J. A. Spencer—an event which took place on Saturday morning last, the 20th instant. He died at the comparatively early age of 51. This announcement will be received with surprise by many, and regret by all; for the courteous manners and genial disposition of Mr. Spencer secured for him a very extensive circle of friends.

Mr. Spencer's name has long been familiar to every photographer—originally in connection with the manufacture of albumenised paper, and more recently as an ardent devotee of carbon printing. Having completed his education at University College, he at an early age devoted himself to chemical science, for his father followed that profession, his establishment being in Lamb's Conduit-street, to which business he eventually succeeded. Previous to this, however, he studied chemistry systematically under Dr. Hoffman, at the College of Chemistry. Having exhibited several of his chemical manufactures, including naphthaline, benzoic acid, hydriodate of quinine, theine, caffeine, &c., at the great exhibition of 1851, he was awarded one of the few bronze medals then given for the excellence of these productions. About this time there was a polytechnic department in connection with the newly-established Panopticon, afterwards the Alhambra—an establishment that has since that period adopted a vastly different *rôle* in catering for the entertainment of the public—and in this department Mr. Spencer received the appointment of demonstrator of applied chemistry—an office he held for some time, fulfilling its duties in an effective manner.

Photography had at that time begun to attract the attention of chemists, and when, afterwards, Mr. Spencer carried on his father's business of chemist and druggist, special prominence was given to the requirements connected with the new-born art-science. It was in 1852 that he may be said to have first given serious attention to photography, and he soon excelled in the copying of pictures and engravings. In 1856 the Arundel Society issued Mr. M. Digby Wyatt's *Notices of Sculpture in Ivory*, and for this work Mr. Spencer produced the photographic illustrations. It was at this period he threw his whole energies into the manufacture of albumenised paper at Shepherd's Bush, and to which he attached, for some time, a department for photographic printing.

Few, even among the devoters of photography, have any idea of the enormous trade in the manufacture and sale of albumenised paper which was carried on by Mr. Spencer. The statistics in connection with the consumption of eggs alone are curious. The sole occupation of two girls consisted in breaking the shells of the eggs employed in albumenising. In one year alone Mr. Spencer used up 247,000 eggs, selling in twelve months as much as 1,200 reams of albumenised paper, which was used not only in this country but exported largely to France, Germany, America, and China. This was more than ten years ago. During his career as a manufacturer of albumenised paper Mr. Spencer introduced several improvements in its preparation, one of which is well known to have been the rolling or pressing of the paper upon silvered plates. "Spencer's paper" was known all over the world on account of its purity and excellence.

Having been one of the first to recognise the importance of carbon printing, Mr. Spencer, at an early stage of the history of this department of photography, devoted himself assiduously to it, both as regards the manufacture of carbon tissue and the production of permanent prints. He then disposed of his albumenised paper business, and having become a member of the firm composing the Autotype Company, he confined his attention exclusively to carbon printing, believing that in it lay the great future of photographic printing. He continued in harness until about a year since, when he retired from active participation in the management of the Company's business, although his interest in everything relating to carbon was unflagging till his decease.

He was one of the first hundred who responded to the call for the formation of the South Middlesex Rifle Volunteers, in which he attained the rank of captain. In this regiment he was considered one of the best shots and most efficient of its officers. The last time he was out—now two months ago—was in connection with his military duties. He was confined to his bed the following day, and gradually sank under the exhaustion consequent upon the rapid development of a fatal disease, the nature of which even then was unsuspected, namely, a cancerous formation at the bottom of the gullet, which rendered the transmission of food to the stomach impossible. To this disease he succumbed at half-past one o'clock on the morning of Saturday last.

When we saw him during his confinement to bed—which privilege we enjoyed more than once—he spoke with calm and cheerful resignation of the probable issue of his illness; and on the occasion of our last visit he expressed the great interest he felt in the recent communication to the Photographic Society of Great Britain by his friend Dr. Monckhoven, his regret at not having been able to attend the meeting to take part in the discussion, and his conviction that he would not be present at another meeting—a conviction at that time shared by his friends.

His brother officers were desirous that he should be buried with military honours, but, in compliance with his expressed desire that his obsequies should be conducted as privately as possible, Mrs. Spencer declined the kind offer; nevertheless his funeral was largely attended by the members of his regiment. His remains repose in Hammersmith cemetery.

Of a kind, cheery, and loving nature the late Mr. Spencer, as we have already said, attracted and retained a large circle of devoted friends, and no man connected with our art-science has left behind more pleasant memories.

"A HYBRID PROCESS."

For some time past I have been devoting my attention to various organic preservatives for washed emulsion plates, and have used albumen in various ways with most encouraging success.

Oddly enough, last week I was trying the coagulation of the albumen by means of hot water, and on receipt of my Journal could hardly forbear smiling on reading your article on a *Hybrid Process*, in which you describe your own success with a similar method. I write now to record a curious bit of experience as regards the sensitiveness of the plates as affected by the preservative coating.

In your article you say you did not find any difference in sensitiveness between the plain washed emulsion and the same coated with albumen. With several of the emulsions I have used I have to say the same; but in two instances a very marked difference was produced by the albumen.

The first was with a commercial emulsion, giving a good plate with a fair degree of sensitiveness. With this one the treatment with albumen lowered the sensibility of the film one-third. In the other instance the sensitiveness was *greatly increased*, the albumenised film requiring only half the exposure needed for the same emulsion used without any preservative; and the most curious thing of all is that there appeared to be no difference in sensibility between the *two* albumenised films! But to make the statement clearer I will put it in another way. Emulsion A required an exposure of ten seconds. When coated with albumen it needed fifteen to produce as much detail. Emulsion B required thirty seconds to obtain a similar result; but when treated with the preservative fifteen seconds gave as fully exposed a negative! Another point worthy of note is that both these emulsions gave a better *quality* of image when treated with the preservative than without it, and emulsion B gave the better negative of the two albumenised ones. This emulsion B is prepared by a formula which I hope soon to publish, as it seems to me to offer sundry advantages over all the other formulæ I have tried.

I very much wish I could endorse your remark that there is no disadvantage to counterbalance the exceedingly great advantages of the simple washed emulsion processes. With many of these emulsions it is easy enough to produce a good, clean negative if the plate be used immediately after preparation; but, down here at least, it appears impossible to get a negative free from spots and other markings if the plate have been kept for even a few days.

I am conceited enough to think myself not quite a "duffer" at emulsion work, and it is with sorrow I have to confess my want of success. I was almost beginning to think that the time and money I had spent over my hundreds of experiments were, after all, thrown away, until I began to use organic preservatives with the washed emulsion films. I am now in a more cheerful frame of mind, and really hope I am on the road to obtaining a thoroughly-reliable and easily-prepared plate.

I recently exposed and developed some emulsion plates which had been kept for seven years in an ordinary plate box, and they were certainly quite as good as when first prepared. The emulsion had a small amount of soluble bromide present in it. The coated plate was soaked in water for an hour, and then for one minute in a mixture of salicine, gallic acid, and sugar. If we ever get a simple washed emulsion to give a plate with keeping properties like this I, for one, should certainly rejoice. HENRY COOPER.

THE PHOTOGRAPHIC PRINTING PROCESS USED IN THE PORTUGUESE STATE PRINTING ESTABLISHMENT.

I.—THE PRODUCTION OF PHOTOGRAPHIC NEGATIVES FROM LINE ENGRAVINGS.

Here, as everywhere else, simplicity is the first condition of success in an operation. In spite of the numerous formulæ for collodions and for silver and gold baths that are published from time to time, there are but few that prove suited for use in the daily practice of a large establishment, especially when a certain amount of work has to be produced by certain rules and in a given time.

In the case of reproductions of line engravings without half-tones the ground of the negative must be perfectly opaque, while the lines, on the contrary, must be perfectly transparent. But few operators are able to produce work fulfilling these conditions, and yet by the want of such a negative the whole result to be produced by photolithography or heliography is placed in jeopardy. We proceed in the way hereafter described.

Two baths serve to clean the plate glass, viz., a dilute solution of caustic soda, used to remove fatty and resinous particles, and a mixture of an aqueous solution of bichromate of potassium and sulphuric acid to remove all other impurities. The plates are then well washed and wiped dry with a linen rag, the last traces of impurity being rubbed off with a little whiting and spirit of wine.

The collodion is prepared in quantities of from ten to fifteen litres, and when iodised with iodide of cadmium it keeps usable for months, but is only suited for copying line engravings without half-tones.

The silver bath is slightly acidulated with nitric acid. For large plates ebonite dishes with lids are used. After being exposed in the apparatus the plate has at once as much pyrogallic acid developer poured over it as is sufficient to cover it wholly; it is then placed upon a level stand adjusted by three screws. A fresh supply of pyrogallic developer, to which a few drops of a four-per-cent. silver solution has been added, is then poured on, and by gentle movements is made to flow backwards and forwards until the negative is developed equally and powerfully all over.

The manipulator washes, fixes with a saturated solution of soda, washes again very carefully, and then pours on a saturated solution of chloride of mercury, which is allowed to act until the whole film has become white. Now follows more washing, and then a coating of a very dilute solution of cyanide of potassium, which blackens the film.

If the proper time for the exposure has been hit the result will be perfect; if not, one can still strengthen with silver and pyro. after blackening with cyanide of potassium and washing the film.

The varnish is of a peculiar composition.

Positive *clichés* for copperplate heliography are produced by tannin plates with an acid developer. Most of the negatives are (either before or after being printed from) drawn off the glass by means of gelatine containing glycerine, and are stored between flat sheets of pasteboard.

FORMULÆ.

Collodion Cotton.

Sulphuric acid of 66°	550 grammes.
Nitric acid of 1·4 sp. gr.	256 ,,
Cotton wool in a very dilute solution of caustic soda, washed, and well dried	20 ,,
Temperature of the water bath	60° C.
Duration of immersion	7 minutes.

Collodion for Linear Drawings.

Alcohol of 40° C.	500 c.c.
Ether of 65°	500 ,,
Collodion cotton	11 grammes.
Iodide of cadmium	6 ,,
Iodide of ammonium	5 ,,
Bromide of ammonium	2 ,,

Developer.

A.

Distilled water	1 litre.
Glacial acetic acid	20 grammes.

B.

Pyrogallic acid	100 grammes.
Alcohol of 98°	1 litre.

Mixture, one litre of A and 50 c.c. B.

Fixing Bath.—A saturated solution of hyposulphite of soda with a few drops of ammonia. Must be prepared a few days before use.

Varnish.—(A very hard varnish resisting heat, to be poured on warm):—

Alcohol of 95°	4 litres.
Yellow shellac	360 grammes.
Oil of lavender	100 ,,
Turpentine	80 ,,

Varnish.—A varnish for alcoholic collodion, to be prepared with very soluble cotton:—

Alcohol of 90°	6 litres.
Gum elemi	80 grammes.
Benzole	240 ,,
Yellow shellac	240 ,,
White ,,	120 ,,
Turpentine	160 ,,

II.—POSITIVE CLICHÉS PREPARED FOR HELIOGRAVURE BY THE DRAUGHTSMAN.

By this very simple process the production of photographic negatives is avoided, and by it very successful heliogravures are produced.

A sheet of ground glass, which has been lightly rubbed with linen rags and powdered sandarac, and then carefully freed from the superfluous resinous powder, serves as the foundation. The draughtsman draws upon this with Chinese ink rubbed down in water and mixed with a little sugar and glycerine, so as to render the drawing a little sticky. When one dusts fine graphite powder upon the finished and as dry as possible drawing, and then rubs it very gently in with cotton wool, a very dense effect is produced. To protect a *cliché* so obtained from injury by damp or friction coat it with negative varnish, which renders the glass transparent.

Under such a *cliché* a copper plate, coated with chromated gelatine or asphalte, is exposed to the light; the etching is done by the formula given hereafter. From a *cliché* of this sort a photographic negative can also easily be produced.

III.—ARTISTIC NEGATIVES FOR PHOTOLITHOGRAPHY AND HELIOGRAVURE.

Upon a sheet of well-polished plate glass spread a film consisting of—

Gelatine	8 to 10 grammes,
Water	100 ,,

to which has been added as much plumbic carbonate as to render the mixture doughy in consistency. The lead salt must be extremely fine and free from granularity. The mixture should be rubbed for a few minutes upon a palette, and then spread with a pencil equally over the surface of the glass, so as to leave no transparent nor apparently transparent places. This film may be dried either in air or by a gentle heat.

The plate is laid upon black paper, and the drawing, which has previously been transferred to the film by tracing paper, is etched with a needle. To retouch one uses a pencil and white colour.

When the film has been freed from the dust raised by the needle the plate is dipped into a solution of sulphuric hydrate, where the white is changed to a deep yellow. The plate is then dried at a gentle heat, and varnished with negative varnish.

The negative is reversed, as is required by the direct typographic photo-engraving process.

By printing, one above the other, several such negatives, whether produced by hand or by machinery, combinations may be obtained which would be very difficult to imitate, and which might be useful in the preparation of papers of value, and so on.

—*Archiv.* JOSÉ JULIO RODRIGUES.

(To be continued.)

OUR APPARATUS.

No. IV.

DARK ROOMS.

THE dark room, or, more correctly speaking, the laboratory, although it can scarcely be called apparatus, is still so intimately connected with the paraphernalia of the photographer that a few remarks will not be altogether out of place. This apartment should be roomy and well ventilated, with no more shelves, bottles, and apparatus in it than are absolutely requisite. The walls and woodwork should be smooth, to prevent accumulation of dust as much as possible, and so that it can be more easily removed if it do accumulate. A good varnished paper over both walls and ceiling is very suitable. Glazed tiles might even be better, but the varnished paper answers every purpose at a much less cost.

The floor ought to be of brick, stone, or asphalte, with a plank raised a couple of inches above it for the operator to stand upon. The window should be sufficiently large to well illuminate the room; for nothing is more trying to the eyes than to go direct from the glass room into the dark room to develope a plate, and if the window of it be very small and glazed with the usual ruby or deep orange glass it is almost impossible to see what you are doing, and the risk of breakage is vastly increased. For this reason have plenty of light of the right kind, and on a level with your hands—not raised much above the head, as I have occasionally seen it in otherwise convenient laboratories, for this position is very inconvenient to examine plates during development, they having to be raised so high that the solutions run down the hands and sleeves, and make the operator in a very dirty state, besides increase the chance of unequal development, which with a low window may be entirely avoided.

No direct sunlight should fall on this window; but if, owing to the structural conditions of the premises, it cannot be avoided, a screen should be adjusted to protect it. Diffused light is much more pleasant to work by than that transmitted through clear glass; tracing paper, ground glass, or some similar substance may be used to effect this purpose. A constant supply of clean water is very important from a cistern sufficiently elevated to give a fair degree of pressure at the taps, which should be small. A fine rose, made so that it can be easily attached, is very useful for washing large plates; but for small work the stream from the tap is, I think, rather preferable.

The sink should be divided into two portions—one to receive the developing and other solutions rich in silver; and the other for completing the washing of the plates, &c. A thick curtain should fall over the outside of the door to protect the room from the accidental admission of white light during ingress and egress, unless the position of the door is such as not to require it. A fastening on the inside is a good precaution. The laboratory should, in fact, be a well-ventilated, properly-lighted, dust-free, private apartment, and used only for the purpose for which it was constructed, bearing, as it does, the same relation to the rest of the photographic premises as the kitchen does to the dwelling-house. Insufficient space or accommodation is, in either case, fraught with disagreeable consequences. Fragile things are jumbled one on the other, everything being in the way of everything else, and the semi-obscurity conducing to breakage and waste.

Breakage, by the bye, forms a considerable item in many establishments, and photographers' assistants have a reputation for carelessness; but I think they should have more allowance made than is generally accorded to them by reason of the gloom and obscurity they so often have to work in. This, combined with a general untidiness—there being a proper place for everything but nothing in its place, or in the same place twice together—still further augments the chance of breakage, and it may be fairly inferred that if premises are kept neatly and in good order loss from breakage and waste will be a minimum. But I am digressing.

Tents

for travelling or outdoor work come again under the legitimate title of apparatus, and a very important part of the apparatus they are. Their forms are legion. Scarcely a season passes without some new design being introduced to our notice. The particular kind may be selected according to the work intended. Whether it be of a heavy or light make, or whether put up for work with the rapidity of an act of legerdemain or to occupy some twenty minutes or so, will depend upon the work required. All should be as commodious as possible to be conveniently managed. Work—and good work, too—*can* be done in cramped-up spaces; but a commodious, well-ventilated tent is not only conducive to good work but also to health and comfort.

If the tent can be carried in a vehicle and fixed up for the day in one place nothing can be better than the old-fashioned pattern. With a wooden tray, a jointed frame, and a light-tight bag to pull over it, a tent is thus made that can be thrown open at will and all the contaminated air dispersed. It stands or is fixed firmly on to a box designed to carry the chemicals, &c., and is independent of any wind and most rough treatment; but if, however, the tent has to be carried by hand, some smaller and lighter form must be used. There are several in the market that answer the purpose remarkably well. Those designated "Edwards' pattern" are as good as any. The three points to be particularly looked to are that the ventilation is good, that there is plenty of space for work, and that it is easily made light-tight during use. If these conditions are fulfilled the tent will answer its purpose whatever kind it may be.

For working dry plates, or, I should rather say, for changing them, an exceedingly light tent or bag may be used. A folding board to which a bag of light-tight material is attached, with sleeve holes secured with elastic bands and of sufficient size for the plates intended to be worked, is a very simple and effective design.

The changing-boxes, again, are very useful. In this case only one size of plate can be used, but with the bags any size can. A tent folding like a chess board, opening square with a light framework over which a bag is drawn, and working through sleeve holes, is a useful form, as it is suitable for developing in addition to merely changing the plates; and for those photographers who wish to see what they have taken on the spot it offers many advantages, being a sort of compromise between the regular tent and changing-bag. It is so light that the photographer may carry it without other assistance in addition to his camera and tripod. Where it is practicable I would always advise the photographer to have some one to carry his apparatus if it exceed five or six pounds' weight, and he has a picturesque country to travel through (for, as a rule, the more picturesque the more fatiguing). He will then be in a better condition, both physically and mentally, to do good work.

Syphons,

for emptying a large bath-holder, &c., are readily made by connecting two pieces of glass tubing with india-rubber tube, and lengthening the long leg with the same. They are more serviceable and not so easily broken as when made of one long bent glass tube, which will snap asunder with a very trifling strain.

Conical-shaped Graduated Glass Measures

are better than cylindrical for the measurement of any quantity less than half-a-pint, and should be selected made of clear, thinnest glass with a heavy foot, accuracy of measurement being interfered with if measures of a clumsy construction are used—that is, of very thick, wavy glass, as often supplied. Glass bottles containing solutions that are frequently used should have lips and not thick rims, it being very difficult to pour small quantities of liquid from thick-rimmed bottles without waste. Glass stoppers are prevented from sticking by being rubbed with a piece of white wax; the rim of the bottle being rubbed in the same manner facilitates pouring.

E. Dunmore.

THE REACTIONS OF CHROMIC ACID AND CHROMATES UPON SUBSTANCES OF ORGANIC ORIGIN, CONSIDERED WITH REFERENCE TO THEIR USES IN PHOTOGRAPHY.*

The addition of acetic acid to gelatine for chromate photography has sometimes been prescribed, notably by Pretsch,[1] Leipold,[2] and Scamoni[3] in photogalvanography.[4] As gelatines to which acetic acid has been added do not stiffen they are quite useless for many purposes—for example, for lichtdruck and the preparation of pigment tissue—as they run off the support.

Gelatine dissolves in acetic acid as gum arabic does in water, so that it is quite believable that carbon pictures can be developed cold with acetic acid, because the unacted-upon glue dissolves at once. Liesegang[5] remarked that years ago. Dilute muriatic acid, sulphuric acid, and oxalic acid have also the same effect. They dissolve the glue without decomposing it, and, added in a very small quantity to water, they effect the solution of the glue while cold. Pigment pictures are developed by dilute acids at an ordinary temperature more slowly, harder, and not so fine as with warm water, therefore the latter is generally preferred. Mumler[6] developes photographic gelatine plates for *Typendruck* cold with acetic acid, because the otherwise usual warm water penetrates and softens the exposed gelatine, and thus causes distortion and swelling.

The behaviour of concentrated gelatine solutions with salts is interesting. Potassic and sodic carbonate, magnesic sulphate, and seignette salts make the gelatine solutions curdle. Alum only precipitates gelatine solutions rich in chondrin, but it also makes those rich in glutin tough and easily stiffened. The same thing was also remarked by Fleck,[7] according to whom sulphates, but not chlorides nor nitrates, generally separate the glue from the solvent.

Caustic potash and soda dissolve glue, much quicker cold than warm, as a brown liquid with decomposition of the glue. Ammonia acts but slightly as a solvent.

The aqueous solutions of glue become putrid very soon, when the jelly becomes fluid and smells of ammonia. At a temperature of from 25° to 30° C. the putrescence often commences in forty-eight hours, or even in twenty-four hours. Carbolic[8] acid added in small quantities prevents this putrescence, and may for that purpose be added with advantage to photographic gelatine, when, in consequence of slow drying or other tedious operations, one has reason to fear a watery solution becoming bad. Large quantities of carbolic acid[9] precipitate the glue from its solutions. Chromate gelatine films, which in the dark room become insoluble of themselves[10] on account of a spontaneous reduction of the chromic acid, cannot be preserved by an addition of carbolic acid. Calvert[11] thought to increase the stability of dry chromate gelatine by this addition; but it was quite useless, as the carbolic acid only prevents the decomposition of gelatine by putrescence. If Fridlein[12] adds a little carbolic acid to the gelatine solution, so that it shall not come into photographic use in a putrid condition, it is appropriate and effective; but it does not help to preserve the sensitiveness of the chromated paper any longer, and therefore I consider the addition of carbolic acid to the chromate bath for pigment tissue rather purposeless.

Salicic[13] acid is also recommended for the same end as a preservative against decay; and solutions of glue to which it has been added keep long and dry quicker than the pure gelatine.[14] Alum also acts as an antiseptic, and is added during the manufacture of glue, in order to prevent it from becoming putrid while drying during bad weather.[15] As a constituent of commercial gelatine I have not found alum in any quantity. Glycerine,[16] when added in great quantity, increases the keeping qualities of glue, as takes place in the manufacture of printing

rollers of glue and glycerine.[1] Lanjorrois's recommendations[2] to preserve the gelatine from decay by an addition of one per cent. of fuchsine is not to be done with good results in chromate photography. Potassic bichromate forms, with fuchsine, rosaniline chromate, which is almost insoluble;[3] and the latter renders the whole chromate gelatine difficult of solution, so that there is great difficulty in developing a picture. The addition of zincic chloride should, according to Meritens and Kresser,[4] increase the stability of gelatine by hindering decay, and should also give more beautiful whites to lichtdruck plates. The addition of one per cent. of chloral hydrate to glue or albumen prevents decomposition for a long time.[5]

Gelatine which has already begun to decay cannot be used for producing photographic pictures, because it has lost all stability and consistency, and, besides, potassic bichromate will render it insoluble in an extraordinarily short time.

Behaviour of Chromic Hydrate and Chromates with Gelatines.

Chromic hydrate forms with glue a coagulated mass, which dissolves on being heated.[6] A lukewarm solution of glue, saturated with potassic bichromate, does not, according to Hylten-Cavallius,[7] gelatinise when it cools. This statement should be cut down to this—that bichromate of potassium certainly delays, but does not prevent, it from gelatinising. The monochromate of potassium behaves in the same way, and so do the chromates of sodium and ammonium. If a gelatine solution to which chromic hydrate has been added be dried in the dark the glue will no longer dissolve in hot water, and its property of swelling up in cold water will also be partially lost. A bichromate solution acidified with sulphuric acid acts in the same way.[8] Bichromated and monochromated gelatine do not change their properties after being dried in the dark; they still remain soluble in warm water. Potassic trichromate, got by evaporating potassic bichromate with nitric acid or chromic[9] hydrate, behaves like a mixture of chromic hydrate and potassic bichromate; that is, it imparts to the gelatine the property of insolubility in hot water without entirely depriving it of its power of swelling in water.

Gelatine containing potassic bichromate, on drying, if it be not present in excess, dries in and forms a transparent film without crystallisation. If the exact points be exceeded, and too much potassic bichromate be added, the salt will crystallise out as *dendrites*, and the film will no longer be of any use for photographic purposes. It seems to be of no little importance to chromate photography to determine the maximum bichromate contents which gelatine can retain without allowing the salt to crystallise out, since amongst its pretensions is that by its means the greatest possible quantity of a salt of chromium can be incorporated with gelatine. I found that all sorts of gelatine had not the same capacity for receiving potassic bichromate, but that, generally speaking, those sorts which absorb most water could also take up most chromium salt. A comparative experiment showed me that good gelatine which could take up from six to ten times its weight in cold water can, as a rule, hold as a maximum from 0·3 to 0·4 parts by weight of chromate without any of it being thrown off by crystallisation after drying, while the inferior sorts, which only absorb from three to six times their weight in water, can only take up about 0·2 parts by weight of chromate. Many kinds of gelatine are decomposed by soaking for twenty-four hours in water of 15° C. Such inferior qualities cannot retain even the addition of 0·2 parts by weight of chromate. These statements hold good for chrome gelatine films upon glass left to dry spontaneously in air at a temperature of from 20° to 25° C. Under the same conditions more ammonium bichromate than potassium bichromate can be added, apparently because the first is much more soluble[10] than the latter, and less apt to crystallise out. From one-third to one-quarter more of the ammonium than of the potassium bichromate can be added to the gelatine, the action of the former being also more favourable than that of the latter. If, however, the chromated gelatine poured upon glass be dried at a temperature of from 40° to 50° C., and in a good current of air, about twice the maximum quantity of potassium bichromate mentioned above can be added to the gelatine without fear of its crystallising out. Such are the favourable effects of rapid drying at a high temperature. This property of the ammonium salt is of importance in the printing process, where one often wishes to introduce as much chromate as possible.

The behaviour of these salts is quite different when the chromated gelatine is placed upon paper. Paper, on account of its porosity, absorbs so much of the solution of a salt of chromium, and thus deprives the gelatine of a part of its chromate; at the same time the evaporation of the water is accelerated. When a mixture of gelatine with potassium bichromate is poured upon paper the proportion of the bichromate to the gelatine may be increased to about 0·6 or 0·7 parts by weight without fear of the formation of *dentrites*.

I may also mention in this place that I did not find it profitable to add to the dry gelatine less than 0·1 part of its weight of potassium bichromate, else the sensitiveness of the chromated gelatine would become very slight indeed, and only weak pictures could be obtained. From this it is evident that the proportions in which chromates may advantageously be added to gelatine are not very comprehensive, though it is superfluous to ascertain the exact limit by weight of the proportionate quantity. J. M. Eder, M.D.

TRANSATLANTIC NOTES: THE VOYAGE.

I have left the north for a time to look after itself, and, taking advantage of an opportunity of renewing my acquaintance with the "new world," find myself on board one of the American liners, going as fast as wind and steam will carry us towards the American shores. Once landed there I mean to wander hither and thither as far as time will permit, and, with the Editors' leave, intend to tell my readers as much as possible of whatever interests me in matters relating to photography, in the hope that such jottings may also interest them.

We have many passengers—how many, indeed, I cannot say, as I've not yet been able to count them, sickness having hitherto kept numbers confined to their berths, as is evidenced by the appearance of new faces day by day. They are a motley crew. I don't, of course, apply the term in a disrespectful sense, as, so far as appearance goes, the respectability of the party is unquestionable, but to convey an idea of the variety, both national and characteristic. There are Dutchmen, heavy both mentally and bodily; Frenchmen, lithe and voluble; Italians, swarthy and reticent; Danes, with thick wooden-soled shoes to keep the wet from their feet, and huge pipes which must keep both hands and face warm; even Bulgarians, or rather a Bulgarian, but he cannot speak a word of English, and keeps himself and his peculiarities to himself; Englishmen, Scotchmen, and Irishmen, and, better still, Irishwomen, who are the life of the party, and ever ready for any amount of singing and dancing, and even a little mild flirtation. Varied, however, as are the nationalities, and, consequently, the manners, customs, and characteristics of the passengers, they agree in one thing, namely, the interest they take in photography on board, and the desire manifested by one and all to be photographed.

"One touch of nature makes the whole world kin."

That "touch of nature" is the universal desire shown by all classes to see themselves in a picture, or even to stand in such a position when a picture is being taken as to be sure they are in, even although they may have no expectation of ever seeing it.

My camera is with me, of course, and I've been at it "tooth and nail" almost constantly since leaving the Mersey; but I do not find it the plain sailing that the published experiences of some of our friends had led me to expect. The captain and officers—no exception to the rule—in their interest in our art most kindly afforded me every facility for carrying on the operations, and the bath-room being placed at my disposal, with a plentiful supply of water laid on, I soon got a contrivance rigged up whereby bath and bottles were suspended so as to swing freely and be always kept on the level. This, however, turned out to have been labour in vain, as the passage hitherto has been so quiet that the bottles stand on a shelf as securely as if in my laboratory at home, and the bath finds a most suitable resting-place in the wash-hand basin.

Pictures of the well-lighted saloon and of the deck and its appliances are easily obtained with all the sharpness and definition of objects at rest, as, although the ship may pitch or roll, or, what is more likely and more generally the case, do both at once, the tripod with its burden moves at the same rate and through a like distance. But it is altogether different when we include in the view animated objects. A "calm sea," on the Atlantic ocean at least, is not so placid as Loch Katrine, but always undulates sufficiently to give considerable motion to the vessel. There being in human nature an instinctive desire to keep straight—that is, to retain the true perpendicular—there is an involuntary but constant adjustment and readjustment of the body, with an effect the very opposite of what too frequently takes place in the studio on *terra firma*, where the sitter moves while the camera is steady; that is, the sitter by his adjustive motion gets the equivalent of being steady, while the camera is in constant motion. Under such circumstances short exposures are absolutely essential, and I am sorry to say that my chemicals (having had to start at an hour's notice a week earlier than I expected), even after ransacking the medicine chest for the means of improving them, are not sensitive enough for the work. But, fortunately, having brought with me a batch of matts and preservers—a remnant of the old positive days—and finding in the aforesaid medicine chest material for a proto-nitrate developer, I have produced several dozens of "framed positives" that have gladdened the hearts of as many of my fellow-passengers.

Positives, however—all very well in their way—become monotonous, and as there was a general desire for groups, copies of which might be sent home, I bethought me of some gelatine plates that had been brought for another purpose, and on trial they proved more sensitive than the wet collodion, and two or three days were pleasantly spent in securing more than passable negatives of groups varying from two to forty-nine sitters. The party included several amateur photographers, and, having a supply of sensitive paper, they gladly undertook the printing, and the result now lies before me in a pile of *cartes de visite* lacking only the smooth surface given by the roller or burnisher; and this want will soon be supplied, as the obliging chief engineer is busy at work extemporising a piece of apparatus that he assures me "will make them shine like a looking-glass."

Now here follows the moral of this long story, and photographers of a money-making turn of mind and with a spare couple of months on hand will do well to listen to it. Passengers from Europe to America have generally eight or ten days that hang somewhat heavily on their hands; they are easily interested in photography, and nothing pleases them so well as to sit singly or in groups, or both, except perhaps getting copies of the pictures so taken *before the day of landing*. They have generally a good many spare shillings in their pockets, and they part with them all the more readily from the feeling that they will be of no use to them in the place to which they are going without the bother of negotiating an exchange. These being the conditions, the aforesaid photographer of a money-making turn of mind will not be "worth his salt" if he cannot manage to do a stroke of business that will not only cover the expense of his two months' holiday, but also leave a not inconsiderable balance.

If my little experience be of any use to him here it is. Let him, first of all, secure the goodwill of the captain, then make friends with the chief engineer, who will be found his "friend in need" in all possible emergencies, and also let him get into favour with the steward. The last-named may be open to a mild "tip," but is easily satisfied, and when so will do much to make the work comfortable. There should be included a small water-tight bath with solution in good working order, a reasonable supply of concentrated developer with other chemicals to match, a tolerably good supply of sensitive paper, toning and fixing solutions, and half-a-dozen printing-frames, with, perhaps, a burnisher also, as every engineer may not be so willing to rig up a substitute as is my friend of the present voyage. The photographer need not fear to go single-handed, as there will generally be found amongst the passengers several amateurs willing to undertake a share of the work, but, failing that, the doctor may always be relied upon as easily taught and eager for the work. JOHN NICOL, Ph.D.

FOREIGN NOTES AND NEWS.

COPPER PRINTING PLATES PRODUCED FROM PHOTOGRAPHIC *CLICHÉS*.—HOW OIL PAINTINGS ARE PHOTOGRAPHED AT MM. GOUPIL'S ESTABLISHMENT AT ASNIÈRES.—ENGRAVING BY ELECTRICITY.—PHOTOGRAPHY BY ELECTRIC LIGHT.

THE *Wochenblatt* quotes from the *American Mechanics' Magazine* the following process for getting printing plates on copper from a photographic negative. The description is short and simple :—

"Take a perfectly clean and polished copper plate, and dip it for thirty seconds in a bath consisting of—

Sulphate of copper	125 grains,
Chloride of sodium	75 ,,
Water	2 ounces,

and slightly acidulated with any acid. As soon as the plate is taken out of the bath it should be well washed, and dried with a fine cloth. It is then ready to be placed under a negative and exposed. When the sunlight is good an exposure of from five to ten minutes will be sufficient. The plate is now dipped into a silver bath only to fix it. In a few seconds those parts of the drawing which were red will become white, and the violet shadows will gradually change to black. As soon as the shadows have become black the plate should be taken out of the silver bath, well washed, and then dried over a spirit lamp. As the black colouring matter is in the form of powder the plate must be varnished in order to preserve the drawing. If, however, the plate is intended to be etched, after it has been dried over the spirit lamp, its back and edges only should be varnished, but the varnish must not pass over the drawing. The black dust which forms the shadows of the drawing should then be carefully removed and the plate rinsed under a strong stream of water, and, while yet damp, it should be dipped into the etching fluid. A good medium is made by—

Nitric acid	1 part.
Saturated solution of potassic chromate	2 parts.
Water	5 ,,

If the black powder be not removed, and an etching medium formed of iodine and potassic chromate or nitric acid be used, the result will be a plate in relief."

A correspondent of the same journal gives the following description, from personal observation, of the way in which photographic reproductions of oil paintings are made at MM. Goupil's establishment at Asnières :—

"New oil paintings are laid perfectly flat upon a table, and then receive the thinnest possible coating of white of egg, well beaten up, laid on with a broad beaver brush; while old or very dark pictures, or such as have matt spots, are rubbed with glycerine to bring out the details. The photograph is usually taken in the open air, on a wide terrace or in a large courtyard, and large pictures are surrounded by large screens, made of a light wood, with dark calico stretched across, in order to keep off all reflected light. An opening is made in one of the screens, which is placed exactly opposite the picture, through which the lens—a very actinic Hermagis—may be pushed. Pictures with clear skies are canted a little forward towards the lens, or else they are turned upside down. When the picture possesses very little actinic colour it must be exposed from four to seven minutes. The collodion used, which is extremely sensitive, consists of iodide of potassium (ground very fine), iodide of cadmium, bromide of zinc, and bromide of ammonium. The silver bath consists of—

Nitrate of silver	7 grammes.
Distilled water	100 ,,
Crystallised nitrate of zinc	3 ,,

In winter there is no zinc, but then there ought to be eight grammes of silver. M. Quinet himself sensitises the large plates with eminent skill. The negatives are seldom retouched, and even in the most difficult cases as little retouch as possible is put on."

According to *Les Comptes Rendus* M. G. Planté has discovered a convenient method of engraving upon glass by means of electricity, which he describes as follows :—"Cover the upper surface of a plate of glass or crystal with a concentrated solution of potassic nitrate by simply pouring the liquid upon a plate previously levelled upon a table or in a shallow trough. Then dip into the fluid which covers the glass, and draw along the edges of the plate a horizontal platinum wire communicating with one of the poles of a secondary battery of from fifty to sixty elements; the other electrode—which consists of a platinum wire covered to the tip with an isolating envelope—is held in the hand and is brought into contact with the parts of the glass covered by the thin salt-solution film where it is desired to draw a letter or a design. Wherever the electrode comes in contact with the glass it makes a shining furrow, and these are more or less sharply engraved into the glass according to the rapidity with which the strokes were drawn or written. When one draws or writes slowly the strokes are deeply engraved, and their width depends upon the thickness of the wire used for the electrode; when the latter is cut to a sharp point the lines may be very fine and delicate. One may engrave with either electrode, but a stronger current is required when the negative pole is used. Though I have obtained these results when using a secondary battery, it is evident that in order to make continuous work possible every other source of electricity must be available, if its quantity and extent be sufficient; so that a Bunsen's column with many elements may be used as well as a Gramme's machine, and even an electro-magnetic machine with alternately negative and positive currents."

In the *Monatsblätter* Herr Baumann, of Cologne, says that after hearing of the portraits taken by electric light he developed electric light himself from a Gramme's machine. To that light he exposed a photometer for fifteen minutes, and found that it had printed up to between the ninth and tenth degrees, and the same result was obtained by exposing a similar photometer the same day during the whole duration of daylight. On taking a photograph by electric light he found that with a globe lens an exposure of ten minutes, and with a three-inch portrait lens an exposure of a hundred seconds, was required. In both cases the shadows were bad and heavy, as no contrivance for concentrating or diffusing the light was at hand.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
May 1	Edinburgh	5, St. Andrew-square.

,, 1	Benevolent Association	160a, Aldersgate-street.
,, 2	South London	John-street, Adelphi.

GLASGOW PHOTOGRAPHIC ASSOCIATION.

THIS Society held a *conversazione*, on the 29th ult., in the lesser City Hall,—Mr. John Stuart, President, presiding.

There was an attendance of about two hundred and thirty members and friends. Around the room there were numerous tables on which were displayed many scientific instruments neatly arranged, and which during the course of the evening were carefully examined by the company.

The microscopes, stereoscopes, polariscopes, &c., were supplied by Messrs. George Mason and Co.

A very fine electrical instrument for blasting purposes was exhibited by Mr. Nelson.

Mr. Smilie had a telephone connecting one room with another, which interested a large number of those present.

Mr. Parker exhibited one of Howard's tents.

Mr. Smithills exhibited a beautiful French-made camera with changing plate.

There were a number of songs well rendered by amateur friends; tea, fruit, and confectionery were well supplied and heartily enjoyed.

The PRESIDENT made a few characteristic remarks, commencing by saying that he had been requested by the committee not to exceed three or four minutes—a request he would comply with in order that as much time as possible might be devoted to the dancing which was to follow. After some general observations, in which he expressed the pleasure he experienced in seeing the assembled company and indulged in a few reminiscences of former times, he concluded by addressing the young members of the photographic profession as follows:—"Be diligent, careful, painstaking; learn all you can about your art-science; read up the literature on it; become proficient in every detail; and remember that although photography has made great advances during its short existence, there are still great things to be done by it. Photography is as yet only in its infancy, and before it there is a great future. I hope that such meetings as the present will help us to rub off some of the sharp corners which are apt to exist between those in the same trade when they do not come into social contact."

At the close of the meeting votes of thanks were heartily given to the committee who had managed the arrangements, to the amateur vocalists who had given their services, to those gentlemen who had supplied instruments, and to Mr. Stuart for presiding.

ANOTHER meeting of the same Society was held on Thursday, the 11th inst., in the Religious Institution Rooms,—Mr. John Urie in the chair.

The principal business was to receive a report from the *conversazione* committee, and to nominate office-bearers for next session.

One of the members then showed a large number of *carte* portraits taken in a studio having a southern exposure, and glazed with ground glass. They were very effective pictures.

In reply to a question how best to mount prints on thin paper so that they might not frill or draw the paper, "mounting medium" was spoken of, and a solution of india-rubber was also recommended. The following were, too, suggested:—To damp the paper, mount with starch, and dry under pressure. Again: to use gelatine that had been first soaked in water, and then dissolved in alcohol.

After a vote of thanks to the chairman the meeting was adjourned.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

THE Board of Management of the above Association met on Wednesday, the 3rd inst., at 160A, Aldersgate-street, when the following gentlemen were elected as ordinary members of the Association, namely, Messrs. Wratten, Reilly, and Marschall.

The other business of the evening having been completed, the meeting was adjourned to May 1st, at 8 p.m.

PHOTOGRAHIC SOCIETY IN BERLIN.

A MEETING of this Society was held on the 21st March,—Herr Brasch occupying the chair.

After the transaction of routine and private business a lively discussion arose on the radiometer, several members having revived the proposition of using it as a photometer by which to regulate their exposures. As some of those present were not acquainted with the radiometer,

Herr DÜBY described it and explained the principles upon which it is based, concluding by expressing his opinion that its adaptability for use as a photometer was of the slightest, as its rotation seems to be accelerated by heat as well as by light.

Herr FRANÇOIS CORNAND could not admit that, as a radiometer seen by him had ceased to turn when the sun's rays were intercepted by a screen.

Herr DÜBY pointed out that by preventing the sun's rays from falling on the instrument the heat of the place where the radiometer stood would also be sensibly diminished. The radiometer was also known to turn, though but slowly, in the dark when placed in the neighbourhood of some source of warmth, such as a stove.

Herr BLANDIEN asked how the radiometer's action compared with that of non-sensitive or but slightly sensitive preparations, and was thus considered to bring the whole question to the *reductio ad absurdum.*

Another member (whose name is not given) related that when he was in America he had heard it proposed in all seriousness that the strength of the light could be determined by the degree of dilatation or contraction of the pupils of the eye of the common house cat—a communication which occasioned great merriment.

Another lively debate arose on the question of the best colour for the dark room window, red glass being suggested for that purpose.

Herr DÜBY preferred orange-coloured glass, because it transmitted fewer blue rays than any of the samples of red glass he had yet seen. Certainly glass of a pure spectral red, he thought, would answer better than orange-coloured glass, but then it was questionable whether glass of a sufficiently pure red could be obtained; so that he (Herr Düby) believed that a combination of red and orange—or, in other words, two sheets of glass, one being red and the other orange—would be the safest window.

Herr LUCK said he had two such orange panes and one of ground glass, and was extremely well satisfied with the combination. He (Herr Luck) then exhibited a sunshade for the objective. It consisted of three parts—square pieces of pasteboard, the inner sides of which are covered with black velvet and the outer with leather. The middle piece is held in a horizontal position over the top of the lens by means of a brass rod which passes through a brass eyelet. The other pieces of cardboard are fixed one to the right and the other to the left of the centre piece. When the sun shines upon the right side of the objective the shade on that side is folded down, and when from the left the left blind hangs down; at other times these two are both folded back upon the centre one.

The contrivance was unanimously pronounced very ingenious and practical. The meeting was immediately afterwards adjourned.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

A MEETING of the above Society was held on the 1st March,—Dr. Vogel occupying the chair.

The CHAIRMAN stated that Dr. Hornig had sent 300 copies of his photographic year-book, for which he, as the President, had thanked him in the name of the Society. He (the Chairman) then introduced the subject of collodion cotton again, and said he wished to show by experiment that a blow or a knock was quite insufficient to induce spontaneous combustion, and that when saturated with alcohol it would run off quietly without exploding.

Herr PRÜMM said that, in consequence of recent orders, Herr Schering could no longer send collodion cotton as he used to do; but that he now dissolved it in a little ether and alcohol, thus preparing a gelatinous collodion containing twenty per cent. of cotton, and sent it in that state.

A committee, consisting of Dr. Weissenborn and Herren Schering, Bergmann, and Junghaus, was appointed to collect materials to support a petition against the existing prohibition of the transmission of collodion cotton.

The Chairman then read a letter from Herr Obernetter, in which the latter described his reversed negative process. Herr Zipser had experimented with the process, and the results were shown. The subject photographed in all the cases was a plaster bust with a background of dark drapery. The preparation of bromide of silver dry plates and of iodide of silver plates appeared very simple. Wet bromo-iodised plates, however, required rather more care in their preparation than ordinary wet plates, if streakiness was to be avoided. The sensitiveness of these plates was, however, not behind that of ordinary plates of the same composition. Herr Obernetter employs this process with success for his coloured plates, for which he must use, according to circumstances, iodide of silver, bromide of silver, or bromo-iodide of silver. With respect to photographs with coloured glass, he says that if a sheet of coloured glass be placed between the object and the negative it must be placed quite close to the sensitive plate and as parallel to it as possible. He, however, prefers to use coloured collodion.

Herr PRÜMM regretted that a plaster cast was the only object photographed. He thought it would have been interesting to have seen some negatives of coloured objects or of living persons, because, as was shown by the experiments with Warnerke's and other dry processes, white objects always gave the most successful results.

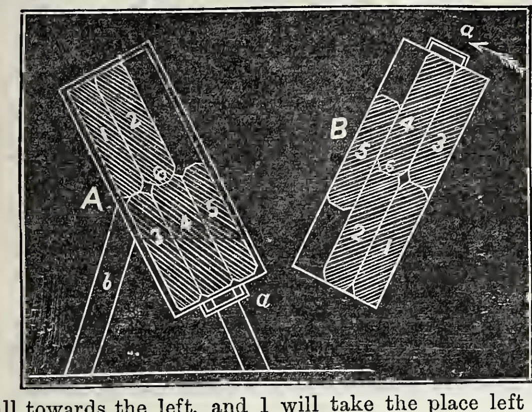
The CHAIRMAN thought that one might sufficiently study the sensitiveness for dark objects in the details of the background of drapery.

Herr QUIDDE asked how it came that this process gave useful results now when it was found useless when tried on former occasions.

The CHAIRMAN replied that it was probably because the washing after sensitising, which washing was indispensable, had been omitted.

Herr Linde spoke at some length on the causes of the present depression of trade, and lamented the length of time required to print a large edition of any picture, so that when an individual became suddenly celebrated, and there was a great demand for his portrait, if the weather were bad the demand might cease before the orders could be executed. According to Herr Linde the Woodbury process is not worked in Berlin, and to get a picture multiplied by that process one would require to send the negative to England.

Herr Bergmann showed an album which he considered particularly adapted for the reception room, as it was almost impossible to abstract the pictures from it. It is a very simple contrivance, consisting of a box thirty centimetres long, twenty wide, and seven in depth. The sides are of wood, the lid and the bottom of glass. The box can be moved horizontally, so that sometimes the lid and sometimes the bottom is uppermost. In each of these positions four *cartes* in one cardboard frame are shown. Every time the box is turned the two upper frames are turned undermost, and in their place two new frames make their appearance, and so on until all the *cartes*, fifty-two in number, have been seen. The accompanying diagram shows the principle of the contrivance. A and B show the layers of frames in section, 6 being the axis upon which the box rotates. Not to make the thing too complicated in the figure only five frames are shown, all made the same size and to fit into the box, leaving a space for one. The frames being arranged as in A, the space next 2 is empty. Turn the box until it comes into the position shown in B, when 5 will run down to the empty space alongside of 2. In this way there will be a new empty space alongside of 4, and if one still turns the box in the direction indicated by the arrow, 4 and



3 will fall towards the left, and 1 will take the place left vacant by 3, and lie on the top of 3. The same thing happens with any uneven number of frames, if they are properly arranged to begin with. *a* is the lock of the box.

Shortly after this album safe had been examined the meeting was adjourned.

Correspondence.

RESTORING AN INERT FERROUS OXALATE DEVELOPER.

To the Editors.

Gentlemen,—It may interest those of your readers who are using the ferrous oxalate developer to know that the activity of the solution which has become spent by use or exposure may be restored by means of metallic iron.

The best way of procedure will be to keep permanently a hank of fine bright iron wire in the solution, and, if necessary, to quicken the deoxidising action by heating the solution and iron wire together until the full effect is produced.—I am, yours, &c., Joseph W. Swan.

11 *and* 15, *Mosley-street, Newcastle-upon-Tyne,*
April 17, 1878.

PERMANENT PRINTS.

To the Editors.

Gentlemen,—I may not quite fully have explained (though I have wished to do so) my principle or idea as regards the permanence of photographs.

I have stated in my letter printed in your Journal of the 19th that I consider it to be an absolute necessity that nothing should be exposed to light which *can* change.

I believe that albumen, gelatine, &c., are liable to change colour or fade as regards the image they bear when exposed to light (I believe also the silver and gold may change); and, to put the matter perfectly plainly, I have thought, and do still believe, that by using a film of cotton charged with permanent colour, the same to be flowed on the print before the final backing of gelatine or glue is applied, is the only way to overcome the difficulty.

The cotton being insoluble in water, and the pigments, according to my plan, being insoluble also, resist the action of the water required for the necessary purposes of the processes of the chromotype patents. My patent cannot apply to any other than these chromotype patents, and is perfectly inapplicable to any other system of photographic printing to my knowledge. For silver prints it would be perfectly useless, and as they are, to my mind, absolutely numbered among the past, I put them altogether out of the question.

So far as my limited experience allows me to judge I should say that the only reliable photographic print to be obtained as regards permanency is that done by the double transfer process of the chromotype patents, humbly submitting that for perfect security my little innovation should be added, whether tinted or in pure white. My object is to secure anything liable to change from the action of light. With what I have written before I think this ought to be sufficient.

Some people say—"We don't want prints to last too long, because we get fresh orders." Is this honest?—I am, yours, &c.,

Harnham Cliff, Salisbury, April 20, 1878. Thos. Parkyns.

A CORRECTION.

To the Editors.

Gentlemen,—Please correct a mistake Dr. Nicol has made in his account of our premises at Lenzie. The large negative he alluded to was only *five* feet long, not "seven," as he has stated.—We are, yours, &c.,

Glenbank, Lenzie, April 22, 1878. T. and R. Annan.

THE LATE MR. LAMPRAY.

To the Editors.

Gentlemen,—Our attention has just been called to a paragraph in your issue of January 18th, 1878, in which you refer to the decease of Mr. Lampray, and state that "he was at one time a member of the *now non-existent* firm of Ordish, Lampray, and Co."

We beg to remind you that the firm is *still* in existence (as it was many years before Mr. Lampray joined it) under the style of T. Ordish and Co. Mr. Lampray was a member of our firm for the short space of about two years in 1861-2.

We should not have noticed this, but fear your statement may have given rise to erroneous impressions.—We are, yours, &c.,

108, *Hatton Garden, London, E.C.,* T. Ordish and Co.
April 20, 1878.

HORIZONTAL LINES.

To the Editors.

Gentlemen,—I may now take it as proved, I suppose, that vertical lines of considerable height, although truly parallel, appear in perspective to converge, according to a simple law of relative distance. But, in order to add confirmation to the views I advocated in my former letter, I may add that the argument is strictly borne out by trigonometrical reasoning. A well-known problem in that science will show any one who cares to work it out that, at 300 feet distance, a line 40 feet in length observed from a point directly opposite to the middle of it subtends (or is opposite to) an angle of 7° 37'; while at a distance of 340 feet the same line subtends an angle of 6° 44'—a diminution amounting to one-eighth, or in the ratio of 1 to 1·12. Here I may remark, in passing, also, that, strictly speaking, in my last letter 340 feet should have been stated to be an eighth, instead of a tenth, part longer than 300—literally, $\frac{1}{7\cdot5}$. This only strengthens my contention, and shows that the side of the tower is some five feet shorter in appearance at the top than at the bottom.

I now pass on to horizontal lines; and, in a general way, presume that no one doubts the evidence of his senses, and that all horizontal lines below the eye seem to run upwards into distance, and all lines above it downwards, to what is technically called the "vanishing point" in the horizontal line. It is the exact amount of this apparent elevation and depression that I propose in a few words to investigate.

Let us, then, suppose a terrace some 300 feet long, the houses in it being 50 feet in height. An observer takes his stand at a distance of 70 feet, directly facing a house 200 feet from one end of the terrace. I want to know how much smaller the last house at the other end of the terrace will appear to be. Calculating as in the case of the tower (*Euclid* I., 47), I find that house is 213 feet distant from the observer, or nearly three times farther off than the house he is standing opposite to, which is 70 feet from him. The apparent height, therefore, of the distant house is exactly one-third of the height of the others, or some 17 feet.

But this diminution is due both to the lines running upwards and downwards, on either side of the horizontal line, which is taken, as in the instance of the tower, at five feet from the ground. The amount of diminution, therefore, has to be divided in the proportion of 5 to 50, or of 1 to 10. In other words, the bottom of the distant house, instead of being five feet below the horizontal line, appears only 1·7 feet below it; and the top of the same house 15·3 feet above that line, instead of being 45 feet.

Let us next suppose the point of observation to be removed backwards to double the distance, or to 140 feet; what should we then find? It is now 240 feet distant from the farther end of the terrace. But the house directly opposite to it is now reduced to one-half of its former apparent height; and the distant house, also, is reduced in the same proportion to 25 feet, as 140 feet is to 240, or as 1 to 1·7, or 15 feet—only two feet less, be it remarked, than in the former case, while the highest house opposite has been reduced by 25 feet. Nothing could prove more strongly than this the value of retiring back from such an object towards ensuring a better balance of lines and less abrupt perspective than is generally to be found in architectural views. It also shows the value of long-focus lenses, where practicable, for such views. They compensate for the apparent loss of size, while preserving the favourable proportion among the lines of the picture secured by the longer distance of the standpoint from the object.

I might pursue the subject into another case, where the eye or a camera is directed obliquely towards the terrace in question; but, while complicating the matter somewhat, no additional light would be thrown on the amount of apparent convergence among horizontal and parallel lines. So, also, horizontal lines on the ground rapidly converge, as anyone may see by observing parallel lines of rails along a mile or two of perfectly straight railway. But I forbear from saying more at present, and hope I have made my meaning clear when demonstrating that all parallel lines of considerable length seem to converge when seen in perspective, and that the amount of that apparent convergence is measured by their distance from the eye of the observer.—I am, yours, &c., James Stothert.

Clapham, April 20, 1878.

EXCHANGE COLUMN.

No charge is made for inserting these announcements; but in no case do we insert any article merely *offered for sale*, that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a *nom de plume* be thought desirable), otherwise the notice will not appear.

Wanted to exchange, a one-gallon copper still and iron furnace complete, a mahogany camera ten inches square, and cameo embossing press for *cartes*, for good backgrounds or accessories.—Address, H. Buttrum, Wolverton-road, Stony Stratford.

A 10 × 8 Weston's patent burnisher, quite equal to new, with extra stand and cover, and spirit lamps, will be given in exchange for a No. 5 Ross's symmetrical or Dallmeyer's whole-plate wide-angle rectilinear.—Address, W. Dakin, Holly Bank, Nether Edge, Sheffield.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

F. S. K.—In our next.

J. W. N.—The grey paper will be found most useful; next to that will be the green. Red is most objectionable. Under the circumstances, papering the interior of the studio will prove preferable to painting it.

Maxwell Jackson.—You will find among our articles and correspondence in the present number several useful hints on the subject of the new developer. The lectures of Mr. Bolas are to be published *in extenso* in due course. A fortnight hence the new camera will be described.

Mezzotints.—Moisten a tuft of cotton wool with glycerine, and with it rub the whole surface of the old oil painting. This will impart such a degree of brilliance to the picture as will enable you to obtain a good negative from it. When the operation has been completed remove the glycerine by means of a sponge moistened with water.

J. Davis.—The artist to whom you allude must be prejudiced or ignorant, otherwise he would not have committed himself to such a statement. A collodion transfer is quite as durable as any other silver print. The diameter of the condensers you require will be about five inches. These can easily be procured, new or second-hand.

L. D.—In the first place, your collodion appears to have been too thin, and in developing you have used the water too warm, which has caused minute blisters that were not observed whilst the picture was wet. It is also possible that you may have squeegeed a little air in. The transfer paper enclosed seems to have been prepared for single and not double transfer purposes.

S. P. Q. R.—We have repeatedly worked with the lenses made by No. 4, and invariably found them good. We are not in a position to indicate the precise difference between the lenses you describe; neither can we account for the non-adhesion of the pictures to the mounts. The better way is to ascertain from the firm who supplied the mounts in what manner they should be used, and what kind of paste to employ.

Pablo (Havana).—1. The front lens of the combination is under-corrected. There is no remedy other than having the contact surfaces reground to a deeper curve. You may, however, try the effect of separating the back lenses in the manner you suggest.—2. Any good water colours may be employed for photographs. To make them take to the surface of the albumenised paper apply the tongue to the picture.

J. H. O. D.—How can it be expected that we should give you any estimate of the value of residues from a small sample of which we have picked out several pieces of broken glass? Send the whole batch to a trustworthy refiner, and he will allow you all that it is worth. Should this advice not prove quite to your liking, then we advise you to erect a furnace and effect the reduction yourself Full instructions for doing this have been given in a former volume of this Journal.

Gelatino-Bromide.—In a note received from Mr. Foxlee, just before going to press, that gentleman, with reference to Mr· H. B. Berkeley's letter, informs us that he has not tried *opaque* gelatine with alcohol in emulsions, his experiments in this direction having been conducted with Nelson's photographic gelatine. This, he says, will carry twenty-five per cent. of alcohol—a proportion which he considers quite sufficient to preserve it from decomposition, and at the same time enabling it to flow easily.

R. Peers —From your description of the lens we infer that the balsam by which the front lens is cemented has given way. Remove the lens from its setting, place it in lukewarm water at first, afterwards removing it to hot water. This will soften the balsam and enable you to separate the flint from the crown elements of the lens. Now make the surfaces quite clean by washing them with a little benzole or ether (collodion will also answer quite well), wipe with a wash leather, and re-cement them by means of a large drop of fluid Canada balsam placed on the centre of one of them. Gentle pressure, followed by moderate heat, completes the operation.

H. M. (Amateur).—We can only give a general reply to your queries. The powder at the bottom of the bottle is undoubtedly bromide of silver; but its presence does not indicate the predominance of either the soluble bromides or the nitrate of silver, and it is in the perfect balancing of these, without either being in excess, that the "neutrality" spoken of consists. The presence of either of these in excess may be ascertained by withdrawing a little of the emulsion, adding a little water, and dividing into two portions—to one of these adding a solution of any soluble bromide, and to the other a solution of nitrate of silver. The special solution by which a precipitate is formed will indicate in what direction a remedy must be sought.

Polaris (Greenwich).—A heliostat is only required when the exposure is to be prolonged. For an exposure of three or four seconds such a piece of apparatus will not be needed. If you call when you next come to town we will show you a very simple and effective design for a small heliostat, the cost of which will not exceed three pounds. In connection with this subject see the description of Monckhoven's heliostat given in our last Almanac. For solar enlargements it is the most perfect of all instruments, as well as the most convenient with which to work. In Mr. Viles's article, in the same Almanac, on *The Solar Microscope*, you will also see much that will prove both useful and interesting in your present course of study. In reply to the query in the postcript: let the diameter of the finder be two inches.

☞ **Editorial Communications should be addressed to "THE EDITORS"—Advertisements and Business Letters to "THE PUBLISHER"—at the Offices, 2, York Street, Covent Garden, London, W.C.**

South London Photographic Society.—The next meeting of this Society will take place on Thursday next, May 2nd, in the Rooms of the Society of Arts, Adelphi, when Mr. W. Brooks will read a paper on *Reproduction and Enlargement of Negatives by the Collodio-Emulsion Process.*

Blistering of Double Albumenised Paper.—In a note we have just received, a Havana correspondent describes the method employed by him in using this paper without the formation of blisters. He keeps the prints about half-an-hour in a solution composed of hyposulphite of soda, six drachms; bicarbonate of soda, one drachm; common salt, two drachms; and water, twelve ounces.

Bigamy.—On Saturday last, the 20th inst., Richard David Turnbull, an artist, residing in Uphampark-road, Turnham-green, was placed in the dock at the Hammersmith Police Court on a charge of bigamy. Mr. Farman defended. Inspector Whiteing, who had charge of the case, said the first wife was not present, but he could prove the second and third marriages. The prisoner's father was here taken out of the court, apparently in a fainting condition. Eliza Cruikshank, the prisoner's sister, was called to prove the second marriage. She said she was present at his marriage with his second wife on the 19th of June, 1862. She did not know the name of the church, as the marriage took place on their way to Sheerness. They had been living together. Eliza Mary Dore, the third wife, who gave the prisoner in charge, said she was living with her father in Castle-road, Newport, Isle of Wight. She was married to the prisoner on the 6th of April, 1867, at the Registry-office, in Plymouth. His second wife, who was in Brighton, had shown her the certificate of her marriage. She had written to the prisoner to fetch her from her father's. The prisoner said he had twice saved her life. He could not live with her, as her temper was too bad. He would rather break stones. In cross-examination, the witness said she met the prisoner at Plymouth. He came as an operator to her brother, who was a photographer. He brought his second wife with him, and said she was his housekeeper. The Inspector stated that he had been informed that the prisoner had married six or seven wives. Mr. Bridge remanded the prisoner, and said he would take bail for his appearance.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician.

For the Week ending April 24, 1878.

These Observations are Taken at 8.30 a.m.

No. 939. Vol. XXV.—MAY 3, 1878.

ALBUMEN IN EMULSIONS.

The peculiar advantages which accrue from the use of albumen in the dry-plate film have been so long acknowledged that it is surprising to find it so comparatively little employed at the present day. This may be partially explained by the fact that the processes in which a film of sensitive albumen plays a part, though producing most perfect results, entail an amount of trouble in the preparation of the plates which in these days of simple emulsions operates strongly in lowering them in public estimation. In addition to this an idea is prevalent that albumen is, of necessity, very deficient in sensitiveness; but, whatever may have been the truth in days gone by, there is now no longer any ground for such a belief. We have, during the last year or more, seen many admirable examples of collodio-albumen pictures produced by means of exposures which, if not attaining the highest point of modern rapidity, would a very few years ago have entitled the process to take rank with the most sensitive of dry plates.

The employment of albumen as an organifier to be applied to the film after the removal, or in the absence, of free silver does not appear to secure the full advantages of that substance, and, moreover, the method of washing and organifying the plate is rapidly giving place to washed emulsion; hence the possibility of securing the benefits of albumen in connection with emulsion without introducing an additional operation into the manipulations possesses at the present time some importance. The preparation of a washed emulsion would appear at first sight to afford great facilities for the use of albumen, and to a certain extent its peculiar advantages in connection with silver have been secured; but unfortunately difficulties of a physical character are encountered which considerably limit the range of its utility, or in many cases entirely neutralise the benefit gained. As we have experimented in this direction on many occasions during the last three years, we propose to give a brief account of what may be done.

We have spoken of difficulties of a physical character in the employment of albumen in collodion emulsion. We presume it is scarcely necessary to tell our readers that these arise mainly, if not wholly, from the fact that albumen is instantly precipitated or coagulated by contact with alcohol or ether. To a less extent its coagulation by silver nitrate militates against its employment except in very small quantity in gelatine emulsion, as, unless very great care be exercised, it coagulates and combines with a considerable proportion of the silver bromide, which must be removed by filtration. In the latter case, however, it is not a matter of much moment, as the qualities of gelatine emulsion are such as not to require the extraneous aid of albumen.

In collodion, however, in spite of the precipitating action of the solvents, it is possible, by the exercise of certain precautions, to introduce the albumen in a state of extremely fine division; that is to say, it is coagulated in such minute particles as to form a smooth, opalescent emulsion capable of producing a film as free from structure as one of silver bromide. If in this mode of using the albumen its full advantages as regards structural qualities of the film be not secured, we may, at least, expect to derive those benefits which accrue from the presence of albumenate of silver, namely, a vigorous and beautiful image and good keeping qualities of the plates.

The first mode of introducing albumenate of silver into the finishep image is due to Mr. M. Carey Lea, who attains his object by precipitating an emulsion containing excess of silver by means of an organifier composed partly of albumen. This method is apparently correct in theory, and is capable of giving very fine results; but in our experiments we have invariably found a small proportion of the dried emulsion refusing to redissolve in ether and alcohol. This may, perhaps, be to some extent due to the character of the pyroxyline employed, but it would seem to arise from the separate formation of particles of silver albumenate dissociated from the precipitated cotton and silver bromide. However this may be, it is certain that a portion of the albumenate is formed in combination with the soluble portions of the emulsion, as proved by the altered physical and other properties of the resulting films.

A modified plan, which has given very excellent results in our hands, consists in precipitating an emulsion containing a slight excess of soluble bromide in a plain solution of albumen—one part of the latter to eight or ten of water rendered very feebly acid with acetic acid. After allowing this to soak for a quarter of an hour it is thrown on to a cloth filter and the excess of organifier gently pressed out; a small quantity of water is then poured through the filter, the object being to remove the excess of albumen adhering to the fibrous precipitate without dissolving that contained in its pores. It is next treated with a forty-grain solution of silver nitrate containing ten or fifteen minims of acetic acid to each ounce for five minutes or longer, according to the character and quantity of the precipitate, which is finally washed thoroughly until no trace of silver remains. The treatment with silver must not be overdone or the emulsion will be rendered "foggy."

The dried emulsion produced in this manner is harder to the touch and less easily pulverised than one precipitated without the addition of albumen; it dissolves more slowly, and requires a longer time to reach its best working condition, but is completely soluble without residue. It gives a hard, structureless film which adheres closely to the glass, and developes quickly and vigorously to a good colour. About the sensitiveness we cannot say much, owing to lack of comparative trials; but we can state that it is certainly not impaired by the addition of the albumenate. A variation of this method, in which the emulsion was allowed to set before treatment with the albumen and silver, did not prove so satisfactory. The dried product became so hard that after several weeks' soaking a large proportion of it remained undissolved; hence we recommend precipitation.

Captain Abney's method of introducing the albumen directly into the collodion is, no doubt, preferable if we can only succeed in surmounting the difficulties which attend its practice. A small quantity of ordinary concentrated albumen as taken from the egg may be emulsified by vigorous shaking, but the greater portion is coagulated in the form of a stringy mass. Dried albumen dissolved in strong ammonia or other alkali forms a convenient way of introducing a larger quantity into the collodion; but the deleterious action of the alkali upon the collodion, as well as its reaction in the presence of silver nitrate, must be borne in mind and allowed for. Caustic potash dissolved in pure alcohol takes up a considerable quantity of dried albumen and forms a convenient way of using it. We have succeeded best in the following manner:—

Supposing the quantity of emulsion to be four ounces, we take one ounce of collodion, to which we add the desired quantity of alkaline albumen, and also the requisite quantity of bromide for the four ounces of emulsion. If cadmium alone, or the double bromide of cadmium and ammonium or zinc bromide, be employed no difficulty will be found in dissolving the desired quantity, but the ammonium salt is impracticable. To the remaining three ounces of collodion the full quantity of silver for four ounces of emulsion, previously dissolved in boiling alcohol, is next added; if the solvents be of ordinary strength the collodion will bear from twenty to twenty-five grains of silver nitrate without exhibiting signs of precipitation—at least until it becomes cool; but if such should occur it does not matter much. Sufficient nitric acid is also used to neutralise the alkali added to the other portion, and to leave a slight excess. The two portions of collodion are then gradually mixed and well shaken after each addition, the silver collodion being poured into the other in preference to the opposite course. Should any of the silver be precipitated as the collodion cools it will be readily taken up again by the emulsion.

Another method which obviates or renders optional the employment of an alkali consists in the substitution of bromine for the soluble bromide in the collodion. It is not a pleasant method to adopt, however, as those of our readers who have had any experience in handling bromine will readily understand. The solvent action of the bromine appears to be sufficient without the aid of alkali; but, whether from decomposition of the albumen or difficulty in accurately measuring the proper quantity, we have not found it to behave in a uniform manner. If the alkali be used in addition it will be converted into bromide and *bromate*, which may possibly introduce a further complication. For these reasons we merely mention the bromine method without recommending it.

In conclusion: we may say that we have obtained more or less favourable results with all these methods, but decidedly the best with the first mentioned. We believe that a more systematic course of experiment would prove the value of albumen when employed in this manner, and therefore recommend its trial to those of our experimental readers who may be inclined in favour of albumen.

TISSUE DRYING.

The season passing away gives carbon workers, comparatively speaking, a time of repose and immunity from many of the difficulties at present inherent in the process. We apprehend that this summer will see a large increase in the ranks of autotype workers, owing to the publicity given to it by the recent discussion on the patent, and the proof that so many professionals are commercially taking it up; but still larger would be the numbers enrolled if by any means the uncertainties attending the working were removed.

It would be perfectly correct to state that carbon printing is simple to a degree, and that a child could learn it in half-an-hour; nevertheless there are in connection with it certain difficulties of a most annoying and perplexing nature, which require practice to enable one to conquer them—some which almost defy a cure. But to state this is almost a truism: in silver printing, with the experience of a dozen or two years, and of hundreds of hard workers—professionals and amateurs—the same rule holds good. To this day how many are there who are not annoyed with blisters or with difficulties in getting a rich purple free from mealiness in a highly-glazed sample of albumenised paper?

In carbon work the drying of the tissue is the one subject of trial and anxiety. A batch of tissue one day may work to perfection, while another prepared only a day later out of the same sample of tissue, and with the same sensitising bath and a similar length of immersion, will not work at all. After an investigation of every supposed cause it is discovered that the mode of drying had been to blame, and the carbon novice received his first lesson that upon the drying of the tissue much depends. Next time, perhaps, he makes his room nice and hot, and leaves the tissue for a few hours, to find it on his return in a heap of clots on the floor; the heat has been sufficient to dissolve the pigment gelatine, and so it has run off its supporting paper.

On another occasion, determined not to melt it in this fashion, he keeps his room very cool, and finds his tissue still tacky at the end of twelve hours; and so the changes are rung, till he finds that there are only certain working limits of temperature which are also governed by the hygrometric state of the atmosphere. Now, in a large establishment, where suitable plant for autotype printing has been erected, it will not be a very difficult matter to select an appartment which, by reason of its roominess and ventilating capabilities, will answer. But—and here is one leading cause for the lukewarm way in which, upon the whole, permanent photography is viewed—in how many establishments where silver printing has reigned for years is there any convenience whatever for "putting up" tissue where it will dry and be free from dust, and yet not in anyone's way? There is not a doubt that this is a capital difficulty in this new branch of photography, and some ready means of surmounting it would give a considerable impetus to carbon printing of all kinds.

Bearing in mind this difficulty of want of space and suitable accommodation in so many instances, we are very much inclined to think that a species of drying cupboard will be found to solve the difficulty. Such a contrivance, we need not say, has been proposed in these pages; but sufficient means have not been suggested for carrying off the moisture quickly enough. What is required is a box sufficiently large to hold a good number of feet of tissue, but which yet would not be too bulky. Naturally, a box or cupboard containing a series of shelves to hold the tissue flat would occupy the least space, and if they were constructed so that each shelf covered the whole area of the box except for a short space on one side, they would, if the shelves were arranged with this space on alternate sides, allow a continuous current of air to pass over the surface of the tissue placed within. Air holes at top and bottom would complete the arrangement, with the exception of the means of creating a current, and this would require to be done artificially. A far simpler contrivance, but less efficient in some respects, would be a box to hold the pieces of tissue suspended side by side over rods, or some similar contrivance, requiring also artificial means for creating a current.

It is to this point we direct attention. The draught created by the burning of a gas flame in a narrow chimney connected with such a box has been proposed, but we think it would be found entirely inefficient; for, besides the consideration that once such means were used, the box would require closing, and all that might be termed natural ventilation and circulation of air stopped, it may be easily calculated that the change of air would be slight. A gas burner consuming six feet of gas per hour is a very large one, and (even allowing for a little additional suction of air caused by the draught) it may be easily calculated that it could not cause more than a cubic yard of air to pass through in an hour's time—a quantity entirely inadequate to carry off the moisture from a few feet of tissue.

It is, therefore, demonstrable that a more powerful mechanical means would be required to do the work effectually; and this, we believe, could be devised at a very moderate cost by means of a fan turned by a specially-constructed turbine, and as every studio is of necessity supplied with water there would be no difficulty in obtaining the requisite fall. Any amount of current could be thus obtained, and the simplest of means could be used, if necessary, to heat the current where gas was available, or, with a little more trouble, by paraffine oil.

We have consulted a clever mechanician on this question, and he informs us that such an arrangement would be by no means costly. He has further promised us, as soon as he is a little freer from his engagements in connection with the Paris Exhibition, to work the matter out and make a model fan for us. Meanwhile we offer the idea for what it is worth to the body of photographers, leaving it open to anyone who chooses to carry it out. We may observe that the exit of the current should be from the top to the bottom of the box to take advantage of the superior specific gravity of moisture-laden air. It will also be seen that, if necessary, the draught might be easily conveyed by lead or other pipes any distance from the source of power—the water supply—if the necessities of the premises called for such an arrangement.

DRY PROCESSES—ANCIENT AND MODERN.

IV.—A COMBINED EMULSION AND BATH PROCESS.

We have, in a previous chapter, spoken of certain advantages which accrue from the combining together of the essential features of two distinct processes, and have shown that we may in such a manner secure the best features of both. We have now to follow out this idea in quite another direction, namely, the effecting of a union between the bath process and the bromide emulsion process.

It is too well known to require much comment that a bromide of silver emulsion, in which there is an excess of the bromide of ammonium, cadmium, zinc, or whatever other soluble bromide has been employed, is not sensitive to light. In the earlier days of collodio-bromide the system of having soluble bromide in excess, and removing it by washing the plate, was fully recognised and practised. In the printed directions for using the emulsion issued by one firm attention is specially directed to the fact that in proportion to the amount of washing the plate receives after being coated so does its sensitiveness increase. A reaction afterwards took place, and an absolute balance of the nitrate of silver and soluble bromide, followed in turn by a reversal of the first order of things—the nitrate being latterly in excess—set in, all these culminating in "washed emulsion," in which all the soluble salts are removed by water.

But previous to this it was proposed by Mr. H. J. Newton, President of the Photographic Section of the American Institute, to combine the emulsion system with the bath system. He made an emulsion containing a certain excess of soluble bromide, and when a plate had received a coating of this it was sensitised by immersion in a comparatively weak bath of nitrate of silver.

When a plate is coated with iodised collodion a dense, creamy film of iodide of silver is obtained by immersing the plate for about two minutes in a bath containing a thirty-grain solution of nitrate of silver; but when a dense film of bromide of silver is desired a silver bath of more than double this degree of strength is necessary, added to which the plate must be immersed for about a quarter of an hour in order to effect the formation of the bromide of silver. It is of no use trying the preparation of a bromised plate with a strongly salted collodion and a silver bath of the ordinary strength; for the bromide of silver formed under such circumstances falls off in patches from the surface of the plate. To impart the great bulk of the bromide of silver to the film Mr. Newton, as we have said, emulsified the collodion to a certain extent, leaving the bath to complete the operation of sensitising the film. Now, while it is quite true that all traces of soluble bromide may be removed from a layer of collodion by washing it with water, it is further true that the necessary degree of washing to effect this properly must be tedious and protracted; for the bromide, although quite soluble in water, appears to cling with a marvellous tenacity to the pores of the collodion, from which it is only eventually dislodged with great difficulty. It yields rapidly, however, to the converting influences of a solution of nitrate of silver, which permeates the pores of the collodion and arrests the soluble bromide wherever it is found by its natural chemical antagonist. After removal from the nitrate bath the silver is, of course, in excess; but a slight rinse in distilled water leaves the film in an exceedingly sensitive condition. By the application at this stage of a suitable preservative a plate possessing exquisite sensitiveness, good keeping properties, and the most absolute freedom from spots or other imperfections may be obtained.

In our trials with the process described we have found either of the following two kinds of preservative yield very successful results. The first of these is one which was applied many years ago by Messrs. Blair and Adams to another process:—Procure two bottles, marked respectively A and B. Put into—

A.

Gum arabic	1 ounce.
Sugar candy	½ „
Water	4 ounces.

B.

Tannin	40 grains.
Water	4 ounces.

Mix A and B together in equal proportions, render the mixture *slightly* alkaline by the addition of ammonia, and let this be poured on and off the surface of the plate two or three times, or until the whole of the film shall have been thoroughly impregnated; after which wash the plate under a rose tap. When dry the plate is ready for exposure.

The other preservative is that which has been applied with so much success by Canon Beechey to the plates now so well known in connection with his name. It consists of a certain quantity of clear, *flat* (not sour) table beer in which has been dissolved pyrogallic acid in the proportion of a grain per ounce of the beer; *e. g.*, a half-pint of beer will require ten grains of the pyrogallic acid. It is best to employ a flat bath for containing this preservative, the plates being immersed for two or three minutes with slight agitation.

Although, from our description, this process may appear to be a little complex, in reality it is not so; and we can very strongly recommend it as a means of obtaining plates of the finest possible quality. The preservatives here mentioned do not belong to the process as it was originally published; but we adopted them simply because they answered better than any of several others that we have tried.

The development is effected by means of alkaline pyro., the exposure required being about the same as that given to a wet collodion plate.

A ready means of rapidly filtering the silver bath and other solutions is an indispensable adjunct to every well-appointed photographic laboratory, and many plans have been suggested as improvements upon the usual funnel and bibulous paper arrangement, the majority of which have taken the form of modifications in the shape of the funnel employed to support the filter, or of the method of folding the latter in order to bring a larger portion of its surface into action. With the ordinary glass or porcelain funnel the paper cone accommodates itself, under pressure of the liquid to be filtered, so perfectly to the shape of the support that only a very small portion of the apex of the filter is left free for the passage of the liquid. Any attempts to bring a larger surface into play tend, by depriving the filter of the necessary support, to weaken it and endanger the success of the operation without materially aiding the object in view. A very simple contrivance which came under our notice a few days ago permits the passage of the solution through every portion of the filter without in the slightest degree removing the support so necessary to prevent the bursting of the paper. It consists in substituting for the funnel ordinarily employed a conical bag of stiff hair-cloth, such as is used for making sieves. This must be so constructed as to be the exact shape of the cone formed by folding a sheet of paper in the ordinary manner, when it is obvious the filter will receive efficient support at every part of its surface. The edge of the supporting cone must be fixed to a rigid hoop of cane or other material, by which, with the assistance of a loop of twine, it may be suspended above the vessel into which the solution is to be filtered. The hair-cloth forms a perfect support for the paper without in any way retarding its filtering power. With aqueous solutions the operation proceeds with such rapidity as to convey the impression that the paper filter has been broken. The material does not appear to be affected by silver solutions or to act injuriously upon their working properties. The instrument shown to us had been in constant use with silver for some months without exhibiting the slightest deterioration. It was made by cutting the cloth to the required shape and cementing the edges with marine glue. It was stretched upon a ring of stout iron wire, also coated thickly with the same substance to protect it from the action of the solution, and though, perhaps, not presenting the most elegant appearance it will, no doubt, act as well as the best. While recommending this we have not forgotten the filter papers combined with netting or gauze for which Mr. Thomas Ross obtained a patent.

A FEW NOTES.

THE FERRO-GELATINE DEVELOPER.—EMULSION SPOTS.—THE GUM GALLIC PROCESS.

The editorial article last week on *Variations in the Iron Developer* is a particularly interesting one. Ever since the introduction of Mr. M.

Carey Lea's ferro-gelatine developer I have constantly used gelatine in some form or another, and can most cordially endorse all that has lately been written in its praise.

As simplicity is always desirable I have for years kept a standard solution by me for use as required. This is made by dissolving sixty grains of good gelatine in six ounces of water and two ounces of glacial acetic acid. A developer may be made up with this solution in place of, and in the same proportion as, the ordinary acetic acid. It keeps well, and may be mixed with a plain developer, as circumstances require. For landscape work it is most valuable.

But of all the purposes for which a ferro-gelatine developer may be employed the most valuable is as an intensifier, particularly when combined with citric acid. An intensifier made thus—

Protosulphate of iron	10 grains,
Gelatine solution	10 minims,
Citric acid	3 grains,

offers many advantages over pyro., especially for landscape work. The intensification may succeed the development proper without any washing, and with a plate just a little under-exposed a perfect negative may be secured; whereas if the plate were washed between the two operations some amount of detail would have been sacrificed.

I am sure I need not dilate on the boon it often is, when working in a tent, to be able to dispense with much washing. In fact, I have often managed to work without any water at all. The plate is intensified immediately after development, and when this operation is complete it is drained for a moment and flooded with a mixture of glycerine and water equal parts, and placed in the draining-box until a proper opportunity for fixing is found. This latter may be deferred for a year or more, if needed, without damage to the plate.

Those who once fairly try this citro-gelatino-ferro intensifier will not be likely to return to the use of pyro., except for very exceptional cases. I could mention several first-rate photographers to whom I have recommended it, and who have since continued its use.

The intensifier will keep in good condition for *years*. In the production of very large negatives, either direct or enlargements from transparencies, the gelatine developer and my pet intensifier have proved most satisfactory. The colour of deposit and quality of negative are everything that could be desired.

To those using these solutions for the first time a word of caution may be necessary. Do not over-intensify. The intensity increases a good deal on drying, and in a still more marked manner if heat be used, and also the colour of deposit is usually very non-actinic.

"*The Hybrid Process.*"—Owing to my communication on this subject last week having been printed as an article instead of a letter, with my address, as intended, the meaning and force of one remark may to some of my readers be a little obscure, and it is on a point of some importance. I remarked that "down here, at least, it appears impossible to get a negative" (with plain washed emulsion) "free from spots and other markings if the plate have been kept for even a few days." I cannot expect everyone to remember I am now living at Torquay, and unless that fact is taken into consideration the importance of my statement will not be readily understood. In this year's Almanac I have recorded my conviction that the spots in washed emulsion films which have proved such a bane to my comfort and peace of mind were caused by simple organic dust, and that moisture was needed for these particles to exert their deleterious effect. Now, with us in Torquay the air is constantly damp from many causes, not the least being the enormous quantity of salt particles it contains, and it is in such a climate that these spots seem to make their unwelcome appearance in extra numbers.

I am aware that my own personal experience in the matter is not the same as that of some other workers. I trust Mr. Woodbury will kindly excuse my mentioning him as a "case on the other side."

Some few winters ago this gentleman passed a few months in Torquay, and during that time made his first (or almost his first) practical acquaintance with washed emulsions. In spite of having to work without proper appliances and altogether in a most inconvenient way he produced several charming little negatives which were singularly free from the so-well-known spots; and I have been since informed by another enthusiastic emulsion worker that neither he nor Mr. Woodbury now ever get a spot.

These discrepancies between the experiences of various individuals are more puzzling than satisfactory. Of course there must be a cause, but up to the present we have failed to discover it. However, I hope I have said good-bye to spots also; but with me it is by going through the extra trouble of using a preservative for the plates.

As my experiments with albumen proceed they become more and more satisfactory, and already I feel such confidence in my plates as would warrant my depending solely upon them during a photographic expedition. I hope soon to be in a position to publish a thoroughly satisfactory formula, although one almost dreads to describe *another* new dry process.

One more note and I cease scribbling for this week. In the valuable epitome of dry processes, new and old, now being given in the Journal, I notice one small error in the description of the gum-gallic process. The process as given last week is as first described by its introducer, Mr. Gordon; but he afterwards much simplified the manipulation, and also, I believe, improved the process by mixing the gallic acid with the gum and sugar. A slight amount of discolouration occurs on the admixture, and at first Mr. Gordon did not think it correct to use it; but further experiments showed it to be harmless.

It is of importance that the mixture be used soon after making; in fact, none of the ingredients must be in solution for long before use. The gum rapidly turns sour, the sugar ferments, and the gallic acid decomposes. In making the solution of gallic acid Mr. Gordon deemed it of importance not to add more than the three grains to the ounce of water, as on proceeding in the ordinary way of pouring hot water on an excess of the acid and allowing to cool he sometimes found that more than three grains were held in solution, and, when mixed with the gum and applied to the plate, a portion of it crystallised out and produced annoying spots.

The best way to make the compound solution is to weigh out the gallic acid (say twelve grains), pour just sufficient very hot water on it to dissolve it, and then make up to four ounces with cold water. Eighty grains of powdered gum arabic and twenty grains of white sugar are now placed in a small muslin bag, and by means of a thread suspended at the surface of the gallic acid solution. The solution of the gum proceeds rapidly without any stirring and consequent formation of air-bubbles; and if the gallic acid have been previously filtered, and rather close muslin be used for the bag, no further filtration will be needed.

As this process is so thoroughly good a one, and likely to prove again useful, I feel I may be excused devoting these paragraphs to one of its important details. Henry Cooper.

THE REVERSED NEGATIVE PROCESS.

Latterly our negative process has made considerable progress through the emulsion process; the formulæ of Mr. Warnerke, especially, are precise enough to lead to good results if they be exactly followed. Still it is not easy, even by his remarkable formulæ, to prepare useful emulsions. Anyone who has made bromide of silver emulsions will know how an operator may worry himself with the work, often being in the dark for three days, and after all be unsuccessful—some slight want of foresight undoing the work of days.

In experimenting how to take separate colours the emulsion process has always rendered me good service. Photographs taken through coloured glass or liquids require very long exposures, and have the great fault of never giving congruous negatives; on the other hand, coloured collodion films give the same results and less incongrous plates. In my experiments, when taking negatives intended for colour printing plates, I required various prepared and *coloured* collodion films. The addition of the colouring matter to the collodion often destroyed my silver bath, and the addition of different sorts of collodion with different salts seems inconvenient; therefore I tried reversing the whole process and obtain the best results. The theory is simple. I prepare a silvered collodion, and use as a bath iodine and bromine salts. By having tried a variety of proportions I am now in a position to publish a very simple formula, which will render it possible for anyone to make further experiments in the same direction.

The preparation is very easy. The manipulations are the same as in our old process, exposure for a whole day involving no drawback. The sensitiveness may be greatly increased, the sensitive films may be coloured with every possible pigment without affecting the bath, and the negatives obtained are indistinguishable from those got by our own process. I produce with the same collodion three sorts of plates—bromide of silver plates, iodide of silver plates, and bromo-iodised silver plates. The latter give exactly the same results as by our ordinary process, and have precisely the same sensitiveness.

1. *Collodion.*—Place in a cooking-pot capable of holding half-a-litre five grammes of nitrate of silver, one drop of nitric acid, and two c.c. of water. Dissolve the silver by heat, and then pour over it 250 c.c. of ninety-six per cent. alcohol; then add six grammes of cotton and 150 c.c. of ether. When the whole is dissolved filter through

spun glass, fine flannel, or collodion filter-paper. The collodion is then ready, but naturally it is better to let it stand for a few days. I have some at present four months' old which is as good as when fresh, and will keep as long. This collodion is the foundation of all.

2. *Bromo-Iodised Plates.*—The glass plates are coated with silvered collodion, as in our old process; then, instead of being placed in the silver bath, they are placed in the following bath :—

Bromide of potassium	8 grammes,
Iodide of potassium	8 ,,

dissolved in 200 grammes of water.

The whole process is indistinguishable from that of silvering a plate, and lasts the same time. When the plate is ready wash both sides well with ordinary water. After washing I coat the plate twice with a solution of—

Nitrate of silver	8 parts,
Water	100 ,,

or an ordinary silver bath, when the exposure is to be short; when the exposure is to be long I add glycerine. After the exposure I develope, without washing, in the ordinary way with iron.

One may also develope with acid instead of with alkali. In developing with iron one gets precisely the same result as by our old process. [We use five parts of iodide of potassium, one part of bromide of potassium, to ninety parts of water and iron developer, and get good results, after washing and coating with silver solution, though not with quite the same certainty as in the ordinary process. One great advantage of the new process consists in the using of only one collodion and the avoidance of the silver bath and the faults that often accompany the silver bath.—Ed. of *Mitth.*]

3. *Iodide of Silver Plates.*—When working with pure iodide of silver I take one part of iodide of potassium and twelve parts of water. In other respects they are treated as the above. These plates give very hard negatives, so that they are especially suited for the reproduction of line engravings, pencil drawings, &c., and I have never copied copper plates more conveniently than in this way.

These plates are also easily used stained. If an aniline blue, soluble in water, be dissolved in the sensitising bath (eight grammes of nitrate of silver in one hundred grammes of water) and the plate stained blue, by this proceeding you will get a plate which is not sensitive to yellow, but sensitive to all other colours, consequently a printing plate for yellow. [Upon *bromide of silver* plates we get plates sensitive to *yellow*.—Ed. of *Mitth.*]

4. *Preparation of Bromide of Silver Plates.*—Bromide of silver plates may be developed by the wet process, but they give flat negatives; on the contrary, with an alkaline developer, or when treated as dry plates, they exhibit the same good properties which are rightly attributed to emulsion plates. The sensitiveness may be increased in a very remarkable way, as I shall hereafter indicate, and I hope by showing its simplicity to encourage many to experiment with it.

I shall assume that I am working with bromide of silver, so I use a bath containing one part of bromide of potassium to twelve parts of water. The collodion is poured on like iodide collodion. The bromide of potassium solution is used like a silver bath, and gives exactly the same appearance to a plate as a silver bath. When the plate is ready wash it well with water under the tap, and expose in the usual way; after the exposure one may either develope at once or wash first. Any *alkaline developer* will do. I use the following :—

No. 1.

Ammon. bicarbonate	20 to 50 parts.
Water	1,000 ,,

No bromide of potassium.

No. 2.

Pyrogallic acid	1 part.
Alcohol	10 parts.

To one hundred c.c. of No. 1 take four c.c. of No. 2. The picture developes in about half-a-minute, and becomes remarkably powerful, if the plate be well washed after the developer, and coated with the silver solution (one hundred water, two silver, three citric acid), the latter being poured off into a glass in which the proper quantity of water and pyrogallic acid has been previously placed. When the picture is powerful enough I fix with cyanide of potassium; but one may strengthen after that, if it be desirable. The process goes on smoothly and certainly, and besides it is simple. If before exposing the plate be coated with certain sensitisers its sensitiveness will be increased. By coating it with preservatives we get dry plates in the simplest way. After being bromised the collodion film may be stained with anything, as with dyestuffs soluble in alcohol or in water, &c., &c. I have never failed in the development. If the wet plate be coated with dilute glycerine it may be exposed without the delay of a single day, or it may be dried and used as a dry plate. [We have done so, and with the best results.—Ed. of *Mitth.*] If a half per cent. of tannin or morphia be added to the glycerine solution the plate becomes as sensitive again, but is apt to become fogged. The fogging may, however, be prevented by the addition of bromide of potassium to the developer.

The sensitiveness of the plate is surprisingly increased when the plate is coated with the following solution :—Nitrate of silver five grammes, water 100; neutralise with caustic ammonia until there is a very slight turbidity, and then filter.

In making these experiments I should advise great attention to be paid to the light used in the dark room, otherwise fog will be unavoidable. The film may be stained with any possible pigment without injury to the subsequent development. *When exposed, the plate should again be washed and developed with an alkaline developer;* then fixed with cyanide of potassium. The plates may be strengthened at will after being fixed.

These negatives have the peculiar characteristics of alkaline-developed bromide of silver plates of giving all the details, even in the deepest shadows, without the whites being quite covered. They have, in short, all the advantages of bromide emulsion plates, and are taken in exactly the same way, only that one is not plagued with the preparation of the emulsion.

I have no doubt that, by changing the proportions, many improvements may be made in this process, and I shall conclude by expressing a hope that any one who may carry his experiments in that direction farther will also publish his improvements.—*Mittheilungen.* J. B. Obernetter.

NOTES ON PASSING EVENTS.

By a Peripatetic Photographer.

The publication of the articles on *Dry Processes—Ancient and Modern*, in this Journal, recals forcibly to my mind the time—now many years ago—when the invention of dry processes formed the prevailing mania of the period. This is the way it was, or seemed to have been, managed :—An enterprising man, whose name I shall designate Mr. Alpha, discovering, from reading the Journal, that Mr. Beta has been receiving a certain degree of praise and credit for his pictures taken on plates preserved by means of (say) honey, determines that he, too, shall be an inventor, and *he* introduces something different from honey—it may be molasses. Mr. Gamma follows with golden syrup; another with raspberry vinegar; a fourth with glycerine; a fifth with wort; and so on, until malt infusion, beer, ale, double stout, chocolate, coffee, tea, and everything in the edible universe capable of yielding an extract or a decoction has been pressed into photographic employment. The imaginative faculties have been stimulated, and the capacity for research enlarged, by such a scientific proceeding as standing upon a chair and from that elevated point of sight subjecting the varied contents of the kitchen larder to a scrutiny far exceeding in fervid intensity that which even the cook herself displays during her most scrutinising moments. Delicious is it to experience those sensations that are the immediate precursors of the "agony of a find;" and such are the sensations still remaining in store for him who shall find something which has not been already forced into the service of photography as a preservative. So far as I know, Worcestershire sauce and mushroom ketchup are still waiting to be requisitioned by the photographic investigator and to be utilised as preservatives and organifiers. Everything else of a culinary or appetising nature, including mustard, has long ago succumbed.

It is gratifying to find that Mr. M. Carey Lea has been busily engaged in further improving the oxalate developer which he was good enough to publish last summer. It will still be some time before every necessary thing is known in connection with this valuable developer; in particular, a classification will have to be made of circumstances under which substances will act as restrainers. A soluble bromide, such as that of potassium, will restrain in the case of one process, but not in another. Acetic acid and oxalic acid have been found most beneficial additions in some instances, but not in others. Circumstances have occurred to prevent me from trying Mr. Lea's suggested addition of gallic acid since it was published on Friday last; but before this "note" meets the eye of the reader I hope, weather permitting, to have had a couple of hours with an oxalate developer held in check by both the collo-restrainer and gallic acid. One cannot thank Mr. Lea too much for what he has freely published concerning this new developing agent, which bids fair to be recognised as a most valuable addition to our development resources.

The announcement of the death of Mr. J. A. Spencer must have filled many with surprise. It seems such a very short time since his well-known face and form were seen moving about among his numerous friends and acquaintances that it is difficult to realise the fact that he is no more. The grey hairs of Mr. Spencer were beginning to impart to him just the semblance of that venerable appearance which reveals "the chinks that time has made;" but in no sense could the deceased gentleman be otherwise described than as a hale, hearty, middle-aged man. By all accounts the quantity of albumenised paper manufactured by the late Mr. Spencer during his lengthened career as an albumeniser must have been something enormous. Had he been a more selfish man than he was he would, in all probability, have never cared to bestow a thought upon the future of photography, or been solicitous as to whether silver or carbon were the better medium in which to hand down photographs to posterity, but, instead, he would have continued to cling to that established form of printing which had so large a claim upon his consideration. I regret to have heard that Mr. Spencer suffered intensely during the latter stages of his brief illness; a death from starvation in the midst of plenty is what cancer in the æsophagus results in, and from such a painful demise may every reader of these "Notes" be spared!

I, too, not in Arcadia, but in the land of *Spots* have dwelt; and Mr. Henry Cooper does not stand alone in this kind of experience. When are we to get at the bottom of this apparently unfathomable mystery of spots in emulsion plates? If one only knew the law which governed their appearance all would be well; but they seem to set all ordinary laws at defiance. For example: I possess an emulsion which is entirely free from spots if I use it after giving it a good shaking up, and yet that same emulsion behaves in the contrary manner if I filter it and allow it to repose for a day previous to applying it to the plate. Now, wherein consists this difference between these two conditions of emulsion? and why should repose cause spots? One would naturally enough conclude that such treatment would ensure immunity from them, but *they* scorn to yield obedience to any physical law. I don't mean to assert that the shaking up of every kind of emulsion just prior to use will ensure freedom from the evil, but it certainly proves a panacea in the case of some samples. Again: there are emulsions in which a spot is never seen under any circumstances; and, alas! there are also samples by which it is wellnigh impossible to obtain a plate that is quite spotless. Some persons assert that carelessness in the preparation is a leading factor in the cause of spots in emulsions; but these people merely record their own ignorance of the matter. Flippancy of assertion is seldom coincident with profundity of knowledge.

(To be continued.)

OUR APPARATUS.

No. V.

I MAY here remark that all bottles should be properly labelled. Nothing shows the slovenly and careless photographer more than a host of bottles, containing different chemicals and solutions, without labels, standing about. The fact of having to trust to the faculties of smell or taste to discover their contents is of itself sufficient indication of the necessity for labelling. Moreover, this mode of ascertaining the contents of a vessel set aside perhaps for months is very misleading, and the wisest of us may fall into error if we place implicit reliance on this method of diagnosis. There is one thing certain—that such a loose method of storage will lead to waste, if nothing worse. Bottles containing compound solutions or powders should have the formula distinctly written upon them, with any memoranda deemed useful when the compounds were made. The usual way of trusting to memory is very uncertain, and, if many experiments are carried on, leads to confusion, when a pencil jotting at the time would prevent anything of the kind, and you would have the satisfaction of knowing exactly what you are working with beyond any doubt. Vessels containing simple substances—aqueous solution of silver nitrate, for instance, or solution of carbonate of soda, &c.—should be labelled as such, with the strength of the solution indicated and the labels varnished; but, whatever method is selected, let it be done in a thoroughly distinct and unmistakable manner. The little time required for doing this will be amply repaid by the certainty and facility with which work can be got through.

Dishes are best made of glass, if of small size. Wooden ones having several coats of shellac varnish are most useful for large work, and answer the purpose well. Glazed porcelain dishes are useful, except for holding solutions of nitrate of silver, which will invariably penetrate and destroy the glaze after some little use. Basins for evaporating old silver baths or similar work should be of Berlin ware, as better calculated to withstand the heat without cracking. The plan frequently adopted of setting a Winchester quart glass bottle containing the silver solution in a pan of water on the fire is fraught with danger, as the unequal thickness of the glass makes it very liable to break and spill the contents. The process is much better and more expeditiously conducted by the use of a Berlin basin, placed on a tripod over a Bunsen burner. The solution can then be evaporated to dryness, or the nitrate fused without danger of fracture.

Dropping-bottles have now taken the place, on the score of convenience, of the minim measure in the measurement of very small quantities, the graduated tube and elastic ball arrangement being as good a form as any. When absolute accuracy is required—as in some of our emulsion or dry-plate experiments — the method of discharging drops from an ordinary bottle cannot be too much deprecated, as no two drops can be assured as being exactly the same quantity. If the photographer will take the trouble to dribble so many drops—say ten—into a minim measure he will see for himself the varying quantities that are poured out for the same number of drops from different bottles of various solutions; at anyrate, the experiment will give him some guide what to expect if he measure in this manner.

Jars for storage are best when made of glazed earthenware, with air-tight lids, or good bungs over which has been pasted smooth paper, to prevent the dust generally contained in the pores of the cork from contaminating the substances they are designed to protect. All corks used in storing dry substances should invariably be protected with leather, paper, or some material answering the same purpose.

Scales for weighing grains or small quantities are most useful if of the pillar form. The strings supporting the pans are in this make kept out of the substances being weighed, and are consequently more cleanly. With hand scales the strings are apt to become contaminated with the different chemicals weighed, and so introduce some chemical not desired into a compound, or scatter it about, causing waste. Glass pans are much superior to metal, and should always be carefully wiped after use and before putting them aside, care being taken that no chemical is left in the holes through which the strings pass. The whole apparatus should be kept nicely polished, and, when not in use, under a glass shade or box, to protect it from the action of air, moisture, and dust. Another and very necessary precaution in using delicate balances is to see that nothing of an adhesive nature is left on the box under the pans, and upon which they are steadied. A good hard rub with a clean, dry cloth should be given to this portion of the woodwork every time they are used.

With respect to mortars and pestles: for most photographic purposes a pint, or No. 4, Wedgwood mortar is most useful, as being a fair capacity and not too unwieldy for small quantities. It must not be used, however, for powdering very hard substances; for this purpose a bell-shaped, turned iron one will be found best, providing the substance to be powdered has no action on the metal or the metal on it. The pestle should be smooth and without flaws, or it may retain and convey impurities in its interstices from one thing to another that is submitted to its action.

Glass beakers of different sizes are amongst the most useful of our glass apparatus. Owing to the thinness of the glass they require handling with caution, and should never be set down on a hard, unyielding surface, such as stone or iron, without a small pad of some elastic material being placed to receive them. Woollen or felt pads are very suitable, and prevent breakage by too sudden changes of temperature, as when a vessel of hot solution is removed from the fire to cool.

Rolling-presses should be kept covered from dust, and carefully protected from damp or any fumes proceeding from chemical operations. If the steel once get rusty it is almost impossible to remove the damage without leaving an uneven surface, unless it be sent to the makers to be refaced. There are so many good forms of this machine in the market it would be invidious to mention any kind as being especially good; but the same precaution for keeping them in order applies to all. For small work I have used one with a stout glass bed with satisfaction for many years. The bearings are best made of steel, brass being too soft and soon wears unequally. If the pressure be controlled by one screw there is less chance of unequal rolling than when several have to be adjusted. In this, as in most other pieces of mechanism, the more simple the action the better. The polished steel or iron work may be kept free from rust when out of use by the application of a thin coating of suet and carbonate of soda, in the proportion of about ten grains of the alkali to an ounce of fat. This thoroughly rubbed over the metal previously made warm, leaving just sufficient to show a smear when rubbed with a clean finger, answers well.

A good pattern for boxes for strong mounted cards is a box about thirty inches long by fourteen or fifteen inches wide, and about an inch deeper than the width of the card, divided into cells across the narrow way. Each division can be labelled systematically from number so and so to number so and so, or lettered, if preferred. The edges of the box should be covered with strips of cloth to keep out dust. If the cards are stored in this edgeways, and not lying on each other, they will be easier to get at, and be better protected from scratches and abrasions that storage and frequent looking over is very apt to occasion. Boxes for negatives are convenient if made without grooves, and about an inch deeper than the height of the negative; in other respects they should be sufficiently large to hold them easily—say for a 6 × 8 negative seven inches deep, eight and a-quarter inches wide, and twelve inches long. A piece of smooth, stiff card must be placed between each. On the upper edge the number of the negative immediately before it can be written. This manner of storing is quite as effectual and protective, besides much more convenient to get at, than placing each in an envelope on a shelf, as many do, or in grooved boxes, which answer equally well but occupy much room without any compensating advantage.

E. DUNMORE.

TRANSATLANTIC NOTES.

HAVING landed at Philadelphia after a most delightful voyage, some of the incidents of which were recorded in my last batch of "Notes," and spent a few days in looking into things in general and photographic matters in particular, I proceed to make a few jottings that most likely may interest the readers of THE BRITISH JOURNAL OF PHOTOGRAPHY. But it may be as well to say at the outset that my acquaintance with the photographic matters of Philadelphia must be but partial in its nature, the extent of the city being so great as to require much more time than was at my disposal to "do" it properly.

Some idea of the magnitude of the city may be formed from a statement of the fact that several of its streets are from twelve to fourteen miles in length, that it covers a larger area than New York, although from the way in which the houses are separated, especially towards the outskirts, the population is very much smaller. Great, however, as is the extent of the city, a visitor may easily get through a greater amount of work in it than in any other city or town, with which I am acquainted, of even less than a third of its size, in consequence of the admirable way in which the streets are arranged and numbered. They all run at right angles from north to south, and from east to west.

Philadelphia is the worst-lighted city I ever saw, the lamps being very few and far between. A practical proof of this lack of lights occurred to myself on the second night of my stay there. I had been invited to spend some time with Mr. Browne, ex-President of the Philadelphia Photographic Society, at 907, Clinton-street. This is a short but aristocratic street running parallel with Spruce-street, but only the length between Ninth and Tenth-streets. The houses are all exactly alike, the only difference being that at the hour at which I called the *jalousés* universally found outside every window in the city—and the country, too, for that matter—were some open and some, and much the greater number, closed. The street was, of course, so dark that to see the numbers was altogether out of the question, but it was not at all necessary. Being between Ninth and Tenth-streets I knew that the first number must be 901 on the south side, then 3, 5, and 7, so that the fourth house must be the required 907. I rang the bell with as much certainty as if I had read the name on the door-plate. While writing of finding Mr. Browne's house, I may say that I received from that gentleman and his family a right hearty welcome. He is an enthusiastic amateur, one of a large number in Philadelphia, and as they all seem to read and admire THE BRITISH JOURNAL OF PHOTOGRAPHY I was treated more like an old acquaintance than a mere stranger.

From a long and interesting conversation with Mr. Browne I learned that in the Quaker City—in which, by-the-bye, I did not meet with a single Quaker, so far at least as being indicated by any peculiarity in dress—collodio-bromide emulsion, so far as amateurs are concerned, has driven the bath and all previous dry processes out of the field. The emulsion most in favour is one containing a free bromide; and, if the specimens I saw are fair samples of what American amateurs are doing with it, there are those that I know in the Old World who must either "put their better foot foremost" or cease to boast that England is ahead of all other countries in the matter of landscape photography.

The solar camera has never been kindly taken to in England or Scotland, probably because the sun is so often hidden behind a cloud; but some work shown me by Mr. Browne made me wish that it might yet become a favourite. It was a print from a 10 × 8 negative which had been made in the solar camera from a quarter-plate taken in a pocket camera, and it contained all the juicy vigour and brilliancy of a direct picture. The solar camera employed was partly home made, and looked more like a toy or a model. The condenser was only about four inches in diameter. The motion of the sun was easily followed by means of two screws, while the whole apparatus could be lifted by one hand as easily as a fiddle case.

Everybody knows how important it is to have locks on boxes in which dry plates are kept, but it is sometimes difficult to get them applied to boxes already in use. I saw on one of the boxes in Mr. Browne's collection a most ingenious and useful lock for this purpose. It consisted of two plates of iron—I think nickel plated—each about three-quarters of an inch by an inch and a-half. These could be applied—one to the lid, the other to the body—without any necessity for opening the box. On the lower plate there was a slot and a slightly-projecting stud, and when the latter was pressed a little to the side the box was clasped, so that it could not be opened until the stud was pressed back to its original position. Below the stud there was a tiny keyhole into which fitted an equally tiny key, and when this was turned the stud became fixed, and could not be moved till the key was again turned. I have never in Scotland seen anything so convenient for the purpose, and hope when I reach New York to see whether they cannot be introduced to some of our apparatus manufacturers, as I am sure dry-plate workers would appreciate them.

It fortunately happened that during my stay in Philadelphia a meeting of the Photographic Society was held, and this afforded me an opportunity of meeting a number of amateurs that I should not otherwise have seen. The Philadelphia Photographic Society is in a very healthy state, composed principally of amateurs, and presided over at present by Mr. Ellerslie Wallace—a gentleman who is known to many of the amateurs of both Scotland and England. The members present received me most kindly and hospitably, and I spent a very pleasant evening with them. America is a big country, and a country of big things, the bigness extending even to photographic picnics or outdoor meetings. The principal business of the evening was the discussion of the report of a committee on a proposal for an outdoor meeting—not a run out and in, with hardly time to unpack the camera, as is too often the case with us at home, but a trip extending over several days, and the enjoyment of a taste of camp life. The subject was evidently one of considerable interest, and nearly every member present spoke, and spoke well, the result being that an excursion of one hundred and twenty-five miles, to extend over a period of six days, was almost unanimously resolved upon, and to settle the question the signatures of all who could and would go were attached to a copy of the resolution. How they manage to arrange matters I don't know; most things seem much dearer here than at home—even the street shoeblack expects ten cents (fivepence) for cleaning a pair of boots—and yet the report of the picnic committee estimated the total expense for the whole six days and nights, including everything, at from twelve to thirteen dollars (£2 10s. to £2 14s. 2d.), or nine shillings per day. The conveyance was to be by canal boat, so that they could stop when and where they pleased; and judging from the genial, jolly spirit shown by those present at the meeting they were likely to have a pleasant time during their anticipated trip.

Photography in Philadelphia, judging from the show-cases, is on the whole somewhat ahead of that in England and Scotland, looked at from the same point of view. Retouching is practised, but not to such a large extent, and the negatives would seem to be fuller of delicate gradation and detail. Cabinets appear to be more in demand than *cartes de visite*, and a highly-glazed surface the rule, a simple albumenised surface being the exception. An embossed oval is the favourite style, and in a large, very large, majority of cases it is surrounded by a highly-ornamented, but far from ornamental, margin—a margin, in fact, in very bad taste, and which tends to attract the attention from the picture itself. Philadelphia contains about five hundred professional photographers; but here, as elsewhere, the wheat, especially "the finest of the wheat," bears a small proportion to the chaff—so small, indeed, that I was told by one of those whose work is of a very high class (Mr. Fennimore, whose name will be familiar to some of the readers of THE BRITISH JOURNAL OF PHOTOGRAPHY in connection with photographic literature) that there are probably not more than four or five first-class establishments in the city. This is, perhaps, somewhat under the mark, but I have no doubt that of the whole five hundred the really high-class men might be numbered on the ten fingers.

Mr. Gutekunst—whose wonderfully beautiful pictures and astonishing panorama of the Centennial Exhibition grounds have been exhibited recently in England and Scotland, seems by one consent to be regarded as *facile princeps* in the art—is worthy of more than a passing notice. Photography has evidently been a good friend to him, and he returns her kindness by executing his work as nearly perfect as it has ever been my privilege to see; and, by sparing no expense, he has made his establishment, for comfort, elegance, convenience, and facility for manipulation, as perfect as his work. Situated in a central part of one of the principal streets, it occupies an entire block or building of about six stories. The ground floor, with two immense plate-glass windows, is a saloon with an oval counter in the centre, at which are employed a number of very pretty and extremely polite young ladies, and *very* pretty young ladies are somewhat scarce in America. The walls are hung with a magnificent collection of photographs of all sizes and subjects, both plain and coloured; and from the bustle there, and also in the office at the rear, it is evident that a very large business is being carried on.

Attracted by the sound of a piano the visitor ascends the stairs leading to an elegantly-furnished and handsomely-decorated waiting-room, where there is quite a crowd of candidates, big and little, waiting their turn to be placed in the posing chairs; but kept from being wearied and in good humour by the music, which is continued during the whole day.

The studio, or studios (for there are two glass houses, or as they are called here "sky-lights"), are entered from the waiting-room, and if the visitor expects from their construction to learn the secret of Mr. Gutekunst's success he will be wofully disappointed. They are constructed precisely in the style almost universal in Glasgow, as described by me in a former series of "Notes"—a broad front light beginning at a height of about nine feet, and coming down to about four, at a small angle, and a side light of about six or eight feet wide, but pretty much blinded up. The sitter is placed on a circular platform some three feet in diameter, and five inches high. This platform is mounted on castors so as to run easily, and it does this so *very* easily that a little practice on roller skates might be a useful preparation to sitting for one's portrait on it. The backgrounds are also on castors, and Mr. Gutekunst seems to trust more to the position of the sitter relative to the lights than to any arrangement of blind, screens, or reflectors. In point of fact, although I saw at least half-a-dozen negatives taken, in which almost as many different effects were produced, the only changes made were the shifting hither and thither of the platform and background, the latter being simply a circular disc sliding on an upright rod on a heavy metal base, and painted in neutral tint from dark to light.

The exposures were, especially in the brilliant light of a clear American atmosphere, long—say from twenty to thirty seconds; but I am satisfied the negatives were all the better for it. In connection with the exposure I saw in use a pretty and, to my mind, novel device intended to overcome the tendency of the eye to become wearied and the expression to get dulled. It consisted of an upright box about fifteen inches high and eight inches square. On one of the sides there was an opening, the size of a *carte de visite*, near the top; on another a similar opening near the middle; on a third another below the last; and on the fourth one near the bottom. The box contained an octagonal cylinder on which were fixed a series of photographs, and as it revolved by clockwork each opening showed eight pictures passing in succession. The upper opening or frame (as it was ornamented so as to look like one) showed a series of eminent men, the second a number of beautiful women, the third some lovely children, and the fourth was rich in the comic element, including clown and pantaloon. The case also contained a musical box which could be made to discourse sweet music, and I feel sure that not a little of Mr. Guteknnst's success in catching the expression of his sitters is due to this pretty device and its effect on the minds of his sitters.

Mr. Gutekunst holds a Lambertype license for Philadelphia, but seems to confine carbon to large work; he showed me, however, some very fine specimens of it. The general impression seemed to be that there would be difficulty in working any kind of gelatine process during the very high temperature they have in the summer months.

The printing seems to receive more attention here than in the old country; and the printers are, on the whole, a more highly-educated class—I mean from a technical and artistic point of view—than those at home, and more attention seems to be given to washing, the use of tissue paper, &c., than with us. Here, as elsewhere, negatives accumulate rapidly, and notwithstanding that generally those four or five years' old are cleaned off, the stock at present on hand is considerably over one hundred thousand. Enlarging by the solar camera is more easily practised than with us, the sunlight being more generally available, and Mr. Gutekunst has two of these instruments pretty constantly in use. Some idea of the quantity of work done in this large establishment may be formed from the fact that while I was there an order was given for two new cutters for cabinet and *cartes de visite*, the economy from the use of which would be a saving of fifteen sheets of paper per day.

But I am afraid I have exceeded the space at my disposal for this batch of "Notes," and therefore must reserve the rest for my next communication. JOHN NICOL, Ph.D.

PHOTOGRAPHY AND THE FINE ARTS.

THE question is often agitated by originators of art enterprise whether photography belongs to the fine arts. Thirty years ago the daguerreotype infringed upon the liberal patronage extended to the painters of miniature likenesses, as large portraits were then only indulged in by a few wealthy families. During the past twenty years photography has made wonderful progress, both in popular esteem and in artistic quality, until the portrait painters acknowledge it as a formidable rival. They would fain decry its merits, but their criticisms are constantly disarmed by use in the preparation of portraits. Formerly the artist would secure fifteen or eighteen sittings from a patron, but now the usual custom is to obtain a preliminary photograph, to outline the figure on the canvas on an enlarged scale, which is constantly corrected by callipers, and after the first sitting for general likeness and colour to paint the drapery from the lay figure, guided by the appearance in the photograph, so that the man of business or the lady of fashion feels that only time can be given for three full sittings. The painters and sculptors will not accept the photographer as an artist, as they claim that his work is the result of mechanical and chemical processes, and does not depend on the necessary quality of design in all artistic work. Still the best photographers study as critically their composition of groups, arrangements of drapery, and position of the individual, as can any one using the brush, and the very difficulty of arranging the focus for all portions of the body, and the distortion in shape and size according to the respective distance from the optical centre, cause the operators to take great caution. With the advance of the profession, no operator can retain his position in a first-class gallery for a single week whose attainments are not greater than a complete knowledge of chemical and mechanical operations.

The want of recognition of photography is a fashion, the relative rank being that accorded in the infancy of the profession, and this is perpetuated by its management as a business. The operators and even the art assistants in crayon and water colours are unknown to the public, the work being credited to Black, or Sarony, or Gutekunst, without any notice of the individual professional talent employed—a system not conducive to the production of individuality of work, only so far as the proprietor of a gallery may have artistic skill, and is thus able to use his several *employés* as instruments to accomplish special ends. Yet no skill can elevate the work of artisans to lofty standards until they become artists, with quickened brains and fresh, original ideas.

The press has been forced to draw a broad line between artists and photographers, not alone because of the sensitiveness of the former class, but also from the unwillingness of the latter to submit to the fresh, healthy criticism which the painters must always meet. Like the artists of the whole West they exclaim that the time has not yet come for a full and free statement of merits and demerits; hence notices can only be given in a general manner, and it is only occasionally that a man can be found who courts the most candid examination and close discrimination of his work. A few months ago the experiment was tried of visiting the principal galleries of Chicago, and while the proprietors would gladly have paid money to obtain flattering notices, yet they instinctively shrank back from the trenchant pen freely employed to review the productions of the artists, and were offended at the plain words of disinterested criticism.

There is very much in the profession of the photographer to command high respect, and it is confessedly so much the popular portraiture of the day that it is knocking loudly for admission into artistic circles. The display of the American photographers at the Exposition Building in this city for a few days of July, 1874, was one of great interest, though no discrimination was made and thousands of inferior pictures were displayed; yet two months later the photographers were reluctantly admitted to a small space in the art hall, and the next year they were excluded altogether. The principle of hanging in the fall of 1874 was the only admissible one in connection with an art hall, for the manager arranged them on the walls according to intrinsic worth and to secure the most desirable general effect; but there was no previous selection, and all were allowed to furnish the same number of pictures. It might seem to many a backward step, and the art committee of another year might feel that it was an ungracious task, since the novelty of the step would provoke much adverse criticism, and few photographers have sufficiently advanced ideas to accord with the scheme; but it might not be a bad movement to make similar advances to photographers as to artists, selecting the best photographers, not alone of the United States, but also of India, Austria, Germany, France, and England, to solicit choice examples of their best work in all departments, and affording also to local operators the opportunity of presenting works of real merit.

All the common groups of pictures in one large frame should be positively excluded, both as unartistic in arrangement and positively uninteresting; for if a small picture has merit it deserves to be studied independently, and no multiplication of similar forms can add worth where it does not really exist. Merit should be the only question governing admission, though the space accorded by the art committee would necessarily limit the number of any special class of pictures to be accepted. Variety would be necessary to secure public attention to the collection, and as the fields of art based on photography, such as the prints finished in crayon, or in water colours, or in oils, crayons drawn after photographs, and similar pictures might properly be included, there would be no reason why this portion of the art display, by judicious pruning and efficient management, might not be made as profitable in developing a love for fine art as any of the departments with more lofty aims.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
May 6..........	West Riding of Yorkshire......	Oddfellows' Hall, Thornton-road.
,, 8..........	Glasgow	172, Buchanan-street.
,, 8..........	Cheltenham Amateur	Savings' Bank.
,, 9..........	Manchester....................	Memorial Hall, Albert-square.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE usual monthly meeting of this Association was held on Thursday evening, the 25th ult., at the Free Public Library, William Brown-street,—Mr. H. A. Wharmby, President, in the chair.

The minutes of the previous meeting were read and passed.

A letter from the Hon. Sec., Mr. W. Murray, was read, announcing that the presentation print for 1877, the *Arch of Constantine*, from a negative by Mr. O. R. Green, was now in the hands of the Autotype Company.

Mr. Moore sent some fine American cabinet and *carte* pictures for exhibition.

The Rev. H. J. Palmer passed round gelatine negatives by his favourite process on glass and on films, also two groups on Bennett's instantaneous plates, with which he was much pleased.

Mr. Weber had some fine lantern slides from negatives by the gelatine process.

The President exhibited a number of $7\frac{1}{4} \times 4\frac{1}{2}$ negatives on washed emulsion plates.

It was proposed by Mr. J. H. T. Ellerbeck, and seconded by Mr. W. H. Wilson, that the question of this year's presentation print should stand over until after the midsummer recess, and that members be invited to prepare negatives for competition for this purpose.

It was also decided to have an excursion to Speke Hall, on May 11th or 18th, if the requisite permission could be obtained.

The meeting afterwards adjourned until the 30th inst.

THE PHOTOGRAPHIC SECTION OF THE AMERICAN INSTITUTE.

At the February meeting of this Society Mr. H. J. Newton, the President, occupied the chair. After some preliminary business had been disposed of,
