"The effect of a strong developer is to reduce intensity, making the image appear thin, and lacking sufficient contrast; while a too weak developer brings the image out slowly and too intensely in the high lights, leaving the shadows comparatively bare. Another effect of a developer of this character is that the reduction set in motion by it is so slow that the shadows become fogged before the lights are sufficiently brought out; and the same effect is caused by a strong developer, because the reduction of silver is too rapid to be properly watched, so that before the developer can be washed off the silver has been deposited on all parts of the negative, giving the shadows a misty, veiled appearance."

Recognising the unfortunate fact that among portrait photographers are occasionally to be found some who are rude and unmannerly—whose every word, gesture, and action produce a discordant and worrying effect on the unfortunate sitter who has submitted herself or himself to the tender mercies of such a boor—Mr. Heighway is of opinion that those who, while not belonging to the above category, but are possessed of an unsympathetic nature fatal to the obtaining of a good expression, may, to a great extent, overcome that cause of non-success by feeling and expressing an interest in, and consideration for, the sitter which will in most cases call forth a corresponding feeling. "There is no formula," says Mr. Heighway, "for making *expression*, but by observing those simple rules of kindliness, courtesy, and consideration very much may be done to set people who visit photographic galleries at their ease, and to lighten to a considerable extent your own trials."

In this work the practical character is kept up to the very last, the concluding chapter being devoted to the reception-room. We here find many useful hints in connection with business matters, such as "appointments," "resittings," and suggestions as to the treatment of sitters. This manual, which has reached a second edition, is replete with useful matter to photographers.

EXAMPLES OF SUBTERRANEAN PHOTOGRAPHY. By WILLIAM BROOKS.

IT is several weeks since we were made aware that Mr. Brooks had undertaken and successfully accomplished the extremely difficult task of taking photographs of the interior of a number of caves in Reigate, situated at a depth of about sixty feet below the surface of the earth. These caves are in the possession of a wine and spirit merchant, by whom they are used as vaults in which to store the various liquors he dispenses.

In the early part of this summer the occupant, Mr. Charles Mead, conceived the desirability of having a series of photographs of these caves taken, and for this purpose consulted Mr. Brooks, who, after several trials and overcoming numerous difficulties, eventually succeeded in obtaining eight fine negatives, from which have been printed, by the Woodbury Company, the examples now before us.

The source of illumination of the caves, the sides of which are encrusted with a greenish-black, slimy matter, was a collection of paraffine lamps. These were of the kind in common use, costing eighteenpence each. Sixteen of these lamps were employed. In the course of the preliminary experiments the lime light was made use of, but it was not found to possess advantages equal to the paraffine lamps, which, when in use, were arranged and distributed so as to illuminate the place evenly, without the lamps themselves being seen. The plates used were gelatine emulsion plates, respectively of the Kennett and Bennett "brands," supplemented by some prepared by Mr. Brooks himself. The lens was a stereoscopic portrait combination, employed with its full aperture, the exposures given varying from one to five hours for each picture. The negatives having been obtained, transparencies were then produced from them by means of collodion emulsion, care being taken to ensure the greatest possible uniformity in regard to the density; for the series of transparencies thus obtained were mounted in juxtaposition, and in this state served to produce a negative of the whole on one plate, from which were printed, in Woodburytype, the eight subterranean views.

The difficult task we have described has been most successfully accomplished by Mr. Brooks; nor must a meed of praise be omitted to be awarded to the Woodbury Company for the excellent manner in which the views have been printed—eight on one sheet.

Correspondence.

GLASS STEREOSCOPIC TRANSPARENCIES.

To the EDITORS.

GENTLEMEN,—In respect to the reply of Mr. S. H. Oakes to my article (which appeared in your issue of August 16th), I beg to inform that gentleman that if he read it once more he will find it was written for the benefit of those who object to cut their negatives in half and transpose them before producing the transparency, or having to make two exposures, which, of course, entails extra apparatus. Cutting the negatives has always been a stumbling-block with many, both professional and amateur, and therefore I contend that the information given in my communication supplies that long-felt want, whatever may be the disadvantages Mr. Oakes may see in it.

He says he has a more lengthy communication on the same subject, which, I presume, he thinks is certain to be better than mine. I hope it may be. In journalism it is always very difficult to write upon any subject without some one finding fault with it. That, in a sense, I do not object to, but I should like to know in this case what are the disadvantages to which he objects. I cannot help thinking that in the reply of Mr. Oakes there is something of narrow-mindedness displayed, as he appears to play the parts of judge and jury.

I gather from the third paragraph of Mr. Oakes's letter that he thinks it unnecessary to make the transparency on glass. For myself I have not found a better substitute. There are now plenty of those French paper transparent slides in the market which will not bear comparison with those made on glass. In respect to turning a glass transparency out to be sold to an appreciative public at a shilling, I think that would be going to the extreme, and I do not think that any manufacturer could be able to turn them out fast enough before the bankruptcy court put a stop to it. I think if a good slide were made to sell at (say) two shillings, or, at the outside, half-a-crown, a manufacturer with divided labour would meet with a fair amount of support that would pay him and command a steady sale.

Whatever I write in regard to photography I give the result of my experiments for the benefit and progress of whom it may concern. For the past two years I have scarcely been able to rank myself as a professional photographer owing to ill health, but have engaged myself more in experimental work, and some of the results I have made known through the medium of the South London Photographic Society and the photographic press.—I am, yours, &c., WM. BROOKS.

Reigate, Surrey, August 24, 1878.

POLYTECHNIC EXHIBITION, FALMOUTH.—We have been informed by the Secretary that in consequence of the large number of photographs exhibited at the present exhibition the awards were not completed in time to be reported in this week's issue, but will be given in our next number.

SUGGESTED TAX ON PHOTOGRAPHS.—I understand that Sir Stafford Northcote has had it suggested to him by a "financial adviser" that if next session he finds it necessary to impose any new taxes he ought to increase the duty on tobacco and impose a stamp duty on photographs. This latter tax ought not to be unpopular, and it cannot fail to be remunerative. Nobody will sympathise with the grievance of the "cad" if, when he buys a *carte* of Mrs. Langtry or Mrs. Cornwallis West, in order that he and his friends may gloat over these fashionable beauties, he is mulcted for the benefit of the State. A tax on photographs is, to a large extent, a tax on vanity and "snobbery," and for fiscal purposes these foibles are surely fair "game."—*Mayfair.*

THE PROGRESS OF POIKILOGRAPHY.—It is a year since we directed attention to some excellent reproductions of oil paintings in *facsimile* executed by means of a process in which photography, aided by oil pigments, was employed so as to produce copies of works of art that could not be distinguished from the original paintings. Since the time of the appearance of that notice Signor Lombardi—under whose fostering care and skilful treatment the process of "poikilography" has been introduced so successfully—has made still further improvements, by which, to the beauties originally inherent in these pictorial treasures, are now added the further advantages of their being produced upon the canvas or other textile fabric desired in permanent pigments. The securing of this end without the sacrifice of other good qualities has been effected only after a long course of experiments, in which difficulties have been encountered only to be successfully overcome. We have already published the chief details of the process of poikilography; the nature of the most recent improvements we cannot yet divulge for several weeks until in due course of time we are enabled to do so by the operation of the patent law under which protection has been granted for the invention. In the meantime we are empowered to freely invite our readers to visit the collection of poikilographs now on view in Signor Lombardi's galleries, Pall Mall East, in order that each may judge for himself the nature of the improvements recently effected.

EXCHANGE COLUMN.

No charge is made for inserting these announcements; but in no case do we insert any article merely *offered for sale*, that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a *nom de plume* be thought desirable), otherwise the notice will not appear.

A first-class burnisher will be given in exchange for a good retouching desk.—Address, J. Stead, photographer, Northallerton, Yorkshire.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

Notice.—Each correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a *nom de plume* as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

Devoniensis.—A rectangular prism will not reflect light into a lens possessing even a moderate width of angle, unless the back is silvered.

Constant Reader.—The American Company are said to produce their admirable phototypic blocks for surface printing by the Leggotype process, the details of which will be found in one of our previous volumes.

Silber.—1. A *mètre* contains one yard and three and three-quarter inches of our English measurement.—2. It would be somewhat impracticable to compile and publish such a directory as you propose, as the time is not yet ripe for it.

J. (Aldershot).—Your idea is scarcely new, for about ten years ago we published a suggestion made by one of our correspondents to the effect that a developing agent might be applied to the plate coated with bromised emulsion previous to its exposure to light, the formation of the image being watched through a hood.

Astronomicus—The telescope to which we alluded as now being in course of construction is a *refractor*, the object glass being twenty-seven inches in diameter. The Melbourne telescope is a *reflector*, the speculum of which is four feet in diameter. From this you will see that there is no inconsistency in our observation.

H. J. R.—Dry plates are not required for the purpose mentioned by you, namely, securing negatives of the houses and scenes in the locality in which you reside. A wet collodion plate, if carefully prepared, well drained, and placed in a tightly-fitting dark slide, will keep quite good for all the time you require it to do so.

M. D.—Thanks for enclosing the cutting, which we have read attentively. It is one of the strangest jumbles of science and absurdity which we have ever perused. The writer must have penned it when he was under the simultaneous influence of science, a desire for penny-a-lining, and some fluid stimulant of a much stronger nature than either tea or coffee.

Auld Reekie.—While denying the premisses *in toto* we quite accept the conclusion; for the experiment recorded is within our own range of experience. What we object to is your method of accounting for it. The subject is one which you had better discuss in the pages of the *Spiritualist* or *Medium*—weekly journals devoted to topics connected with psychology.

George Hogg—The kind of phosphorus known as "*Bolognian*" is the most effective for producing phosphorescent photographs. Make into a paste a mixture of sulphate of barytes and a solution of gum tragacanth; then place it in a crucible, which must be covered and exposed for half an hour to a very strong degree of heat. A whitish product is obtained, which is the phosphorus in question. It must be reduced to a fine powder and carefully preserved in a well-stoppered bottle.

W. Fisher, Jun.—There is no distortion, viewing the question from the prospective point of view, nor is there any want of truth, mathematically speaking, in a portrait obtained under the circumstances recorded. But, viewed from quite a very different standpoint, there is both distortion and want of truth in the same picture, because it conveys to the spectator an idea entirely at variance with truth. The boulder weighing only four pounds is simply made to "tell a lie" when it is introduced into a photograph under such circumstances as to convey the idea of its being a rock of the height of thirty or forty feet. Respectable photographers should never lend themselves to tricks like this, by which the art is degraded.

W. W.—We hope to be in a position soon to publish valuable information resulting from the observations of the recent eclipse. This, however, will scarcely meet your difficulty, which must remain unsolved for another century or two, we fear.

J. W. B.—A gelatine emulsion may have its soluble salts removed either by the means described by Messrs. Wratten and Wainwright in our last Almanac or by forcing through one of those syringes which have been introduced for effecting the removal of salt from butter. The congealed, although not dried, gelatine is placed inside the cylinder, and the piston being then forced down upon it causes the emulsion to emanate from the holes in the end of the instrument in vermicular forms. This is received in plain cold water.

Geo. Ross.—Major Russell's *quick* tannin process will certainly answer the purpose better than any of those you mention. We cannot here give more than an outline of that process:—Let the collodion contain eight grains (to the ounce) of bromide of cadmium; excite the plate in a sixty-grain bath for at least a quarter of an hour, wash thoroughly, and then apply a ten-grain solution of tannin, which must afterwards be removed by washing when dry. The exposure required is rather less than that necessary to be given to a wet collodion plate, it being of course understood that the image is to be developed with alkaline pyro.

G. P. B.—To prepare ox-gall try the following:—Procure from a butcher half-a-pint of the gall, place it in a clean saucepan and add one ounce each of common salt and powdered alum. Place it over a fire, and when it boils remove it for half-an-hour to cool; then boil again, and repeat this boiling and cooling three or four times. After this allow it to settle for four hours and decant off into a bottle, into which put a few drops of essence of lemon; cork and preserve for use. Our correspondent's inquiry has relation to the "best" mode of preparing ox-gall, and we give the foregoing as the best of which we are at present aware. Should any reader know of a better we shall be glad to have it communicated.

A. E. D.—This correspondent's occupation as an artist in a photographic establishment enables him to overhear the conversation which goes on in the studio, and he is of opinion that it would be both amusing and interesting if those who know the pet expressions of operators to the sitters when about to "expose" would send them for publication. "My experience," he observes, "in this matter is that each man has a favourite expression which he repeats to each sitter; and, even if he take a brother operator, he, through force of habit, still gives the final warning to 'keep quite still,' or (as one principal of an establishment used to say) 'now, perfectly rigid'—an expression devoid of artistic association. The operator, I now hear, does not warn sitters when the exposure is to take place, but tells them he will let them know when it is done! Another whom I remember always said "now, do try and look a little more miserable!' and behold a grin was evoked. Another conversation I overheard between two operators about testing the strength of a nitrate of silver bath. One said the argentometer was a fair test for indicating the strength of an *old* bath. The other disagreed, saying that the ether and alcohol interfered with the argentometer giving a true register of the strength. Whether true or not I should think if it registered as low as ten grains to the ounce there could be no doubt about its wanting replenishing." After reciting other instances of overheard conversations, our correspondent concludes by again asserting that great interest would be felt if those competent to do so would collate and report such expressions. We shall gladly receive such.

Received.—Draper's *Scientific Memoirs.*

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 957. Vol. XXV.—SEPTEMBER 6, 1878.

ON THE ALLEGED ADVANTAGES OF PRELIMINARY EXPOSURES.

It will be remembered that a few weeks ago, in our number for July 12th, we had occasion to refer to the alleged increase of sensitiveness obtained by a brief preliminary exposure of silvered paper to the light previous to its being placed in the printing-frame. Some little ambiguity exists as to whether the gain claimed is actually a general increase of sensitiveness, or whether it consists only in obtaining, as Mr. A. M. de Silva states the case in *Anthony's Photographic Bulletin*, *more detail in the lights.* We are also in doubt as to whether the writer, in speaking of "tinting" the paper, intends to convey that an actual discolouration is to be produced by the pre-exposure or whether the latter is to be so brief as to produce no visible effect. However that may be, the remarks we made at the time referred to, and based upon a *literal* repetition of Mr. de Silva's experiments, showed that we had been unable to reproduce the effects obtained by that gentleman.

Since then, however, an accidental circumstance arose which led us back to somewhat similar experiments in a modified form, and the results were such as justify us in recurring to the subject, more especially as we are unwilling to condemn, through a misconception, what may possibly be not only theoretically correct but also practically useful. In describing the new experiments we shall endeavour to point out where the misconceptions and ambiguities have arisen to produce such a variety of opinions as exist upon the alleged efficacy of pre-exposures.

The circumstance to which we have alluded occurred in the course of some trials of the printing qualities of three or four different descriptions of sensitive paper. These were exposed, side by side, under a rough sort of actinometer scale, formed by the superposition of various thicknesses of fine-grained paper, and it was noticed on one occasion that after exposure for a whole day a certain number of tints had become visible upon each sample of paper under trial; and, further, that during nearly one-half of the time of exposure the only change that had taken place was in the gradual strengthening of the tints already impressed, no fresh ones becoming visible. From this we inferred that the limit of actinic transparency had been reached, and that the light was incapable of penetrating through a greater number of thicknesses of the paper composing the scale.

Judge of our surprise, then, when upon again exposing the frame next morning one of the samples of paper within an hour showed a new tint, and in the course of the day each of the others successively followed suit. It was very obvious that the strength of the light could not have varied to such an extent as to enable it to penetrate in a single hour a thickness of semi-opaque material which had perfectly resisted its action during a whole day. It might certainly be so under some circumstances, but in this case both days were bright and sunny; in fact, as nearly equal in actinic power as it is possible for two consecutive summer days to be.

The only conclusion we could arrive at was that the previous day's exposure had had its share in the effect; that, in fact, an invisible action, occupying an appreciable time, must take place before the visible impression is produced. Looking at the facts in the most straightforward manner, it is impossible to deny the justice of so much of the theory involved; for, were it not so, the immediate—nay, instantaneous—effect upon exposing a piece of sensitive paper to daylight behind a negative would be the production of a faint image in all its details. Against this it may be urged that light requires an appreciable time to penetrate even so transparent a medium as the atmosphere, and that, therefore, the varying density of the details of the negative would retard its progress and so cause the gradual appearance of the different portions of the picture. But, even granting the truth of that, we have to get over the fact that a piece of silvered paper entirely devoid of visible image is capable of producing one under development, showing clearly that an invisible action has really taken place.

In order to test the matter in a practical manner we constructed a scale of only four "tints," composed of one, two, three, and four thicknesses respectively of the same paper employed previously. We found by experiment that the approximate exposures necessary to colour the paper under each of the tints were fifty seconds, two minutes, six minutes, and twenty-one minutes. A strip of sensitive paper was now exposed for fifteen minutes under four thicknesses of the same paper used for the scale, or, in other words, it received something less than three-quarters of the exposure necessary to produce a visible discolouration under those circumstances of lighting. It was then placed side by side with another strip of unsunned silver paper in the four-tint actinometer and exposed; for the sake of clearness in describing the results we will designate the exposed strip *a* and the unexposed *b*.

After thirty seconds' exposure *a* showed the first tint clearly, in one minute the second also very distinctly, while *b* gave the first faintly. In a minute and a-half no further change beyond a strengthening of the tints was noticeable; but two minutes produced the third tint on *a* and the second upon *b*—the latter very faintly. Up to five minutes' exposure no fresh tints appeared, and at this point there was scarcely any difference to be detected between the first tints upon the two slips; but No. 2 was distinctly stronger upon *a* than the corresponding one on *b*, at six minutes No. 3 was feebly shown upon *b*, and seven minutes brought out the fourth and last upon *a*, *b* remaining perfectly uncoloured.

We make no apology for thus minutely describing this simple operation, but ask our readers to study it carefully, as it contains, to our mind, a very plain exposition of the action and effect of the preliminary exposure. We expose simultaneously two strips of sensitive paper, each perfectly uncoloured, and at the end of seven minutes the most feebly-illuminated end of one of them shows a result which the other would have required an exposure *three times as long* to produce, while at the same time the action at the better-lighted end is practically identical in each case. This agrees entirely with Mr. de Silva's experience in obtaining a tint through his yellow paper mask upon the sunned paper while the unexposed part remained clear, and we may now say a word or two upon the discrepancies between these results and our former ones.

In the first place we previously followed that gentleman's instructions literally, and slightly tinted the paper *visibly* by direct exposure to the light. Now we are of opinion from the above experiment (and others of so similar a character that they are not worth recapitulation) that so soon as visible discolouration commences any advantage otherwise obtainable is lost. The only object of the auxiliary exposure is to set in motion and *nearly*, but not quite, complete the invisible change, and so render the paper more sensitive to feeble rays. The effect is simply to accelerate the starting power (if we may so term it) of the visible action, which, when it once commences, proceeds with equal rapidity upon the sunned or unsunned paper, and in proportion as the exposure is prolonged so does the advantage accruing to the feebly-lighted tints gradually disappear. In the experiment previously quoted, with an equal depth of tint in the lower shades the highest grade on the scale is reached in one-third of the time upon the pre-exposed paper; but so slowly does the visible action progress under the four thicknesses of paper that after half-an-hour's exposure little, if any, difference is noticeable between any of the tints on the separate papers.

It will, of course, be understood that in employing a scale of four widely-distinct tints, as we have done, the effect will be far more pronounced than if the delicate gradations of a negative were in question; but, at the same time, it is plain that in the case of a very dense negative, provided that detail exists in the high lights, there will be a chance of bringing it out without bronzing the shadows or over-printing the half-tones. The function of pre-exposure, whether applied to paper or to a film in the camera, is the production of more detail with a given exposure; in the case of printing, at least, it is a misnomer to call it an increase of sensitiveness, for the time required to produce the necessary depth of reduced silver in the shadows will not be appreciably reduced. In a camera exposure the conditions are altered; the necessary depth of deposit can easily be obtained in the lights if only the feeble details can be brought within the scope of the developer, and in this connection the result may be practically a reduction of the exposure necessary to produce a certain result.

Theory and practice, it is needless to say, are two very different things; and while we are ready to uphold the correctness of the principle of auxiliary exposures, we do not for one moment believe or wish others to believe that the advantages are to be attained without a good deal of care and judgment. We know how widely authorities differ as to the utility of the various "dodges" and patents which have appeared, such as coloured glass in the camera, translucent caps for the lens, exposure of the plate to the flame of a candle, and sunning the paper (or "dashing" it, as Mr. de Silva is pleased to call it). We are ready to believe that where one man fails with all or any of these methods another may succeed; it is merely a matter of comparative skill and thought in carrying out the details of *the principle*. "Judicious fogging" is one of its epigrammatic designations, but "fog" means a general reduction over the whole surface of the plate, which is certainly not the case if the auxiliary exposure be carefully and properly applied. Following Dr. Spottiswoode's suggestion, we might, did time permit, enter into a mathematical discussion of the problem, and prove that the gain is in inverse proportion to the actinic value of the gradations of the picture; that, in fact, it is greatest where it is most needed—in the deepest shadows.

A NEW MATERIAL FOR BACKGROUNDS.

No matter how fine may be a photographic portrait, no matter how exquisite its modelling or how perfect its *chiaroscuro*, if the background of such a portrait be bad the eye cannot readily appreciate the points of excellence in presence of the defect. Many an otherwise fine portrait has been condemned by the *cognoscenti* or rejected by the client on account of spots, patchiness, or inartistic inequalities in the background—defects which it is impossible to remove save by the expenditure of much labour on the part of the retoucher. Nor are these defects due solely to slovenly manipulation; for in the majority of cases they are found to be attributable to the exceedingly imperfect backgrounds to be found in so many studios.

Without implying aught save the highest degree of skill on the part of the manufacturers of backgrounds at home, it still must be admitted that an incentive to further efforts in this branch of manufacture has recently been given by the importation of "grounds" of transatlantic preparation, in the adornment of which imitative art has been laid under contribution to a very great extent.

We always are, and ever have been, most ready to gladly acknowledge every improvement—whether in the æsthetics, the chemistry, the practice, or the mechanics of photography—with which we have been favoured from America; and in this spirit we acknowledge a matter which, although belonging to what some may consider the less important things of photography, yet is, in our estimation, destined to exercise an important influence for good. It belongs to the category of studio appurtenances, and which may be pressed into photographic service, doing double duty, namely, as a blind and as a background. It is in the latter capacity that we speak of it at present.

From Messrs. J. Avery and Co., the well-known window-blind manufacturers, Great Portland-street, we have received several samples of an American material entitled "The Empire Patent Cloth." This material was originally prepared (under a patent to which reference will be made hereafter) for the purposes of window blinds; but it was soon discovered by a sharp photographer that it possessed exceptional value as an article to use for backgrounds. The material is a textile fabric—not very thick, but exceedingly pliant. Its surfaces are prepared in such a manner as to render almost invisible the meshes of which the fabric is composed, which is the point that chiefly concerns photographers—the surface being both quite dead (in the sense of its being matt or non-reflecting) and also possessing a singular uniformity of colour. These qualities testify to its being, *par excellence*, a material suitable for plain backgrounds.

In the collection of samples with which Messrs. Avery and Co. have favoured us we recognise no fewer than twelve distinct varieties of colour, a large number of which are suitable for backgrounds, some being, of course, much more so than others; and we have been informed by the principal of the firm that it is quite easy to prepare the fabric so that each side shall be of a different colour.

Upon subjecting larger samples to the practical test of being photographed they amply bear out all our anticipations, the effect produced being very excellent.

It might be thought that in accordance with our custom when treating of patented articles we should here give details of the manner in which the fabric is prepared. This will follow in due course; but, meanwhile, we may state that a benzole varnish being employed as the menstruum in which the pigment is contained water does not appear to produce any deleterious effect upon the fabric. Among photographers the material will, undoubtedly, meet with a hearty welcome.

COPYING OIL PAINTINGS.

In treating of this subject last week we broke off our instructions at the point where the due lighting of the canvas was under consideration—a subject of primary importance, no amount of skill and attention, even with the use of the most complete apparatus, being able to counteract the effects of improper illumination. We have laid down as a practical canon that "the nearer the illuminating area lies towards the edge of the picture the more is its reflection thrown away from the lens." And this will be found the best method of allowing the light to fall upon the picture, sufficient allowance being made for the respective sizes of picture and skylight. Thus, for instance, it would clearly be wrong to have only a portion of the lights uncovered a few feet wide with a picture ten or twelve feet long.

To give an example of the mode of illumination we recommend we will suppose a picture is firmly arranged in its place in the studio and focussed accurately, which may be done with the full aperture and all the skylight uncovered. Upon looking at it, standing immediately in front of the camera, we should possibly see a mass of glare and light which would quite obscure the details of the picture even to the eye; far more would it do so when photographed. If, now, the blinds be gradually covered over so as to leave only about two or three feet in advance of the picture for the light to come through, a magical effect will be produced. All the glare will disappear, and from corner to corner the picture will be visible, and will photograph equally well, excepting, of course, that want of accordance in the scale of colours which we are always familiar with.

The next step—the exposure required—is one of some little difficulty, as it is obvious that the less the light employed the greater the difficulty in giving sufficient exposure to the plate and in obtaining density. Some old pictures throw off so little actinic light that the exposure needed may be an hour or more, and they are the more difficult seeing that, as a rule, the older they are the more uneven is their surface, requiring in consequence the greatest restraint in lighting. But with careful and well-judged timing a negative of fair intensity will be obtained with the most difficult picture. As much density as possible should be obtained without forcing it before fixing, and then a judgment can be formed as to the process to be employed for intensification; but we must here say that it is only in rare cases that it need be resorted to. In nineteen cases out of twenty any picture brought to the studio should photograph so as to give a negative requiring no intensifying after fixing, a little extra pyro. and silver only being required before the application of the hypo., which should always be used in preference to cyanide, the latter having a tendency to reduce intensity in some cases. When sufficient printing density has not, however, been obtained the negative should be well washed and pyro. and silver used. If the negative be very weak it may be preceded by a wash of iodine in water about the colour of sherry. In a case so exceptional that none of these expedients give sufficient density Schlippe's salt may be used, or, indeed, any of what may be called the special intensifiers with whose action the operator is most familiar.

In cases where the picture cannot be removed the lighting is often entirely of a fixed nature, and very little under any control; but even then it will usually happen that there will be one or more windows whose light *must* be screened to avoid reflections. The rule we have laid down may be brought to bear in forming a judgment in such cases. Mirrors, too, may have to be made use of again, but placed much at one side of the picture.

It will frequently happen that the canvas is covered over with a sort of milky-looking film. This must be removed or mitigated before beginning operations, or it will fog and destroy the brilliancy of every negative, whatever exposure be given. It may arise from three causes:—First, a deposit which gradually accumulates upon all surfaces in dwelling-houses when they are not kept clean by friction, &c.; secondly, from a gradual change of their surface which some varnishes undergo in course of time; and, thirdly, from an improper application of the varnish in the first instance, which causes the effect to be seen at once.

The first effect may easily be remedied by sponging with clear cold water, followed by gentle rubbing with a clean dry cloth, the picture after this simple process being sometimes wonderfully improved. The second defect should only be temporarily cured by the photographer, who, of course, would not think for a moment of varnishing a painting entrusted to him. But if the picture be free from cracks he may put a few drops of nut oil upon its surface, and gently smear it all over by means of a rolled-up piece of linen, gently rubbing it over till a mere trace is left behind. This will not injure the picture, and for the time will cause it to present the appearance of a recently-executed painting, in which state it will photograph very easily. The whole can then be removed by one or two perfectly dry cloths, and the picture be none the worse for the operation. This last plan is best put in force after the picture has been sponged and dried. The third defect we have named can only be cured by removal of the varnish and revarnishing by an experienced picture cleaner.

In conclusion: we would say that beyond the simple methods we have pointed out no tampering whatever should be attempted with any picture entrusted to the photographer for copying, as incalculable damage may easily be done through apparently the simplest treatment.

RECENT PATENTS.

No. XIV—WOODBURY'S METHOD OF PHOTOGRAPHING FROM A CAPTIVE BALLOON, AND HIS PORTABLE CAMERA.

At the last photographic exhibition held in London there was exhibited a camera which, as respects compactness and portability, possessed certain features of novelty, the leading one being found in the fact that the packing-case—a neat mahogany box—forming part and parcel of the camera was used for the twofold purpose of forming a packing-box for the instrument when folded up as well as that of a base-board on which to erect the camera when expanded for use.

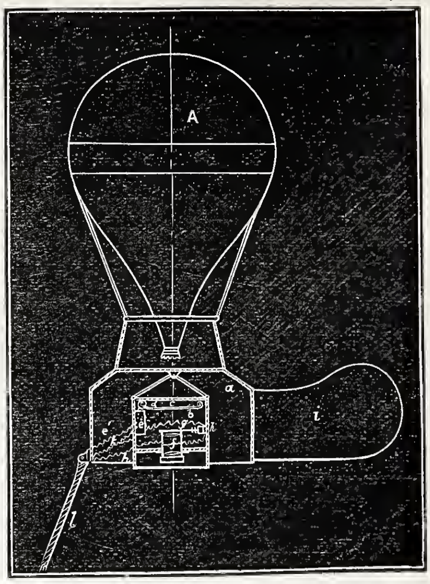
We are at length in a position to redeem the promise we made when, in alluding to it last year, we observed that as it had then just been patented we should embrace an opportunity of describing it in detail as soon as the specification of the patent had been published. This we do in the present article.

Conjoined with the portable camera, Mr. W. B. Woodbury, the patentee, has also secured in the same patent a second invention, which consists in the means of obtaining photographic views of *terra firma* from a balloon anchored, so to speak, at any desired height above the earth's surface. In what manner this is proposed to be effected will be discovered from the following detailed description. Following the order of the specification of the patentee, we deal first with the balloon and afterwards with the portable camera, between which instruments, we desire it to be observed, there is nothing in common farther than that, to save time and trouble, both inventions happen to be associated in the same patent:—

This invention relates, firstly, to improvements in apparatus for obtaining photographs from a sufficient height above the surface of the earth by means of a "captive" balloon (or balloon held down by a rope) carrying the necessary photographic apparatus, the necessary manipulations for the purpose of manipulating such apparatus and obtaining the photographs being effected by an operator on the earth by means of suitable electro-magnetic apparatus actuated as desired through insulated wires entwined with or supported by the rope which connects the balloon to the earth. In the place ordinarily occupied by the car of the balloon is attached a box of sufficient size and of suitable material, open below, and having attached to one side of it the rope by which the balloon is held. At the opposite side of the box is fixed a vertical plane of as light material as possible, serving as a sail or rudder, the action of the wind upon which prevents the balloon from turning round. In the inside of the box is suspended upon a pivot fixed in the top of the first box a second box or camera, which thus remains always horizontal. This second box or camera is provided with a suitable photographic lens, pointing downward, at the proper distance above which is arranged horizontally a dark slide provided with two rollers carrying a sheet or strip of flexible tissue made sensitive to the action of light in the way well understood and practised. One of the rollers is provided with clockwork, by the revolution of which the sheet of sensitive tissue is drawn forward from one roller to the other, as desired, and this clockwork is made to revolve for a sufficient time, when desired, by the action of electro-magnetic apparatus connected with it, and set in operation by completing or interrupting a current of electricity made to pass through insulated wires passing to the earth either with the rope which holds the balloon or suspended to such rope. The clockwork may be actuated by a spring retained by a detent, which can be released by the electro-magnet when required, or it may be actuated by a detent or driver operating upon a ratchet wheel, and set in motion by the electro-magnet. Another electro-magnet, actuated by separated insulated wires, actuates a shutter arranged in front of the lens, which latter can thus be instantaneously uncovered and reclosed when desired. The instantaneous shutter may be composed of a disc of metal, ebonite, or other suitable material, having an aperture near one of its sides, and made to revolve rapidly in front of the lens when required by means of an india-rubber or other spring when released by the catch or detent already described; or a shutter made to oscillate from side to side may be used. Three wires are extended between the balloon and the earth—one to operate the clockwork which actuates the sensitive tissue, one to operate the instantaneous shutter, and the third to make the return circuit to the earth.

In the accompanying diagram *fig.* 1 is an illustration of this part of the invention. A is the balloon; *a* is the box in place of a car; *b*, the camera; *c*, the sheet of sensitive tissue wound round two rollers, and actuated by the clockwork *d*, which is set in motion by electro-magnetic apparatus in the frame *e* by means of the wire e^1. The lens *f* is uncovered when required by the instantaneous shutter *g* set in motion by the electro-magnetic apparatus *h* by means of the wire h^1; the rudder or fan *i* is attached to the box *a* to keep the latter in one position. The wires e^1 and h^1, and the return wire k, are contained in the rope l, by which the balloon and apparatus described are held to the earth. When the balloon is elevated to its proper position, with the sensitive tissue in its place, and the lens focussed for the extreme distance, electric communication can be made with the shutter, thus giving an instantaneous exposure to the prepared surface. The electric communication being then transferred to the wire in connection with the clockwork will cause this to move for a sufficient distance, thus giving a fresh sensitive surface for the next exposure, and so on, thus enabling a series of photographs to be obtained while the apparatus is elevated at the same or different altitudes.

FIG. 1.



The special claim made by Mr. Woodbury in regard to this portion of his invention is the combination, with a captive balloon, of the photographic apparatus actuated by means of electricity, conveyed as required through wires supported by a rope which retains the balloon to the earth, substantially as described and shown. Also, the arrangement of a tail or rudder for the purpose of keeping in its proper position the captive balloon provided with the photographic apparatus, substantially as described and shown.

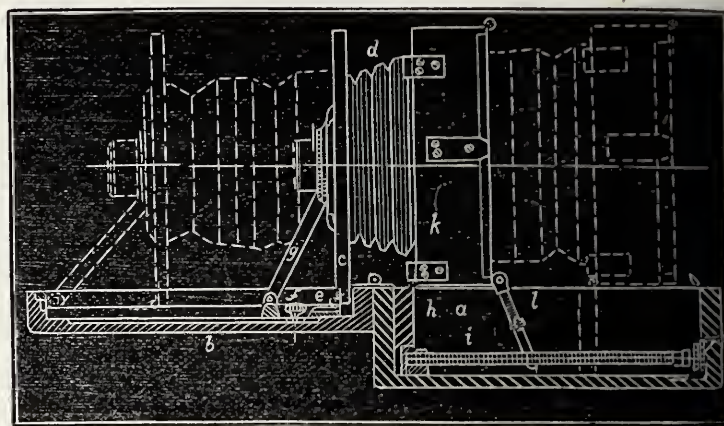
The second part of the invention consists of a novel form of photographic camera, so arranged as to be in the form of an ordinary box with a hinged lid, the body of the box containing the "bellows" or expanding part of the camera, and the shallower part or lid of the box containing the movable front of the camera carrying the lens. When opened the bottom of the box is supported upon any sufficiently rigid stand or frame, and the hinged lid being thrown back carries the front and lens, and gives sufficient firmness and length for long-focussed as well as for short-focussed lenses. To determine the position of the lens a marked scale is fitted into the lid, by which the point to which the front of the camera should be drawn out is very nearly found, final accurate adjustment being made by means of a screw working in a nut fixed to a slide moving horizontally in the body of the box and carrying the back part of the camera. When closed the apparatus resembles an ordinary writing case or despatch box. The back part of the camera is attached to the frame which slides in the box, as already described, by means of a hinged joint, and a screw of adjustable length is arranged between a joint at the bottom of the box and a joint at the bottom of the camera, so that the back of the latter may be thrown more or less out of a vertical plane if desired. The sliding frame which carries the front of the camera (in the lid of the box) is made capable of turning upon a vertical pin or screw, so that the front of the camera may be made more or less parallel with its back if desired.

The slide for holding dry plates is constructed as follows:—A thin wooden frame, joined at the corners, has at one end an opening, through which two dry plates, placed back to back, can be inserted, a piece of thin metal of a bent or waved form being placed between them to act as a spring and keep them in contact with the frame when inserted, a thin wood or metal shutter or cover closing the opening against light.

Instead of the ordinary wooden slide for uncovering or exposing the plates the inventor prefers to use a sheet of thin, flexible metal, which can be bent to one side during exposure, and again resumes its original shape when closed; or a stouter sheet of metal may be used, only the joint upon which it turns back being formed of a thin, flexible piece of metal.

In the accompanying drawing, *fig.* 2 illustrates this part of the invention, the box being shown open and the camera in its place:—a is the body of the box and b its hinged lid, both shown in section; c is the lens fixed to the front of the camera d, which is hinged to the frame e sliding in the lid b. The frame e has its ends rounded, so as to be capable of turning round the screw f, by which it is fixed when adjusted; g is an adjustable stay for holding the front c more rigidly; h is a frame which can be made to slide backward and forward in the box a by means of the screw i, and which has hinged to it the back of the camera k, the vertical plane of which can be adjusted by means of the variable-jointed screw l. The position of the lens and front of the camera are adjusted in the lid of the box, and the back of the camera in the body of the box, as shown in dotted lines.

FIG. 2.



The whole of the apparatus folds, when required, into the box, which can then be closed and locked.

The features claimed are the novel construction and arrangement of photographic camera, one part of which fits into, and is adjustable upon, the lid of a box, whilst its remaining part fits into, and is adjustable upon, the body of the same box, substantially as described and shown in the diagram. Also, the method of constructing the sliding shutter or its hinge of thin, flexible metal, substantially as described.

The camera here described, as we have stated, was shown at the last exhibition of the Photographic Society of Great Britain, where it proved an object of much interest.

According to present appearances the time is not far distant when an "instantaneous" shutter will form as necessary a part of the dry-plate photographer's equipment as are his lens and camera—if not for all his work, at least for a great part of it. The extraordinary degree of sensitiveness which is now attainable with dry films, combined with the assistance rendered in the same direction during the last few years by the opticians, is bringing into vogue an entirely new class of subjects—subjects which a short time ago it was impossible to attempt, scarcely even to dream of, unless wet plates of the very highest quality were employed. There can be little doubt that as we become more familiarised with the new power thus placed in our hands "instantaneous" photography will come more and more into favour, and the necessity will arise for an effective and, what is of equal importance, simple mechanical arrangement by which exposures measuring but a fractional part of a second may be given. The simplest plan by far which has yet been introduced is the so-called "drop shutter," which consists of a strip of metal or wood sliding vertically in a slotted framework, and in the centre of which is an aperture of adjustable dimensions. By suitably-adjusted springs this aperture is made to pass rapidly across the front of the lens, and the exposure thus given may be regulated within certain bounds by varying the width of the aperture in the sliding shutter. This simple arrangement is only surpassed by some of the more elaborate and, consequently, expensive instruments in one respect, namely, that some of the latter are, by ingeniously-contrived mechanism, made to give a longer exposure to the foreground than to the sky in order the better to secure natural clouds; for it is obvious that, however short the exposure may be, if it be sufficient for terrestrial objects the clouds will require less for their proper rendering. If the "traverse" of the "drop" shutter be changed from a vertical to a horizontal direction we can then utilise the principle (first adopted, we believe, by Mr. J. R. Johnson in his pantascopic camera) of a triangular or converging aperture through which to make the exposure. It is plain that if a converging slit, the narrowest part of which is uppermost, be made to pass horizontally in front of the lens, the lower part of the latter will be exposed for a proportionately longer time than the upper part, according to the degree of divergence given to the edges of the aperture, one of which may be fixed and the other adjustable at pleasure. We give this as a "wrinkle" (not new, perhaps) for the benefit of the mechanical portion of our readers.

BROMIDE OF ZINC.—CITRIC ACID IN EMULSIONS.

I have been trying the method of making zinc bromide described in a recent editorial article, and, as far as I can judge from so short an experience, it is likely to be a very great assistance to those who are so placed as to be unable to obtain the salt ready for use. I have made an alcoholic solution of the cadmium salt of known strength, and simply immersed in it a few clippings of common sheet zinc, which appears to be sufficiently pure for the purpose, and, I fancy, acts more quickly than when the metal is employed in the granular form.

It is advisable before immersing the zinc in the bromide solution to dip it for a few seconds into dilute sulphuric acid, and then to wash it well in clean water. This removes the thin film of oxide which invariably covers the surface, and causes the bromide of cadmium to attack it at once. If it be thrown into the bromide before this cleansing operation has been performed some time will elapse before the solution commences to act, and then the reduction of the cadmium proceeds very slowly. With granulated zinc the case is far worse.

If the double bromide of cadmium and ammonium be employed the reduction appears to take place more rapidly than with cadmium alone, and the result is, of course, a solution of double bromide of zinc and ammonium, which I prefer to zinc alone. With some descriptions of collodion the zinc salt alone seems to exercise too caustic an action, especially if the bromising has been done some time before sensitising; but with the addition of ammonium there is less "rotting" of the film, and at the same time the facilities for obtaining density are greater, while the well-known opacity of the film obtained with zinc is not lost. A further and by no means unimportant advantage is that the ammonium salt is something like one-third the price of cadmium.

Three separate quantities of the same collodion were bromised, respectively, with the double salt of cadmium and ammonium, with zinc alone, and with zinc and ammonium—the same relative quantities of bromine and of silver being employed in each case, and the same conditions, as far as possible, being observed throughout. The first gave a clear, transparent film, developed rapidly, but required some little pushing to get printing density; zinc alone intensified easily to any desired extent; while zinc and ammonium gave, if anything, rather too much density unless treated very "gingerly." The two last films were scarcely distinguishable as regards opacity, though they differed widely in appearance from the first mentioned.

Zinc bromide alone, with three grains of free silver and two drops of nitric acid to each ounce of emulsion, gave, twenty-four hours after sensitising, the most peculiar result I have ever attained in emulsion work. The emulsion itself, though very dense, was almost entirely devoid of even the orange tinge of colour—ruby it certainly did not show. A plate was coated and washed, when it presented a dense, smooth, yellowish-brown colour by transmitted light, and when dried a most strongly-marked steel blue—quite as dark, though not so brilliant, as the temper colour of watch springs. This seemed anything but promising; but upon moistening with alcohol after exposure the change was very remarkable, the colour being many shades warmer than before drying—in fact, a bright, though not deep, orange. I did not anticipate any very great result, and was therefore considerably astonished upon developing a picture which was in every way satisfactory, and with any amount of density—the first instance, in my experience at least, where the latter quality has been obtained with one of the blue or cold-toned emulsions. Can this be a peculiarity of the bromide formed in the manner described? I have used zinc frequently under almost identical conditions and never attained a like result.

I may further add that the emulsion was divided into two parts—one of which was "washed" and the other "precipitated." The resulting emulsions gave films of much the same character as before washing (though rather thinner), but were *entirely useless* photographically, not only refusing to give density, but showing scarcely any capability to form an image of any sort.

The method the Editors have described for the preparation of zinc bromide will prove a great boon to many emulsion workers, as it will enable them to prepare cheaply and in a convenient form a salt which is difficult to obtain in most localities, and, when obtained, is no less difficult to handle accurately; its preparation by the ordinary methods in an amateur's laboratory is little less than an impossibility. It is, no doubt, the most useful of all bromides for emulsion; but for washed or precipitated emulsions I have always experienced considerable difficulty in using it in connection with free silver. With a slight excess of bromide, or in an unwashed emulsion, it answers admirably.

While on the subject of free silver I may remark that one of the substances mentioned in your leading article, last week, on *A New Method of Correcting Emulsions* I have had in use since the beginning of the present year. I allude to citric acid, which I have used alone and in conjunction with nitric acid for some time. My experience of its properties is simply this—that never until I employed citric acid did I believe in the possibility of washing or precipitating an emulsion containing free silver so as to obtain an invariably successful result. Now I do; and, not only that, I find it possible to use a very large excess of silver, giving great sensitiveness and, at the same time, facilities for obtaining density equal to the old collodio-bromide process. I speak of excess of silver; but, according to the Editors' view, it is no longer excess (in the sense of soluble silver) if sufficient citric acid be used. At anyrate, it gives sensitiveness combined with density; but if you allow the emulsion to "ripen" too long *it ripens into a jelly*. This, however, need not occur if it be used in moderation and due care be taken in the sensitising. I mean to try some of the other "correctors" as soon as I have time.

W. B. Bolton.

NOTES ON PASSING EVENTS.

By a Peripatetic Photographer.

The great event of the past month is the discovery of the cause of the deterioration of certain carbon prints, which have not retained their whites in a manner so unspotted as to warrant us in affirming that they have kept the promises they were assumed to have made—by deputy. Well, seeing that it is now known that a few samples of white paper will acquire a yellowish tint when exposed to the light, let us be thankful for the knowledge, because, in a sense, the proverbial axiom "to be forewarned is to be forearmed" applies here. As it is a small matter, and one that can be easily remedied, I need say no more about it except this—that infinitely sooner would I accept the portrait of a dear friend or the photograph of a favourite landscape printed in the most objectionable carbon, and upon the most objectionable and yellow-stained transfer paper mount, than in the richest, most blooming, nay most *luscious*, silver printing. It was my good fortune to receive, about eight or nine years ago, a work on a certain photographic subject, and to which I have sometimes occasion to refer. This work contains, among other illustrations, a carbon print as a frontispiece and a silver print in the body of the book. At that time opinions were a little divided respecting the technical merits of the two prints. "Never no more" will there be any dubious comparison instituted between them! In the silver print the whole details of the face, the hands, and the feet (for the argentiferous photograph represented a bare-footed peasant girl) have departed, leaving in their place nothing but sickly yellow paper. The blacks, too, have become a dingy, faded brown. As for the carbon print, it appears by the force of contrast to be even more brilliant and beautiful than it was originally. After this, who will institute comparisons between the two methods?

I am about to offer to photographers a bit of good, practical, commonsense advice, based upon a bit of recent experience. The subject of my photographic effort on that occasion belonged to that useful quadrupedal family one of whose members has long been celebrated in runes, if not in rhymes, as having, by the application of its horn, "distort to realms ethereal" borne the braggart hound that worried, &c., &c. In short, my subject was a cow with a crumpled horn. The animal herself, including the head and the crumpled horn, I managed to pourtray with the greatest ease; but not so the tail of the patient bovine—*it* persisted in indulging in pendulum-like efforts to wage ineffectual war upon sundry flies. I gave it up as a bad job, and left the field with four negatives of "crummie" *minus* the tail. A thought occurred to me—the caudal appendage of one cow bears a marked resemblance to that of any other animal of the same family. The result of a friendly interview with a butcher was my eventually obtaining several negatives, of various dimensions, of bovine tails, which, like the cloud negatives of a landscape photographer, could be pressed into service when the original tail had been indulging in oscillatory movements during exposure. The idea is applicable to horses and other animals as well as to cows. The offending member in the original negative may either be "stopped out" and the other printed in by a subsequent operation or, better still, it may be removed entirely by means of a strong solution of iodine in cyanide of potassium, and the film containing the supplemental tail attached, by transparent cement, to the negative. It requires care, but it *can* be done, and that, too, most effectively.

The six lectures *On the Application of Photography to the Production of Printing Surfaces* delivered by Mr. Bolas a few months ago before the Society of Arts, and which have just been published, form an excellent epitome of the chief advances hitherto made in this direction. Those who were present at the delivery of these lectures assert that a more successful effort at illustrating the practical details of the various processes described has never been made—a statement which, from a partial knowledge of the lecturer, I am well prepared to accept. It would prove of incalculable benefit to photographers if such a course of practically-illustrated lectures were given under the auspices of the Photographic Society of Great Britain during the ensuing winter. It is valuable to *read* such lectures after they have been delivered; but how much better is it to *hear* them, and witness the various experiments conducted in a skilful manner!

(To be continued.)

ON INCREASING THE SENSITIVENESS OF AN ORDINARY EMULSION.

Although I have always held, and still hold, that for ordinary landscape work a slow-acting plate—that is, a plate prepared with an emulsion containing a trace of free bromide, and requiring an exposure of from five to ten minutes—is more certain in its action and less troublesome in its manipulation than in cases where anything like the rapidity of wet collodion has been sought for, there are times and circumstances when a considerable increase of sensitiveness is desirable. That a rapidity far in excess of ordinary wet collodion may readily be obtained with gelatine emulsions, and that at considerably less cost than with collodion, has been abundantly proved during the past six months; but gelatine, in the hands of probably a majority of those who have tried it, is still a kittle substance. While the successful few are fighting its way to popularity it may not be altogether labour in vain to point to a way whereby the sensitiveness of an ordinary collodion emulsion may be vastly increased.

The fogging propensities of alkaline or neutral solutions, which so troubled operators in the early days of photography, laid the foundation of a belief in the necessity for free acid almost everywhere—a belief which is even now difficult to eradicate, and which caused the alkaline method, when first suggested by the late Mr. T. Sutton, to be received with much distrust and no little opposition. Like many of the suggestions, however, of that close experimentalist it deserved more attention than it received at the time, and the seed then sown is likely now to bear fruit.

Readers of The British Journal of Photography cannot fail to have noticed the persistency with which Mr. H. J. Newton, of New York, has laboured at emulsions; and, although from the not infrequent high-flown style of American photographic literature his experiments and the results deduced therefrom may not have met with so much attention as they deserve, there can be no doubt that his proposal to render a plate thoroughly alkaline before exposure enables it to receive a developable image in a fraction of the time required without such preparation. In a former note on this subject I stated that I had in my possession several portraits by Mr. Newton, including one of himself, taken in an ordinary studio with an exposure of only three seconds, under circumstances which required at least three times as long with wet collodion; but in those cases the alkaline accelerator was applied to the moist emulsion, and the exposure made while in that state.

From a number of experiments made during the past fortnight, as well as from information gathered from other workers, I have reason to believe that the accelerator is equally applicable to plates that are to be dried, although the amount of acceleration does not appear to be quite so great.

The first experiments were made with a commercial washed emulsion that had been in my possession since May, 1877, and which gave a rich, creamy film that transmitted the ruby tint indicative of an emulsion in good working order. Plates simply coated with this and dried were found to require an exposure of from five to seven minutes, and were easily developed to fulness of detail; but they obstinately refused to acquire anything like sufficient density, and in spite of much painstaking care were covered with apparent dust marks.

A subsequent batch was washed till greasiness disappeared, and flooded—some with Newton's solution of tea, some with a ten-grain solution of tannin, and some with ordinary bitter beer; and they all, without exception, were easily developed to printing density. But for the best results an exposure of nearly half as long again was required in the case of the beer, and at least a third with the tea and tannin, while the dust markings had disappeared.

A third batch of plates were then prepared, with the same organifiers or preservatives, but after washing one half of each was immersed for half-a-minute in the accelerator and again washed before the organifier was applied. The effect of this treatment was very marked. Although the first few plates received only about half the exposure given to the previous lots, the images on the halves that had been rendered alkaline were fully visible before the application of the developing solution. In spite of a much larger supply of bromide they showed a slight tendency to fog, and that long before a trace of an image had appeared on the other halves. With a view to make quite certain that the "accelerator" really acted as such, and not merely as an aid to the developer, a number of the plates were exposed for various lengths of time and then cut in two, and the halves developed separately, the result being that, while the alkaline halves yielded good negatives, no amount of pushing would give more than skies and higher lights on the others.

Similar experiments were made with a variety of emulsions, including that made by Mr. Newton, which, I understand, originally contained an excess of silver that was subsequently decomposed by a chloride, and also that used by most of the Edinburgh workers, in which the salts are used in as nearly as possible their combining proportions and afterwards adjusted so as to contain the merest trace of free bromide. In all cases the result was the same—a large increase of sensitiveness whenever the accelerator was employed, and that without any corresponding disadvantage except the additional trouble, but that may be reduced to a minimum by having the solution, which will keep indefinitely, in a dipping bath.

Regarding the relative merits of the three organifiers employed in the foregoing experiments, the superiority lies undoubtedly with the tea. Beer is considerably slower than either of the others, but works clean; and unless the exposure has been excessive it requires no bromide or other restrainer in the developer. With tannin the image is inclined to hardness, and the deposit is generally of a bluish-purple colour that is objectionable from a printer's point of view. Tea seems to have the good qualities of both without the faults of either; and, as the alcoholic solution will keep indefinitely, it simply requires dilution to be ready for use. The solution used, being a slight modification of that employed by Mr. Newton, is as follows:—

Assam tea	1 ounce.
Alcohol	4 ounces.
Water	4 „

Boil gently for one minute, let stand till cold, and filter. The organifier is made by adding an ounce of this to a pint of water. The accelerator was Mr. Newton's, and consists of—

Carbonate of soda	180 grains,
Bromide of ammonium	2 „

dissolved in twelve ounces of water.

My notions as to the theory of the action of the accelerator I must reserve for a future article, as I shall conclude this by saying, on the evidence of the negatives now lying before me, that by its aid, especially in conjunction with the tea preservative, I can get as good a negative—and by that I mean as fully-exposed a negative—in one minute as without it I formerly got in ten. John Nicol, Ph.D.

RECENT PHOTOGRAPHS OF THE EARL OF BEACONSFIELD.

Being aware that of late years Lord Beaconsfield has expressed a very decided reluctance to have his photograph taken, we cannot avoid suspecting that Mr. Jabez Hughes will be an object of envy to many of the fraternity who have tried, but tried in vain, to bring influence to bear upon the Premier to submit himself to the magic gaze of the photographer's lens. The following clever article on this subject appeared in the *Isle of Wight Times* of the 29th ult.:—

That we cannot fully support the policy of the Premier our readers are well aware. Our remarks, therefore, will not bear the interpretation that we have yielded to the fascination of this too popular statesman. They are grounded on reflections suggested by a calm examination of a remarkable series of his portraits recently produced by our well-known townsman, Mr. Jabez Hughes.

It has been remarked by a witty writer that photography has added another "penalty of greatness;" no sooner does a man achieve fame than a craving arises to possess his photograph, and, as no one is able to resist the demand, the photographer—more merciful than the headsman of old—proceeds to take off his head. The simile may be extended, for by the old way the man's career was cut short, but by the modern one his influence only increases. Some of our great men seem to submit more readily than others to this modern penalty. Of this our present and past premiers are marked examples. Mr. Gladstone has taken kindly to the modern custom, and from early manhood to his present ripening age photography has made us familiar with the changes time has made on his expressive face. His last portrait is curiously symbolical of his career; for, having surrendered the destruction of ancient abuses, he is now represented in his shirt sleeves hewing down old trees. On the other hand the Premier seems, for a reason we cannot understand, to have been chary of supplying food for the camera. He has been coy, and his visits to the glass-room have been few and far between. When the future historian, in descending to details, contrasts these two remarkable men we hope this curious fact may not escape attention.

That photographs are abundant of his lordship we are aware, but they are not recent ones; for we have been informed that an interval of more than ten years occurs between the taking of his previous and these last ones. Can the same be said of any other popular man? And what a change has occurred in this decade! *Then* he and his party were struggling, metaphorically speaking, to sow the mustard seed of the conservative tree, and *now* its branches, unfortunately, spread all over the land. If the reputation of Gladstone be as a fixed star, and that of Beaconsfield but as a meteor, we cannot deny that it is a brilliant one, for, like him or not, he is one of the most remarkable men of our time. When he took the daring step of going to Berlin to measure swords with the Bismarcks, Andrassys, and Gortschakoffs, many of us who did not believe in him dreaded the result; but whether for good or ill he undoubtedly made his influence felt, and he left the congress a greater man than he entered. Differing as we do, we cannot help feeling a secret gratification that when among the wily diplomats the representative of Old England was a match for them all.

With these feelings we study with increased interest this interesting series of portraits. The artist, Mr. Hughes, seems to have been impressed with the exceptional honour of taking the portraits, and has made the most of the occasion. There are profile views of either side of the face, full face, three-quarter face; with the hat on, and without; looking you straight in the eyes as if demanding what you thought of him and his policy, and looking away into the far-distance as though speculating whether his work will end in huge failure, as we fear; or, anticipating the brilliant success that possibly he may believe in. But the one we are most inclined to is where he is reading a newspaper. This may arise from a professional bias. There is no mistaking that he is studying the article; it is probably some deservedly caustic critique on his foreign policy, for the earnestness of the expression shows that he is deeply interested. Altogether the series are very interesting, and are as excellent as photographs as they are artistic as portraits.

THE REACTIONS OF CHROMIC ACID AND CHROMATES UPON SUBSTANCES OF ORGANIC ORIGIN, CONSIDERED WITH REFERENCE TO THEIR USES IN PHOTOGRAPHY.*

Behaviour of Chromated Gelatine with Heat and Moisture.

The behaviour of a mixture of potassic bichromate and gelatine with heat and moisture in the absence of light varies very greatly, owing to apparently trifling changes in the proportions of the reacting agents. All the operations mentioned in this section were, when the contrary is not expressly mentioned, conducted in the dark. Potassic bichromate does not change a gelatine solution when boiled five to ten minutes on the water bath; also, the mixture, when afterwards dried, still retains all the properties of the original gelatine. But if the heating at 100° C. lasts one or more hours, more water being added to make up for that lost by evaporation, the fluid becomes thick and stiffens at a comparatively high temperature. If the bichromated gelatine thus boiled be dried and then treated with cold water it swells up well, though not so readily as formerly, but will have for the most part lost its solubility in hot water. Indeed, fifteen minutes' boiling is often sufficient to deprive gelatine, after drying, of its solubility in hot water. Many photographers have also observed that even when bichromated gelatine has been heated for a short time at 60° or 80° C. an insolubility of film is afterwards experienced; but I cannot substantiate this observation.

It is, however, advisable in all cases not to heat the mixture of gelatine and bichromate more or longer than is necessary for the solution of the glue; and if the gelatine be previously swollen in cold water a temperature of from 40° to 50° C. should be sufficient. The idea that too much bichromate of potassium can of itself produce insolubility I believe I must correct so far as to say that the effect of a high temperature, as above mentioned, is produced more quickly when the bichromate solution is concentrated. The greater the bichromate contents the more difficult of solution is the gelatine after drying, especially if the films are dried slowly. Sensitised carbon tissues require, twenty-four hours after drying, a somewhat warmer (about 2° to 5° C.) water to dissolve them than before being bichromated. Batho[1], who has experimented in this direction with different sorts of tissue, has arranged a table showing the degrees. According to it unsensitised carbon tissue, which dissolves at 28° to 32° C., would, other influences (such as light or reducing agents) apart, when sensitised be soluble at 33° to 35° C. As to the effects of various degrees of concentration of potassium bichromate on the hardness, brilliancy, &c., of the carbon picture and upon their influence in the development of granularity in lichtdruck plates[2] one can only take up these points in detail in a practical work specially devoted to the subject.

Generally speaking, however, one may assume that the higher the percentage of the bichromate contents the more granular the film will be, and the poorer the bichromate contents the smoother the film. But the drying temperature has also a great influence on the formation of the texture, as a very low temperature as well as too[3] high a one makes a film free from granularity. Certain additions which keep the glue fluid, such as acetic acid and calcic chloride, favour the formation of granulation even when the films are dried at a low temperature. Acetic acid produces a very fine granulation. Thick films produce a coarse grain. Very concentrated gelatine solutions furnish a very rough printing grain (lichtdruck). One requires to use, according to the quality of the gelatine, from eight to sixteen times its weight of water[4]. Old plates give a finer grain than fresh ones. If two plates be dried at the same temperature, but one in a greater current of air than the other, the grain will be coarsest on the former. In exposing, sunlight gives a finer grain than diffused light.

So far as carbon tissue is concerned, however, we can only say that, generally speaking, dilute bichromate baths give more brilliant prints than concentrated ones; that, generally, tissue sensitised upon weak chromate baths give harder prints than those prepared upon concentrated baths. This general rule presents the advantage of allowing a thin or flat negative to be printed on tissue sensitised on a weak (say one to two per cent.) bichromate solution, and a dense negative on tissue prepared in a stronger (say five to six per cent.) solution. Too weak a bath gives no half-tones; too strong a bath produces reticulation[5]. Compare the foregoing remarks with those which will follow on the various concentrations of the bichromate bath in summer and winter.

When carbon photography was first introduced it was supposed by Rousseau and Masson[6] that the mixture of bichromate of potassium and gelatine, when stored in the dark and at an ordinary temperature, would keep for a very long time. This is, unfortunately, not the case. It is not at all necessary to heat the bichromated gelatine in order to render it insoluble. It is sufficient to let the bichromated gelatine stand a few days at an ordinary temperature in a damp, gelatinous condition in order to deprive it of its solubility in warm water. Even when standing for only twelve hours in the damp condition the decomposition is remarkable. Sensitised tissue which has stood so long damp gives bad prints. In the case of lichtdruck plates the insolubility is much later in appearing, because the films do not lose their capacity for swelling up in the same degree as their solubility in hot water. In photogalvanography and all those photographic processes in which the complete solution of all the unlighted gelatine parts takes place, the setting-in of insolubility is much more injurious than in lichtdruck, where the power of swelling up only requires to be preserved. A photogalvanographic plate should not remain damp more than twenty-four hours[7]. Bichromated tissue which has required a long time (in damp weather) to dry developes with difficulty, and the result is not so clear and brilliant as if the tissue had been quickly dried. Tissue should not take more than six to eight hours to dry[8]. This is a warning to photographers to dry their bichromated gelatine quickly, but, on the other hand, not at too high a temperature, as the long heating of gelatine that has been dissolved in water also produces insolubility.

Bichromated gelatine dried in air is much less liable to become insoluble through lying in the dark at an ordinary temperature than when in the gelatinous form; still, it does usually become insoluble in about eight days—often on the second, third, or fourth day, but sometimes, again, not for several weeks, and even under favourable circumstances sensitised tissue has been *usable* after being kept for months,[9] though not without deterioration in quality. Generally it is best to use sensitised paper one to three days after preparation, as one can then assume with greater certainty that it has not yet undergone any change. In cool weather sensitised tissue keeps about twice as long as in warm

* Continued from our issue of April 26th, page 198. The reason for the long delay in publishing the continuation of this prize article by Dr. Eder is that the publication of the *Photographisches Correspondenz*, to which we are indebted for the article, has been suspended for six months.

weather; also, that sensitised on a weak bath keeps longer than that sensitised on a strong bath. Audra's observation[1] is interesting. It is that bichromated gelatine films (carbon tissue) when stored for two years in the dark room became so perfectly insoluble that even boiling water had no longer the power of dissolving it.

I have closely studied the effect of atmospheric moisture upon the keeping qualities of bichromated gelatine. Paper coated with bichromated gelatine (carbon tissue) keeps longer unchanged when kept in the dark in a drying box containing calcium chloride than in the ordinary atmosphere of a room. After eight days in printing a picture upon such tissue there is scarcely any observable change. Paper kept in this way is also much more soluble in hot water than that kept in ordinary air; the latter is also more inclined to fog. But if bichromated gelatine paper be kept in such a chamber, the bottom of which is covered with water, and in which, consequently, the air is saturated with water vapour, it will become insoluble twice as fast as tissue kept in air; often in a week such tissue would be almost perfectly insoluble in water. The bichromated gelatine films should, therefore, be stored in as dry a place as possible if it be desired to make them keep for any length of time in a usable condition. Besides, bichromated tissue which has been dried in dry air gives clearer and purer prints than that dried in damper air. This observation, which was made by Liesegang,[2] is perfectly correct. In America, according to Vogel,[3] the damp air from the lakes and rivers is the cause of great difficulties in the carbon process, causing the tissue to become insoluble very readily. According to a private communication from Leipold the same thing takes place in England and Portugal.

Gelatine containing only a small proportion of bichromate keeps best. With the increase of the bichromate the liability to become insoluble in the dark increases; that, at a high temperature, insolubility occurs spontaneously in damp bichromated gelatine more rapidly than at a low temperature, has already been mentioned.

An air-dried mixture of gelatine and bichromate of potassium becomes insoluble in hot water after being long heated to 100° C. This appearance only becomes distinctly evident after several hours' heating at that point; but long before that point is reached, and, in fact, in a very short time, the decomposition will have proceeded far enough to disturb the regular course of the photographic bichromate process. After heating for a few minutes to 150° C. bichromated gelatine becomes insoluble.

These conclusions apply both to chondrinous and glutinous gelatines. Gelatines rich in chondrine, however, are more likely than the other sort to be liable to insolubility, both when heated and when left standing long at an ordinary temperature.

The conclusions of the practical photographer are to the same effect; and he does not, on account of the facts just mentioned, cease his endeavours to dry the sensitive bichromated gelatine films so as to retain their original solubility—as is especially necessary in photogalvanography and carbon printing. Swan,[4] Liesegang,[5] Vogel,[6] Monckhoven,[7] Woodbury,[8] Boivin,[9] Liebert,[10] and Vidal,[11] all warn us against the slow drying of sensitive tissue, on account of its inducing insolubility. Other authors[12] also recommend us to dry rapidly, so that the gelatine should not remain long in a moist condition. It is also necessary to dry the film rapidly when it is requisite that the property of solubility in hot water be preserved. J. M. Eder, M.D.

ROYAL CORNWALL POLYTECHNIC SOCIETY.

Photographic Department.—Judges' Report. By Thos. Hart.

The Judges have much pleasure in bearing testimony to the great advance made in their department during the past twelve months, and to the exceedingly high character of the exhibits. The rules of art, in form, composition, light and shade, &c., seem to have been studied to good purpose by some of the photographers, and the consequence is that in many of their works there is a marvellous perfection that ministers to our noblest gratification; and the Judges hail with pleasure all those who are trying to lift photography out of the mechanical abyss, where it has too long remained, into a higher and purer sphere, and feel that they recognise, with their brothers of the brush, that the essence of art is spiritual.

Professional Photographers.

1. For the best landscape, size not less than 14 × 11 inches. First silver medal has been awarded to E. Forhead, Ventnor, for his fine view of *Old Church, Bonchurch*, No. 604.

2. For the best landscape, size not less than 11 × 9 inches. First bronze medal to Marsh Brothers, Henley-on-Thames, for their view in *Quarry Wood*, near Great Marlow, No. 619.

3. For the best landscape by the collodion emulsion process, size not less than 9 × 7 inches. First silver medal to W. England, for his splendid Swiss view, No. 666. Mr. England exhibits fifteen gems—views in Switzerland—all in his well-known style, possessing the highest artistic excellence. They are full of atmosphere—broad, yet exquisite in detail.

4. For the best interior, by any process, size not less than 11 × 9 inches. First silver medal to A. J. W. Penn, India, for his fine Indian interior, No. 684.

5. For the best portrait taken direct, size not less than 14 × 11 inches. First silver medal to W. M. Harrison, Falmouth, for his fine study, *Portrait of a Boy* (untouched), No. 639. This is more like a photograph from an "old master" than a study from life. It is full of artistic feeling; soft in outline, where it ought to be; the lines just strong enough where required, and all subservient to the face. It is a photographic triumph, reminding one of the "studies" seen in Rome and Florence.

6. For the best portrait, size not less than 10 × 8 inches. First bronze medal to Robert Slingsby, for his *Portrait of a Lady*, No. 650. This is a very fine study, beautifully modelled, well lighted, and very soft—one of the finest portraits in the collection, from an artistic point of view.

7. For the best group, composition or otherwise, size not less than 14 × 11 inches. First silver medal to Chaffin and Sons, for their group, *Checkmated*, No. 614. This is a very fine composition, though the high lights in the faces are rather too strong. This remark applies particularly to No. 611, *The Musicians*, which seems underexposed, and to No. 612, *Popping the Question*, in which the heads are out of focus. But the Messrs. Chaffin are working and striving in the right direction, and, with a little more well-directed perseverance, we believe they will attain to the highest excellence. We hope to see their works again next year.

8. For the best enlargement, landscape (in carbon), size not less than 20 × 16 inches. First silver medal to W. M. Harrison, for his enlargement (untouched), No. 637. This is a view at Seaton, Devon, and is very fine in detail.

9. A first silver medal (special) is awarded to W. Brooks, Reigate, for his truly wonderful photographs of caves, &c., taken sixty feet under ground. The difficulties in a case of this kind must be immense, as they are taken by artificial light. Mr. Brooks had to deal with yellow rays as well as with the darkness of the caves. By whatever process he did them we consider the specimens sent triumphs of photographic art. They have all the characteristics of photographs taken in open daylight, being beautiful in detail, &c. The discovery is capable of being applied in various ways; and in a mining country, like Cornwall, it may be invaluable, as it shows that our deepest mines can now be photographed successfully. What next?

10. A special first bronze medal is awarded to Robert Faulkner and Co. for their powder enlargement, *Dorothy Morrison*, No. 585. This work is wonderfully delicate in detail, fine in colour, and is altogether a very artistic production. Messrs. Faulkner and Co. exhibit several others equally good.

11. A first silver medal is awarded to David Hedges for his *Studies of Animals from Life*, No. 596. These pictures are in the artist's best style, and unapproached.

Reuben Mitchell, of Bolton, sends some fine examples of dry-plate work, No. 582 being especially good.

Adam Diston's carbon enlargement, *The Broken Toe*, is a well-composed interior. The picture No. 609, *Henry Kirke White in his Study*, lacks focus, and the objects behind are too sharp; but Mr. Diston is working in the right direction, and we expect some fine specimens of photography from him. We hope to see his work here again.

Felix Bonfils sends several fine photographs from Egypt, &c., No. 634 being extremely good.

H. Garrett Cocking sends several splendid studies in his well-known style, No. 657, *Gitana*, being remarkably good.

Messrs. Geo. F. Dew, J. Milman Brown, T. Nesbitt, and the Cleveland Photographic Company send specimens of good and earnest work.

Messrs. W. H. Oakley and Co. send photographic appliances, with many improvements, in apparatus, &c.

Amateurs.

The amateur department is also very well represented, and has several workers "running hard" many professional photographers. Mr. Chas. A. Ferneley, for instance, exhibits six *Sketches near Reigate*, which are photographic gems; but we cannot understand how Mr. Ferneley, with his artistic feeling, could leave his skies so white; a little cloud here and there would make them perfect. The first bronze medal is awarded to his picture, No. 707.

T. M. Brownrigg has the first bronze medal for his *On the Blackwater*, No. 703.

Harry A. H. Daniel is awarded the first bronze medal for his *Cottage, Lynmouth*, No. 717. He exhibits a good collection of photographs by the wet collodion process, some of which are exquisite in detail.

[11] ,, ,, ,, Vidal. 1877, p. 5.
[12] *Photo. Archiv*, vol. ix, p. 28.

Other exhibitors sending good works are Mr. Louis W. England, Mr. Henry N. White, Mr. Edward Brightman, and Mr. J. Dudley Radcliffe.

A first silver medal is awarded to H. N. White, Isle of Wight, for his splendid series of photographic ceramics. These would do credit to any professional photographer. Mr. White must have an intense love for the art or he could not produce such work.

ON PROCESSES OF MAP PRODUCTION BY PHOTOGRAPHY.*

Photolithography and Photozincography.

In all the processes noticed in the last section it is necessary to repeat the printing operation by exposure to light for every print produced. The rate of printing will consequently be more or less dependent on the sensitiveness of the paper, the strength of the light at the time of exposure, and the state of the weather; the printing operations can, moreover, only be carried on during the few hours of daylight. In the photo-mechanical processes now about to be described these grave disadvantages are obviated, and, once the photographic image has been produced upon the printing surface, prints may be made in any numbers, quite independently of light or weather.

The simplest and most generally useful of these mechanical processes is photolithography, or the analogous photozincography, the principal difference between the latter and the former being merely the substitution of a thin, smooth plate of grained zinc for the thick, heavy lithographic stone. For maps of large size zinc is certainly the most suitable, and offers in other respects all the advantages of stone; but the latter being better known is generally preferred for ordinary work of moderate size.

In ordinary lithography the image may be produced on the stone or zinc either by *transfer* from a drawing on paper with the solution of resinous soap known as "autographic ink," or by *drawing direct* on the stone with a similar ink or crayon. So in photolithography there are two similar methods of obtaining the photographic image—either by transfer from a photographic print in fatty ink; or by impressing the image direct on the stone by applying a photographic negative on a suitable coating sensitive to light, and removing by means of a solvent the parts unaltered by light. The transfer method, being the most convenient, is the one in general use.

The first photolithographic process on record is that proposed by Jobard, of Brussels, who, in 1839, obtained lithographic proofs from stone or zinc plates that had been treated with iodine or bromine. This process never came into practical use, and has been quite superseded by two distinct methods—one dependent on the alterability of asphaltum under the influence of light; the other on the reactions of the alkaline bichromates upon gelatine and other colloid substances.

Asphaltum Methods.—In 1852 MM. Lemercier, Lerebours, Barreswil, and Davanne proposed a method of lithophotography in which a stone was coated with a solution of bitumen in ether, exposed to light under a reversed negative, and developed with ether, which dissolves the parts not affected by the light, while the exposed parts, being insoluble, remain and form the image. (Benzole, chloroform, or turpentine may also be used instead of ether.) After development the stone was prepared with acid and gum, and inked in the same way as an ordinary lithographic drawing.†

Since then many other similar asphaltum processes have been proposed and have been worked with great success, both for subjects in line and half-tone; but, owing to the length of exposure required and the uncertainty of the results, this process is not well adapted for general use, and has, I believe, been almost abandoned in favour of the collochromate methods.

Collochromate Processes.—Paul Pretsch, whilst working out his photogalvanographic process, hereafter to be described, discovered that if a mixture of gelatine and bichromate of potash be spread upon a suitable support, and, when dry, exposed to light, then again moistened and inked in with a roller charged with printing ink, the ink would only take upon the parts altered by the light, and thus impressions could be obtained by transferring the design to zinc or stone.

Pretsch does not seem to have made any practical use of this discovery, but shortly afterwards, in 1855, Poitevin independently worked out a photolithographic process on the same principle, which has been the foundation of all the present processes of photolithography and photocollotype, and is worked to the present day for the reproduction of the Belgian topographical maps. Poitevin impressed his photographic image direct upon the stone and not by transfer.

The first practical *transfer* process of photolithography seems to have been suggested by Asser, of Amsterdam, early in 1859. He coated unsized paper with starch, and then floated it on a strong solution of bichromate of potash. When dry it was exposed to light under a well-intensified negative. The print was next heated with a flat iron, then moistened and inked in with transfer ink by means of a roller, and thus an impression was obtained which could be transferred to stone or zinc.‡

* Continued from page 417.

† See Davanne, *Chimie Photographique*, p. 456.

‡ *Photo. News*, vol. iii., p. 146.

The next transfer processes were the Southampton process of photozincography, which was founded on Asser's, and Mr. Osborne's process of photolithography. These two processes, though quite independent one of the other, were identical in principle and almost so in details, the only difference being that Mr. Osborne added a certain proportion of albumen to the mixture of gelatine and bichromate, and then treated his prints with boiling water in order to coagulate the albumen and leave a slight coating of it on the paper, so as to obtain a "grip" on the stone during the process of transfer.*

These processes have occasionally been used with fair success for the reproduction of shaded maps, architectural views, and other subjects in half-tones; but they are not by any means suitable for such subjects, and are best adapted for the reproduction of maps and drawings boldly executed in dot or line alone.

They may also be used for copying prints or engravings of all kinds on the same, larger, or smaller scales; but engravings, and even many lithographs, are generally more or less unsuitable for the purpose. The best results are obtained from original drawings specially prepared to suit the requirements of photographic reproduction, in strict accordance with the rules already given.

The following outline of the Southampton method will give an idea of the operations. Like the pigment-printing process already described it depends upon the property possessed by a dried layer of gelatine and other colloids, when mixed with an alkaline bichromate, of becoming insoluble and repellent of water under the influence of light. The procedure, too, is much the same as in the simple pigment-printing process, except that, instead of the fatty ink which forms the image on the photo-transfer print being mixed with the gelatine, it is applied to the surface of the print after exposure to light. The inked print is then washed in hot water, by which the colloid coating in the unexposed parts is dissolved and carries away with it the superfluous ink not retained by the lines forming the image. The negatives are obtained by the methods already described applicable to the reproduction of subjects in line.

Having obtained a suitable negative, the next operation is to produce from it a photograph in greasy ink which may be transferred to zinc or stone. To prepare the sensitive paper, a sheet of bank-post paper is coated twice with a mixture of six parts of gelatine and four parts of bichromate of potash dissolved in one hundred parts of water, dried in the dark, and glazed to give it a smooth surface. It is then exposed to the light under a negative for one or two minutes to the sun, or until the finest lines are distinctly visible. When sufficiently exposed, which may be ascertained by the whole of the detail appearing in brown upon a bright yellow ground, the print is taken out of the printing-frame and passed through a lithographic press in contact with a polished stone or zinc plate which has been coated with a lithographic transfer ink, and thus receives an even coating of the greasy ink. The inked print is immersed for a few minutes in tepid water to soften the gelatine still remaining soluble in the parts not acted on by light, and then laid on a sloping glass or metal plate and gently washed with a sponge and warm water till all the unaltered gelatine is removed, carrying the superfluous ink with it. The lines, on which the light has acted, remain insoluble and retain the ink, forming a clear image of the subject in a greasy transfer ink, precisely similar to the ordinary lithographic transfer drawing. When all the details are clearly and sharply defined, and the ground is quite free from ink, the print is rinsed in clean water and dried. It is then ready for transfer to stone or zinc. J. Waterhouse, *Capt.*

FOREIGN NOTES AND NEWS.

Dr. Eder's Request for Assistance.—A Direct Positive Process.

Owing to the absence of Dr. Hornig in Paris the publication of the *Photographische Correspondenz*, of which he is the editor, has been suspended for nearly six months, but has now been resumed. In the current number, which has just come to hand, Dr. Eder intimates that he is at present collecting materials for an exhaustive paper on collodion and pyroxyline, but that he finds considerable difficulty in arriving at the facts as observed by other experts on the following points:—The behaviour of collodion during its spontaneous decomposition; the age at which it sets in; and the circumstances most likely to induce it. He, therefore, begs any chemist or photographer who may be willing to give him the benefit of his experience to address his remarks to the care of the editor of the *Photographische Correspondenz*, who will forward them to Dr. Eder, by whom they will be thankfully received.

1. He wishes trustworthy information as to the properties of collodion cotton which has been kept for *years*, also as to the circumstances under which it was kept, and, when possible, as to its preparation as well as the eventual results of the reaction of the cotton.

2. He would be exceedingly grateful to anyone who would send him a sample of spontaneously-decomposed collodion cotton.

3. He would like to receive communications respecting the usefulness or uselessness of long-threaded, tough, collodion cotton for the ordinary wet silver process (for example, whether it induces rents when intensified), as well as the worthlessness of many short-threaded, friable cottons for the dry process.

The *Wochenblatt* gives the following method, by Herr Pellett, of producing drawings upon a white ground intended to be either strengthened or coloured by hand. The process is based upon the reduction by light of ferric chloride to ferrous chloride. The latter salt is not affected by a solution of ferrocyanide of potassium, while the former is immediately turned blue.

The paper upon which the print is to be made is sensitised by being dipped into a solution of—

Water	30 grammes.
Ferric chloride	3 ,,
Oxalic acid	1·5 gramme.

The oxalic acid may be replaced by an equivalent quantity of any other organic (especially vegetable) acid. If the paper do not contain sufficient size a little dextrine, isinglass, or some similar material may be added to the bath. The paper is then dried in the dark and may be kept, without losing its sensitiveness, for an indefinite period.

In order to reproduce a drawing place it upon a piece of dry sensitised paper, and place a sheet of glass above that again. In summer an exposure of about thirty, and in winter of from forty to seventy, seconds in the sun will be sufficient. In the shade from four to six minutes, and, when the sky is dark and overcast, from a quarter of an hour to forty minutes, will be required. Electric light acts very powerfully, the exposure varying according to distance and the density.

After the exposure dip the paper into a solution of eighty grammes of ferrocyanide of potassium in 500 grammes of water, which immediately turns all the unreduced parts of the ferric chloride blue. The picture should then be well washed and fixed in the following solution:—

Water	500 grammes.
Pure muriatic acid	50 ,,

Then well wash and dry.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
Sept. 11	Glasgow	172, Buchanan-street.
,, 12	Manchester	Memorial Hall, Albert-square.

THE WEST RIDING OF YORKSHIRE AND SHEFFIELD PHOTOGRAPHIC SOCIETIES.

The first united meeting of these societies was held at Bolton Abbey on Wednesday, the 14th ult. Although the morning was exceedingly wet a good number had the courage to start from Sheffield; but by the time the two societies arrived at Ilkley, the place of meeting, the day gave promise to be fine, and immediately after they had secured their seats to start by conveyance to Bolton Abbey—a distance of about seven miles from Ilkley—the sun broke out and the drive was greatly enjoyed by all the party.

On arrival at the Abbey grounds there was an immediate display of cameras, ranging from 5 × 5 to 10 × 8. All used dry plates, for which there was plenty of scope. In less than half-an-hour the Abbey was surrounded, and the noble pile of ruins withstood the play of both large and small photographic ordnance. Some members who had no desire for photographing, and consequently had not taken cameras, assisted those who had, either in attempting to improve the view by their personal attractions or in selecting views.

At half-past four o'clock all were in the conveyances, which were supplemented by a private one that had shortly before joined them, from Mr. Sachs' establishment, Bradford. The order was given to start back to Ilkley, where a good knife-and-fork tea had been provided at the Rose and Crown, at which place the party arrived about six o'clock, having picked up on the way one more member of the West Riding of Yorkshire Society who had travelled all the way from Colne, in Lancashire, to join the meeting.

After doing justice to the "good things" provided by "mine host" a start was made to look round the picturesque visiting place, Ilkley, the party taking the direction of the high hill south of the town, and after a pleasant walk of half-an-hour they reached the magnificent rock known by visitors as the "Cow and Calf," where a most extensive view is seen over Airedale in the direction of Otley, Harrogate, York, &c. Here a glowing description of Ilkley and its surroundings was given by Mr. Garbutt and others well acquainted with the locality.

On the return of the party to the Rose and Crown Hotel, a meeting was held, Mr. Firth, President of the Sheffield Photographic Society, occupying the chair. All the names of the gentlemen were announced at the conclusion of a very able and eloquent address by the Chairman, who proposed the health of the members of the West Riding of Yorkshire Photographic Society, seconded by Mr. Dakin, and responded to by Mr. Cook, who, in return, proposed the health of the members of the Sheffield Photographic Society. This found a ready seconder in Mr. Burrow.

Mr. Cook gave a lengthy description of scenes round about the Abbey, and particularly one which he entitled "The Rising Mist."

Mr. Burrow—who is one of Yorkshire's best amateur dry-plate workers—gave a slight *résumé* of his experience in dry-plate work, referring to different abbeys and ruins he had photographed, and kindly offered to lend any of his negatives, which are chiefly 12 × 10.

Mr. Holgate having attested the excellency of Mr. Burrow's plates, Messrs. Dakin, Sachs, Garbutt, &c., addressed the meeting, which was brought to a close at half-past eight o'clock, all expressing their enjoyment with the day's excursion.

PHOTOGRAPHIC SOCIETY OF VIENNA.

At the last ordinary meeting of this Society the chair was taken by Herr Melingo, owing to the absence of the President, Dr. Hornig, at Paris, where he was acting as Austrian Commissioner.

The Chairman intimated that before leaving Vienna Dr. Hornig had had an audience with the Minister of Commerce, and he had great hopes that the question which had been raised as to the transmission of collodion cotton might soon be settled in a way that would give satisfaction to photographers.

Herr Luckhardt showed two negatives and prints from them which had been sent by Herr Brand, of Bayreuth, and read the description of Herr Brand's method of producing these so-called *plastic* negatives, at the same time remarking that he could not recommend it, as he considered what Herr Brand called its advantages to be disadvantageous to the lens. The process consists in producing denser effects by rubbing two drops of glycerine on the back of the lens by means of a ball of tissue paper, so that the picture simply looks as if the subject had moved during the exposure.*

A letter from Dr. van Monckhoven was then read, in which he gave an account of his method of enlarging. The pictures which accompanied his letter were produced from old cabinet-sized negatives that Herr Luckhardt had given him long ago. The pictures were enlarged direct from the varnished and retouched negatives by means of a dyalising enlarging apparatus specially improved for the carbon process, and having a new negative-holder capable of holding a plate from *carte* size to 16 × 18 inches. There are also eight different lenses, which make it possible to enlarge all these sizes of negatives. As soon as the picture has been projected and focussed the focussing-glass is replaced by a frame on which is a sheet of the carbon tissue specially prepared for "hot climates and enlarging." This tissue is much more sensitive than the ordinary tissue, and gives a better result and more delicate half-tones, even with a rather hard negative. Dr. van Monckhoven usually exposes his enlargements until the photometer has registered half a tone, which usually requires about four minutes in the sun. When the print is hard he defers the transferring of it for twenty-four hours. When the print is of medium softness he transfers in seven or eight hours; and when soft, like those made from Luckhardt's negatives, he transfers it at once. He only uses the single transfer process, as he reverses the negative in the enlarging apparatus. The rest of the letter need not be given here.

A discussion followed on the way in which Mr. Gutekunst printed his panorama of the Philadelphia exhibition.

A sample of transparent paper intended to be affixed to the back of a negative for the purpose of receiving the retouching was then exhibited by Herren Mayr and Fessler.

Shortly afterwards the meeting was adjourned.

Correspondence.

BENNETT'S RAPID GELATINE EMULSION PROCESS.

To the Editors.

Gentlemen,—I shall, no doubt, receive in a few days some plates from your Coventry correspondent who is troubled with thinness of gelatine films, and shall be better able then to give him advice.

I have had the advantage of examining the work of several experimentalists, with whom fog from actinic light in the dark room and over-exposure were the only faults, with a single exception, in which latter case the gelatine having become decomposed (ordinary household gelatine having been employed, which is quite unsuitable), the bromide was no longer held in suspension by the gelatine, and excessive thinness was the result. One gentleman dried his plates in the ordinary ruby light of the dark room, which to a certainty will cause fog.

With a plate (twenty-four hours' emulsion) four feet away from the ruby glass, with a fish-tail jet inside the lantern, twenty minutes' exposure to one half of the plate—the other being protected by a card—caused, and will always cause, where only one thickness of the ruby glass is employed, a considerable fog on the plate. It developed, perhaps, half as dark as the sky, as an ordinary negative ought to do when finished.

* This method is a very unwise one. The only effect that such treatment is capable of producing is that of destroying the definition and blurring the picture.—Eds.

There being no need to keep plates or emulsion in the way of what we term non-actinic light for above a minute, and *never* so close as three or four feet, the fault of fogging need not occur. In several instances that I have already named the observance of this precaution has in each case obviated it. If there be no fog, and suitable gelatine has been used—which will seldom decompose, and which, therefore, will always hold the bromide in proper suspension—the image will quickly come up to any intensity, with the shadows perfectly clear.

I should recommend the bromised gelatine being agitated whilst the silver nitrate is poured in a thin stream into it; and I do not think your correspondent need attribute his want of density to the way in which it was poured in, as the other liabilities to error are the most common. I may, however, be able to tell him more exactly after seeing his plates.—I am, yours, &c., CHAS. BENNETT.

August 28, 1878.

[The foregoing letter was received too late for insertion in our last number; but since it was written we have received from Mr. Bennett the further following communication, which possesses great interest.—EDS.]

GENTLEMEN,—The plates that I have received from your Coventry correspondent appear to have been prepared in almost a sufficiently non-actinic light, the first plate which was developed without exposure standing the test of the developer with very little trace of fog. The chief faults, however, were, firstly, decomposition, the silver bromide being strewn on the plates in particles visible to the naked eye. The decomposition had taken place before coating, which is evidenced by the particles having, on coating, settled upon the plate, and caused around each a minute comet, but always in the direction of the corner at which they were drained. The gelatine, apparently, at the time of coating had approached half or three-fourths towards total decomposition.

Where a drying-box is made with the shelves too close, and especially with a deficient current of air as well, the decomposition will sometimes set in after the coating; but on *these* plates the comets in the direction of the dip tell their own tale.

Another fault was in *too close draining*—the film requiring to be double the thickness, at the very least. This, together with the fact of the gelatine (on account of its decomposition) having no longer held the bromide in proper suspension, caused the films to be so transparent that, notwithstanding the advantage of a backing which I applied to them, the halation was so great as to cause the lights to encroach upon the shadows to such an extent as to appear to veil the whole negative, so that the developer could not be kept on long enough to bring up the sky and high lights, as it should do. But although the transparency and attenuation of the film was excessive, and at least three-fourths of the silver bromide was of no service to the emulsion whatever, I think you will see from the plates I enclose that alkaline development alone will bring up these films to any required density. One of my own preparation, which I also place in the box, will, perhaps, show what they are really capable of under proper treatment. You will also, no doubt, notice the difference between an unexposed portion of the film on your correspondent's plates, where the silver is in a visible state of division, and on mine, where the film is without structure or mark.

Your correspondent, I understand, emulsified for three days, which, combined with the extraordinary electrical disturbances lately experienced in England, may account for the decomposition, so long a period rarely having elapsed lately without a storm. It does not follow by any means that such is the cause of the mishap, because the plate I enclose with his had thirty-six hours of emulsifying, and was prepared at the end of June, when, I believe, the electrical storms were almost as bad. I think the way he pours in the silver solution would not have caused the failure, and that, perhaps, if he change his gelatine, coats twice as thick, is equally careful as he has already been about his light, and exposes four to five seconds with the *smallest* stop of his six-inch slow symmetrical lens, he will soon be out of his trouble.

Your correspondent—as I gather from a note accompanying his plates—is of opinion that the result was equally thin whether with the shortest exposure or longest. He speaks of F 16 "instantaneous;" and, again, "portrait lens, full aperture, thirty seconds." This proposition I have quite disproved, as you will see from one negative, where the slide is pulled out an inch at a time. Each exposure was two seconds with the smallest aperture of a slow symmetrical lens, and at the third draw of the slide was over-exposed.

A gentleman once brought me a few similar plates, developed; the lens used was a rapid rectilinear of seven and a-quarter inches focus, No. 3x stop, exposure fifteen seconds. I have not that stop with my lens, so I cannot tell the relation of the aperture to the focus; but I believe it is half-way between full aperture and small ditto. *The negatives were burned up.* A better exposure would, perhaps, have been one-fifteenth of a second, made with a drop shutter with an elongated aperture.

Generally speaking, the exposures that are given lead to half the trouble, and would, perhaps, suit some other processes better than a gelatine emulsion one. Your correspondent, with a full-aperture portrait lens and *flap* shutter, which he also used, would hopelessly over-expose the plates he sent me, unless a considerable restrainer were used. A portrait lens with quick *drop* shutter and a mild developer containing one drop of liquid ammonia would be suitable for a street view or group with 72-hour plates; whilst, again, a marine view would be over-exposed and yield the thin image now complained of, leading the operator to hastily condemn a process to which he had not given fair play. In taking a marine view in May or June, with plates such as I have just been favoured with, I should, if using a rapid rectilinear or rapid symmetrical, certainly stop a little of the light off, and use a drop shutter—by a drop shutter meaning an elongated aperture with elastic spring, which is better than a round aperture passing the lens by simply dropping, as the former plan allows the *full* power of the lens to be acting on the plate longer in proportion than the latter plan.

One hint which I intended to make concerning attenuation of films was that, when your correspondent intimates that he has carried out the formula in every particular, I presume he has not omitted to use distilled water; gelatine—a substance so liable to decompose—could not possibly be kept bottled in water of any other quality. I am particular even to have the flask it has been contained in thoroughly scalded before using again.

I have in the foregoing entered somewhat into detail believing, from the number of solicitations which I have received for a few further hints, that this gelatine process is interesting a good many, and trust these few remarks may dispose of any remaining difficulties.—I am, yours, &c., C. BENNETT.

September 2, 1878.

[Every one interested in the subject of the production of rapid gelatine plates will feel greatly indebted to Mr. Bennett for the care and patience he has displayed in giving such directions as will tend to eliminate all sources of liability to fail with this process. The experimental negatives to which allusion is made in the course of his letter are now in our office, where they may be seen for a few days previous to our despatching them to Mr. Danks.—EDS.]

STEREOSCOPIC TRANSPARENCIES.

To the EDITORS.

GENTLEMEN,—In reply to Mr. Brooks I beg to say that where I consider him to be in error is in the fact that he goes a roundabout way to do what is a very simple matter, and that he advocates a most pernicious plan of printing when a much better one is equally open to him and to others who have anything in the shape of apparatus at all coupled with the smallest modicum of ingenuity. I am aware that most of the stereoscopic transparencies in the market are done by contact printing; but I have given contact printing a fair trial more than once, and I cannot too strongly denounce the practice for many reasons, amongst which the following occur to me prominently at this moment:—

1. Probable damage to the negative, and more than probable damage to the delicate film of the emulsion or dry plate.

2. Loss of sharpness where sharpness is a desirable quality, as it unquestionably is in a photograph that has to undergo the test of being considerably magnified. In camera printing, by the way, the sharpness of the picture can be regulated with the greatest nicety, whether extreme sharpness or the reverse be thought desirable.

3. All the advantages of "combination printing" entirely out of the field; for by no amount of skill or ingenuity could be obtained any of the beautiful effects which have been produced by this means, and by which, I may add, no end of beautiful and novel effects may yet be produced.

I have now briefly given Mr. Brooks the secret of what I consider the main disadvantage of his plan, and I could go on at some length to treat of the matter; but as my paper will, I hope, soon be placed before the public, I am naturally unwilling to anticipate the matter it will contain. I shall, therefore, refer Mr. Brooks to that source for further information.

Mr. Brooks accuses me of narrow-mindedness, because I appear to play the part of judge and jury. If he mean by such a remark that I write with an air of authority I cannot help it. He might as well call a schoolmaster narrow-minded for putting a little scholar right when he sees him doing his task in a clumsy, roundabout way.

Mr. Brooks cannot for a moment have supposed I should care for any rubbishy paper transparencies that happen to be in the market. I cannot even bear the sight of a paper photograph in any shape or form for the stereoscope, and would not have one in my house. Nothing short of a daguerreotype or a glass or gelatine transparency is fit for the stereoscope.

It happens to be gelatine I was thinking of when penning the paragraph referred to in Mr. Brooks's letter; and I need hardly explain to photographers familiar with the advantage of using tissue—for cloud and other negatives—the desirability of using some such tissue for transparencies for the stereoscope, mounted between suitably-perforated cards.

Successful experiments in this direction lead me to speak with confidence on this point, and why this has never been done before has always been to me the marvel of marvels, considering that manufacturers are mostly alive to their own interests. All one has to do is to print, by means of the camera, a transparency on glass, occupying the proper position, strip with gelatine or other tissue, and mount as I have already suggested.

For my own part I do not think a good stereoscopic transparency dear at a guinea; but it is possible I may be too sanguine in saying they can and will be produced at a shilling a piece *one of these days*, for I know Mr. Breese could not produce them profitably at five shillings each. That, however, has nothing to do with it; for Mr. Breese was a genius, and consequently, in all probability, a poor man of business. I have heard him complain bitterly of the way he had been swindled right and left all his life. Still I am quite willing to agree with Mr. Brooks that the lowest limit in price for a good transparency should be half-a-crown.

I may mention, in conclusion, one great advantage in camera printing, and that is that no one with a grain of sense would ever dream of cutting the negative or the transparency, even if the camera happened to be absurdly unlevel when the negative was taken, as it sometimes is in the hurry of photographing breaking waves, cloud effects (where the line of the horizon requires to be shown), balloon ascents, birds on the wing, and other subjects taken at moments more or less exciting.—I am, yours, &c., S. H. Ashley Oakes.

16, *Silverwell-street, Bolton, September* 3, 1878.

EXCHANGE COLUMN.

A new interior background (conservatory) will be given in exchange for a good landscape ditto. Photographs exchanged.—Address, H. Cooper, 46, Louise-road, Northampton.

Wanted, a developing tent on wheels for 10 × 8 work, with fittings, in exchange for a Voigtlander's 10 × 8 orthoscopic lens.—Address, H. Dyball, 3, Lower Notting Hill Terrace.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

Photographs Registered—

Patterson and James, Ramsey, Isle of Man.—*Photograph of Bishop of Sodor and Man; Photograph of Bishop's Court, Isle of Man.*

James Thomson, Liverpool.—*Photograph of Wood Carving*, "*Tam O'Shanter and Souter Johnnie.*"

Marshall Wane, Douglas, Isle of Man.—*Photograph of Andrew W. Gray.*

Notice.—Each correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a *nom de plume* as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

John Frankland (Blackburn).—Thanks. In our next.

Erratum.—In our last number, *Copying Oil Paintings*, page 108, line eight from bottom, for "camera" *read* "canvas."

J. Malcolm.—Gold is precipitated in a metallic form from the solution of the chloride by the addition of protosulphate of iron.

Thos. C. Lord (Huddersfield) encloses a *carte* portrait of a child, nicely enamelled. Mr. Lord practises enamelling professionally.

M. P. J. A.—Metagelatine is merely common gelatine that has been subjected to certain treatment by which it loses its power of becoming jellyfied or solid.

W. S.—It will afford us pleasure to see examples of Icelandic photography. We were not aware that our art-science had any devotees so near the north pole.

Geo. Fisher.—No action can be taken until you have consulted your district surveyor. Lose no time in seeing him, and apprising him of the proposed alteration.

C. M. A.—Of the two lenses the cemented single achromatic is best adapted for ordinary landscape work. For architecture or copying the triple lens will prove much the better of the two.

L. R. M'Lachlan.—If you mean a *carbon* enlargement we should prefer it for such a purpose to a collodion transfer; but if the solar enlargement is to be in silver, then the collodion transfer will be better.

Geo. F. Hunter.—Non-actinic varnish applied to the windows will answer very well; but you would act more wisely in making use of coloured glass. It is now easy to obtain ruby glass well adapted for the purpose.

Obliged Reader.—A solution of bees'-wax in turpentine will answer quite well as an encaustic paste for photographic prints; but the addition of a small proportion of oil of lavender will make it more pleasant to work with.

M. A. (Oxon).—It was in the year 1869 when the meeting of the British Association was held at Exeter. Professor Stokes was president on that occasion, and, if we recollect aright, devoted a large portion of his opening address to optical science.

Green Isle.—A photographic society did at one period exist in Dublin, but it has been discontinued for many years. Seeing that there are numerous able photographers and chemists in Dublin there is no reason why another effort should not be made to form a new society. If such a step were taken the resulting society, if well "officered," would prove one of the best in Europe.

An Apprentice.—A piece of common hard sandstone will answer as well as anything else for roughening the edges of the plates. Such a piece of stone, nicely cut, may be obtained at a cost of a few pence at any leather warehouse or other place where shoemakers' furnishings are sold.

Dr. R. L. Maddox.—We are much pleased to have heard from our correspondent once more. The Almanac has been sent as requested. We trust that Dr. Maddox is about to revisit England, if only to see the progress made by his child—the gelatino-bromide emulsion process.

Constant Subscriber.—We are unable to give detailed directions as to the best method to proceed in mounting prints in quantity for book illustration. If personal application were made to such firms as are in the habit of executing this kind of work some of them would doubtless give the desired information.

One in a Fog—Render the bath neutral by means of a solution of bicarbonate of soda—indeed you may add sufficient of this solution to turn the bath quite of a pale, milky appearance; then filter, sun, and, if necessary, even *boil* the bath solution, which will then be all right. The fogging was caused by impurities in the water with which the bath was diluted.

A. P.—Our correspondent writes:—"1. Will you or some of your correspondents kindly inform me whether Captain Abney's albumen-beer plates are to be had commercially? If so, where? I wish to try them, but have at present no facilities for preparing them myself.—2. Will some one favour me with the names of some British photographers, amateur or professional, residing in Spain?"——In reply to the first query: we are not aware of any one who supplies plates prepared by the beer and albumen process. They may be prepared so easily that "A. P." ought to do so himself. Will some correspondent please reply to the second query?

J. Ekralc.—1. No; there is no necessity for mounting the lenses otherwise than in strict parallelism to each other. Convergence, in such a case, would lead to inconvenience.—2. To obtain a stereoscopic picture of a "ghost," let the group be arranged in a natural position, with attitudes and expressions suited to the occasion. Now give three-fourths of the full exposure required, and, cautioning the sitters not to move, cap the lenses and make the figure that is to personate the ghost take his or her place in the position assigned; then uncap the lens and give the remaining fourth of the exposure. When developed the "ghostly" figure will be well defined and distinct, although transparent to such a degree as to enable the objects on the other side to be visible through the figure.

Quarter Deck.—Several years ago—probably now over twenty years—an invention was made by Professor Piazzi Smyth by means of which a telescope, or a photographic camera, could be retained in a perfectly steady manner for several minutes on board of a ship even when the ship was being heaved and tossed by the billows. It was based on the principle of the gyroscope, and consisted of a heavy wheel that was caused to rotate at the speed of about eighty revolutions per second, the frame upon which it was supported having been accurately balanced on gimbals like a mariner's compass. When in motion and supported in this manner the large rotating wheel is absolutely insensible to any movement which the outer frame may experience at right angles to the plane of rotation. It is only necessary that this plane shall in the first instance be placed horizontally to ensure a table placed upon the inner frame of the spinner being entirely protected from all the possible angular movements of a ship; and a telescope placed upon such a table, and once directed to a star, has kept it in the field without the aid of a hand, even when the ship was pitching and yawing heavily. In an instrument of similar construction you will find the means of solving your problem.

Paragon Mounts.—From Mr. Richard Crowe, Liverpool, we have received specimens of his "paragon mount." This consists in printing by lithography and in a photographic tone of colour a ground upon the *carte* mount, the said ground being either quite plain or having ornamental corners. The print having been trimmed to an oval or other shape is pasted upon the mount, the gloss of the albumenised surface of the former contrasting with the matt of the latter.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician.
For the Week ending September 4, 1878.

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 958. Vol. XXV.—SEPTEMBER 13, 1878.

A FEW WORDS ON THE PRODUCTION OF TRANSPARENCIES.

Mr. W. Brooks's paper on *A New Method of Making Glass Transparencies* has elicited the criticisms of gentlemen equally interested in that delightful branch of photography, and the discussion which has been going on in our correspondence columns has turned principally upon the relative merits of contact and camera printing. With the commercial side of the question we have at present nothing to do. The price at which a transparency can be produced or will find a ready market is a matter resting entirely between the manufacturer and the public; and though we can fully agree with all that has been said as to the desirability of popularising this most perfect of all styles of photograph it is beyond our province, as it is against our rules, to interfere in such matters.

But the subject has other bearings equally as important as the commercial, in which the amateur producer is more especially affected; and it is in this direction we wish to follow up the discussion and to point out in what particular respects the rival methods of production are most likely to recommend themselves. A careful perusal of Mr. Brooks's article will show that the method he there proposes is put forward with a special object, namely, to simplify the operations when performed upon a small scale or by the amateur. Mr. S. H. Ashley Oakes, however, considers the new method a "roundabout" one, and, looking at it from one point of view, perhaps it is; but so is the plan of cutting the negative, and so more emphatically is the camera method to the small producer, especially if unfamiliar with the requisite manipulations.

The two methods of printing in the camera and by superposition are essentially different in character and in application, each possessing its own special advantage; but we cannot help thinking that Mr. Oakes, who is an enthusiast in a particular branch of transparency work, has lost sight of the real gist of the matter in adopting the line of argument he has done. It is beyond the possibility of denial that for combination printing the camera is a *sine quâ non;* and even for plain stereoscopic work on a large scale it affords facilities which contact printing does not, and cannot, attempt to compete against. But to the ordinary amateur it is a question whether the advantages thus acquired are sufficient to recompense him for the extra outlay in special apparatus, and for the extra trouble involved in the adoption of a comparatively unfamiliar system of manipulation.

Let us glance briefly at the advantages accruing from the use of the camera, setting aside the class of pictures which are so intimately associated with the name of the late Mr. Breese, and which few, if any, photographers—amateur or professional—have succeeded in imitating. First of all, there is no necessity to cut the negative, the operation of reversing the two pictures being performed in the camera. Secondly, we have the power of enlarging or reducing the picture as represented in the negative in order to include more or less of the subject in the fixed bounds of the stereo. transparency. If we add to these the somewhat ambiguous recommendation mentioned by Mr. Oakes in his last communication—"the possibility of obtaining extreme sharpness *or the reverse*"—we have exhausted the list.

With regard to the first advantage a great saving of time and trouble will accrue where a large number of pictures have to be produced, and a single adjustment of the camera will ensure the absolute uniformity of the results as far as regards the distance of the centres; but most amateurs, we imagine, would prefer some simple plan—such as that proposed by Mr. Brooks—or would even be content to spend a little more time in adjusting each half of the transparency separately, rather than "build" a camera for the express purpose.

The second recommendation—the power of enlargement or reduction—might possibly be useful in some cases; but seeing that a stereoscopic picture, whether on glass or paper, must conform to the same rules as regards size, we fail to find any reason for the necessity of any departure from the scale depicted in the negative. We should imagine that any intelligent person taking a negative for stereoscopic purposes would select his point of view in such a manner that the proper amount of subject would be included within the limits of a stereoscopic slide; and if such negative be available for paper printing it would be equally so for a glass picture. Of course, cases may arise where it is impossible, from optical or other reasons, to include the proper amount of subject in the space at disposal, and it is in these exceptional instances that the benefit of the camera would be chiefly experienced.

We do not exactly catch Mr. Oakes's meaning with regard to "extreme sharpness or the reverse," especially when we look back at his preceding sentence, in which he speaks of the desirability of sharpness; but if, under any circumstances, the "reverse" be the case, surely it is an easy matter to obtain any degree of "woolliness" by separating the negative and the prepared plate in printing by superposition.

Against the few advantages we have named we may place as a set-off, first, the necessity for special apparatus; for we cannot agree with the statement that "anything in the shape of apparatus at all, coupled with the smallest modicum of ingenuity," would lead to satisfactory results. Rather, we should say, the difficulties would be increased. Then the matter of illumination forms a serious obstacle. In daylight it is comparatively easy to "rig up" a simple reflector to throw a tolerably evenly-diffused light upon the negative; but very many amateurs are not so situated as to be able to utilise the hours of daylight during the winter months (when transparencies are mostly produced). Reduced to artificial light, a condenser becomes almost a necessity if the best results are required; but whatever means be adopted to secure even illumination it means extra trouble, vexation, and uncertainty.

Another objection will be found in the greatly-increased exposure required in camera printing, even when employing the most rapid plates. This alone will form a serious consideration to the amateur, whose time available for photographic pursuits is usually limited, and who will, in the majority of cases, prefer contact printing with its few seconds' exposure to an ordinary gas flame or paraffine lamp. Finally: the quality or character of the negative forms a far more important element in camera printing than is the case with the alternative method. Good results may be obtained by the latter with negatives of widely-different character; but the best results in the camera are obtained with negatives almost too thin for paper printing, and very great care and skill become necessary to produce a pleasing picture if a plate of more than ordinary density be in question.

Mr. Oakes speaks of contact printing as "a most pernicious plan," and divides his impeachment of it into three chief heads, with only two of which we are at present concerned. First, he mentions the probability of damage to the negative, and more than probable damage to the sensitive film. This will depend very much upon the quality of the glass used, and upon the exercise of care in removing any dust or "grit" which may become attached to either surface. In a great variety of experiments with different dry plates, extending over nearly two years, we have been in the habit of using one particular negative, which we keep as the standard by which to test the qualities of the different processes. It is upon the ordinary crown glass employed for landscape purposes, neither better nor worse than the ordinary run of such glass, and received a single coat of negative varnish such as we are in the habit of using. It has probably been in contact with some hundreds of dry plates, but it does not yet show signs of much damage or ill usage. As regards damage to the sensitive film there is, perhaps, more reason to speak, especially with washed emulsion ones unprotected by any preservative; still, with a little care, no danger need be anticipated even on this score. It is easy, however, to apply a preservative, and if a dilute solution of albumen be selected for the purpose there will not be the remotest risk of damage.

In the matter of sharpness the quality of the glass will also have a great deal to do with the result. Most crown glass has a concave and a convex side, and if two concave surfaces be brought together there will no doubt be an appreciable loss of sharpness. But by noting the curve of the glass (if any) and acting accordingly the defect may be reduced to a minimum; and if the printing be performed at a little distance from the light it will require a very critical eye to detect any falling off in the definition. The thin glass generally employed for transparencies adapts itself so readily, under slight pressure, to the curvature of the thicker negative that very little cause of complaint remains if the printing be performed in an intelligent manner.

The convenience to the amateur of being able to use the same plates he is accustomed to work out of doors and to dispense with any additional apparatus will, we think, ensure for contact printing a longer continuance of favour than Mr. Oakes seems disposed to accord to it. In saying this we do not wish to appear to undervalue the camera, which, as we have before stated, is indispensable for some descriptions of work, and, under certain circumstances, is no doubt preferable to the rival method. We shall be glad to see Mr. Oakes follow up his crusade in favour of high-class stereoscopic work; but trust that he will not allow himself to be prejudiced against the genuine efforts of others in a similar though not identical direction. We are all indebted to Mr. Brooks for his valuable paper, which, even from Mr. Oakes's point of view, scarcely deserves the wholesale condemnation he has heaped upon it.

DRYING PRINTS.

The apparently very simple matter of drying albumenised paper prints is by no means the easy and straightforward thing that it appears, and, as we do not remember details of any amount of fulness having been given on this subject, we purpose considering a few points of interest that arise during this by no means unimportant operation.

Most large printing establishments have methods of their own—some good, some bad—and others no method at all beyond a haphazard way of getting through the work somehow. Whenever a piece of work has to be performed by a number of hands allowance has to be made for the fact that the principal cannot always overlook its progress, and all systems, whether designed on a large or small scale, must allow for this fact. Thus, the chemist in his laboratory often invents new processes of manufacture which, if carried out on a large scale, would enable him to make a fortune. He patents his discovery perhaps, and finds too late that the process, which in his own master hands worked admirably, breaks down when submitted to the rough test of manufacture by the comparatively unskilled hands of the average workman, who will not take special pains to produce a certain result.

And so in photography. How many careful, conscientious workers—beginning at first with no external help, and able to point with pride to their early efforts, perhaps a dozen years' old, showing no trace of fading—in after years, with their reputation made, find their more recent pictures (produced in thousands for each former unit), with the best paid help and with the aid of the best apparatus and most perfect general arrangements, show signs of fading before they have been many years sent out of their hands! The truth is they have not been able to be in every spot at once, and some one of the helpers has been careless or worse, and so upset every calculation and rendered worthless the best system.

In nothing could a better exemplification of this be offered than in the drying of albumenised prints. One of the commonest methods is to dry the print between sheets of blotting-paper. Some day something happens—hypo. left about instead of being cleared away; an accidental and unnoticed stoppage in the water supply; in fact, any one of the hundred unexpected incidents of the kind which will occur, and a few half-washed prints will in consequence get placed between the blotting sheets, and leave behind a store of hypo. to injure an unknown number of succeeding prints dried between the same sheets.

The best plan we have seen adopted for drying prints by the sheets is as follows:—The prints, taken out of the water one by one, are laid upon well-washed pieces of linen till each "sheet" is covered; another sheet is then placed on the top to be covered with prints, followed by another sheet, and so on till all are arranged. A little gentle pressure then removes the greater part of the moisture, and the prints are now placed between sheets of blotting-paper for a final drying, where they are left till ready for sorting or cutting.

Some photographers use linen cloths only, others merely blotting-paper or board. Now, this double-drying plan carried out in its integrity is very good, but most particular care has to be taken that the routine is thoroughly followed day after day. No holiday time and short hands, no press of work, no oversight, no neglect in consequence of a bad printing day leaving few prints to attend to, can be permitted to interfere and allow a batch of prints to be left in the sheets over the day, or everything will go wrong.

We know of a case where this system was practised, when the principal personally overhauled the sheets one day and found a few score of damp prints that had lain forgotten between the lower sheets for several days—a state of things which could scarcely help ending disastrously for the prints in course of time, if not at once. The prints had been put aside one day and left, and then been forgotten. We have narrated this incident as one of the many possible ways in which this system might fail. Therefore we think that *every day* the principal or a responsible subordinate should see, when this method of drying is pursued, that every linen cloth or blotting-paper or card, whether used or not, should be hung up to have an airing and to dry. In winter and damp weather this is especially desirable, for the paper sheets would be permanently damp if not separated and dried, and the evil effects that might follow from such a result need not be enumerated; and of course periodically the linen cloths should be well washed and rinsed in clean rain water.

Perhaps the most popular method is to hang up the prints by American clips till quite dry, and it is one which has much in its favour, the only foreign enemy being dust, and that can easily be guarded against if there be suitable space at command. One chief drawback to the use of the clip, beyond the space required for hanging, is the liability of the prints, if on paper, having a gloss at all beyond the average, to show when quite dry a multitu le of fine cracks, which gives the mounted print a very unsightly appearance. There is no remedy for this except taking the prints down before they are quite dry, or drying between sheets.

We have recently seen, at the studio of a gentleman whose methods of working we have before alluded to, a modification of the plan of drying between sheets which seemed to reduce the possibility of ill results through carelesness to a minimum. With a description of it we will close this article.

The prints were placed as before described between the linen cloths, and when all were collected in a heap it was turned over and the lowermost one first submitted to the next process. We would here note that in some establishments it is customary to supersede the final drying between paper by placing the prints before a fire and so drying them off quickly—a very good plan in many respects.

In the studio in question this plan was formerly adopted, but it was found that so much time was lost in "watching" the print as to interfere seriously with the general routine of the establishment. Instead, therefore, of taking the prints to the fire a gas drying apparatus was arranged, and of such a simple nature that it could not get out of order. A sheet of tinned iron was hinged to the wall near the sorting cupboard, and under it was placed a star of gas jets at such a distance as to make the plate hot, and yet not so hot as to scorch the prints; on this they were dried most easily and quickly, and no time was lost. The plan has been in operation for nearly a year and is much liked. It has been found that the best plan is to cover the tin over with a piece of tissue paper (not tracing paper) and place the prints upon it *face downwards*, as they then dry much flatter. We may have something to say on a future occasion upon sorting, cutting, and mounting prints.

REMINISCENCES OF A VISIT TO DUBLIN.

No. I.

When in Dublin attending the recent meeting of the British Association for the Advancement of Science we made a few jottings, which may prove of interest to our readers.

The number of professional portrait photographers in that city is very great. Sackville-street and Grafton-street, more particularly, contain numerous studios. Taken as a whole the work produced is excellent. In several show-cases we found pictures of a quality we have never seen surpassed either in London or elsewhere in the United Kingdom. The Dublin photographers do not seem backward in adopting such improvements as from time to time are brought out. The sight of a Cadett's pneumatic shutter suggests the reminder that when visiting the studio of Mr. J. V. Robinson (Millard and Robinson), Sackville-street, that able photographer showed us in his own practice an improvement he had adopted upon the method we described of grasping the air-ball in the hand and giving it a squeeze when the exposure was about to be made. Mr. Robinson's method was much simpler and better, as it left both hands at liberty. He merely placed the ball upon the floor, and, putting one foot on it, he gave it the desired pressure when it was necessary to uncap the lens. We have since then tried this method of exposing with great advantage. Mr. Robinson does not confine himself to portraiture—a fact attested by several charming landscapes of local scenery we saw in his show-case.

Having a vivid recollection of what Mr. Lesage wrote to us several years ago with regard to the effect of some blue glass sashes in his studio, we made a point of calling to see them. We found that his studio lay in a S.E. and N.W. direction (our remarks here must be accepted as only *approximately* accurate, being based upon the position in which we saw the sun one afternoon). The sitter faced the south-east, and of course during the forenoon the sun would beat upon the sitter, who was placed at the north-west end. But on the right hand of the sitter the room was fitted with supplementary interior sashes filled with blue glass, one side of which was ground glass. Now, in taking a portrait, if the sun were obscured the plain glass of the studio windows would suffice for the admission of light, because the sitter would be merely illuminated by a bright, cloudy sky. If, on the contrary, the sky were cloudless and the rays of the sun likely to interfere with the equanimity of the sitter or the perfection of the lighting, the movable sliding sashes could be utilised, and blue ground glass interposed between the sun and the sitter. A southern light is a bad master, but may prove to be a most excellent servant when means like those here briefly described are employed to hold it in check.

Having seen an excellent portrait of a "subject" very difficult to take, obtained in the studio of Messrs. A. and G. Taylor, of London and numerous other towns and cities, including Dublin, we were induced to visit their establishment in Stephen's-green, adjoining Grafton-street. This firm here, as well as elsewhere, appears to do a very large business in enlarged coloured photographs, many of which we noticed were ready to be framed and despatched to their respective *clièntele*. Examining these paintings somewhat crucially we saw that the faces were to a great extent finished with transparent oil pigments, which accounts for the excellent manner in which the likeness is preserved. The studio is so constructed as to enable the sitter to be placed at either end, and during the short period of our visit we saw negatives taken which, as respects their fine light and shade as well as posing and other artistic attitudes, we have never seen surpassed elsewhere.

In the show-case of one photographer we saw, ranged side by side, portraits in silver and in carbon—of course from the same negative. The former were indicated as being evanescent; each of the latter were, on the contrary, to be considered a "joy for ever." Now, after all that we have written in support of carbon printing and its peculiar virtues, no one will be likely to suspect us of proving false to our colours when we say that if it had not been for the peculiar technical knowledge of the specialities of the two methods of printing we possess we should, as a mere matter of beauty, have given the preference to the fading silver prints rather than to the enduring carbon ones. We are not in a position to say how long the prints referred to have been exhibited in the show-case; but if the time has not been *very* great, then we should say *(more Hibernico)* that the photographer must "kick up a row" with his printer for his carelessness in allowing prints to be passed showing such unmistakable tokens of sulphurisation as one or two of these did. On the other hand, his carbon man must be taught that in the eyes of an unreflecting public permanence alone will form but a poor substitute for other qualities expected in a photograph.

At the railway station, while *en route* for the beautiful suburban town of Kingstown, we saw a show-case which struck us as being exceedingly effective. It was of somewhat large dimensions and backed with a fabric—velvet, if we mistake not—of a dark maroon colour, puckered up in a peculiar yet pleasing and artistic manner. In the cavity between each "pucker" was a *carte* portrait, and, forming a centre-piece to the whole, was an elaborately-painted enlargement in a gilt frame. Having never seen anything of this character in London we here direct attention to it for the benefit of any who may desire to take advantage of the suggestion.

We have mentioned Kingstown. We were never more surprised than at the discovery of the very low state of photography in that charming town, which is only a few miles distant from the Irish metropolis. It may be that there are more photographers there than the *very* few whose "establishments" are situated in the principal commercial street of the town; certainly during our visit we did not see any others. In the window of one of these temples of art had lodged such a quantity of dust as provoked the remark from a professional friend in our company that it was "at least an inch thick." This we unhesitatingly assert is not quite in accordance with fact; we, at anyrate, did not think that there was quite such an aggregation of "matter in the wrong place" as this. There was, however, very much room for improvement. The public like to see a shop interior neat and tidy, and, other things being equal, will patronise such a place. Judging from a circular which was put into our hand, two of these "artists," whose "galleries" are next door to each other, appear laudably desirous of not leaving the public in ignorance as to whether it is Codlin or Short that is the friend. With the twofold end in view of giving one of these "artists" a greater amount of publicity than he is likely to obtain by the distribution of handbills at his "studio," and also of enabling such of our readers as, being placed in similar circumstances, may be desirous of a model upon which to base their own appeals to the public, we here append, *verbatim et literatim*, the circular in question:—

Clarendon's Photographic Gallery, 94 Lower George's Street. Kingstown. No connexion whatever with the house next door. In consequence of mistakes made by persons wishing to patronize Clarendon's Gallery, J.N.C. respectfully requests his Friends and the Public to observe that he keeps no BOYS watching about the doors of his GALLERY. and particularly desires his Friends and the Public not to be led away by "URCHINS" on the LOOK-OUT FOR CHANCES. The Name and Number CLARENDON.94 are plainly written over the doors of J.N.Cs, Establishment, which he hopes his Friends and the Public will not mistake as he is most anxious that their Cartes should be taken in a Superior Style and which can only be done at J.N.Cs, *Long Established Gallery* All kinds of Photographs taken including the OLD POSITIVE now puffed up by others under the new name of "FERROTYPES"

The statement in the concluding sentence is doubtless an unkind cut at his ferrotyping neighbour; still, Mr. Clarendon speaks no more than the truth in asserting the identity of the "old positive" with the modern "ferrotype."

RECENT PATENTS.

No XV.—BINOCULAR OR SPACE PHOTOGRAPHS.

This is a patent obtained by Carl Heinrich Lehmann, of Stargard, Pomerania, for "an improved method of taking binocular or space photographs."

Previous to giving the specification—in which, to prevent any mistakes, we prefer to adopt the phraseology, pure and simple, of the patentee—we may state that it consists of a method of taking ordinary single pictures by means of a large lens, which shall be all stopped up with the exception of two apertures at its margins.

It is well known to opticians that a body, if seen with but one human eye, appears as a plane, and not as a solid or body resting in space. The latter impression we receive only by catching with the other eye other points and planes of the object which the one eye cannot behold.

In the art of photographing no method has been hitherto known or used which, according to theory and experience, produces on the eye in looking at a photograph an effect or appearance of objects being seen with two eyes; or, to use another expression, as standing free in space, or in relief, and allowing an estimation of the space between two points more or less distant from the spectator.

It is required or expected in photographic pictures, more than in any other kind of pictures, that they should produce upon us the impression of reality, or of an object seen with both eyes. It will be necessary before all that the picture should not contain any lights, shadows, outlines, and perspectives which would not be seen with two eyes, and if such be found, nevertheless, they may be called adulterated lights, shadows, outlines, and perspectives.

By the method hitherto employed in photographing and other uses of the *camera obscura* (which method consists in either permitting the rays of light to enter through the whole surface of the object-glass, or through such part of the same as does not divide the entering rays) such adulterated lights, shadows, and the like, must be produced; or if the aperture for the light be very small, and the distance very large, the object will appear as if seen with one eye only. If, however, an object-glass of larger size, quite uncovered, should be used, lights, shadows, outlines, and perspectives will appear on the picture as they should be seen by one eye with a pupil as large as the object-glass, but such an eye would not see at all.

If, for instance, a photograph were to be made by a sufficiently long or a sufficiently narrow tube placed at the lever of the two eyes, and perpendicular upon the line between the two eyes, so that neither the right nor the left eye could look through the whole aperture of the tube, the averse aperture should not be visible upon the picture. The picture, taken with the object-glass uncovered, will nevertheless show the impression of the light of the full aperture. This light I call adulterated as well as the perspective.

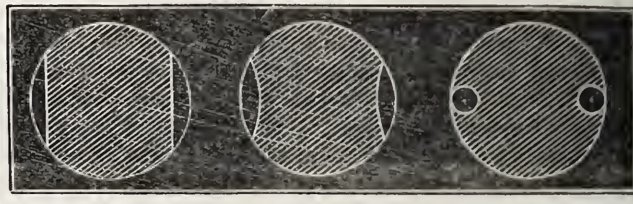
These adulterated lights and other effects I avoid by my improved method, which involves the covering of the object-glass as herein described. I make the light of the object fall upon the receiving plate in the same manner as the rays of light of an object seen enter through the two eyes and unite in the impression of one picture.

The lens apparatus, combined with the *camera obscura*, may be well compared to the human head. The object-glass represents the eye, and the said improved method chiefly consists in giving the effect of two eyes to this one eye by covering the object-glass in such a manner as to make the light enter only through two separate apertures. Hence I term the pictures thus produced "binocular pictures."

Any particular form of the two apertures allowing the light to enter is not essential, and any suitable material may be used for those parts of the object-glass through which the light is not allowed to pass.

In the accompanying drawing, *figs.* 1, 2, and 3 show in what manner the object-glass may best be covered. This method of

FIG. 1. FIG. 2. FIG. 3.



covering the object-glass may be applied to glasses of any size. With small object-glasses care must be taken that the case projecting to shade the object-glass does not too much limit the scope of view. This difficulty may easily be prevented by suitably widening the case.

The picture will become the more perfect the more nearly it is made in accordance with the position and construction of the human eyes. For this purpose it is best to use an object-glass of more than two and a-half inches in diameter. If possible, a space of two and a-half inches (the average distance between the pupils of the eyes) should be covered upon the object-glass, and on both sides of this untransparent space ample space should be left to admit sufficient light to produce the picture. If I place an object-glass thus prepared in opposition to an object in the same place which my eyes had previously occupied, the rays of light, equal in strength and direction, having before entered my eyes, will now fall into the eyes of the object-glass. The picture thus produced will in consequence make exactly the same impression with relation to the proportions of size and distance as if the object were beheld with the living eyes.

Suppose I should place before the apparatus a globe on which the degrees of length and breadth had been marked: if the picture show the degrees from 1 to 180, or more, the globe must obviously be smaller than two and a-half inches in diameter; on the contrary, it must be larger, or the distance from the object-glass must be less in the same proportion as a smaller number of degrees appear upon the picture.

The size of an object is not estimated by numbering the degrees, but the impression of it is received by the size of the angle formed by the axis of the eyes in fixing an object.

With the pictures produced by my improved method the effect will be the same. The object of the photograph will always appear more natural and more agreeable to the eye than in ordinary pictures. My said improved method may be applied in any photographic apparatus, no essential modifications of the usual proceeding being necessary. Photographic pictures produced by my said invention may be readily distinguished from ordinary pictures.

Having thus fully described my said invention and the manner of performing the same, I wish it understood that I claim the improved method of taking or producing photographic pictures or photographs by using a photographic apparatus with its object-glass prepared or partially covered by any untransparent fabric or substance, leaving two separate apertures of convenient form to permit the light to enter, and whereby I obtain photographic pictures, which I term binocular pictures, as above described.

We have only at present to remark that if Herr Lehmann attempt to take single photographs by the method proposed, in the expectation that they will possess stereoscopic relief, he will find himself greatly mistaken. This dream was indulged in by a few in the early days of our art-science; but for optical and physiological reasons, into which we shall not here enter, it was speedily discarded.

Among the various mechanical devices for effecting the exposure of a plate in the camera without the sitter being aware of the fact is one which has been brought under our notice by Mr. William Weaver, High-street, Runcorn. It is evidently carefully thought out; certainly it is most ingeniously contrived, simplicity being a leading feature throughout. A very light shutter slides up and down between two deep grooves in a frame fixed *inside* of the camera and close to the front. Although light, this shutter still possesses a degree of weight sufficient to enable it to fall by the force of gravity to the bottom of the frame, in which position it covers up the lens, effectually preventing the access of light to the interior. A thin piece of flexible silk string is attached to the shutter, providing the means by which it is pulled up. By the aid of a small bent tube, capable of being pointed in any direction, and placed in the top of the camera, the string can be conveyed in any desired direction, either behind or to one side or the other. While the focussing is being effected the shutter is pulled up, thus allowing free access of the light through the lens to the ground glass. This having been done the shutter is dropped, the dark slide containing the sensitive plate inserted, its shutter withdrawn, the lens uncapped, and a favourable moment awaited when the exposure may be safely made. This is done by pulling the string, which may be either only a few inches or a hundred yards in length. Of course it is done without the attention of the sitter being attracted, for the string is very thin, and it may be pulled without the sitter being made aware of it, and also without giving a jar to the camera. After a sufficient length of exposure has been given the string is eased and the shutter drops. The camera which has been submitted to us for examination is that in every-day use by Mr. Weaver. Having employed it constantly since the beginning of June he is enabled to speak as to the efficient manner in which it does its work. So far as we can see this will prove a most useful addition to the mechanical appliances by which photography is becoming more and more simplified as regards at least its manipulative details. In Mr. Weaver's lens —a *carte* portrait combination—we also find a drop shutter ingeniously fitted. A slit, like that in use for the insertion of Waterhouse diaphragms, is cut into the lens-hood, just in front of the anterior lens of the combination; but this slit is cut into both sides of the hood, so as to permit of an oblong steel shutter passing through it—the shutter, of course, containing an aperture the size of or larger than, the diameter of the front lens. This provides for an instantaneous exposure being given.

It is rather amusing to notice how, in the course of photographic practice, different experimentalists move round and round in circles, as it were, like a straw in an eddy, continually passing and repassing the same spot without exactly touching it. At the last meeting of the Photographic Society of France (the report of which we are compelled to hold over till next week) M. Fabre, of Toulouse, made a communication on the subject of precipitated emulsions. That gentleman has found, as many others have done, that an emulsion which works to perfection before precipitation is frequently found to be perfectly useless afterwards. This result he attributes to the action of the hot water used in precipitating, which, by the rapid causes the silver bromide to escape and agglomerate into coarse, sandy volatilisation of the ether, bursts the cellules of the precipitate and particles. Without disputing the correctness of this theory it may be remarked that the same result occurs when *cold* water is used, and when there is no such *bursting* of the particles of collodion. M. Fabre goes on to say that some writers have asserted that the coarse particles of bromide thus formed have parted with a portion of their bromine, and consist in reality of sub-bromide. We do not recollect to have seen such a theory propounded; but it is satisfactory to find that our author is ready to combat it, holding that the change is merely a molecular one. He then proceeds to show how the trouble may be prevented. It arises, he believes, from the power of resistance of the cellules of the pyroxyline being insufficient to overcome the tension of the ethereal vapours, and shows that by adding a larger quantity of *coton resistant* the defect may be considerably modified. However, he gives us an alternative of two methods by which a precipitate may be formed, which, after re-solution, will behave in identically the same manner as before precipitation. The first consists in "concentrating" the emulsion before precipitation by leaving the stopper out of the bottle for twenty-four hours. The second and preferable plan is to pour out the emulsion into a dish, and when the surface has solidified it is to be cut up and treated with an equal bulk of warm water, the flocculent mass being broken down with a spatula and transferred to a precipitating glass for collection. It is then washed and dried in the usual manner. This appears to us to be a decided step towards the old system of working. Washing the emulsion was superseded by precipitation. Precipitation has had its day—has been weighed in the balance and found wanting—and now we have one of its own friends recommending at least a partial return to the older style. We have no doubt that it will be found to be an improvement; but why adopt half measures?

THE DARKENING OF PAPER ON EXPOSURE TO LIGHT.

Few processes have been subjected to such a series of adverse criticisms as the so-called carbon or pigment process. No sooner has it thoroughly recovered itself from one series of attacks than it is assailed with another. We now hear a great deal about transfer paper becoming more or less discoloured by exposure to light, and hints are dropped that existing carbon prints must be looked on with suspicion, in consequence of a possibility that their paper basis may darken by a long-continued exposure to the action of light. Notwithstanding all this we do not hear of the very early carbon prints becoming yellow or dark in the whites.

Cellulose, or vegetable fibre, does not darken on exposure to light, provided it is in a pure state and is perfectly freed from the incrusting matter which accompanies it. This is true, whether the cellulose is obtained from cotton, linen, hemp, jute, esparto grass, wood, or other material. Some vegetable fibres—such as cotton and linen—are freed from their incrusting matter with great ease, a comparatively slight treatment with detergents and bleaching agents being sufficient to effect this and to lay bare the true vegetable fibre or cellulose. In the case of linen and cotton the work of the paper-maker is much facilitated by the fact that the raw material has had a little knocking about in the world before reaching his mill; and the practical outcome of the matter is that paper made from linen or cotton rags does not become darkened by exposure to light—at least not to any injurious extent.

At the time when the early carbon prints were made almost all high-class papers were made exclusively from rags; and as this paper consisted of nearly pure cellulose, prints on it retained their whites intact.

While carbon printing has been developing itself the paper-making industry has undergone considerable changes. I pass over the use of esparto grass as a paper-making material, and consider that which has long been the dream of the paper-maker, namely, the economical manufacture of a good paper stock from wood. It is possible to so purify and clean the fibre of wood as to remove the whole of the incrusting matter, and to leave pure and white cellulose which shall be capable of retaining its colour when exposed to the action of light; but it is much easier to remove a part of the incrusting matter and to bleach the rest. Paper made from this imperfectly-purified wood pulp or fibre becomes gradually dark on exposure to light, and this in proportion to the amount of incrusting matter left unremoved. It is probable that a wood paper so far purified as to be quite capable of resisting the action of light would cost more than a rag paper of similar quality.

Orioli, who has contributed much to our knowledge of paper-making materials, when writing about ten years ago, stated that wood stock which has been treated with chloride of lime (bleaching powder) tends to become yellow, and that which has been treated with mineral acids tends to become reddish on exposure to light, while if iron be present a darker tint arises.

Let us now pass over the methods which have been devised by Orioli, Houghton, and others for the treatment of wood pulp, and consider the actual state of the case as it stands at present.

In Austria and Germany numerous pine forests are cultivated (some of the latter belonging to Prince Bismarck) solely with a view to making wood paper and paper stock, and much of this material is imported into England. The wood paper of the present day possesses excellent general qualities, and its colour is good; but, unfortunately, it is not sufficiently purified to resist the action of light. This is well illustrated by an inspection of the exhibits of wood stock and wood paper shown in the Paris Exhibition, as most of these display signs of darkening where the light has acted.

I recently noticed a curious illustration of the darkening action of light on pine wood. An auctioneer's bill had just been removed from the board on which it had been mounted for exhibition, and on the board was a clear and distinct photograph of the printed bill, as the light shining through the thin paper had darkened those parts of the wood which were unprotected by the opaque printing ink. No doubt a recently-planed board had been used for mounting the bill, as the contrast between the light parts and the dark parts was considerable, the altered parts having much the same tint as ordinary York paving-stones, and the date of the bill showed that the action had taken place quickly. In this case, it may be noted, the wood fibre was denuded of none of its sensitive incrusting matter, while the worst commercial samples of white wood-paper only contain a small proportion of this alterable material.

Cellulose, or vegetable fibre, when pure and free from incrusting matter, is not darkened by being immersed for a few seconds in strong sulphuric acid or in ordinary nitric acid; but the presence of incrusting matter generally gives rise to a discolouration, which often indicates the source of the fibre.

Now for the practical application of the foregoing notes. Although a very bad paper will sensibly darken when exposed to light for a few days, it is obvious that a long exposure—say twelve or eighteen months—will be required in order to thoroughly demonstrate the suitability of any given sample for the manufacture of transfer paper. In the meantime, however, transfer paper must be had, and I think that manufacturers who take the following precautions will be quite safe.

In the first place, they should require a guarantee from the paper-maker that the material supplied is made entirely from rags; and they should select a paper which is naturally white—not a yellow paper which has been vamped up with a blue pigment. Rag paper, I repeat, is seldom dangerous, as the incrusting matter is easily removed by the paper-maker; and, even if it were not entirely removed, the consequence would not be serious, as imperfectly-dressed cotton or linen fibre is by no means comparable to defectively-prepared wood paper, as far as regards sensitiveness to light.

In the second place, the manufacturer of transfer paper would do well to test his raw paper in the following manner:—About an ounce should be boiled for half-an-hour with a two-per-cent. solution of sodium carbonate, and after the pulp thus obtained has been well washed it should be soaked for an hour in a one-per-cent. solution of hydrochloric acid. After this it should be thoroughly washed with hot water. A little being now collected on a fine wire net and dried we have a sample of paper similar to the original, but free from sizing materials. Pieces of this can now be tested by immersion in cold sulphuric acid and cold nitric acid respectively.

The above is the best advice I can offer at the present moment; but experiments are now in progress which will, probably, throw further light on this subject. THOMAS BOLAS, F.C.S.

NOTES ON PASSING EVENTS.*

BY A PERIPATETIC PHOTOGRAPHER.

HAVING read what has been written in a recent number regarding the taking of photographic views of the interiors of caves by means of paraffine lamps, I inquire if no practical means have yet been devised by which the singularly-actinic energy of incandescent magnesium may be made use of for such a purpose. It is well known that the light emitted from this source possesses a greater amount of chemical energy than that from any other source whatever, rendering it pre-eminently *the* light for photography. The material itself, too, is of such a price as to render this cheaper than any other of the *powerful* lights. Why, then, is it not more generally made use of in photographing nocturnal and underground scenes? I am well aware of several pictures of the Mammoth Cave of Kentucky having been obtained by the magnesium light, and one therefore naturally inquires why our caves and mines at home cannot be photographed by similar means. The reply, I think, will not be very difficult to give. It is an unfortunate circumstance in connection with the burning of magnesium that an exceedingly dense smoke is emitted, which smoke, composed of magnesia, renders the surrounding atmosphere so foggy as to prevent any photography from being practised after the first attempt has been made. Now, in a cave of large dimensions this difficulty is not felt to the same extent as when one is crouching in a circumscribed position. In the former case the smoke has some chance of getting away and becoming dissipated through space; but in the latter the light has scarcely been allowed to burn for three or four seconds ere one is enveloped in a dense cloud. It is well understood that through the agency of large and flexible tubing the smoke may be conveyed away some distance; but still this does not meet the difficulty in an adequate manner. What is required is a method by which no smoke whatever will be emitted. Various proposals have been made for effecting this end, among these being the passage of the smoke through channels moist with acid which will dissolve the magnesia as it comes in contact with the sides and roof of this channel, as it inevitably must. A friend of mine set himself three or four years ago to grapple with this difficulty, and I understand that his endeavours have been crowned with a larger measure of success than has yet fallen to the lot of others. The means by which he obtained this success have not yet been divulged, which is a pity, as it would facilitate the application of the magnesium light to the purposes of photography.

* Concluded from page 424.

In common with many others I have been much pleased at seeing in a recent number of this Journal a contribution from our old and at one time well-known friend, Mr. W. J. Stillman. Photography suffered a serious loss when he was induced to lay aside his amateur camera and throw himself into political and journalistic life as special war correspondent of a powerful London daily newspaper. The Eastern question being now so nearly settled, it is to be hoped that this energetic experimentalist and able writer will see it to be conducive to his comfort to resume his investigations in photography.

Like too many of the more recent meetings of the British Association, the Dublin one has passed without making its mark on photography. I suppose it is in the nature of things that photography cannot be represented both at meetings of societies specially devoted to this art-science and also at the British Association. Let us be thankful that the photographic "thoughts that burn" find a channel of expression somehow, even if that should not be at the annual congresses of scientific men.

Everyone who has read the various writings or speeches of Mr. H. J. Newton, the President of the Photographic Section of the American Institute, must be cognisant of the great amount of time and trouble he has bestowed upon the subject of the improvement of the alkaline developer for dry plates. This gentleman having turned his attention to the ferrous oxalate developer recently introduced to the public through the pages of THE BRITISH JOURNAL OF PHOTOGRAPHY, and having made certain modifications in the manner of its preparation, is now enabled, after a brief trial, to give as the result of his experience an important expression of opinion, namely, that he feels justified in saying that it promises to be the developer of the future for emulsion plates. This, coming from Mr. Newton, is not a little important.

NEW SILVER SALTS IN EMULSIONS.

SINCE last week I have been engaged in some experiments intended as preliminary to a thorough inquiry into the new method of correcting emulsions described in an editorial article two or three weeks ago. My object has been, so far, to try the comparative effects of some of the substances recommended in that article, and to weed out those which seem to produce an inferior effect to the rest, thus economising both time and trouble. It is true that, working as I have done, the results obtained may differ from those given by the same substances when added to the emulsion; but I think my method should give at least an approximate idea of the probable action of the agent employed.

The course I have followed has been to prepare an emulsion containing excess of silver restrained by nitric acid. Citric acid (my favourite) I have in this instance eschewed, for the obvious reason that, as it forms one of the list of substances to be tested, its employment in connection with any of the others would only lead to uncertainty as to the real active agent. Two emulsions were prepared—one containing an excess of one grain, and the other four grains of silver nitrate in each ounce. After coating the plates they were allowed to set, and were then plunged into a solution of the substance to be tested, being allowed to remain there until the "greasy" lines had quite disappeared, after which they were well washed under the tap and dried without preservative.

Tested in this manner the results were briefly as follow, the comparison being made with a plate prepared from the same emulsion and simply washed previous to drying:—Citric acid of the strength of ten grains to the ounce produced no difference whatever in the sensitiveness or density of the plate, the only feature distinguishing the image from that obtained on the simply washed plate being a slightly colder tone. Phosphate of soda fifteen grains to the ounce produced a denser-looking film before exposure, and gave a decidedly denser image under development, the difference being especially noticeable with the emulsion containing the larger excess of silver. But, in addition to the increase of density, the latter emulsion also gave a distinct veil over the whole surface of the plate, and, upon a very minute examination of the film before fixing, the shadows and portions which should have been perfectly clean were found to be covered with a very fine "mottling," as if the surface had been delicately stippled. This, however, was unnoticeable after fixation.

A solution containing fifteen grains to the ounce of neutral oxalate of potash gave still greater density than the last-named salt; in fact, it was a matter of the greatest ease to obtain absolute opacity with alkali alone. The same veil was produced with the larger excess of silver, but in this case the mottled appearance was absent. Dilute acetic acid produced no effect, but acetate of soda (fifteen grains to the ounce) gave a result intermediate between the phosphate and oxalate. Tungstate of soda proved similar in effect to the others, but the difference was less marked than in any of the preceding cases. In no instance did there seem to be any alteration in the degree of rapidity.

As the result obtained with both citric and acetic acids was entirely negative, while acetate of soda proved effective, I saturated the citric acid solution previously employed with carbonate of soda, forming a solution of citrate of soda. Plates treated with this gave an accession of density nearly equal to the oxalate, but differing greatly in colour. A considerable portion of the free silver contained in the film was found to wash out and suffer decomposition in the solution instead of in the film, the two acid solutions alone remaining clear; still a sufficient quantity remained behind to show that the various silver compounds formed were capable of producing an important effect upon the resulting image.

Some of the results recorded—notably those with the uncombined acids—appeared, at first sight, to differ in an unaccountable manner from what I had anticipated; and I should like to point out where the discrepancy arises, and in what respect the addition of the substances to the emulsion itself would be likely to act differently. Very few of my readers require to be told that neither citric or acetic acid added to aqueous solution of nitrate of silver (of ordinary strength at least) will produce a precipitate. This is owing, not to the solubility of the citrate and acetate of silver in *water*, but to the action of the nitric acid liberated by the decomposition of the silver nitrate. If a small quantity of the acid silver solution used for intensification be cautiously neutralised with a caustic alkali it will be found to deposit, first of all, a white precipitate of citrate or acetate of silver; but when the point of neutrality is passed the precipitate will be dark brown oxide of silver.

In order to obtain a precipitate of citrate or acetate of silver it is necessary to employ an alkaline citrate or acetate, and then the nitric acid goes from the silver to the alkaline base, allowing the insoluble silver compound to fall. This explains the reason of the negative results obtained with citric and acetic acids as recorded above, and would possibly also account for the continued washing out of small traces of soluble silver salt from the precipitated emulsion, as described in your editorial article.

I have said that no precipitate occurs between citric acid and *aqueous* silver solution; but if alcohol (or collodion) be substituted for the water as solvent the case is quite altered. If nitrate of silver be added in the usual manner to collodion containing a few grains of citric acid in place of bromide a perfect emulsion of finely-divided citrate of silver is formed; with alcohol alone as the solvent the citrate is, of course, precipitated. I have not tried acetic acid in the same manner with collodion; but in alcohol it causes no precipitate (properly speaking), but merely a peculiar turbidity, arising, apparently, from the presence of innumerable extremely minute crystals. In the case of sulphuric acid, which behaves in a similar manner to citric, the non-production of a precipitate in aqueous solutions has been attributed to the solubility of sulphate of silver in water; but its very feeble degree of solubility certainly does not warrant such an assumption. I am inclined to think that the presence of free nitric acid is essential to the production of such a result, and this view is borne out in the case of citrate of silver, which is (I believe) perfectly insoluble in pure water.

I mention these peculiarities in order to point out that the form in which the correcting agents are applied either to the emulsion or to a plate containing free silver is a matter of some importance, but more especially in the latter cases. In using an uncombined acid it would, I think, be advisable, after allowing a sufficient time for the completion of its reaction, to follow it by partial neutralisation with alkali. Perfect neutrality (or alkalinity) would, no doubt, produce fog; but I think at least a portion of the free acid might be advantageously got rid of. In conclusion: I may say that my object in publishing these crude experiments and the accompanying remarks is to point out what might possibly prove pitfalls in the way of some who may attempt to follow the editorial lead. W. B. Bolton.

PHYSICS IN PHOTOGRAPHY.

In taking a retrospective glance at the remarkable phenomena exhibited in photography an endeavour will be made to explain them as far as possible by the light that may be thrown upon them by modern research, and, at the same time, to suggest extensions which probably may be given to this branch of science by further investigations. We may, perhaps, be open to rebuke from some for venturing to call photography a science; but, surely as long as there are problems in it to be solved which require direct scientific solution, and which perhaps indirectly lead to the research in other directions, so long at least must it be something beyond a mere industrial pursuit. It is not the fashion to deny to electricity the honourable distinction of being a science, although it has become an industry in its application to telegraphy. Why, therefore, it should be considered correct to consider the study of the chemical action of light upon compounds as something to be remitted to the intellect of those who are merely interested in it commercially it is difficult to understand. It would surely be much better that men of science, who employ photography in their laboratories and observatories, should endeavour to understand the science of attack with the weapon they are using, instead of regarding it as a simple mechanical agency which is only worthy of the attention of, perhaps, a half-educated assistant. If our men of science, who employ both, were to be as ignorant of the principles of electricity as they too often are of photography, research would be very much restricted in its results; and it may, it is believed, be said with truth that a familiarity with even the first principles of photography would very much extend it. We may remark, by the way, that to instil a love of science into youth an education in photography would seem to be of great value, as experiments can be made which have a real meaning to the experimenter, and which, by allowing an almost endless variation, offer an unlimited field for the exercise of the reasoning faculties. A study of photography, in short, must encourage the study of chemical and physical sciences, if a distinction may be made between the two.

Photography must undoubtedly be divided into two distinct branches—the direct production of the visible image by light itself, and the development of the invisible image by chemical means. The recognition of the former we owe to Wedgwood, and of the latter to Daguerre. The discovery of the former is much less remarkable than of the latter, since, without any particular research, a discolouration of a compound by light must have been noticed; whereas the development of an invisible image would have been a matter of theoretical reasoning, unless accident showed its feasibility. We know that the development of Daguerrean images was discovered accidentally by Daguerre, and we also know that the development of the image on paper was discovered accidentally by Reade. Without two such wonderful strokes of good fortune the growth of photography might have been retarded for years. The years which succeeded the discovery of the developable image were productive of research into many of the phenomena exhibited by the action of light on sensitive compounds, and, owing to the great intellects who gave their attention to it, many important problems in photography were solved. Succeeding these years, however, were others in which little was done in the absolute science of the subject, though great progress was made in perfecting the processes which had been brought forward. Within the last few years a fresh start in researches in all directions seems to have been made, and much that is valuable in elucidating the correct theories on which photography is based has been demonstrated, and it is to this to which attention will be drawn.

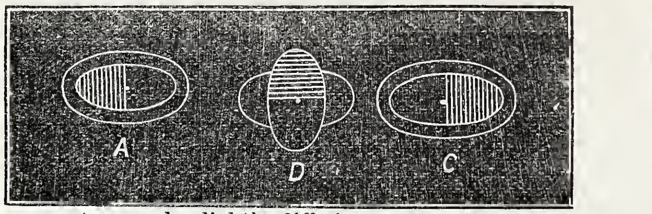
With the risk of being tedious, ground which has been well trodden must once again be briefly gone over, in order to estimate the progress which more recently has been made. Scheele, the Swedish chemist, as is well known, found that the blackening of silver chloride (which was the basis of Talbot's pictures) gave up chlorine on exposure to light, thus proving, as it were, that the blackening was due to the formation of a new chemical compound. As far as can be traced not much more was known regarding this compound; but it was a generally-received notion that it was a sub-chloride of silver, and up to the present time we find that such is the accepted opinion. In the second edition of Hunt's *Researches on Light*, published in 1854, p. 79, a remarkable experiment is noted. He says:—"The exposure (of silver chloride) in the water was, in another case, continued for several days, but no greater degree of darkening occurred; but a curious fact was noticed. It was found that during the night nearly all the chlorine which had been liberated during the day was recombined, and that the darkened powder became lighter." . . . He then, after recounting other experiments, says (p. 123):—"From other experiments I am inclined to believe that the first action of the solar ray is to liberate one-half of the combined chlorine, which is very readily, moisture being present, replaced by oxygen. By the continued action of the exciting cause the oxide is decomposed, and metallic silver, in a fine state of division, is formed over the surface" (of the paper).

P. 125:—"The absorption of oxygen, or rather its combination, with the decomposing chloride is proved by another very easy experiment. Some pure chloride of silver was arranged in a bent tube, closed at one end, and the other end immersed in a bottle of distilled water In this state the chloride was exposed for many days to the action of sunshine, during which time it was frequently shaken for the purpose of exposing the whole of the powder and its influence. As the chloride darkened the water rose in the tube, and it gave a precipitate of chloride of silver on the addition of the nitrate, thus appearing to prove the substitution of oxygen for chlorine under the agency of solar radiation. It was quite evident that some absorption of atmospheric air had taken place. This explanation will also serve for the iodide, bromide, and some other salts of this metal (silver)."

This last experiment has lain fallow for years, and it is only recently that it has had any meaning beyond that indicated in the quoted paragraph. It must be borne in mind, however, that the visible change in the chloride is here under consideration, and that the invisible effect of light was not mentioned.

With regard to the developable and invisible image: till within the last few years it was a debatable point as to whether the action of light on a sensitive compound was really a chemical change or simply a physical action. One school held that the sensitive compound was not altered in composition at all, but that in some mysterious manner the atoms of the molecules composing it were shifted, and possessed a new property which was denied to it in the original form. Diagrams were introduced to render this subtle change clear to the student, one of which is reproduced (*fig.* 1).

FIG. 1.



In A we see two ovals slightly differing in size, each of which was intended to indicate one of the atoms composing a molecule of the sensitive salt. When the ovals coincided the molecule was supposed to be in the ordinary state, but after light acted upon it for a certain time the ovals occupied the position shown in B, and after a further action of light they occupied the position shown at C, in which it again became incapable of proper development, and gave rise to what was known as *solarisation*, the part of the "*latent image*" formed by these solarised molecules refusing to *develope*. By solarisation was meant the phenomenon which occurred (more especially if silver films containing iodide were used), when any portion of the plate received a lengthened exposure to any very bright part of the lenticular image, such as that of the sky. In solarisation we have a term which is as unmeaning as is "polarisation" in some of its applications, but since it has passed into the technical language of photography we are bound to employ it. By the term "latent image" was meant the invisible (and usually) developable image impressed upon a sensitive film; and it will be used, where convenient, with the reservation, once for all, that its applicability is not admitted any more than is the term "developer," as applied to a solution which may cause the deposition of metallic silver from a solution of silver nitrate, since such a solution is effective whether applied to an exposed sensitive film or not. The advance of photography has literally been impeded from the neglect of using accurate language. As regards this peculiar condition which the molecule was supposed to have attained after its impact with light, there seems to be no ground for its adoption. The idea seemingly arose from a supposed necessity which existed for a difference in condition between the visible and the merely developable image. By a strictly logical inference there need be no difference between the two, beyond this—that there should be a difference in the number of molecules absolutely altered, and in no other respect. Perhaps the most telling experiment giving *direct* evidence of the similarity of the two images was that made by Poitevin, in which he proved the dissociation of iodine from silver iodide, by placing metallic silver in contact with the film. After exposure to light, on separating the two, he found that the latter had absorbed iodine, as proved by treating it with mercury vapour. The *circumstantial* evidence of the truth of the chemical theory of the invisible image, however, is so strong, that on that alone we are bound to accept it; at the same time we are not prepared to say that there are no other physical forces which must play a part in its development—in fact, it must be so. We may say, then, that at its *first formation* the developable photographic image is formed by the reduction of the sensitive compound to one of a less complex nature. Thus, silver chloride (argentic chloride) is reduced to silver sub-chloride (argentous chloride) with the liberation of chlorine; and silver bromide to silver sub-bromide, with the liberation of bromine, and so on.

We must now allude to the development of the photographic image. We may divide the methods of development of the image on silver compounds into three:—(1) The condensation of mercury; (2) the deposit of metallic silver from a soluble salt of silver by means of a reducing agent such as ferrous sulphate; and (3) the reduction of the sensitive salt of silver itself to form the image.

The first method is the earliest, dating from the discovery of the daguerreotype process, and till within very recent times the reason of its efficacy has been a subject of controversy. Quincké has lately thrown a light upon it in one of his memoirs, and his explanation seems to account for it in a most perfect and philosophical manner.

In the daguerreotype process, it will be remembered, a silvered plate is subjected to the vapour of iodine (or of iodine and bromine), and thus receives a fine layer of a compound which is sensitive to light. When a plate so prepared is exposed to a lenticular image in the camera the light causes the iodide (or bromo-iodide) of silver to throw off iodine (or this together with bromine), which is immediately seized by the silver beneath, and thus forms a deeper layer of the sensitive salt. The depth, almost immeasurable though it be, depends on the intensity of, and length of exposure to, the light. (That this is the case has been proved by the fact that, if the sensitive layer be removed by a suitable solvent, the surface beneath is shown by reflected light to be etched to a greater or less degree.) The invisible image thus formed is exposed to mercury vapour, and the dew condenses on it proportionately to the depth of the layer. Quincké, in his memoir *On the Edge Angle and Spread of Liquids on Solid Bodies*,* shows that the edge angle of a drop of liquid on a solid body varies from zero to a constant quantity, according to the thickness of any fine layer of impurity which may be on the latter. When this layer attains a certain value then the edge angle of the drop will remain constant. The thickness, or rather the thinness, of the layer may be appreciated when it is stated that it bears a relation to what is called "the radius of the sphere of sensible action of molecular forces," and is usually greater than ·00005 millimetre. In this case the sensitive plate is the solid body, and the invisible image forms different thicknesses of impurity. By this difference in the edge angles of the mercury dew, condensed on different portions of the latent image, the light is reflected in different ways, which gives rise to the visible image.

This explanation entirely does away with the necessity, which previously seemed to exist, of the silver iodide (or bromo-iodide) being reduced to the metallic state, in order to cause condensation, or—perhaps it might be said—to cause the formation of an amalgam of mercury and silver.

The next method of development speaks for itself; the metallic silver is deposited in fine granules and is attracted by the salt which has been altered by the influence of light. Perhaps further investigation will show that development is dependent on what is known as the Brownian movement, or the rapid movement of small suspended particles in a liquid. If this movement be dependent on the electrical condition of the neighbouring body, as has lately been supposed; and if, as Dewar has shown, the condition of an exposed sensitive salt is electrical, then the deposition of the metallic particles of silver on the image is accounted for in a satisfactory manner.

The last mode of development is principally employed with silver bromide, and is known as the alkaline method. When a film of collodion or gelatine holds a sensitive salt on a plate, the portions exposed to light are reduced to the metallic state by the application of an oxygen absorbent, such as alkaline pyrogallic acid. Since the image is invisible it must be remembered that but a few molecules of the sensitive salt are reduced by the action of light to the less complex and developable form. We therefore must look for some further action between the developer and the rest of the unaltered compound. It has lately been proved that silver bromide or silver chloride cannot exist in *close* contact with metallic silver. It invariably forms the developable salt. Thus, if we take a glass plate, silvered by any of the well-known processes, and expose it to the fumes of bromine or to hypobromous anhydride, it will be found that it is impossible to secure a film of argentic bromide until the last trace of silver has been attacked, after which the true colour of argentous bromide gradually gives way to the well-known colour of argentic bromide. We may try the experiment with bromine water and the same holds good. The action of chlorine on silver is the same as of bromine; but the action of iodine seems to be different, the fully-saturated compound, argentic iodide, being formed at first. In other words, this compound is more stable than argentous iodide.

Now the alkaline developer, when mixed with a soluble bromide of an alkali, has the property of much more readily attacking the argentous than the argentic bromide, presumably because the soluble bromide used in development combines with the former, giving rise to an apparently difficultly-reducible compound, whilst it refuses to combine with the argentous salt. It is thus easy to see, if this property of the developing solution be connected with what was stated in the preceding paragraphs, how development takes place. The developer is applied to the exposed film, and the minute quantity of argentous compound is reduced to the metallic state, and at once this particle of silver which is in close contact with the unaltered compound combines with it and forms new argentous bromide. This is ready for attack by the developer, and thus the action spreads till the whole thickness of the sensitive salt is reduced to the metallic state where the greatest exposure has taken place. An interesting result† of this action is afforded by the fact that, if a film of unexposed argentic bromide be superposed over one that has been exposed, the image impressed on the latter can be developed in the former so long as close contact is secured. It has been said that this action is due to the solubility of the silver bromide used in the alkaline development. To some extent this is true; but it is evident that this cannot be explanatory of the whole phenomenon, since the same effect is produced by using, with the pyrogallic acid, potash as the alkali in which the silver bromide is absolutely insoluble. We have been thus particular in showing the cause of this alkaline development, as it explains some phenomena to which attention will subsequently be called, and which otherwise would be inexplicable, except by reversing usually-accepted physical laws.

ON PROCESSES OF MAP PRODUCTION BY PHOTOGRAPHY.*

Photolithography and Photozincography.

Zinc plates possess great advantages over lithographic stones on account of their superior lightness, cheapness, facility for storage, and less liability to breakage, and are, therefore, to be preferred in reproducing plans of large size. For fine work stone is considered by some to give better results than zinc, but I believe that, if due care be taken, as good prints may be made from zinc as the best from stone.

In the Southampton process the whole of the unaltered gelatine is removed from the paper, and the objection has been made that, in consequence of this, the ink on the lines being left on ridges of gelatine is more liable to spread in transferring; that the fine lines are liable to be washed away by the dissolution of the gelatine beneath them, and that the prints are liable to slip during transfer. To remedy these defects various methods have been proposed for retaining the gelatine on the paper.

One of the best of these methods has been perfected by Captain Abney, who has patented it under the name of "papyrotype."†

A tough paper is coated with gelatine and subsequently treated with alum or chrome alum. It then receives a coating of gelatine and bichromate of potash, as in the Southampton process. After exposure to light the print is drawn through *cold* water, and is then "squeegeed" down on to a smooth metal plate and inked in with a soft gelatine roller charged with transfer ink. The ink "takes" only on the parts exposed to light, while the ground of the print remains clear. When the image is fully inked up the print is dried and exposed to light to harden the gelatine thoroughly by the action of the light on the bichromate salt still remaining, and is then ready for transfer to stone or zinc.

Among the advantages claimed for this process the principal are these:—The ink which forms the lines is not left on ridges of gelatine, as in the Southampton method. The fine lines are not liable to be removed. The surface of the transfer will have no tendency to slip during transfer. In practice this method was not found to answer in this country so well as the ordinary one; but a modification of the latter has lately been introduced into the Surveyor-General's office, with the same object as the papyrotype, and seems to answer well.

The paper is prepared as usual with two coats of gelatine and bichromate of potash. It is then put away for a few days, in order to allow the gelatine to become hard and insoluble. When required for use it is coated again with a mixture of gelatine and bichromate of potash of about one-third the usual strength, and is then exposed to light and inked in the usual way. The washing is done with cold water instead of with hot.

A method of photolithography by transfer, which yields excellent results in line, and even reproduces half-tones fairly well, is a modification of Asser's process, invented by Mr. Toovey, of Brussels, who coats paper with a solution of gum arabic mixed with bichromate of potash, and, after exposure to light under the negative in the usual way, places the transfer-print face downwards on the stone with several thicknesses of wet blotting-paper over it, and leaves it under pressure for some hours in a powerful press.

The gum on the parts not exposed to light being soluble is forced into the stone and prepares it, while the lines, being hardened and rendered insoluble, leave the stone quite free from gum and ready to take printing ink from a roller when passed over them, thus producing an image which may be printed from as soon as the soluble bichromate salt has been washed out, because the bichromated gum is a most powerful preparation for the stone, and, indeed, is difficult to remove without grinding the stone down to some depth.

This process requires care in adjusting the amount of moisture to be applied to soften the gum so that it may not be squeezed under the lines and block them up, and it has not, I believe, come into general use.

There are two disadvantages which militate against the employment of the transfer processes of photolithography for the finer and better class of maps. The first is the difficulty of obtaining reproductions perfectly true to scale, owing to the unequal expansion of the transfer paper in the various washings and squeezings it has to undergo. Although this unequal expansion and contraction is very slight, and for most practical purposes may be disregarded, it has greatly hindered the more universal adoption of this valuable method for the reproduction of the official maps in England and foreign countries.

Mr. Rodriguez, of Lisbon, has, however, lately introduced an improvement into the transfer process with the object of doing away with the possibility of stretching in the course of any of the operations.‡ Instead of using paper as the support of the coating of gelatine on which the photographic image is impressed he uses a sheet of tinfoil about the thickness of thin paper. This is first smoothed on a very finely-grained lithographic stone, and then laid down quite flat on a sheet of zinc. After being cleaned with alkali and well washed the tinfoil is brushed over with a solution of gelatine and bichromate, dried rapidly, and is then ready to be exposed under a negative in the usual manner. To ink the print the sheet of tin is first plunged into water, and then carefully laid down wet on a lithographic stone, so as to avoid folds, the gelatine side being uppermost. The film is then inked in with a roller. After the first inking in the print is left for about a couple of hours, and is then inked in again, and afterwards washed with a sponge and water. It may then be lifted off the stone and dried. The operations of transfer are the same as usual.

The second disadvantage of the transfer methods is the almost unavoidable spreading of the lines under the operation of transferring, which makes a photolithographed map look heavy and unsightly compared with a lithographed one. This defect may, however, be diminished very much by skilful manipulation and taking care to have as thin a coating as possible of gelatine on the paper, and to use a good, hard, transfer ink in small quantity. With these precautions and with a suitable original results may be obtained from photolithographic transfers which will well compare with ordinary lithography, or even engraving, in sharpness and delicacy.

These special defects of the transfer methods may be in great part obviated by impressing the photographic image direct on the stone, as originally proposed by Poitevin; but this plan has again other disadvantages of its own which render it less suitable for map work than the transfer process. It has, however, been used extensively and very successfully in the production of the Belgian topographical maps on the scale of 1 : 20,000.

In the process used for the Belgian maps the stone is covered with a very thin coating of a mixture of gelatine and bichromate of potash, rapidly dried, and exposed to light under a reversed negative, which is obtained by reversing the position of a dry tannin plate in the camera, and allowing the light to act through the glass on the underside of the collodion film. A thin coating of printing ink is then applied all over the stone with a roller, and the surface is afterwards washed with warm water in which a little starch has been dissolved. This gradually removes all the soluble parts of the gelatine coating, leaving on the stone a clear image of the map. The stone is then covered with gum, and, after drying and remaining for a short time, is ready for printing, and capable of yielding 1,500 good impressions.*

For line work zinc plates are also used and prepared in much the same way.

This process has undoubtedly some advantages as regards accuracy of scale and the quickness and cheapness of the operations. On the other hand, it has disadvantages as regards the difficulty of securing perfect contact between the stone and the negative; the necessity for a reversed negative; the prints being limited within a single negative, and the inconveniences of working with heavy stones.

Besides the foregoing many methods of photolithography have been proposed, but, as for the most part they are only modifications of the processes I have described, which are all good and may be considered typical, it will be unnecessary for me to go further into details regarding them.

FOREIGN NOTES AND NEWS.

The Berlin Photographers' Assistants' Society.—A Monument to M. Nicephore Niepce.—Photography in Schleswig-Holstein.—A New Yellow Photographic Paper.—Schaarwächter's Camera.—Härtwig's Chloride of Silver Collodion.

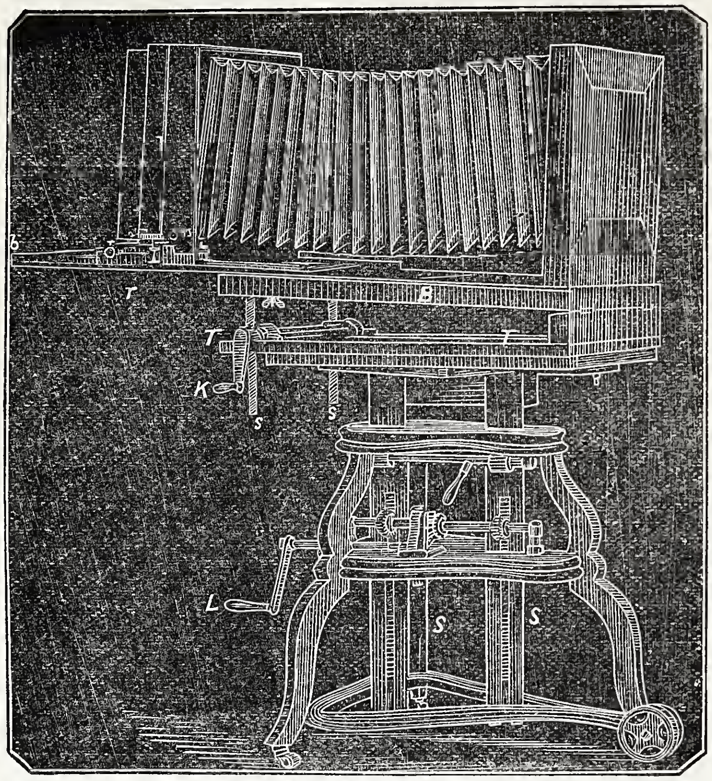
The annual meeting of the Berlin Photographers' Assistants' Society was held some time ago, and the state of the funds was reported satisfactory. The principal object of the Society is to obtain situations for the members, and in this it is singularly successful. A year or so ago a short account of the Society and its rules was given in these columns.

The *Monatsblätter* reports that a project is on foot, headed by M. A. Galopin, the *maire* of Chalons-sur-Saone, to erect a monument in that town to M. Joseph Nicephore Niepce, M. Daguerre's rival, as the inventor of photography.

Dr. Vogel was lately invited to visit, in the capacity of juror, the provincial exhibition of Schleswig-Holstein, at Flensburg. There he was agreeably surprised to find photographs taking a leading place amongst the exhibits. More than half the photographers who exhibited showed carbon prints. Only two persons exhibited landscapes, but of portraits there were a great variety in silver and carbon, large and small, the former both direct and enlargements. Dr. Vogel was particularly struck with the excellent tone of the cardboard mounts, which harmonised admirably with that of the photographs. Altogether, considering the size of the province, there was a most gratifying display.

According to the *Papier Zeitung*, a very cheap yellow photographic paper is shortly to be brought into the market. It is prepared by diluting pure egg albumen with a saturated solution of bichromate of potassium in soft water. Upon this mixture the paper is floated and dried quickly in an oven, well protected from actinic light. Of course it must be pressed and stored in the dark. In the same way, omitting the albumen, paper tinder is prepared from unsized paper. This preparation takes fire very easily, and is the *fern seed* or *grass paper of tobacconists.*

The accompanying illustration, cut from the *Photographische Mittheilungen,* represents a new camera constructed by Herr Garcis for Herr Schaarwächter, of Berlin. The camera rests upon a table T T, from



which it is raised up by means of hinges at the back and the screws S S in front. By the aid of the latter the camera can either be made perfectly level or sloped down towards the front, or tilted up from the back. The screws are moved by means of the crank K, and the table T can be drawn out so as to follow the movement of the camera without it being necessary to lift the whole stand. The arrangement of the tripod can be seen by reference to the diagram. The footboard of the camera itself, B, is furnished with a continuation, *b*, which runs in grooves and allows of the camera being drawn out to almost twice the length of B. This continuation carries the focussing-glass, which can be moved on a horizontal axis by means of the screw, *r*, and on a perpendicular axis by means of another screw, which is not shown in the diagram. The focussing arrangements are those described in the third German edition of Dr. Vogel's handbook. The advantages possessed by this camera-stand are that all the cranks can be easily reached by the operator from his place at the back of the camera, and that the camera can be drawn out to an extraordinary length with great ease.

The *Photographische Correspondenz* gives the formula for Härtwig's collodion, which is rather popular in Germany. Prepare the following solutions :—

Nitrate of silver	8 grammes in	8 c.c. distilled water.
Chloride of calcium	1 gramme	in 20 c.c. alcohol.
Citric acid	1 dramme	in 20 c.c. ,,

Then heat in a wash bottle 180 c.c. alcohol, and while continually shaking add the silver solution and then eight grammes of collodion cotton. The solution is best kept warm in the sand bath. 150 c.c. ether should now be added, a little at a time, and stopping to shake up; then, light being excluded, add the twenty c.c. of chloride of calcium solution, and, lastly, the twenty c.c. of citric acid solution. The collodion, after standing a few hours, is now ready for use with gelatine, chalk paper, or direct upon glass. The prints are toned after being washed in a fixing bath containing gold.

Our Editorial Table.

Scientific Memoirs. By John William Draper, M.D., LL.D., &c.
London: Sampson Low, Marston, Searle, and Rivington.

Physicists will accord a hearty welcome to this volume. It consists of a collection of memoirs and essays on scientific subjects, published by the author at various intervals during the past forty years in numerous journals, pamphlets, and the transactions of learned societies. Many of those of less interest have been abridged or condensed. Those only are included in this volume which are connected with the effects of radiation or of radiant energy. Many of our readers are doubtless aware that for these investigations the talented author, Dr. Draper, has been awarded the Rumford medal for discoveries in light and heat by the American Academy of Science.

There are thirty of these memoirs selected for publication, and several of them have relation to topics of interest to scientific photographers, such as the Production of Light by Heat and Chemical Action—the Invisible Fixed Lines in the Sun's Spectrum Detected by Photogaaphy—Studies in the Diffraction Spectrum—The Daguerreotype Process—On Lunar Photography—On the Taking of Portraits from Life by Means of Photography—On the Chemical Condition of a Daguerreotype Surface—On Microscopic Photography, &c.

To one of the memoirs, *On the Taking of Portraits from Life by Photography* (from the *Philosophical Magazine,* September, 1840), there is prefixed a note to the effect that this memoir contains the first published description of the process for taking daguerreotype portraits. That it was possible by photographic processes, such as the daguerreotype, to obtain likenesses from life was first announced by Dr. Draper in a note to the editors of the *Philosophical Magazine,* dated March 31, 1840, as may be seen in that Journal for June of that year. This distinguished *savant,* it is now well known, was the first who ever obtained a portrait by means of photography. Alluding to this Sir David Brewster, in an important article on photography in the *Edinburgh Review* for January, 1843, says :—" Dr. Draper was the first, we believe, who, under the brilliant summer sun of New York, took portraits by the daguerreotype. This branch of photography seems not to have been regarded as a possible application of Daguerre's invention, and no notice is taken of it in the reports made to the legislative bodies of France. Daguerre had not at that time taken any portraits." In the chapter under notice we have a detailed account of the conditions at that period found requisite in order to obtain a portrait by means of photography. To enable our readers to form an idea of the difficulties inherent to the obtaining of portraits in those early days we give the following extract from Dr. Draper's memoir on that subject :—

" When the sun, the sitter, and the camera are situated in the same vertical plane, if a double convex, non-achromatic lens—four inches in diameter and fourteen in focus—be employed, perfect miniatures can be obtained in the open air in a period, varying with the character of the light, from twenty to ninety seconds. The dress is admirably given, even if it should be black; the slight differences of illumination are sufficient to characterise it, as well as to show each button, button-hole, and every fold. Partly owing to the intensity of such light, which cannot be endured without a distortion of the features, but chiefly owing to the circumstance that the rays descend at too great an angle, such pictures have the disadvantage of not exhibiting the eyes with distinctness, the shadow from the eyebrows and forehead encroaching on them.

" To procure fine proofs the best position is to have the line joining the head of the sitter and the camera so arranged as to make an angle with the incident rays of less than ten degrees, so that all the space beneath the eyebrows shall be illuminated, and a slight shadow cast from the nose. This involves, obviously, the use of reflecting mirrors to direct the ray. A single mirror would answer, and would economise time; but in practice it is often convenient to employ two—one placed with a suitable mechanism to direct the rays in vertical lines, and the second above it to direct them in an invariable course towards the sitter.

" On a bright day, and with a sensitive plate, portraits can be obtained in the course of five or seven minutes in the diffused daylight. The advantages, however, which might be supposed to accrue from the features being more composed, and of a more natural aspect, are more than counterbalanced by the difficulty of retaining them so long in one constant mode of expression. But in the reflected sunshine the eye cannot support the effulgence of the rays. It is, therefore, absolutely necessary to pass them through some blue medium, which shall abstract from them their heat and take away their offensive brilliancy. I have used for this purpose blue glass, and also ammonia-sulphate of copper, contained in a large trough of plate glass, the interstice being about an inch thick, and the fluid diluted to such a point as to permit the eye to bear the light, and yet to intercept no more than was necessary."

The *Scientific Memoirs* will be much prized by men of science in this country, who have ever known and valued the rare endowments of Dr. Draper. The work contains numerous illustrations, and is embellished with an admirably-engraved portrait of the able and distinguished author.

La Photographie en Amerique : Traité Complet de Photographie Pratique. Par A. Liébert.
Paris: 6, Rue de Londres.

From the title it will be seen that M. Liebert's work is written in his native (French) language. It contains numerous illustrations, twelve of these being devoted to showing the various effects that may be obtained by certain arrangements of the blinds in the studio. There are also illustrations showing the value imparted to a portrait by the judicious retouching of the negative, together with two examples of "chromotypie"—a branch of printing in which M. Liebert is known to feel much interest.

Every department of practical photography is here treated. In addition to the wet and dry collodion processes, and to the production of negatives and prints, several chapters are devoted to carbon printing, photography in printers' ink, Woodburytype, photo-engraving, and and photo-enamelling. We observe that, in addition to the various processes of photo-engraving described in the body of the work, the new process of M. Michaud has been received just in time to be inserted as an appendix before going to press. By this process has been produced some most excellent work, for examples of which we are indebted to our Paris correspondent, Mr. W. Harrison, and to which we shall devote an article as soon as the English specification of M. Michaud's patent is published.

An English translation of M. Liebert's excellent treatise would be much appreciated by the numerous English-speaking *confrères* of the author both in this country and in America.

Meetings of Societies.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

This Society met for the last time this season on Friday, the 5th July,—Dr. Vogel occupying the chair.

The Chairman communicated to the meeting the news of Dr. Weissenborn's death, and the members rose to their feet to testify their respect for the memory of the deceased. He (the Chairman) then said that Mr. Seavey had recently visited Berlin and had shown him a portrait of his daughter taken in Paris by M. Klary by the instantaneous process of M. Boissonas. Mr. Seavey assured him that the exposure had been *one* second, and that a Dallmeyer 3 B lens had been used. The picture was said to be sufficiently exposed, but was somewhat raw and inartistic, and failed as an example of good lighting according to the rules laid down in M. Klary's own pamphlet. In fact, it gave one the impression of having been taken in a perfectly-open glass house where no screen or curtains shaded the light.

Herr Schaarwächter was sure that with specially-favourable light he would himself be able to take such a picture in one second.

Herr Quidde thought that, owing to its south exposure, Paris enjoyed better light than Berlin, and, of course, a perfectly-uncurtained studio would allow the exposure being shortened, though, as the specimen before them showed, it did not add to the beauty of the resulting picture; but, on the whole, he was inclined to attribute the rapidity of M. Klary's work to his chemicals.

The Chairman said that one might easily succeed in getting pictures with a very short exposure if one were to work with a fresh iodide of ammonium collodion, a fresh and as slightly as possible acid silver bath, and a moderately strong developer. In a few days, however, the collodion would lose its sensitiveness, and the silver bath would deteriorate; in short, it would be impossible to count upon getting equally good results for any length of time from the same preparations. Whether M. Klary's preparations remained sensitive or not he could not say, but he had heard from America that his collodion, silver bath, and developer had been in the market there for months, and that at first one could work very quickly with them, but that they soon became less sensitive.

The discussion then gradually came round to the subject of collodions in general, after which a series of cabinet pictures, of anthropological and animal studies in India, were handed round. They were the work of Herr Schirmer—an operator in the employment of Messrs. Bourne and Shepherd, Calcutta.

A letter was read in which Dr. Richard maintained that it was a mistake to reject sulphide of potassium as an intensifier on account of its injuring the operator, as with proper attention paid to ventilation he was sure it would do no harm to persons using it.

The Chairman remarked that sulphide of potassium acted far more powerfully than usual when the plate was previously laid in a solution of iodine. Of course that intensifier could not be used for portraits, as it made them much too hard. With regard to the harmlessness of sulphide of potassium, he could not agree with Dr. Richard, as the fumes of sulphuretted hydrogen thrown off were not only injurious to the lungs of the operator but were also deleterious to the other chemicals in the room. Besides, for the purpose required, Eder and Tóth's lead intensifier was much better.

Some remarks were then made upon Captain Abney's recent experiments on the action of dyes upon bromide of silver, which had led him to agree with Dr. Vogel's theory on the subject, from which he previously differed.

Herr Quidde thought the explanation of the result of Captain Abney's experiments was to be found in the after-action of the rays of light, many bodies which were luminous when light fell on them being phosphorescent in the dark, the question being whether such phosphorescent light could not produce some photographic light. If not, then there must be many other substances which had the power of retaining light and giving it out afterwards.

The Chairman hoped to be able soon to furnish a list of substances in which the property of after-lighting was observable.

Herr Quidde mentioned another sort of photographic after-action which he had occasionally observed. A print was printed upon salted paper (not arrowroot paper) by simply salting and silvering the paper, and immediately above that a print from a second plate was laid, also printed on salted paper. A weak impression of the first plate would after some time be visible upon the back of the second. He had frequently observed this phenomenon, but only with plain salted paper—never either with arrowroot or albumenised paper.

The Chairman said the phenomenon was not new to him, but he did not think it could be attributed to after-action of the stored-up light. It was known that, in printing, a quantity of a reducing gas, whose composition was as yet unknown, was developed. This reducing gas penetrated through the pores of the salted paper, and was absorbed by the porousness of the bundle of paper pressing on it. Naturally the development of gas would be most powerful where the greatest reduction had taken place, namely, in the shadows; subsequently the pressing substance would give off the gas again, and if a new sheet of paper were laid upon it the gas would penetrate the latter, and thus produce by reduction the secondary image. This phenomenon had not been observed in the case of arrowroot or albumenised paper, because their pores were almost closed. With respect to the difficulty of distinguishing collodion cotton from gun-cotton—an objection which had been urged against allowing the free transport of the former—he (the Chairman) said anyone could distinguish them, as collodion cotton dissolves in a mixture of ether and alcohol, while the other cotton did not.

The subject of collodion and collodion cotton was continued for some time, after which Herr Prümm gave an account of his expenses during his visit to Paris.

The question-box was then examined, and the two questions found in it having been answered, the meeting was adjourned until the 20th of September.

Correspondence.

MR. CHAS. BENNETT'S RAPID GELATINE PROCESS.

To the Editors.

Gentlemen,—I think the Editors' foot-note at the end of the valuable and singularly-precise letter of Mr. Chas. Bennett in last week's issue should have been printed in italic capitals, for this gentleman has indeed displayed great care and much patience in giving directions to all comers; indeed, I never before received so much kindness of this sort from a gentleman whom I had never seen or known, but I hope some day to have the pleasure of a friendly conversation with Mr. Bennett.

I am sure this process is *the* one *par excellence*; for why complain of too much sensitiveness in the photographic film, as many do? Cannot the lens be stopped down to almost anything? and why should not practice enable an operator to work just as certainly in the chemical manipulations of a gelatine emulsion as it does with an ordinary process which may be much slower? If we have the power of rapidity we may use it or not at our discretion; but if we have it not, and *require* it, we then are powerless.

I have written this letter to publicly thank Mr. Bennett for his kind assistance, and hope soon to be able to say I am perfectly successful with this process; for I have not yet mastered all my difficulties, but am fully determined to "practice and persevere, for that which is *easily* gained is *lightly* valued."—I am, yours, &c., J. M. J. Danks.

5, *Jesson-street, Coventry, September* 10, 1878.

Photography at Sea.—When, many years ago, the daguerreotype process was in vogue no limits were assigned to the capabilities of photography. One person gravely asserted the possibility of our being able to see objects as small as a mouse in the moon. It was only necessary to obtain a small and sharp daguerreotype picture of our satellite, enlarge it by the camera, and examine this *enlarged* daguerreotype by means of a powerful microscope, and the thing was done. This was, of course, very absurd, but it must yield the palm to the following, which we find in a provincial contemporary, under the heading given at the commencement of this paragraph:—A discovery is alleged to have been made by Mr. Gresham, a practical mechanician, of New York, of a method by which a ship may be photographed on the high seas, distant from 100 to 5,000 miles—the photograph giving the name, the latitude and longitude, and the destination, taken from chalk marks on her deck. Mr. Gresham, after a long series of experiments, has found that he can produce an artificial mirage, the principle of which, he says, is the same as that which reflects in the middle of the desert of Sahara the images of lakes and waters a thousand miles distant. This artificial mirage can, so far as has yet been ascertained, be only produced by petroleum and asphaltum. All that is necessary is the possession on board a vessel of a few pounds of asphaltum, with a censer to burn it in, and a small battery to heat the wires by which it should be surrounded. By a machine invented by Mr. Gresham the artificial mirage is reproduced on tin. The instrument used for photographing the objects seen in the mirage is called by the inventor the "phantasmograph," and is at present in a very crude form. He anticipates, however, that it will before long be brought to perfection, and that the marine insurance companies, when they realise its value, will "only be too glad to insist that all vessels shall carry the necessary apparatus." They will thus be cognisant of the whereabouts of the vessels upon which they have sold risks. At four o'clock precisely, on a clear afternooon, clouds of carboniferous smoke shall, Mr. Gresham proposes, be sent up from ships at sea, the required information as to names and soforth being previously marked in chalk in large letters on their respective decks. Then the photographic instruments are set. One vessel photographs the artificial mirage of another at a distance of perhaps more than 4,000 miles, and on arrival at port the intelligence thus obtained is conveyed to those interested in the matter.

EXCHANGE COLUMN.

A good cabinet lens (trial required) wanted in exchange for apparatus or accessories.—Address, Vincent Hatch, Huddersfield.

I wish to exchange a Ross's $7\frac{1}{4} \times 4\frac{1}{2}$ rapid symmetrical, for No. 5 Ross's slow ditto, in perfect order.—Address, W. H. Belchamber, Cockshot-hill, Reigate.

A dissolving view magic lantern will be given in exchange for a telescope, microscope, or Winter's plate electric machine.—Address, W. J. C., 106, Platt-street, Alexandra Park, Manchester.

Wanted in exchange for a number of coloured lantern slides (Scripture subjects), by Carpenter and Westley, a good *carte* camera and 12×15 bath, with anything useful in photography.—Address, Photo., 77, Peas Hill-road, Nottingham.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

Notice.—Each correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a *nom de plume* as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

F. W. Bannister.—Received.

J. J. A.—Thanks. In our next.

O. T. L. M.—Yes; in this case the firm must be held responsible for the action of the representative.

T. W. T.—The only person who could properly explain the difficulty is at present in the South of Italy, and will not return for several weeks.

C. G.—Mr. Hardwich is not now connected with photography in any way, but has for the past seventeen years been a clergyman of the church of England.

X. Y. Z. (Glasgow).—The copyright in a photograph is vested in the person on whose behalf it was executed. For the rest you must consult a solicitor, as we could not undertake the responsibility of advising you.

Old Subscriber.—Obtain from any optician a large untrimmed spectacle glass of seven inches focus, and cut it in two equal halves by the diamond; now cut them round and trim the edges, and you will have lenses suitable for a stereoscope.

W. Brooks.—Our correspondent, in reply to Mr. Oakes, says that he (Mr. Brooks) does not deal with probabilities, but with facts which he has worked out himself. He hopes to see Mr. Oakes's further communication on stereoscopic transparencies at an early date.

John B. Hart.—The historical matter in Hunt's *Treatise on Photography* is most invaluable. In the optical portion of the work, especially as regards that portion to which you have directed our attention, the explanations given are not in accordance with the best instructions at the present time.

John Frankland (Blackburn).—Our correspondent encloses photographs of a useful kind of camera-stand that may be easily improvised for subjects of diminutive stature. It consists in inserting a stout iron rod into the tubular body of a head-rest, the top of the rod sustaining a small hinged table upon which to place the camera. The idea is good and will prove useful to many.

H. G. I. says:—"Will you or some of your correspondents kindly inform me the name of the composition (and how it is made) of the article used by photographers to put on the *carte de visite* just before burnishing, so as to add an extra gloss to the *carte?*"——Try the effect of a solution of two grains of Castile soap to the ounce of alcohol. This solution is usually employed for the purpose mentioned.

A. Davis.—Let the bath contain forty grains to the ounce, add two grains more bromide than usual to the ounce of collodion, give a prolonged immersion in the bath, and develope with a fifteen-grain solution of iron containing one-eighth of its volume of acetic acid. For groups the latter of the two lenses mentioned will prove the more rapid, unless both are stopped down to the same extent, in which case the former will work rather quicker.

G. B. D.—Unless we made a personal inspection of your studio we could not offer any advice. The only thing that we can at present suggest is that you place a camera close up to, and at the centre of, the background, and with a *very* wide-angle lens take a negative of the opposite end of the studio. Next, remove the camera into the directly opposite position—that is, to the extreme end of the studio opposite to the background—and with the same lens and camera take a similar negative. From these two negatives send us prints.

A Country Parson.—Gas bags are destroyed quite as much by the chlorine present with the oxygen as by the oxygen itself. Its absence may be ensured by dissolving hyposulphite of soda in the washing-bottle, and causing the oxygen, as it issues from the retort, to ascend through the washing-bottle in a series of very minute bubbles. This can easily be effected by inserting the delivery tube in the bottle in such a manner as to cause it to slant, and also by having a series of small holes in its upper side so as to permit the oxygen to issue from the pipe through these minute holes instead of through the lower, and open, *end* of the tube. By attending to these conditions the oxygen, while being washed, will be rendered free from chlorine.

Cambria.—It will prove more satisfactory if you employ a large *Nicol's prism* as a polariser instead of making use for this purpose of the usual bundle of glass plates. The expense of the former is, of course, the chief objection—we may say the *only* objection—that exists in the way of its being generally adopted; but if rumour is correct respecting your financial position this will not prove any objection in the present instance. We are fortunate enough to possess a very fine Nicol's prism of medium dimensions, by which the light from a magic lantern is admirably polarised. If you call we shall be happy to show you how it is utilised. The angle of polarisation of the bundle of glass varies in proportion to the number of plates composing the bundle. Brewster has said that while twelve plates of crown glass give a polarising angle of 74°, the angle is reduced to 60° when twice this number of plates are employed.

C. F. C. (Blandford) says:—"You spoke last week in a very commendatory tone of Rouch's new camera, nor can anything be said too much in its praise; but I think one thing escaped you: the back, from its construction, cannot swing the *right* way; its only swing exaggerates the convergence of perpendiculars. The ingenious makers can surely overcome this only defect by adopting a double hinge, which would make the instrument absolutely perfect."——In reply: our statement that the base-board could be fixed by means of a screw not only at a right angle with the ground glass but at any angle within several degrees of this, so as to provide for the swinging of the back and the consequent securing of non-convergence of the perpendicular lines in architecture, was warranted by the construction of the instrument we examined. On application to Messrs. Rouch and Co. we have been informed that they make some cameras with the tilt *backwards* only, so as to be suitable for landscapes pure and simple, the backward tilt being for the purpose of securing the utmost sharpness in the immediate foreground; in others, the bottom of the body is slightly bevelled or sloped, so as to allow the base-board to be placed at a considerable angle within the perfect square. This enables tilting of both kinds to be practised. It is probable that our correspondent has examined one of the former, or purely landscape, kind; we have been shown both descriptions of instrument.

Outdoor Meeting.—The members of the Manchester Photographic Society and the Liverpool Photographic Association have arranged to hold a friendly meeting at Hawarden, on Saturday, the 21st instant. Permission has been kindly given by the Right Hon. W. E. Gladstone to photograph the old and new castles as well as other points of interest in the park.

The Medal Awards at the French Exhibition.—We learn that the jurors in the photographic section of this exhibition have now made the medal awards. We are not yet in a position to indicate those to whom these medals have been awarded, although we have heard that in the list are to be found the names of Messrs. Payne Jennings, A. L. Henderson, and S. Fry. Full details will appear shortly. In the meantime we understand that each fortunate awardee has been apprised by private letter of his good fortune.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician.
For the Week ending September 11, 1878.
These Observations are Taken at 8.30 a.m.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 959. Vol. XXV.—SEPTEMBER 20, 1878.

SLOW *VERSUS* RAPID PLATES.

A few weeks ago we devoted an article to the consideration of the comparative merits of extremely rapid plates and those of a lower degree of sensitiveness for the general purposes of the landscape photographer, expressing an opinion that in cases where the highest degree of sensitiveness is not specially required the slower plates are more to be recommended on the score of reliability. Since then the question has been much discussed, both publicly and in private, and we think we are correct in saying that the concensus of opinion is in favour of the view we adopted. But as in matters of this description a "grain of practice is worth a bushel of theory," we have applied a series of practical tests with a view of placing our opinion upon a more solid basis, and, with the permission of our readers, we will proceed to record the results.

It must be distinctly understood that we speak of general landscape work as usually practised by the *ordinary* amateur. We do not allude to work of any one special class, or to which the entire energies of a skilled operator are solely devoted; under such conditions it is, of course, possible that such a degree of accuracy in the details of manipulation may be attained as to render success, if not absolutely invariable, at least approximately so. We have to deal more particularly with the work of the average amateur who, as opportunity occurs, goes forth to battle with the numerous troubles and uncertainties which surround landscape photography and dry plates especially, and who, without the high degree of technical skill which comes of constant and systematic practice, has to do the best he can with subjects of every class and under a variety of different circumstances. Here it is obviously impossible, or at least undesirable, to aim at the attainment of any special qualities, but rather the object should be to secure the best general results; and we maintain, and shall endeavour to prove, that it is unwise in the extreme to strive in the direction of rapidity to the detriment of other good qualities.

It has been urged in opposition to our view that whatever may be the normal degree of sensitiveness of the plate, whether it be rapid or comparatively slow, it is equally easy to keep within the limits of correct exposure. We think, however, that the fallacy of such an argument must be patent to any thinking mind. *Primâ facie*, it must be more difficult to calculate to infinitesimal portions of time than to larger ones, and the argument of "erring in proportion" must therefore fall to the ground. But even granting the possibility of timing the exposure with equal exactitude in the two cases, we shall endeavour to show that with the same proportionate error in timing a quick and a slow plate the same relative results will not be obtained, the difference being in favour of the latter.

In order to eliminate as far as possible all disturbing elements, we decided to make our experiments with two collodion films of different degrees of sensitiveness rather than pit collodion against gelatine. We do not suppose that the principle differs with the vehicle employed to carry the sensitive material, but we deemed it preferable to secure uniformity. We therefore employed *(a)* an ordinary (or slow) commercial emulsion, and *(b)* a rapid emulsion of our own preparation. We found by experiment that, under certain conditions of lighting, *a* required an exposure four times as long as *b* in order to produce similar results, while by altering the conditions the ratio was increased to five or six to one.

Thus, with the full aperture of a rapid symmetrical, and on an open and pretty-evenly illuminated subject, four seconds and fifteen respectively with the two emulsions gave scarcely distinguishable results; while, with the smallest stop, forty-five seconds and three minutes were the relative exposures necessary for the same subject. In a similar manner, changing the subject from landscape to indoor portraiture, the *a* emulsion required an exposure of ninety seconds to produce a result corresponding with that obtained with *b* in twenty seconds, and, even with that difference in the exposures, the latter gave slightly more softness in the shadows. So far there is a difference in favour of the more rapid emulsion, in proportion as the quality of the illumination is decreased; and, though the discrepancy thus exhibited does not properly come within the scope of our argument, it should be borne in mind by those who are in the habit of using plates of varying degrees of rapidity.

The next experiment consisted in the exposure of a pair of plates for six seconds and twenty-four respectively, employing the full aperture of the lens. This, it will be seen, was fifty per cent. more than the correct exposure in each case. A second pair received exposures twice as long as the normal, viz., eight and thirty seconds. The subject comprised brick buildings, ranging from within a few yards of the camera, the extreme distance being composed of foliage and houses some five hundred yards away—the whole bathed in the warm light of an afternoon sun. The plates were developed separately, and each was treated in such a manner as to produce the best result obtainable under the particular circumstances.

Now, it will be observed that in each pair of plates the same proportionate error of exposure was made, and yet the results were quite out of proportion. With the fifty-per-cent. error the rapid plate gave a flat but not hopeless picture, though decidedly inferior to the properly-exposed plate from the same emulsion. The slow plate, beyond exhibiting a greater softness, was little inferior to the standard. The second pair of plates exposed for twice the proper time showed that the more rapid of the two was hopelessly overdone, the distance being nearly obliterated before the details in the immediate foreground were properly out. Thinking that the development might possibly be in fault, another plate was exposed for the same length of time, and a developer weaker in alkali and containing less bromide was applied; but in this case the distance was more completely lost, while the gain in the foreground was inconsiderable. The slower plate, though flat and wanting in contrast, still showed the minutest details in the distance, presenting a marked contrast to the other.

The development was conducted in each case so as to preserve as far as possible the distance irrespective of the foreground, or at least to secure such harmony as was possible between the two without entirely losing the former. This will explain the apparent under-exposure of the foreground in the doubly-exposed *b* emulsion plate; the distance was lost before the foreground had had time to appear properly. We may here take occasion to point to the incorrectness of the general belief formerly in vogue (and which we have quite recently seen put forward by a writer in a foreign journal), that the use of a large dose of bromide in the developer enables the distance to be preserved while detail is being worked up in the foreground and shadows. Nothing could be more erroneous, as it must be palpable that whatever developing action may be going on in the feebly-exposed portions of the image it must be at the same time producing a still greater effect in the relatively over-exposed distance; and, though it may not be immediately noticeable, the first application of the intensifier will render it only too plainly visible in the thickening and filling up of the better-lighted portions. It is quite possible in attempting to save the distance of an over-exposed landscape to give the remainder of the picture a character of *under*-exposure. We have seen very many so called under-exposed pictures whose *real* fault we have little hesitation in setting down to the opposite cause.

So far the experiments have been to test the latitude of exposure in connection with a modified development, the latter being arranged to suit the special circumstances; we will now turn to latitude of exposure under *similar* development. To test this we employed a bi-lens camera, giving to each half of the plate a different exposure, and developing with a view of ascertaining the limits between which the same treatment was capable of giving a *printable* result. It must not be supposed that we expect in this mode of treatment to obtain perfect results with two very different exposures; but, as there are several degrees between perfect success and absolute failure, we were desirous of ascertaining whether slow or rapid plates afford the greater security against failure from injudicious or improper development—to test, in fact, the comparative *latitude of development*.

With six-inch stereo. lenses and a quarter-inch stop we found the relative exposures for the two plates to be twelve seconds and one minute respectively; three pairs of plates were then exposed, one-half of each plate receiving an over-exposure amounting to twenty-five, fifty, and one hundred per cent. in the respective pairs. The results were even more distinctly in favour of the slow plates than in the previous experiments; for the rapid ones may be said to have broken down at the first step, while even with double exposure the slow ones gave comparatively satisfactory results. With only twenty-five per cent. of error the quality of either half was very little inferior to the standard.

Now, without wishing to "tread on anybody's corns," or to deny the right of using the most rapid plates to those who choose to do so, we must adhere strongly to the opinion previously expressed on this subject, that for the ordinary amateur and for ordinary purposes "slow" plates are much better calculated to give satisfaction. It must be borne in mind that the plates which we now dub "slow" would a few years ago have been justly entitled to a very different term. In warning our readers against the abuse of rapidity (for abuse it is when misapplied), we do not wish them to fly to the opposite extreme, because it is an undoubted fact, as shown by Mr. Charles Bennett, that the greater the normal rapidity of the film the better is it suited to the rendering of feeble detail. Plates of such a degree of rapidity as to combine this quality with the equally-important one of reliability are now easily prepared. Having pointed out the danger we are content to leave our readers to use their own judgment in avoiding it.

BLISTERING OF ALBUMENISED PAPER.

Those who aspire to albumenised photographs possessing a very high glaze have frequently to encounter an annoyance of a tantalising nature—the blistering of the surface. Much has been written concerning this evil, and numerous are the nostrums which have been recommended as a panacea.

We were recently conversing with Mr. John J. Atkinson, of Liverpool, on this subject, and he narrated a little incident which possesses some significance. A very highly- or double-albumenised sample of paper was supplied to a customer, who soon afterwards complained that, while in every other respect it was quite perfect, it blistered to such an extent as to render it worthless, This determined Mr. Atkinson to withdraw it from sale; but previous to doing so he forwarded samples of the same stock to several other photographers, requesting them to test and report upon it, taking the precaution of not giving a hint as to the alleged fault for which it was condemned. To his surprise, not less than to his gratification, in no single case was there any allusion to a blister having been produced. Determined to arrive at a solution of the discrepancy in results, and probably having a surmise as to the cause, Mr. Atkinson at length found that certain conditions, which were under the control of the photographer, operated in the production of blisters or of securing immunity from them.

When a paper heavily coated with albumen is thoroughly desiccated before being excited upon the nitrate of silver bath, the conditions under which the albumen loses its adhesion to the surface of the paper are so nearly complete as to cause numerous blisters to appear at a subsequent stage of the operation of printing. On the other hand, it is found that when the paper, while quite *dry* in the popular sense of the word, yet falls short of actual desiccation, the tendency to blistering is reduced. If the paper were placed in a damp atmosphere for some time previous to its being excited blistering would be impossible, because the albumenous coating would become in such a condition as to attach itself very firmly to the sizing of the paper upon which it is spread. By no possible means could paper that had been sensitised while in this state be brought to show any indication of blistering.

The chloride of soda in the albumen, owing to its deliquescent nature, conduces to the retaining of the albumenised surface of paper in a state far short of desiccation when it is kept in an atmosphere possessing an average degree of moisture; it is only when the atmosphere is exceedingly dry—a condition which does not infrequently occur during hot, dry summers—that such desiccation of the film takes place as to induce blisters.

From what has been said the real remedy for blistering will almost suggest itself. It consists in abstaining from sensitising the paper unless it be in a condition removed to a considerable extent from actual desiccation. There are various ways in which this condition may be induced. One of these, which is practically the best, consists in removing a small quantity from the dry stock-room or cupboard and transferring it to a cool, but not necessarily damp, room, from which it is taken day by day to be sensitised, according to the exigencies of business. The moderate change in the conditions under which the paper exists in the hot, dry cupboard has been found quite sufficient to secure the desired freedom from blistering.

It is also found by Mr. Atkinson and his friends that even when, during a period of great heat, drought, and consequent dryness of the atmosphere, the albumen is in a contractive and non-adhesive state, the ill effects of such a condition may be entirely overcome by adopting the expedient of passing a moist sponge over the back of the sheet, and allowing a little time for the moisture to percolate through the paper and influence the condition of the albumenous surface. When sensitised after this operation the prints obtained as the result of such treatment will prove all that can be desired as regards adhesiveness of the albumen.

This evil of blistering has been so prevalent during the past summer that we feel certain our readers will be glad to receive the hints respecting its cure we here give, consisting as it does of the matured experience of Mr. Atkinson, Dr. Liesegang, and other friends who have been engaged in subjecting this matter to the test of practical experience.

PROTECTING THE HANDS FROM CHEMICALS.

We have, on a previous occasion, incidentally alluded to the possible injury to the hands or the system generally from the continued exposure to the various liquid chemicals that a photographer in busy practice has so repeatedly to experience. The perpetual wetting of the fingers, even with the simple iron developer, their immersion in the hypo., and possibly in bichromate of potash solution or in the gold solution in toning, may seem simple causes, and not likely to have any ill effects; but it is well known to medical men and others that some agents which applied for a short time have no visible effect have, after a considerable number of repetitions, a very important action on the human economy. We do not, in this connection, allude to cyanide; the dangers from absorption of that poisonous compound have been too often pointed out to require any further cautions to be given.

We are led to a consideration of this subject by having frequently observed during the process of hand-shaking with the many photographers we meet with from time to time that so many of them have hands of peculiar dryness, and in more cases than one which we can call to mind the hands have been in a state that could only be termed diseased, the characteristics being the same in each case. The subject is rather a delicate one to advance before, perhaps, one who a moment before it was noticed was an absolute stranger; but to the body of photographers collectively we may address our observations, and we would here ask them to send their experience to us, if any of them have reason to believe that the pursuit of photography has had any effect upon their hands. The condition in the pronounced cases we have noticed had attained a point far beyond the dry stage, till the skin had a kind of scaly roughness, and an actual sore had formed.

We think that, pending the obtaining of sufficient data to form a proper judgment upon, photographers would do well to consider whether they could not more efficiently guard their hands against the possible danger, as the result, if merely to obtain more sightliness—which absence of stains would entail—would be worth some pains to secure; for if it were possible to remove the reproach of stained fingers from the practice of the art we think a very popular step would be taken. There are naturally but two ways in which progress in this direction could be made, beyond that extra carefulness which there is no need for us to impress upon operators generally—in the first place, a more free use of such mechanical aids as the plate-holder, pneumatic or otherwise; and, in the second, the adoption of some covering for the hands.

With regard to plate-holders: if their use were more common there cannot be a doubt that clean workmanship would be more common, and the great aid they are in preserving the fingers from stains we know from our own experience. We have found the solid red india-rubber pneumatic holder, attached to the end of a long handle, invaluable for the dark room, and we are able to use it with comfort for plates up to fourteen inches. True, there are some who object to its use on the ground of waste of time; but we have tested it ourselves, going through all the operations of taking a plate from the dark slide and applying the developer a certain number of times with and without the use of a holder, and we have found that when done in a systematic way, and the holder left in a particular spot, there was not the slightest loss of time from using it; in fact, if anything there was a gain.

As coverings for the hands there are finger stalls and gloves. The former may do for occasional use for a special purpose, but are quite out of the question for operating in, for the stains would extend beyond the limit of their length; and, beyond that, it is very injurious to the system to cover any part of the skin closely for any length of time by a substance impervious to air.

We have now to consider the use of gloves, and we most unhesitatingly recommend a pair of india-rubber ones for universal adoption by all photographers to whom the handling of chemicals is, or may be, injurious, and to all who desire the hands to possess a presentable appearance the whole working day through. There is a great prejudice against their use, on the grounds that they are "namby pamby," not "businesslike," &c.; but we have not a doubt that anyone who may give them a fair trial sufficiently long to get used to them would never be without their aid again. Some photographers make a point of using them occasionally during the working of large plates, and on one hand only; but what we wish to recommend is their invariable use in the operations of developing in particular, and in any other when danger is apprehended from the contact of chemicals with the cuticle. The gloves should not be kept on the whole of the time, but merely put on for the special moment and taken off as soon as possible. Perhaps the bulk of professional photographers do their own posing and the developing of the plate, an assistant performing the other operations; to such the gloves will be of great value. As soon as they enter the dark room the gloves are put on and the developing—that part of the dark-room work which entails most stains, &c.—performed; the gloves are then removed, and the studio entered again with hands free from stain and other injurious action of chemicals only half washed off, for the busy man cannot thoroughly cleanse his hands between every plate he developes. We wish our readers to adopt our recommendation for a week. We are very confident of the result.

A word now as to the gloves themselves. At the india-rubber or waterproof material warehouse many kinds of gloves will be found; the kind, however, to be used by photographers is not the solid india-rubber glove, but that made of a material like the well-known waterproof overcoats—a thin, woven material, covered on one side with a thin coating of india-rubber. There is not so much wear in them by a long way as the solid rubber, but the latter are useless from the length of time taken to get them off, owing to the rubber clinging to the skin; indeed, when inspecting a variety of gloves we found on trying one of this kind on that we could not get it off, and on inquiring of the shopkeeper were informed that the right way was to "peel" them off, turning them inside out in the process. But the cloth-lined kind slip on and off with the greatest ease, provided the right size be selected at first. They work a little easier with constant use. They have a drawback, viz., the seams (which are strongly sewn, and then covered with thin rubber cemented on) are liable to burst or break into fine holes, a single one of which, though almost invisible to the unaided eye, will let in a very large quantity of liquid. The maker, however, would repair them for a trifling sum.

Here is our final advice with regard to their use, with which we will conclude:—There is constantly given out from the skin aqueous vapour, and this condenses on the gloves, so that after a good day's photographing the gloves will be found quite damp inside, and will not come on and off easily. Therefore, every evening after the day's work is over it will be found advisable, indeed necessary, for comfort and to preserve the gloves *sweet*, to turn them inside out, wash with a little soap and water, and then by next morning they will be ready for use again, and always pleasant to use.

THE TECHNOLOGICAL EXAMINATIONS BY THE SOCIETY OF ARTS.

Bearing in mind that a short time ago we recorded a grant of seven pounds by the Photographic Society of Great Britain to the prize fund of the Society of Arts, in aid of their technological examinations, we are now in a position to give some account of these examinations, having received the programme for the ensuing year.

This Society has had for several years in operation a system of examinations in the technology of trades and industries; and the principle on which it is established is to encourage those engaged in any handicraft to combine with their manual dexterity a certain amount of the science underlying their operations. In the list of subjects already embraced in the programme for the coming year photography is included.

On the subjects in general of these examinations it is essential that the candidate (who must be actually engaged in the special branch of industry in which he desires to be examined) should, in order to pass, possess, in the first place, such an elementary knowledge, at least, of abstract science as will enable him thoroughly to understand the scientific principles of which his art or manufacture is an application; and, in the second place, such a knowledge of the application of those principles in his trade as will show that he is practically conversant with the various processes and manipulations of the factory or workshop. The theoretical knowledge must not be a mere "cram" of empirical dicta; nor the practical knowledge a mere committal to memory of descriptions of manufactures picked up from text-books.

The examination in each industry may, therefore, be considered in three parts. The first part includes those branches of science a knowledge of which is requisite as a foundation for sound technical instruction in that particular industry. The second part relates to the technology of the manufacture, or the special application of the various branches of science to it. The third part relates to the practical skill in the manufacture itself.

The candidate's knowledge of general science will be tested by the May examinations of the Science and Art Department. The examination in technology will be by a special examination paper, to be worked in conjunction with these examinations. The practical skill will be judged by the returns of the candidate's employment, for some time past, in the particular art or manufacture. In those branches of industry in which free-hand and mechanical drawing, painting, and designing for manufactures are required the candidate's power will be tested by the examinations of the Science and Art Department, and on the result of the combined examinations the Society of Arts will award certificates. These certificates will be of three grades, according to the proficiency of the candidate:—

(1.) The elementary grade.
(2.) The advanced grade.
(3.) Honours.

Each grade will further be subdivided into two classes—first and second class. A candidate who has obtained an elementary or advanced certificate may be again examined for one of a higher grade in a future year.

We now proceed to show the special application of these general rules to the examination in the general science, the technology, and the practical knowledge of the competitor in photography, premising that he may elect to be examined in all or any of those branches mentioned.

Part I.—General Science.

1. *The Elementary Certificate.*—For this certificate the candidate will be required to have passed in the elementary stage of the following subjects:—

Subject 10.—Inorganic chemistry.
Second grade art (free-hand drawing).

He may then count marks in any of the other subjects given in technology.

2. *The Advanced Certificate.*—For this certificate the candidate will be required to have obtained at least a first-class in the elementary stage of—

Subject 10. Inorganic chemistry,
Also a second grade art (free-hand drawing and perspective),

and to have passed in the elementary stage of—

Subject 8. Acoustics, light, and heat.

He may then count marks in any of the other subjects given in technology.

3. *Honours.*—For honours the candidate must have at least passed in the advanced stage of the science subjects given in paragraph 2, with a second grade art (free-hand and model drawing and perspective). He may then count marks in any of the other subjects mentioned in paragraph 4.

4. The following branches of science are more or less involved in the practice of photography, and may be studied with advantage:—

Subject 1. Practical, plane, and solid geometry.
,, 8. Acoustics, light, and heat.
,, 10. Inorganic chemistry.
,, 11. Organic chemistry.

The student may also with advantage take up practical geometry, free-hand, and model drawing (second grade art).

Part II.—Technology.

5. The characteristic properties of pyroxyline for the manufacture of collodion and the various substances employed for the purpose, as well as the solvents, such as ether, alcohol, wood naphtha, &c.; different qualities of collodion.

6. The various processes, both wet and dry—including the daguerreotype—and the principles involved in each; emulsions, both with collodion and gelatine; paper processes, developers, acid and alkaline intensifiers, &c.

7. Processes for portrait work, landscape work, copying pictures, maps, engravings, and documents of all kinds; printing in silver and other metals, in carbon, Woodburytype, vitrified enamels; toning and fixing.

8. Special applications of photography to engraving, typography, photolithography, including the various processes for collotype, &c.

9. Special applications of photography to astronomical and microscopical purposes, as well as for recording meteorological and other observations.

10. Lenses and the various purposes for which they are specially adapted; the construction of cameras and other apparatus, &c.

Part III.—Practical Knowledge.

11. The candidate must forward to the Society of Arts a certificate, on a form supplied on application, certified by his employer, stating the nature of his employment in a photographic establishment, and showing that he is practically conversant with at least one branch of the art. He may also be required to send specimens of his work.

Prizes.

The following prizes are offered by the Society of Arts in each of the fifteen subjects* to such candidates only as obtain first-class certificates:—

To the best candidate in honours, £10.
To the best candidate in the advanced grade, £7.
To the best candidate in elementary grade, £5.

The following special additional prizes are offered:—

By Wyndham S. Portal, Esq., to the second and third best candidates in the elementary grade, paper manufacture:—

A prize of £3
A prize of 2

By G. N. Hooper, Esq., to the second and third best candidates in the elementary grade, carriage building:—

A prize of £3
A prize of 2

By J. W. Peters, Esq., to the second best candidate in the advanced grade, carriage building:—

A prize of £3

By the Worshipful Company of Spectacle Makers, to the second best candidate in honours, in the advanced grade, and in the elementary grade respectively, in the manufacture of glass:—

A prize of £5 5
A prize of 2 2
A prize of 2 2

By the Photographic Society of Great Britain:—

A prize of £7

A candidate cannot take a prize of the same grade more than once, and, having taken a prize of any grade, he cannot take one of a lower grade in a subsequent year.

REMINISCENCES OF A VISIT TO DUBLIN.

No. II.

While there are numerous localities in and around Dublin that will repay well the visit of the photographer who goes forth in quest of fine scenery, it is unquestionably in Wicklow—which is situated happily within easy distance of the capital—that the beauties of nature, not altogether unaided by art, are to be found in the richest profusion. To this "garden of Ireland," as Wicklow has long been designated, the eyes of the members of the British Association were turned as to a scene where they could revel with the least possible amount of travelling or of personal discomfort.

The lovely town of Bray, which lies on the shore of a fine sweeping bay, may be regarded as the key to, or the starting-point for, the tit-bits of the mountain scenery of Wicklow. Bray should be made the head-quarters of the nomadic artist who desires to "do" a week's photographing amid scenes which, for the extremes of grandeur and quiet sylvan beauty, it is almost impossible to find surpassed anywhere.

Bray is situated about twelve miles from Dublin, and is a favourite summer resort of the citizens, many of whom take up their quarters here at the commencement of the bathing season and remain till the chill winds of October remind them that it is time to leave their temporary marine residences. Bray Head is a lofty, rocky promontory which bounds the beach on the south; and it is not easy to account for the paucity of fine photographs which may either be obtained from or of this fine headland. Below on the right are jagged, precipitous rocks projecting out of the sea; in front are seen in the distance the Hill of Howth, Kingstown Harbour, Dalkey Island, Killiney Hill, and at the spectator's feet reposes the town of Bray, with its silver sands crowded with visitors seeking health and enjoyment. It would be easy to fill a folio with

* Which we do not here enumerate; it is enough to say that photography forms one of them.—Eds.

charming photographs obtained here; but for some reason the professional landscapist does not appear to have considered it worth his while to do such justice to this favoured spot as its merits demand, or, if he had done so, we, at anyrate, failed during the period of our visit to Ireland to see such evidences of it as we had expected. As we hinted in our last article, Dublin is well situated with regard to the number of professional portrait photographers; what is required to do justice to Wicklow scenery is a band of amateurs who, working for pleasure alone, are in a better position to devote time to the discovery of the numerous scenic gems in which the locality abounds.

Evening was approaching when we started from Bray, and, accompanied by genial friends, we walked to the Dargle. This sylvan solitude is a deep ravine, at the bottom of which flows the dark mountain stream from which the name of the glen is derived. It is only in certain dispositions of the light that the ordinary monocular camera could do any justice to this weird scene of sublimity and beauty. To photograph it as it ought to be done, so as to convey an adequate idea of its picturesque aspect, recourse must be had to the binocular camera, the dissimilar images formed by which, and combined in the brain through the agency of the stereoscope, will alone afford a just conception of the imposing scene.

Here we have precipitous cliffs of vast height, one of which—the "Lover's Leap"—was pointed out by one of our friends as, half hidden, it lay on the opposite side of the ravine embowered in verdure which almost concealed its natural beauty; there we find winding paths down the sides of the mountains on both sides which lead to the base of the beetling cliffs, where amid rocks and through chasms rushes the foaming torrent, ever and anon losing itself amid wooded depths and overhanging banks seen impending on either side. From this to the summit of the sides of the glen the foliage is singularly rich and prolific, being composed of oaks, firs, larches, and other trees, with an undergrowth of myrtle, laurestinas, briar, woodbine, and dog roses. It was rather too early in the season to see this grand scene enriched with the golden tints of autumn; but we could well imagine what it would be. Here we advise the tourist photographer to wander, for he will find much choice food for his camera. Only one precaution with respect to his chemicals will be needed—the foliage towards the bed of the torrent is but dimly lighted, and the rocks are of an exceedingly-dark colour, therefore his plates must possess great sensitiveness—more especially must they be very sensitive to those rays commonly designated "non-actinic."

In this neighbourhood is to be found the beautiful village of Enniskerry, of which we can only speak the sentiments of others, time not permitting our extending the walk in that direction. It is situated in the demesne of Lord Powerscourt, and as respects picturesqueness of situation, cleanliness, and inherent beauty it is believed to be almost without a rival in this or any other country. Many of the members of the Association availed themselves of the courteous invitation of Lord Powerscourt to visit the scenes of romantic beauty on his estate, including the famous Powerscourt Waterfalls, which are upwards of a hundred feet in height. Here there is much that will prove most enticing to the artistic photographer.

In Wicklow, too, are other scenes dear to artists and to photographers, and of which we have seen displayed in Dublin several fine photographs. We allude to "The Devil's Glen," "The Seven Churches," and Glendalough, with the fine round tower—an emblem of a form of worship now extinct. How seven churches came to be erected in a solitary mountain-girded position no one appears to have offered any explanation. We are, therefore, free to imagine that one church only originally stood there, and when it fell into a state of disrepair it was found to be cheaper to erect a new one than repair the old one. Hence, probably, the *seven* churches.

From the few remarks here made, and which are chiefly of a topographical nature, it will be seen that the members of the British Association enjoyed no common opportunity for gratifying their love of the beautiful in nature, and that those among our readers who are landscape photographers and are a little uncertain in which direction to travel with their cameras in search of health and fine scenery may with excellent effect visit Ireland. Dublin is easy of access from Euston and other railway stations. One may start from London in the evening, and at seven o'clock next morning be in that famous old city and within an hour's railway journey of the scenes we have faintly endeavoured to depict.

There is scarcely a branch of photography in which gelatine is not in one way or another capable of serving some useful purpose; but beyond a doubt its most valuable feature is found in its reactions with chromium compounds, upon which are based nearly the whole of the numerous methods of permanent impression now practised. For "tissue" making purposes and ordinary carbon printing it answers admirably every purpose required of it, and it would, perhaps, be difficult, if not impossible, to find an efficient substitute; but in many other processes—as, for instance, the numerous modifications of printing in fatty inks—it has been already superseded, wholly or partially, by other substances, foremost amongst which we may mention albumen and gum arabic. For still another class of work the list of substances which behave in an analogous manner may be further extended, nearly all, if not all, the albumenous, gelatinous, and vegetable gummy principles possessing the peculiarity of becoming insoluble under the action of light (and sometimes without such action) when combined with chromic salts. For some purposes the necessity of heating the gelatine in order to render it fluid forms an objection to its use; in others, on the contrary, it is a positive advantage, or, rather, the fact that it is insoluble in cold water constitutes the advantage. In addition to gum arabic the vegetable kingdom supplies a number of substances which have been utilised in this direction—such as starch, dextrine, gum tragacanth, and probably many others which have never been tried. One of the latter—mucilage of linseed—we have found most convenient and efficient, as well as inexpensive, for various purposes; but it seems especially adapted to the requirements of the "dusting-on" process, forming a perfect substitute, and in some respects an improvement upon the usual gum and glucose or dextrine mixture. It acts admirably with no further addition than the necessary quantity of bichromate and a drop or two of glycerine according to circumstances. We have also applied it successfully in forming an insoluble surface upon paper for transfer purposes, and as a substratum for dry plates. It also forms a cheap and ready means of waterproofing dishes of paper or wood for developing and other purposes, and may fulfil many other requirements in the laboratory of the amateur.

PARIS INTERNATIONAL EXHIBITION.

The distribution of the medals and prizes at the Paris Universal Exhibition has been a cabinet question, and is not to take place this month, simply for this grave reason—that at the date first inconsiderately named neither of the chambers of the senators and deputies would be sitting, and their members being at the present moment dispersed all over France in their respective localities would, therefore, not be present, or would incur great inconvenience, loss of time, and expense to come expressly to Paris for that event. The administration has, therefore, too late found this out, and fearful that they might be badly received by the chambers on the monetary questions which *will* arise at the final close of the Exhibition, have found it really necessary to adjourn the distribution of awards until the chambers are sitting, so that the senators and deputies can very properly take their part in the ceremonial. The distribution of medals, &c., has been postponed until October 21. This change had a very disagreeable result, for the Mareçhal de Macmahon had invited the crowned heads of Europe and all the great personages thereof to add *éclat* to this display. He became *furious* at having to announce the delay, which again raised the question of his resignation.

Awards (First List).—Class 12.

Gold Medals.—Vernon Heath, Henry P. Robinson.

Silver Medals.—William Bedford, Autotype Company, Elliott and Fry, Robert Faulkner and Co., Alexander Henderson, Payne Jennings, Notman and Sandham, Robert Slingsby, Leon Warnerke.

Bronze Medals.—Charles Ernest Bartoux, Albert Boucher, T. M. Brownrigg, Samuel Fry, George Hare, David Hedges, A. L.

Henderson, Liverpool Dry-Plate Company, London Stereoscopic Company, Mawson and Swan, W. L. H. Skeen (of Colombo), William Sherlock, H. Vanderweyde, Frederick York. W. Harrison.

Asnières (Seine), Paris, Sept. 14, 1878.

[In addition to the medal awards above given by Mr. Harrison, our Paris correspondent, which are confined to Class 12 (Photographic Proofs and Apparatus), we understand that in Class 15 (Mathematical and Philosophical Instruments) gold medals have been awarded to the two leading photographic optical firms of London, whose names have so long been associated with the manufacture of photographic lenses. But concerning these, and doubtless many other awards, we are unable to say anything in a more definite form until the award list has been officially and fully published.—Eds.]

BLUE BROMIDE FILMS AND OTHER MATTERS.

From Mr. W. B. Bolton's remarks at page 423 of The British Journal of Photography it appears that he had not realised the fact that a bromised film, possessing a blue tint by transmitted light, is capable of yielding a negative of printing density. It is true that a washed emulsion of this class has a decided tendency to give thin images; but for some time past "blue" emulsions have been regarded not entirely with disfavour. It was only after a considerable number of trials that I succeeded in producing a blue emulsion, and I have never been able to determine a certain method of doing so. When this peculiar form of emulsion was first produced I believe that the albumen introduced into the collodion was supposed to influence the silver bromide physically. This idea, however, appears untenable, as the presence of albumen is unnecessary.

I am inclined, nevertheless, to think that where this formation of the silver bromide takes place the albumen confers the property of density, hardly obtainable without it. In varying my formulæ I never know what kind of emulsion will result—whether red, orange, yellowish, or blue, purplish-blue, or greenish-blue. The last emulsion I made was *intended* to be as rich in colour as possible; instead, however, the emulsion turned out much like that described by Mr. Bolton as having been kept twenty-four hours after sensitising. It seems probable that weak solvents, or the addition of water to the alcoholic solution of silver nitrate used for sensitising the collodion, may conduce to this effect, which is, after all, a form of granulation of the silver bromide. Methylated solvents, I am inclined to think, favour the production of the ruby variety of emulsion. Mr. Bolton writes:—"I have used zinc frequently under almost identical circumstances and never attained a like result." This was just my case. Now, "blue results" are the rule. When such an emulsion (without albumen) is washed, even after thoroughly drying the pellicle previously to washing, as advocated by Mr. Bolton, the results on development are slow, thin, and poor.

I do not remember having noticed a blue film become warmer in colour on moistening with alcohol; but I have an emulsion that gives a film which, when still in the moist condition, is blue, or nearly so, by transmitted light, but which, when dry, transmits yellowish rays, though the film is so dense that with a strong light, and with shaded eye, it is difficult to perceive any colour; on moistening with alcohol the film becomes more transparent.

This effect is probably caused by a shrinking of the film during drying, whereby the particles of bromide are brought closer together.

To revert to another subject: I thought that it was usual to prepare transfer paper with a coating of sulphate of barium incorporated with the gelatine. This being the case, how does any discolouration of the paper become apparent?

Yet another query: will citric acid attack silver sub-bromide in an emulsion? If so, how? Herbert B. Berkeley.

OBSERVATIONS ON THE EMULSION PROCESS.

[A communication to the Photographic Society of France.]

In the preparation of an emulsion by the method of M. Chardon the orange tint which the bromised collodion takes after sensitising with nitrate of silver in slight excess is an index of success. This fact has been recognised by the inventor of the process, and has been given by several writers as an unfailing test of quality. Such an emulsion poured upon glass a short time after sensitising gives a transparent film of a reddish-orange colour by transmitted light, and which, washed in distilled water, furnishes plates the dried films of which are hard and brilliant, and intensify without the slightest difficulty with the alkaline developer alone.

We proceed, however, to precipitate the same emulsion afte having neutralised the excess of silver with chloride of cobalt; th powder thus obtained, washed, dried, and redissolved, gives result but slightly different if the bromised collodion be not too old, bu absolutely opposed if the collodion be ten months or a year old.

In the first case, if the collodion be not too old, the film obtaine with the redissolved emulsion will be a little less brilliant and tran parent and of a reddish-yellow colour, the intensification by mean of the alkaline developer alone being less easy. In the second cas (with old collodion) the powdered emulsion gives matt, dusty film of a lemon-yellow colour by transmitted light, and the image refuse to intensify either with the alkaline developer or with pyrogallic aci and silver. This want of success may, it is true, be reduced i a certain measure by employing a larger quantity of *coton resistant* but then the sensitiveness of the films will be greatly diminished which is to be avoided.

This modification in the state of the emulsion, which from excellen becomes bad by the mere act of precipitation, can only, in my opinion be attributed to that operation. The careful study of M. Chardon' pamphlet has enabled me to apply a simple remedy for the defect.

During the precipitation with warm water it seems that th cellules of pyroxyline which contain the silver bromide burst in con tact with the hot water, owing to the tension of the vapour of ethe and alcohol. These broken cells then permit the bromide to escape which latter agglomerates in the form of coarse, granular particles.

Several writers have admitted that the granular form of bromid is in reality sub-bromide of silver, Ag_2 Br. According to this hypo thesis it may be said that the bromide of silver, Ag Br, in the stat of fine division and in contact with a large quantity of hot water, i decomposed to Br and Ag_2 Br, just as carbonate of silver in th presence of a large quantity of boiling water produces sub-oxide o silver, Ag_2 O. Accepting this hypothesis, it would appear that it i only necessary to precipitate the emulsion in the presence of bromin water or in a solution containing chloride of cobalt in order to preven the formation of the granular sub-bromide, whereas experienc proves that the latter is formed in spite of such conditions. I an inclined, therefore, to believe that the coarse bromide is only a mole cular modification of silver bromide, Ag Br. Without disputing th existence of the sub-bromide, Ag_2 Br, I may repeat the followin experiments, which tend to prove the correctness of my hypothesis:—

1. If we sensitise with nitrate of silver a bromised collodion re cently prepared, we obtain a large proportion of the coarse form o bromide. (For the explanation of this see M. Chardon's *brochure.*)

2. If to an old bromised collodion we add a fresh quantity of *coto resistant*, and after the lapse of some little time we sensitise it, w obtain a powdered emulsion of good quality. I may remark that in this case we merely augment the resistance of the cellules to the tension of the vapours of ether and alcohol.

3. If we take a quantity of this same emulsion, dilute it with a large quantity of ether, and precipitate it in hot water, we shall obtain the granular bromide as a consequence of my hypothesis. In fact, the resistance of cells of pyroxyline remaining constant the tension of the ether vapour has augmented, and consequently we have bursting of the cells and formation of the granular precipitate.

My theory explains sufficiently well the facts, and has enabled me to apply a remedy for the defect. If we study the experiments last cited we shall see that, given an emulsion producing good results previous to precipitation, if we desire to ensure identical results after the performance of that operation we shall have to adopt one of the two following courses:—

1. Precipitate the emulsion after having concentrated it. In summer it will suffice to leave the bottle uncorked for twenty-four hours previous to precipitation; or, better, uncork the bottle and cause it to revolve so as to allow the emulsion to flow repeatedly over the whole internal surface, which will favour evaporation. (This method is identical with that suggested by M. Plücker, if my memory serve me.)

2. I prefer the following method:—After neutralisation with chloride of cobalt allow the emulsion to rest for ten hours; shake it vigorously and pour it into a porcelain dish. When the surface has become solid divide it by means of a spatula of platinum or glass, and pour on to it a quantity of hot water equal, at the most, to the quantity of emulsion employed; by means of this spatula the tufts of precipitated emulsion are collected and transferred to a precipitating glass. After changing the water several times the precipitate is thrown on to a cloth, filtered, and finished in the usual manner. I prefer to employ alcohol for the last washing.

The powdered emulsion thus obtained differs in appearance from that produced by M. Chardon's method. It should be placed to soak for some time (an hour) in the alcoholic solution of quinine which is used to form the final emulsion. The latter is of a ruby red-colour, gives films brilliant and transparent, and which intensify with the alkaline developer alone.

Let me add, in conclusion, that if before sensitising the bromised collodion we add to the latter about two per cent. of nitrate of uranium rendered slightly acid the rapidity is considerably augmented and the negatives are more brilliant. I shall be happy if these few remarks prove useful in extending the practice of M. Chardon's process, or in causing its adoption by amateurs who, discouraged by a first failure, have set aside this admirable process. M. Fabre.

RESULTS OF EXPERIMENTS IN CONNECTION WITH DARKENING OF TRANSFER PAPER.

At page 412 of the number of The British Journal of Photography, published on August 30th, I stated that papers from several mills in various parts of the country had been collected and some of them prepared in various ways, and all submitted to the action of direct sunlight. The exposure has now lasted thirty days, and the result is highly creditable to the principal Scotch manufacturers, while, at the same time, it indicates pretty clearly what may be used and what should be avoided.

In the first place, it is quite clear that neither the gelatine or chrome alum are causes of discolouration, as it is impossible to notice any difference between the specimens prepared with those substances and those not so prepared. Neither do the various methods of sizing seem to have any influence in bringing about discolouration or preventing it, and, therefore, we are constrained to look to the material of which the paper is composed for an explanation of the evil. The majority of the samples experimented with were slightly tinted, or rather brightened, by almost imperceptible shades of blue, red, or yellow, and in all cases those tints completely disappear during the first few days' exposure; but beyond the disappearance of the tint no visible change had occurred, except in two specimens which became slightly yellowish, showing that the bleaching of the pulp had been imperfectly carried out.

This fact plainly indicates "natural colour" papers as those most suitable for transfer purposes, and of these there were three varieties included amongst the experimental specimens—paper from pure rags, from a mixture of rags and esparto, and from esparto alone. Before exposure to light these specimens were equally good in colour, but not so bright or purely white as some of the others; but a few days' exposure showed a marked degradation in the esparto varieties, and at the end of a week a perceptible change had also occurred in those of esparto and rags. The colour in both kinds continued to deepen, till, as they lie before me now, the exposed parts are not far from what is known as a "French grey." The pure rag specimens, on the other hand, are quite as pure in colour as before exposure, so that without examining the jotting at the back it is quite impossible to say which is the exposed and which the protected half.

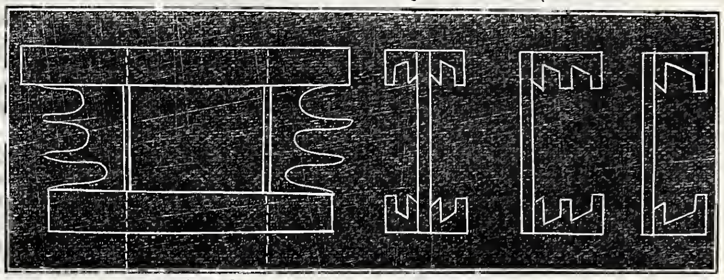
From all this it would seem perfectly clear that there need be no difficulty in getting suitable paper for transfer purposes, all that is necessary being to see that it is made from pure rags and of the variety known as "natural colour"—that is, bleached sufficiently by the usual chemical method to render unnecessary the giving of an adventitious brilliance by the addition of colouring matter of any kind. John Nicol, Ph.D.

A REALLY EFFICIENT REGISTERING AND EFFECTIVE LANTERN-SLIDE CARRIER.

[A communication to the Manchester Photographic Society.]

This carrier entirely obviates the nuisance of having to remember the size of the slide put into the lantern some time previous, and also the necessity of having to go through a course of lessons on numbers, names, and sizes, and then not being able to register only about one-half the slides. All that is necessary is simply to remember that there are three sizes of lantern slides in common use—York's, Ferrier's, and Woodbury's—and whichever one is shown on the screen the operator has simply to put it into the carrier and push it as far as its slot will allow. What can be simpler?

The slides can be registered from either side of the carrier. This in itself is a great advantage over any carrier which can only register from one side. Another advantage amongst the host possessed by this carrier is that the operator is not compelled to reduce the size of his pictures and to have them always one shape, which may cut off an important portion of some pictures. The pictures may be of any shape wished by cutting a paper, card, or tin mask the desired shape and putting it into the slot made in the carrier for that purpose; and by having a variety of masks (which would cost



almost nothing) the shape of the pictures may be altered at will, or the pictures may be left the shape the manufacturer thought best.

The same slot allows a blank, either dark or coloured, being used to imitate the curtain rising or falling, or a strip of paper or glazed calico pierced to imitate falling snow or other effects; or, by having very pale cold glass or gelatine as slides for the extra groove, various tints on the screen may be obtained, and by using two different colours as one slide variety may be secured without adding to the bulk. By using blanks, either dark or coloured, in the same groove side-wings opening and closing either from the side or centre may be imitated, or the pictures may be shown opening from the centre either vertically or horizontally any shape or colour. The slides may be passed through the carrier panorama fashion, or produce a peculiar effect by passing the slides along both grooves. After using springs in my slide-carrier for years I now find them quite unnecessary, as making the groove very slightly inclined answers every purpose. By having two very small rollers attached to the carrier, with a small piece of elastic tubing drawn over them and a small handle to the end of one roller, you may have some of the effects to move in the most even manner.

This carrier—with which can be registered the pictures on the screen any shape, and have an almost endless variety of effects without disturbing either carrier or lantern—is, I think, by far the most portable carrier I have seen. It measures *seven* inches long, four and a-half inches wide, and less than three-quarters of an inch thick, and weighs only *three ounces three drachms.*

The construction of the carrier will, I think, be easily understood from the above rough sketch. David Young.

PHYSICS IN PHOTOGRAPHY.*

We have hitherto treated the question of a sensitive compound from what may be called a chemist's point of view; but it has also its physical aspect, and to enable us to understand what has recently been done in photography this latter must be briefly touched upon. To commence with, we are met with a difficulty in nomenclature which ought not to exist. Unhappily chemists and physicists employ the term molecule in a different sense. The physicist's molecule, for instance, in one place is defined† as "a small mass of matter the parts of which do not part company during the excursions which it makes when the body to which it belongs is hot." To avoid misapprehension the expression molecular group will be used for the physicist's molecule for want of a better, the word particle being rather too indefinite, and being usually applied to a group of molecules of visible size—a state of aggregation which is by no means necessary. The question as to the possible variation of the number of molecules composing a molecular group has not been entered into, as it would be trenching on ground which has been explored by others in relation to a different subject; but this may be stated as a matter of observation—that some compounds of silver which are sensitive to light are capable of forming two molecular groups, one of which absorbs the blue rays, and the other the red rays.

The iodide and bromide are the salts of silver which, either separately or together, are chiefly employed for securing a developable photographic image; and it is these with which we shall principally deal, though the chloride and one or two other combinations will come under review when considering certain new phases in photography. The points to which attention must now be directed are the radiations to which these compounds are sensitive; and these are evidently dependent upon the absorption that takes place in them individually. If we take precipitated silver bromide and fuse it into a crystalline mass, and examine it spectroscopically, we find that it energetically absorbs all rays from the extreme violet to the green, and also less markedly in the yellow of the spectrum; whilst if we place a slab of it before the slit of the spectroscope, and photograph the spectrum of white light passing through it, we find that it completely cuts off the ultra-violet rays; so that we may say that the red and perhaps the ultra-red rays are the parts of the spectrum in which but slight absorption takes place. Now, since

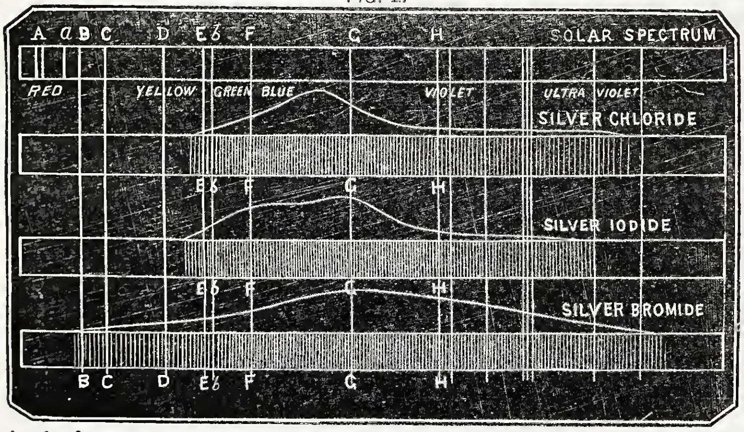
* Continued from page 438.

† *Theory of Heat*, Maxwell.

absorption means work done in the absorbing body, it is evident that we may expect some action to take place in the silver bromide when exposed to these rays; and the action may be a chemical change or a rise in temperature, it being remembered that the latter may co-exist with the former, since it may be produced by the result of chemical action as well as by the absorption of the radiation. The question, then, arises—On what does the possibility of a chemical change in a compound depend? This is a question very easily asked but not so easily answered. It must evidently depend, amongst other things, on the capability of the molecules of the compound to throw off some atom or atoms, or on their capability of acquiring some vibrating atom or atoms of a body with which they may be brought into contact; in other words, that the molecule shall be in a state verging on indifferent equilibrium, and seeking re-arrangement of the atoms when the impulses of the waves forming the radiations impinge against it. Taking for granted that the chemical theory of the formation of the photographic image holds good, we know that the atom of the halogen is thrown off from the molecule of the silver compound behind two atoms of the metal combined with one atom of the halogen. Thus, silver bromide (Ag_2Br_2) is split up into argentous bromide (Ag_2Br) and bromine. If a film of the yellow sensitive salt be exposed to the spectrum an image is developed on all the parts which it absorbs; in other words, absorption in this case means chemical action. Similarly with the iodide: where the absorption of radiation is most energetic there we have a chemical change. With the chloride we have a different phenomenon; crystalline chloride is nearly colourless, and the absorption of every part (though not necessarily of the invisible regions) of the spectrum must be nearly equal; but we find that this salt is sensitive only to about the same radiations, under ordinary conditions, as the iodide. An explanation of this will be offered at a more advanced stage of these articles, but it may be as well to note the fact now. In the accompanying diagram the ordinary results of the exposure of the three chief silver compounds to the spectrum are shown (*fig.* 2).

When we obtain a molecular grouping in which the red is absorbed, we may expect that the same chemical change may take place as when

FIG. 2.



in the former state. This is not a necessity, since, instead of a reduction to a less complex form of molecule, the new compound, formed by the aid of light, might be rendered more complex by annexing other foreign atoms. An example of this we have in Hunt's experiment, already quoted, where it is evident that the violet sub-chloride would be sensitive to light if it were proved that light alone caused the absorption of oxygen. Again: in the combination of chlorine and hydrogen, when exposed to light, we probably have a greater complexity of molecular structure introduced.

In the ordinary state in which silver bromide is formed in a collodion film (we will take this compound as it is the one which has been principally examined), we have it in the state in which the blue is absorbed and the red transmitted; but there are means by which it may be made to absorb the red. We may obtain the bromide in either state by what is known as the "emulsion process." Briefly, this process may be described as one in which an emulsion of silver bromide is formed in a viscous liquid, such as collodion or a solution of gelatine, by first dissolving a soluble bromide in it and then adding to it a solution of silver nitrate. The particles of solid bromide thus formed remain suspended in the fluid. In the emulsion with collodion we can get the silver bromide in various states according to the rapidity with which we add the silver nitrate. Thus, if we add it rapidly, we get a mass of silver bromide which is coarse and has a tendency to subside, and which, when poured upon a glass plate and dried, gives a film transmitting white light; whilst if we add it drop by drop and shake it up between each addition we find that the bromide remains suspended for days, and that a film of it transmits orange light. If we take the emulsion, however, as first described, and place it in a still, and bring it to a state of ebullition, distilling over the ether and alcohol solvents of the collodion, thus breaking up the heavy particles of the suspended bromide, and then wash the contents of the flask in water to get rid of all soluble salts (which must necessarily exist owing to the double decomposition of the soluble bromide and the silver nitrate), we shall find, on redissolving the mass, after washing with alcohol, that the film will transmit lavender or a sky-blue light. On the other hand, if the solvents from the emulsion which transmits the orange light be allowed to evaporate spontaneously and the solid residue be then washed and redissolved, the film will still transmit red light. It will thus be seen that silver bromide may be secured in two states, *in one of which it principally absorbs the blue and in the other the red.* The chances are that the former is sensitive to the less refrangible rays of the spectrum, whilst the other is only sensitive to the more refrangible rays.

The emulsions, if made exactly as described above, might or might not give a film which, after exposure to the image formed in the camera, would develope without blackening all over under the action of the developer, or, in photographic *parlance*, might or might not develope without fog. If the soluble bromide be in excess in the emulsion, and be then washed out as described, the sensitive films would be free from this evil; whereas if the silver nitrate were in excess this would not be the case. The cause of this difference in behaviour has lately been explained, though the means of correcting the emulsion has long been known. The reasoning will perhaps be rendered more clear if the experimental proofs be recounted in the order in which they were made. W. DE WIVELSIE ABNEY.

(*To be continued.*)

AN APPARATUS FOR THE FILTRATION OF THICK FLUIDS, ESPECIALLY ADAPTED FOR THE FILTRATION OF GELATINE FOR THE CARBON PROCESS.

[A communication to the Vienna Photographic Society.]

I HAVE occupied myself almost exclusively for eight years with the carbon process, and have consequently had to work continually with gelatine, without being able to find a suitable filtering apparatus for this colloid. It is, therefore, easy to suppose that I took every possible pains to construct such an apparatus, and my efforts have at last been crowned with satisfactory results. I believe I shall render a service to photographers—especially to those who have to do with gelatine—to apothecaries and chemists, as well as to those manufacturers who have to filter thick fluids, colloids, and grease, by describing my invention.

There are four principal difficulties which beset the filtration of certain bodies—as, for example, gelatine—which are only partially removed by all or any of the apparatus as yet invented. My apparatus removes them completely. These difficulties are—

1. The filter paper soon becomes dirtied, the pores being closed up by the sediment, which is heavier than the fluid to be filtered. I obviate this by causing the pressure of the substance to be filtered to press upwards—that is, to filter from underneath upwards.

2. The filter paper tears under strong pressure. This, however, does not take place when the filter paper is supported on some pervious, but not very pliable, material. For this purpose I have employed, with very good results, the felt which is used in beershops for placing under glasses, and to ensure that no hair shall be carried off from it I enclose the felt in a layer of flannel.

3. Thick substances—such as melted fat, castor oil, syrups, glycerine, solutions of gum, gelatine, and albumen—pass with considerable difficulty through filter paper, and must, therefore, be greatly diluted with water—a proceeding which often carries many inconveniences in its train, especially for photographers who glaze their pictures with gelatine or busy themselves with the carbon process. To remove this difficulty the pressure of the fluid upon the filter paper must be increased; and my apparatus allows of a ten, twenty, thirty, or forty times greater pressure than the ordinary filter, as the height of the pressing column of fluid can be increased at pleasure.

4. Certain oils, fat, wax, bitumen, stearine, &c., as well as gelatine, can only be filtered at such a temperature as shall keep them in a fluid condition. Therefore my apparatus is furnished with an outer covering which may be filled with warm or hot liquid, and in which the required temperature may be maintained, by means of a small spirit or petroleum lamp, up to a temperature of 80° R—as, for example, for the filtration of gelatine. It will be sufficient to fill this outer covering with water, but for a higher temperature oil *should* be used. My apparatus combines in itself all these improvements.

The former consists of two vessels communicating with one another by means of a tube, which is made longer or shorter according as it is requisite for the fluid to be filtered to produce a greater or less pressure. Round the upper edge of the undermost vessel a strong brass ring, two or three centimetres in depth, is soldered. Over this ring comes the filter paper, above which is a round cover of strong felt enclosed in flannel. In order to prevent the liquid to be filtered from finding its way down the sides of the brass ring under the filter paper a strong iron ring is pressed, by means of a screw, against the felt, so that no free space can exist between the ring and filter paper. Besides, in order to prevent the felt from pressing, owing to the weight of the fluid to be filtered upon the filter paper, so as to tear it, a wire netting is placed over it to press back the felt.

This apparatus is quite sufficient for filtration when the fluid does not require to be heated. The fluid to be heated is poured into the upper vessel and passes through the tube into the undermost vessel, passing through the felt and filter paper. In order to be able to collect it over the felt there is an edge above the strong brass ring which forms a receptacle, and is furnished on one side with a waste pipe. If it be necessary to warm the substance to be filtered—as, for example, gelatine—the whole filtering apparatus is enclosed by this outer vessel and a second tube is fastened to the other side, so as to allow the warming fluid to circulate, entering continually by the one tube and leaving by the other. The heat is kept at the same degree during the whole operation by a small lamp. The rapidity of the filtration does not depend solely upon the pressure, but also partially upon the density of the fluid and upon the kind of filter paper.

My apparatus, which I use continually, is scarcely 1·5 metre high, and filters ten litres of solution containing fifteen per cent. of gelatine in two and a-half hours. In large works, where a great deal of filtration has to be done, one upper vessel might be made to feed a number of vessels containing filtrate. The pieces for lengthening out the tubes screw out or in and are removable. To empty both the outer and inner vessels of the apparatus the fluid is removed by means of tubular openings connected with cocks. My apparatus may be obtained of tin with the outer covering of brass from Herren F. A. Wolff and Sohne, the sole manufacturers and patentees. T. Szretter.

THE TORPEDO AND THE CAMERA AT THE DESTRUCTION OF THE "ROYAL GEORGE."

While the inky billows of midnight were dashing in unbroken succession against either shore of the turbulent Sound (this was on Tuesday night), and the rolling of distant thunder was heard reverberating through the heavens, and the watchful sentinels at Willett's Point Fort were sweetly sleeping behind the parapets, a piratical craft was making her way toward the metropolis, slowly, but none the less surely, gaining here a point and there a point, against the unfavourable wind. None knew of her approach. Lights she had none, and her crew were silent as a Potter's Field grave. Silently she dropped her anchor under the very guns of Fort Schuyler and the Willett's Point Works. There she lay till yesterday morning, making not a sound to arouse the suspicions of the innocent Long Islanders, who were almost within her grasp. When daylight came, and the sun came up over the old woollen factory behind Fort Schuyler, the pirate was first seen from the fort. Men were on her decks and in her rigging, and, although her anchors were down, her sails were up. Her cut was that of a clipper, and she showed every indication of being capable of great speed. Although some of the natives who have some knowledge of the sea insisted that the vessel was a cat-rigged schooner with a leg-of-mutton jib and a cutaway stern, it was soon the almost unanimous opinion that she was a man-of-war in disguise, and this opinion was still further strengthened when it was seen that at her maintopmast floated the dazzling red flag of the Commune. It was expected, of course, by the indignant neighbours that General Abbott, who has charge of the fortifications, would at once open fire on the impudent stranger. Every minute a stunning cannonade was looked for. But no cannonade came. The fort paid no more attention to the vessel than if she had been a tipsy excursion boat from Coney Island. The natives felt deserted. The wolf was at the door, and no friendly gun in the forts would interfere in their behalf. They began to pack up their soft-shell clams and prepare for flight. They changed their minds, however, when General Abbott, accompanied by a number of his officers, all in full uniform, walked down the Government pier at about ten o'clock in the morning, were rowed out to the stranger, sprang upon her deck, and engaged in conversation, apparently, with her crew. The vessel lay about 700 feet from the pier, and she was a mystery that none of the old sea dogs could manage. She had so many queer points. In the first place she had no rudder. Then it was seen that her maintopmast wasn't a topmast at all, but only a slender flag-staff. There seemed, too, to be something the matter with her rigging. Every few minutes a halliard or stay parted, and a sail came rattling down, making an hour's work for some poor fellow to tie the stay up again with strings. Besides, it was soon noticed that the soldiers from the fort were doing all this work, while the pirate's crew kept their places on deck and in the rigging, never moving a muscle. It was clear that the General was in undisputed possession, whereat the Long Islanders rejoiced, because the Long Island household fires were once more safe. When the officers and privates returned to the shore the latter were closely questioned (for the natives have a proper respect for the dark blue cloth, and keep carefully away from it), and they said that the schooner was a fair prize, captured without bloodshed, and that she was to be blown up. A crowd of 200 natives accordingly gathered on the pier immediately (it being then eleven o'clock) to await the blowing up (which was to be at two).

At about noon a number of officers and some ladies went down from the fort, accompanied by about a dozen privates carrying some unknown machinery, which they at once began to put in position at the end of the pier. This machinery consisted of four photographic instruments, a small but very fine scientific clock, an electric battery, and all the machinery necessary for a telegraph office. There were also two small beer kegs, coated outside with pitch, and a large coil of submarine cable. The kegs, each of which contained fifty pounds of powder, were taken out near the vessel in a row-boat, and both sunk—one about twenty feet from the vessel's bow, and the other as far from her stern. They were connected with the cable, the boat got out of the way, and the torpedoes were fired, one at a time, by the simple telegraph key on the pier. Each of them sent a column of water into the air about fifty feet high, which immediately relapsed into nothingness; but no damage was done to the schooner. Then two more torpedoes were sent out and connected with the cable at about the same distances from the schooner as before. These were fired simultaneously, with the same result as to the churning and hoisting the water, but again without injuring the vessel.

It was noticed throughout these experiments, and with great horror on the part of the spectators, that the pirate's crew still remained on the vessel, and that no preparations were made to take them off. How many men might be below decks of course it was impossible to tell, but there were four in sight—one at the wheel, one in the main rigging, one amidships, and one near the bow. These were the same positions as the men were in when the schooner was first seen. Gradually, very gradually, as the tadpole turns into the butterfly, or the caterpillar into the beautiful frog, it dawned upon the Long Island mind that the piratical vessel was the identical old schooner that for a long time had been carrying targets out for the gunners to shoot at; that she had been partially dismantled; that the men on her deck and in her rigging were dummies; and that she was going to be blown up to give a subject for some scientific photographs. The schooner, which was so old that her name had long since disappeared, was christened the "Royal George," (principally by people who had nothing to do with her), and all was ready for the tragedy. The electrical apparatus for taking photographs of moving bodies was put in order. It is as simple as possible. The four photographic instruments were put in line, each pointed at the fated schooner. Over them was a light wooden framework, from which were suspended four light boards, like shingles, so arranged that when they dropped they covered the tube. These were suspended by light cotton threads, which in turn were fastened to light fuses, which connected with the telegraph wires. When the circuit was made the electric spark ignited the fuse, the fuse burned the thread, and in a second or so the board fell before the lens and the negative was made.

The "Royal George" had all her sails hoisted except her jibs. She was to be photographed in the highest style of marine art, sailing along over a deep blue sea. The officers had some idea of saving the sails, and, perhaps, a mast or two, by having them hauled out of the *debris* after the explosion. But when two o'clock arrived a new difficulty had to be encountered. A strong wind was blowing, and this, catching the "Royal George's" spreading sails, had drifted her out of position away from the place arranged for the torpedoes, and far out of the focus of the photographic machines. An officer went out to her with several boat-loads of privates, and by taking her anchor ahead and pulling her up she was gradually put in position again.

"Why don't they hoist her sails, and sail her where they want her?" a spectator inquired.

"Because she ain't got one of them arrangements behind to steer with," replied a soldier, who, no doubt, could discount a sailor on guns, but who didn't quite know the name of a rudder.

The two kegs of powder were fastened to the schooner's bottom, dropping down about three feet. The water was far too deep (about thirty-five feet) to anchor them on the bottom. They were put as near the centre of the ship's bottom as possible, one on each side. The photographic plates for the negatives were kept in one of the buildings as long as possible to protect them from the sunlight, and when all else was ready two soldiers came running down the long, steep hill with the plates under their arms. When the instruments were all ready, General Abbott announced that he would fire the torpedoes. Everybody stood on tiptoe and held his breath. The ladies from the fort looked as anxious as if they were about to see a hanging. Every neck was stretched toward the doomed schooner.

"Hold on," said General Abbott; "wait a minute," and he adjusted something about the keys, and everybody breathed freer again.

"All ready."

General Abbott pressed two fingers upon the key. There was a loud booming noise, seemingly under the vessel, and a little smoke. This was in the first second. Then a great heap of water, about twenty feet high, rose up out of the Sound. This was the second thing seen, and occupied the next second. Then the "Royal George," sixty feet in the air, rising high above the smoke and the water, in ten thousand pieces, each piece a mere splinter, a piece of kindling wood, the pieces revolving and striking against each other in the air. Third, fourth, and fifth seconds. Then a descent of the *débris*, not so rapid as the ascent, the whole mass coming down together with a crash on the water. It makes a little ripple; the smoke dies away; the pieces float away. The "Royal George!" Oh, where is she?

And all this time, which was about the time occupied in winking twice, electricity and the sun had been working together, and had photographed the scene. A hundred small boats flew to the scene of the wreck, and hundreds of the small pieces were picked up for relics. For the four brave mariners who went (up and) down with their ship their bodies are bleaching beneath the waves. It would have puzzled anybody to find a square foot of either sail or masts. General Abbott was fully satisfied with the result, and four excellent negatives were obtained. The General says, however, that the vessel was torn into smaller fragments than he desired; but that it was almost impossible to judge how much powder would be necessary to demolish so shaky a hulk. A hundred pounds of powder, he says, was a very moderate allowance. The photographing was under the immediate charge of Sergeant von Sothen, who has attained great proficiency in the art. This was von Sothen's last work in the army, as his term of enlistment expires this morning, and he expects hereafter to be connected with the Photolithographic Company of this city.—*N. Y. Times.*

[Mr. von Sothen, who photographed these torpedo explosions, informs *Anthony's Bulletin* that in the last torpedo explosion the key of the battery communicated simultaneously with the torpedo and the camera, the subsequent exposures being secured at intervals of half-a-second between each. The time given was from one-sixteenth to one-twentieth of a second, according to the focal length of the lenses used.]

FOREIGN NOTES AND NEWS.

PLOHN'S MATT VARNISH.—CONCLUSION OF HERR VON STEFANOWSKI'S REMARKS ON RETICULATION.—WILDE'S METHOD OF APPLYING ALBUMEN TO GLASS PLATES.

IN the *Photographische Correspondenz* Herr Plohn gives the following formula for a matt varnish which, when poured on the back of the negative, gives it an opal, glass-like appearance and facilitates re-touching by sun or petroleum light, as well as the printing in direct sunlight. The ingredients of the varnish are—

Ether	280	grammes.
Alcohol of 36°	200	,,
Benzine	140	,,
Sandarac	16	,,
Thin, fluid collodion	200	,,

In this month's *Mittheilungen* Herr von Stefanowski's remarks on reticulation of the carbon film are continued. The first part of the present paper treats of the causes of reticulation, and the second part of the means of prevention. The principal cause of this annoyance Herr von Stefanowski takes to be the presence of some foreign fluid or gas between the picture film and the support, and this foreign body, he thinks, is most frequently soluble gelatine.

"Gelatine, especially the lighter sorts, is not only soluble in warm, but also to a certain extent in cold, water; as may be seen by draining off the water in which a quantity of gelatine has been soaked, and then heating the water, to which alcohol is now added, when the water will immediately become white, owing to the alcohol precipitating the gelatine which had been dissolved by the cold water. In the same way, when fastening the exposed carbon tissue upon its temporary or permanent support, a certain quantity of soluble gelatine particles collect in the water under which the transfer is made, and if the water be not frequently changed that quantity is materially increased by the number of prints and the rising temperature of the water.

"These free, soluble gelatine particles collect on the pigmented side of the picture, so that afterwards they are enclosed between the picture and the support. Of course, during the development the parts of the picture where this soluble substance is do not adhere properly to the support, and those parts of the picture film which are thus partly free are expanded by the greater temperature of the water and fall down in reticulated folds. The lighter the gelatine of the carbon tissue the more pictures there are soaked in the same water, and the higher the temperature, especially in summer, of the water used for fixing the picture to the support the more soluble gelatine adheres to the picture film and is squeezed down in a reticulated form. The form taken by a drop of water when squeezed between two glass plates will give a tolerably good general idea of the appearance of reticulation as seen in carbon prints developed upon glass, and will give a pretty convincing proof of the correctness of the foregoing theory.

"As the prints which are latest put upon the support are also generally the last developed I can account in no other way for Dr. Richard's statement—that the pictures last developed most frequently show reticulation—than by supposing that he does not often change the water under which he places the picture on the support, and that therefore it is that water, and not the developing water, which is the cause of his mishap.

"A further cause of reticulation is the rapid drying of the bichromated tissue at too great a heat. Carbon tissues—especially those which only contain sugar instead of glycerine or soap—shrink together, owing to the loss of all moisture, so that when placed upon the support they do not expand to their former size, and a further expansion takes place during development. If the support be also susceptible of expansion—as, for example, in the single transfer—all goes well and there is no reticulation; but the latter frequently appears when the support used is firm and incapable of expansion, and most frequently when uncollodionised plates are used.

"There are two other things which I regard as causes of reticulation. They are:—Alkaline baths, which give the gelatine a tendency to dissolve, and the impurity of the gelatine from which the tissue is made, and which, by organic decomposition, destroys the cohesion of the gelatine molecules, and, as a foreign substance, decreases its adhesive power.

"The last causes of reticulation of the carbon film worthy of mention are the too great solubility of the tissue, induced by too warm developing water, and too long a stay in the washing water or fixing bath; and, lastly, the contracting property of the collodion.

"*Precautions against Reticulation.*—Anything that tends to strengthen the gelatine film may be used as a preservative from reticulation. As one of the best of media I may cite spirits of wine, which is a safe and rapid remedy, either used as a component of the bichromate bath, or as an addition to the water under which the picture is placed on the support.

"The best way, with a view to economy, of using alcohol as a remedy for reticulation is the following:—The bichromated tissue, squeegeed upon a glass plate, should be dipped for two or three minutes in a special vessel containing alcohol, and afterwards hung up to dry.

"The alcohol bath, on the one hand, renders gelatine film firm, and not liable to reticulation; and, on the other hand, it draws out to itself all the moisture of the paper, protects it against organic impurities, and facilitates its rapid drying.

"The drying will generally occupy from half-an-hour to an hour, and it is advisable to sensitise in the early morning all the tissue likely to be required during the day. Then, as the alcohol bath accelerates the spontaneous insolubility of the carbon film, the batch should be developed as soon as possible—at latest on the third day after sensitising.

"As the bichromate salts are perfectly insoluble in alcohol the alcohol bath may be used for a long time; and when at last, by the absorption of water, it has become too weak it may be redistilled. The addition of alcohol to the bicarbonate bath or washing water is not practicable; because as the former must, from time to time, and the latter immediately after use, be thrown away there would be a great loss of alcohol.

"Another preventive measure, especially suitable for very soluble tissue, is not to use it until the third day after being sensitised, when the film will have spontaneously commenced to become insoluble. The slow eight or ten hours drying of the sensitised tissue in an airy room at a low temperature is also of importance in the prevention of reticulation, which generally appears after rapid drying.

"After all has been said it will be seen that the tissue, or, in other words, the gelatine, is the principal originator of reticulation; but the addition of a small quantity of sulphuric acid to the steeping water, the frequent renewal of the same, and the gradual development of the picture, beginning with luke-warm water and increasing the temperature, are good general rules for the operator."

At a recent meeting of the Vienna Photographic Society reference was made to some special preparation of albumen used as a substratum by Herr Wilde. In what the speciality of the preparation consists is not mentioned, but its success probably depends in no small measure on the care with which it is applied, minute directions for which are given, and which would probably be equally applicable to any preparation of albumen:—

The albumen should be filtered before each time of using, so that, besides the stock bottle, an empty one should be kept capable of containing from half-a-kilo to a kilo. Into the mouth of this bottle a glass funnel, lined with a sheet of filter paper, is inserted, and a little of the albumen is filtered into it whenever one wishes to coat plates. For coating an ordinary collodion pouring bottle is the best, and several should be kept for that purpose. In pouring in the albumen do not froth it too much, and wait a few minutes until the froth subsides; then remove any remaining air-bubbles with blotting-paper. The well-washed and dried plates have a little of the albumen spread over one side by means of a soft, elastic brush, after which the albumen is poured over them in the same manner as if it were collodion. If any particles of dust adhere to the plate, or if any air-bubbles remain, then the plate must be cleaned again, and the operation recommenced. The superfluous albumen should be poured off into a bath, and then returned to the stock bottle. The plates are then rested upon blotting-paper, and leaned against the wall to dry; or, better still, they are placed in a plate-rack, where a bath placed under them receives the albumen that drips from the corner.

As the prepared side of the plate is difficult to distinguish from the unprepared side, when the plate is dry a small, white chalk mark may be made at one corner of the prepared side. This mark can easily be wiped off. When prepared in the foregoing way the plates are said to be always ready for use again with merely a superficial polish or rubbing up.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
Sept. 26	Liverpool Amateur	Free Library, William Brown-st.
,, 26	Oldham	Hare and Hounds, Yorkshire-st.

MANCHESTER PHOTOGRAPHIC SOCIETY.

THE ordinary meetings of this Society were resumed on Thursday, the 12th instant,—Mr. Alfred Brothers, F.R.A.S., President, occupying the chair.

The minutes of the last meeting were read and passed.

The PRESIDENT said that the proposed exhibition had been abandoned in consequence of the small number of exhibits promised.

Mr. D. Young exhibited a lantern carrier, and read a description of it. [See page 449.]

Mr. W. J. Chadwick disputed Mr. Young's claim to originality in the carrier before the meeting. He (Mr. Chadwick) exhibited his back-pressure valve for preventing explosions in lantern practice, and showed some negatives on Swan's plates—all sufficiently dense. One of the negatives represented Mr. Chadwick holding a wax vesta, by the light of which it was taken.

Mr. Coote had again fallen into trouble with his plates, and exhibited some of large size quite spoiled by curious markings.

Mr. Pearson showed some negatives taken on board a steamer.

The Secretary laid the *Bulletin* of the Belgian Photographic Society on the table.

The members then adjourned to the lantern room, where Mr. W. J. Chadwick, with Mr. McCall as spokesman, exhibited a large number of views of Paris, &c., kindly lent by Mr. York for the occasion.

The meeting, which was very largely attended for September, passed the usual complimentary votes, and was then adjourned.

PHOTOGRAPHIC SOCIETY OF FRANCE.

The ordinary monthly meeting of this Society took place on the 2nd ult.,—M. A. Davanne, President of the Council of Administration, occupying the chair. Dr. Hornig, one of the Austrian Commissioners at the Exposition of 1878, and President of the Photographic Society of Vienna, took part in the *séance.*

After the transaction of the usual routine business,

M. Bardy, who fulfilled the duties of secretary in the absence of M. Perrot de Chaumeux, read the following communication from M. Devaux, a chemist, of Gy (Haute-Saône), addressed to the President:—

"I have the honour to make you acquainted with a process I some time ago devised for giving to photo-engravings after nature the grain necessary to the production of the half-tints.

"My process consists in printing simultaneously the grain and the photographic design by interposing between the negative and the sensitive surface a thin transparent granular pellicle. A granular pellicular negative may also be employed.

"The pellicles and negatives are rendered granular by means of an etched impression. Nothing is easier than to obtain the plate necessary to the production of the impression. It suffices to take an electrotype impression from a plate of copper previously covered with a resinous grain, after the manner adopted by engravers in aquatint.

"If the method which I have the honour to lay before you should appear to you to offer any advantage I beg that you will communicate it to the members of the Photographic Society of France."

M. Despaquis observed that it was seven years since he first proposed the interposition of a granular surface to facilitate the production of a grain, and for the retouching of positive proofs.

M. Davanne remarked that it had also been proposed for the same purpose to employ tulle, or net, or any similar material composed of regular meshes.

M. Chevrier, of Châlons-sur-Saône, addressed a pamphlet to the Society, in which he made an appeal to all photographers and persons employing photography with a view of promoting a subscription to raise a statue to the memory of Nicéphore Niepce. The proposal was well received by the Society, and it was resolved to receive subscriptions for the purpose mentioned, and to publish the names of subscribers in the *Bulletin.*

Dr. Hornig stated that a similar subscription made in Vienna had realised 200 francs, and he had pleasure, in the name of his colleagues in Vienna, in opening the subscription list with that amount. The meeting warmly thanked Dr. Hornig for his kindness.

M. E. Lacan, in the name of Capt. Waterhouse, presented to the Society that gentleman's pamphlet on the application of photography to the reproduction of maps and plans, and received the thanks of the members.

The Secretary having read his review of the French and foreign photographic journals, a communication was made by M. Fabre, the Secretary of the Photographic Society of Toulouse, on the subject of emulsion processes. [See page .]

The Chairman remarked that M. Ch. Audra had already pointed out the advantages which appeared to be derived from the preliminary evaporation of the ether and alcohol by pouring the emulsion into a dish and treating it directly with hot water.

M. Franck de Villecholle said that by employing the water too hot a larger proportion of bromide of silver was formed in the granular state, and that he obtained a far better result by not allowing the water to exceed the temperature of 40° C.

M. Balagny also spoke favourably of the preliminary evaporation of the ether and alcohol, stating that he preferred not to employ the addition of quinine to the final emulsion.

M. Mieusement presented to the Society an album containing thirty photographic proofs, forming part of 140 negatives produced by order of the *Commission des Monuments Historiques.*

The Chairman, in thanking M. Mieusement for his presentation, congratulated him on the success of the proofs, observing also that the commission were to be complimented for the course they had followed, in entrusting the work to competent artists instead of trusting to the chance of obtaining in the different localities pictures of various forms and sizes, as had been previously the case. Instead of a collection of pictures differing greatly in quality and size, the commission had now secured the uniformity so desirable in a work of that class; and as the negatives had been bought, and not the prints, all that remained was to see them handed down to posterity in a permanent form and not by the fugitive method of silver printing. He (the Chairman) presented, in the name of M. du Marché, a collection of pictures representing general views as well as the finer architectural details of the church of Brou.

M. Michaud presented a typographic plate of a portrait of the late King Victor Emmanuel, obtained by the processes he had communicated to previous meetings.

Mr. Gurney, of New York, and M. Marc Ferrey, of Rio de Janeiro, also sent specimens of their work.

Mr. W. Harrison read a communication from the Rev. H. J. Palmer on the subject of gelatine emulsions. The substance of this has already appeared in other communications in our columns, so that it is unnecessary to reproduce it here. It deals chiefly with the employment of ox-gall, as proposed by Mr. Palmer some time ago.

The Rev. Mr. Palmer received the thanks of the Society for his communication, and the meeting was then adjourned.

PHOTOGRAPHIC SOCIETY OF VIENNA.

At the last meeting of this Society—the chair being occupied by Herr A. von Melingo in the absence of Dr. Hornig—the first subject discussed was the transmission of collodion cotton.

The President then read the list of the Voigtländer and the Society's prizes, after which

Herr Luckhardt read a communication from Herr Wilde on the subject of his preparation of albumen, which he recommends for overcoming the disadvantages of badly-cleaned plates. Herr Luckhardt was quite convinced that Herr Wilde's preparation was quite different from all the already-known preparations of albumen. [See *Foreign Notes and News*, page 452.] The preparation had no injurious effect upon the collodion or silver bath, and kept well both before and after being poured on the plate, and even increase the sensibility of the film.

Herren Jaffé, Löwy, Ungar, Wrabety, and Dr. Székley each took a bottle of it home to test and report upon its qualities.

Baron T. Szretter showed and explained the use of an apparatus specially adapted for filtering gelatine for the carbon process. [See page .]

Herr Luckhardt then exhibited Dr. Stein's apparatus for photographing the curves of the pulse and the voice, as well as some very successful glass negatives of pulse and sound curves.

Baron Schwarz demonstrated several multiplying processes, which, though not directly connected with photography, were regarded with great interest by the meeting.

The so-called "Schmittdruck" was exhibited, as well as Baner and Co.'s process.

An Edison's electric needle was next shown; after which,

Herr Luckhardt called attention to the large photographs sent to the Paris Exhibition by Herr Victor Angerer. The size of one was one metre by eighty centimetres. As it was then rather late, it was resolved to postpone the opening of the question-box until the next meeting, and the meeting was then adjourned.

Correspondence.

DETERIORATION OF ALBUMENISED PAPER.

To the Editors.

Gentlemen,—I enclose a piece of non-sensitised albumenised paper, half of which—that marked with a cross—has been exposed in a south window for about a week. On close examination you will see that the exposed portion has assumed a slightly yellow colour.

Does not this show why silver and carbon prints grow yellow with age? It is not because they are *photographs* that they fade, but because they are made of paper. I am now exposing a piece of paper made by Messrs. Marion and Co., and hope in a short time to send you the result.—I am, yours, &c., A. A. Campbell Swinton.

Kimmerghame Dunse, N.B., September 7th, 1878.

P.S.—Some years ago I remarked how notices written on writing paper have become yellow after having been pasted on notice boards in a room to which sunlight had access.

[The specimen enclosed is one of the most marked cases of rapid fading by the action of light that has yet been submitted to us.—Eds]

DRYING PRINTS.

To the Editors.

Gentlemen,—After reading the article on print drying in your last issue, I feel tempted to describe the system I use as being more simple and, I think, better than any one you have mentioned in that article. If you think I am wrong I bow to your superior knowledge. However, I give it to you for what it is worth.

My plan consists in having two sheets of very stout millboard large enough to lay the sheet of paper upon, and two sheets of good tin of the same size. After the prints have been well washed, take one sheet of millboard, upon it lay out a sheet of tin, on that lay a sheet of blotting-paper, and upon that lay the prints on top of each other, all with their faces upwards; and upon the last one another sheet of blotting-paper, the other sheet of tin, and then the other millboard. Now pass the batch endways through a clothes wringing-machine, and you can put any amount of pressure on, as it will not harm the prints, nor press them out of shape.

After passing them right through twice (not backwards and forwards) I have always found them dry enough to be placed between sheets of tissue paper until they are wanted for mounting, or they are dry enough to be trimmed and mounted at once after pressure. The prints strip from one another with the greatest ease.

Sheets of paper that have been very much covered with blisters in the washing water have come out all right when treated in this manner; but when I have dried such sheets by hanging them up I have found the albumen surface to peel off. I have placed as many as sixty pieces of paper after washing one on top of the other, and never had a print spoiled or torn by the above treatment.—I am, yours, &c.,

25, *Williamson-street, Liverpool,* RICHARD CROWE.
Sept. 17, 1878.

EXCHANGE COLUMN.

I will exchange a Ross's $8\frac{1}{2} \times 6\frac{1}{2}$ doublet, folding camera for same, tripod, Howard's tent, and sundries, for a gentleman's gold watch, or offers other than photographic apparatus.—Address, D. W. J., care of Mr. Edge, Llandudno.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

W. A. B.—After sensitising rinse the paper in distilled water, and it will keep good for several weeks.

B. O. T —A leather bellows body for a camera may be obtained from any of the principal London camera manufacturers.

W. A. M.—The patent for inserting a piece of coloured paper in the lens cap need not excite your emotions, seeing that it has lapsed several months ago.

E. S. B.—All requisite information respecting the time for sending in pictures for the forthcoming exhibition will be found in a paragraph in the present number of the Journal.

D. F. S.—There is no photographic exchange club which, so far as we know, exists at present. But it will not be difficult for you to effect an exchange with some photographic friend.

JOHN BERINGER.—We have never tried the preparation of that kind of varnish, hence cannot give the information required. Respecting the production of enlargements, see our last ALMANAC.

X. Y. Z.—The copyright has still three years to run; but we have authority to state that by addressing a note to the person named permission to copy the photograph will be given you with great readiness.

L. J. (Manchester).—The lighting is of too uniform a character, and it is to this that the flatness of the face is owing. Erect a dark-coloured screen on the left side and you will see what a great improvement in the modelling of the face will have been effected.

S. MURRAY SMITH.—Certainly; carbonate of soda may be employed in alkaline development. If you had been an attentive reader of this Journal you would have ascertained that this discovery was made long antecedent to your first experiments in alkaline development.

J. K. NIGHT.—By the adoption of obvious precautions such stains in the prints would never occur. *Never* touch, or allow anyone in your employment to touch, a sheet of albumenised paper after hyposulphite of soda has been handled, until by carefully washing the hands they are known to be scrupulously clean.

M. A. (Oxon).—While there are several passages in Shakespeare which, taken verbally and isolated from the context, are capable of being construed photographically, we are not aware of any which quite resembles the idea you express. The nearest approximation to it, of which we are aware, is—"Drawn by the powerful sun."

TYRO.—1. It is evident that decomposition has set in. The brown matter deposited is evidently gold, and it will be more satisfactory and less expensive to make a new toning-bath than to waste gold in an attempt to resuscitate the old one.—2. The address given in the advertisement will prove quite sufficient, the advertiser being well known in that locality.

GEORGE BEATTIE.—While we are unable to indicate what you designate the "very best" formula for practising the dusting-on process, we are happily in a position to give one that has been thoroughly tried and has given great satisfaction:—

Dextrine	1 ounce.
Grape sugar	1 „
Bichromate of potash	1 „
Water	1 pint.

Of course the quantities here given may be reduced to any extent, provided the relative proportions are retained.

JOSEPH L. HILL.—Under certain circumstances it is both judicious and necessary to raise the temperature of the silver bath even to nearly the boiling point, such as when it gets charged with alcohol and ether; but, as a rule, it will work in the most satisfactory manner when its temperature is similar to that of a warm, genial atmosphere, or from (say) 60° to 65° Fahr.

W. KNOWLES.—1. Modify the proceeding by adding the acetic acid to the albumen and, after stirring well and allowing a little time to elapse, then adding the water. We have never known of failure to result in the preparation of this mixture.—2. The proper kind of rubber is a fine black sample, which may be ordered through any dealer in india-rubber goods—3. Give it a gentle boil, and add alcohol to make up for evaporation.

X. Y. Z. (Perth).—1. The defective markings on the negative are far more likely to be due to the collodion than to the silver bath. Obtain a sample of rather old and red-coloured collodion, and try again. Should the markings still appear, try the effect of dissolving a little soluble cotton in the collodion so as to impart to it greater body without increasing the proportion of iodides. Should you still experience non-success write again.—2. The solution mentioned is intended for use as a lubricant to the surface of the mounted picture previous to applying friction by means of a heated polished steel burnisher.

J. A. P. BAKER.—Of all kinds of stereoscope yet introduced for examining paper pictures the very worst is that in which the picture is illuminated through a small aperture in front. It is bad, for one reason, because the side light thus thrown upon the photograph shows the texture. The best form is that in which there are no sides or front, thus allowing the light to fall from every direction. It will be remembered that when we described the American stereoscope, several years ago, we laid special stress upon that feature. Let it be understood that these remarks have reference only to slides printed upon paper, and not to transparencies.

RECEIVED.—*Autotype Notes*; Major Gubbin; J. Owen; and W. G. Helsby. Registrations in our next.

☞ Editorial Communications should be addressed to "THE EDITORS"—Advertisements and Business Letters to "THE PUBLISHER"—at the Offices, 2, York Street, Covent Garden, London, W.C.

THE FORTHCOMING PHOTOGRAPHIC EXHIBITION.—We wish to call the attention of our readers to considerable alterations that have been made in the rules for sending pictures to the Photographic Exhibition, which will open next month at 5A, Pall Mall East. In former years pictures were sent direct to the Gallery, but this year all cases are to be addressed to the "Photographic Society of Great Britain, care of Mr. J. Bourlet, 17, Nassau-street, Middlesex Hospital, London, W." However, pictures delivered by hand, and not in cases, will be received at the Gallery on Friday and Saturday, September 27th and 28th. These are the last days on which pictures will be received at either address. For further particulars application should be made to Mr. E. Cocking, the Assistant Secretary of the Society, 57, Queen's-road, Peckham, S.E.

AN INTERNATIONAL PHOTOGRAPHIC ALBUM.—Photography has found many applications of late, and the practical use made of it by the police is not the least important. In connection with the appalling catastrophe on the Thames the camera did much to assist in the identification of the bodies; and there are still photographic records in the hands of the police which, together with the particulars of clothing found upon the drowned, will doubtless lead in the end to clear up all doubts in connection with this lamentable affair. The London police now make it a rule to secure a photograph of all bodies found, and copies are sent to stations all over the country, where people having missing friends may see the pictures. In Paris, the assistance that photography may lend in judicial matters is recognised even more fully, and there is a photographic staff at the *Rue de Jerusalem*, presided over by two skilled operators, who enjoy the rank of inspectors of police. In Berlin, again, especially since the attacks upon the Emperor, the chief of the police, Herr von Madai, has made great use of photography in the registry of criminals. Herr von Madai has suggested that there should be international records of criminals kept by the aid of photography, and in order to start the project has furnished the European capitals with an album containing portraits of all the chief delinquents in Prussia. In this country, as our readers are well aware, we also make it a practice to photograph all criminals; the county gaols send up to Scotland Yard copies of their photographs, while governors make an exchange of collections among themselves. As it is, the portraits of our own malefactors make up a vast series, and, if criminal photography is to become an international industry, we shall want a special library to contain the results. In the meantime, there can be little doubt that the system of keeping portraits of prisoners in this way must exert a salutary check upon crime.—*Observer*.

JOURNAL OF PHOTOGRAPHY.

No. 960. Vol. XXV.—SEPTEMBER 27, 1878.

NEW IMPROVEMENTS IN PLATINOTYPE PRINTING.

As would have been seen from the transactions of the recent meeting of the British Association, the platinum printing process of Mr. William Willis, Jun., which was described three years ago in The British Journal of Photography, has been subjected to further modifications, the alterations that have been made having the important effect of greatly simplifying this process. Previous to describing the details of the improved method—which were not given in the paper read before the British Association—we shall first present an outline of the process as formerly practised, with an account of the chemical changes produced.

A sheet of smooth and plain paper having been partially excited by being floated for a short time upon a three-grain solution of nitrate of silver was, after being dried, washed over with a mixture of ferric oxalate and chloro-platinite of potassium, which, having been poured upon the surface, was distributed by means of a pad of cotton wool. The paper, sensitised in this manner, was afterwards dried and exposed to light in the printing-frame, the exposure given being only one-sixth of that which would have been required to produce an image upon silvered albumenised paper. When withdrawn from the pressure-frame the paper was immersed for a few seconds in a solution of potassic oxalate, followed by similar treatment—first, in a weak bath of solution of oxalic acid, then in a sulphocyanide of gold toning bath, and, lastly, in hyposulphite of soda followed by water.

In the improved method of carrying platinotype printing into effect the preliminary wash of nitrate of silver has been entirely dispensed with. There were two reasons for its adoption:—One was that through the agency of the subsequent toning bath a warm tint might pervade the finished picture. Another was that when it was made use of the image was found to be more thoroughly attached to the paper—sunk, as it were, in its meshes—than was the case when no such argentic treatment was had recourse to. *Why* it exerted such an influence upon the deposition of the platinum was never very well understood. Nevertheless the fact remained as has been stated. The withdrawal of the silver as an element in the preparation of the paper was of course attended by the simultaneous withdrawal of the sulphocyanide of gold toning bath, and also that of the hyposulphite of soda, neither of which existed save as adjuncts to the primary employment of the silver. The chemistry of the silver, the toning, and the fixing may, therefore, be expressed as follows:—The platinum image (of the formation of which we have not yet spoken) was of a black colour; conventionalism demanded that all photographs be warm; a little silver, followed by warm toning, gave a sop to conventionalism; and hyposulphite of soda was the fitting wind-up to the employment of the silver. But all this has been changed.

We shall now describe the process as we saw it carried out on the occasion of a visit we paid last week to the laboratory and *ateliers* of Mr. Willis.

A sheet of plain paper—plain in the sense of its having neither been albumenised, silvered, nor salted in any way—was laid down upon a large slab of glass, which was placed in a horizontal position. By convenient clips the paper was secured at the corners. The windows of the room, we may premise, were fitted with yellow blinds. A small quantity of a sensitising fluid was poured upon the centre of the paper and spread over its surface. The sensitising fluid was composed of—

Ferric oxalate	60 grains.
Potassic chloro-platinite	15 „
Plumbic chloride	2 „
Water	1 ounce.

Why the lead salt in the above formula has been imported into the process we are not absolutely certain, unless it be that it helps to give the image, produced at a subsequent stage, a stronger hold of the paper than would be the case were it omitted. At anyrate it seems to fill the place of the now discarded nitrate of silver in an effective manner. This solution is spread over the surface of the paper by means of a flannel squeegee, formed by bending the fabric over a piece of india-rubber tubing placed upon the edge of a slip of plate glass. The paper is now hung up to dry, and as soon as all surface moisture has disappeared the drying is finished before a stove or fire. The paper is now ready for exposure under a negative; it may either be used immediately or it may be kept until it is convenient to expose it, for it possesses excellent keeping properties. Prints have been obtained a month after the preparation of the paper, the quality of these being such as to indicate no difference whatever between them and prints upon paper freshly prepared. This is a valuable feature, and one which photographers will not be slow in appreciating.

The exposure under the negative is about one-third of that required in the case of albumenised silvered paper; in other words, it possesses three times more sensitiveness than ordinary albumenised paper. Although a *visible* image is produced by the action of light, it is found that the duration of exposure is more easily determined by an actinometer than by the inspection of the image. It may be recollected that in the account we gave of the original process three years ago we stated the sensitiveness to be five times greater than that of albumenised silver paper. This was the case; but the increased sensitiveness was owing to the presence of silver on the paper, and as this material is not now used the diminution of the sensitiveness is thus accounted for. However, as we have seen, it is still much more sensitive than ordinary silvered paper.

While the paper keeps well previous to being printed upon, it also keeps for a considerable period afterwards, or previous to development. The time of the operator may, therefore, be wholly bestowed during the day upon the printing, reserving the development till the light has diminished to too great a degree to enable the printing to be continued.

To develope the image a bath must have been prepared in the following proportions:—

Potassic oxalate	120 grains.
Potassic chloro-platinite	7 „
Water	1 ounce.

This solution is placed in an enamelled iron dish, and strongly heated by means of a Bunsen gas burner placed underneath. Previous to immersing a print in this solution let us inquire what change has taken place in the paper by the exposure to light, so as to ascertain the functions of the developing solution.

The paper, it will be remembered, was coated with a solution of fer*ric* oxalate combined with a solution of potassic chloro-platinite. Now, the former exerts no action whatever upon the latter; but upon being exposed to light it is converted into fer*rous* oxalate, which is a reducing agent for platinum. When, after exposure to light in the printing-frame, the picture is examined it is feebly though distinctly visible, although up to this stage the platinum has not taken any part in the performance. The visible picture is composed of ferrous oxalate, and it would have been equally visible had no platinum been present.

We have now to consider in what manner the ferrous oxalate, which has been formed by the light, is made to act as a reducing agent for the platinum. Before it can do so it must first be in solution, as no chemical action takes place between two bodies unless one of them be in a liquid form. So far as we know there is only one solvent for ferrous oxalate, namely, potassic oxalate; hence the print is drawn over or brought into contact with a solution of this salt, the result being an instantaneous reduction of the platinum with which the ferrous oxalate was in immediate contact. Up to the instant when the potassic oxalate is applied the atoms of the two agents are side by side in the paper, the ferrous oxalate being held in check, so that it is incapable of reducing the platinum until it is itself first acted upon by a solvent. No sooner, therefore, is the print placed in contact with such a solvent—in this case potassic oxalate—than the solution, simultaneous with its formation, attacks and reduces the platinum salts with which it formerly reposed harmlessly. The image is thus formed of metallic platinum—or "platina black," as we have sometimes heard it designated—which is well known to be one of the most stable substances in nature.

As far as the image itself is concerned the print is now finished; but in order to get rid of the salts in the paper it is washed for about five minutes in a bath containing a very small quantity of oxalic acid and a few drops of nitric acid. Subsequent immersion in about three changes of plain water, taking altogether about half an hour, completes the operation.

Prints produced by the process described are exceedingly durable. They have been subjected to several tests, which, if applied to silver prints, would have proved destructive. Among these tests are nitric, hydrochloric, sulphuric, sulphurous, and hydrosulphuric acids; the alkalies; bichloride of mercury; hyposulphite of soda; cyanide of potassium; sulphide of ammonium, and others, none of which exert the slightest action on the print.

Those who are familiar with the details of the earlier method adopted by Mr. Willis, Jun., will not fail to see in what respects this indefatigable experimentalist has improved this valuable method of printing, which has a most important future before it in other directions than in the production of prints upon paper.

THE INTENSIFICATION OF NEGATIVES IN HALF-TONE WITH BROMIDE OF COPPER.

Amongst many useful things connected with photography which scarcely secure the amount of patronage they deserve may be ranked the method of intensification which was saved from oblivion by Mr. L. Warnerke and Captain Abney. Unearthed by the former gentleman from some out-of-the-way corner where it had long flourished unseen, the formula was brought into prominence in an article *On a Neglected Method of Intensification*, by Captain Abney, who also described in a scientific manner the *rationale* of its working. Based, in the first instance, upon the bleaching of the developed image by means of a solution of bromide of copper, this plan differs from others of a similar character thus far—in that the increase of density is gained by the employment of a plain solution of nitrate of silver, and the additional strength is, therefore, entirely due to silver and not to the substitution of any new metal.

When utilised to its fullest extent the accession of density is so great as almost to unfit it for subjects in half-tone, though, by modifying the process slightly and proceeding with due caution, satisfactory results may sometimes be attained in cases which would prove hopeless under any other mode of treatment. But, by giving a little study to the pecularity of the change brought about in the nature of the image, it is possible to produce a variety of results under special circumstances, and we have found the capabilities of the process considerably extended. According to Captain Abney's analysis of the reaction performed, the darkened image produced by the application of a solution of nitrate of silver to the "bleached" film consists of a mixture of bromide and sub-bromide of silver, the metal of the sub-bromide being drawn from the solution. As a subsequent treatment with alkaline pyro. or ferrous oxalate reduces the whole of the image to the metallic state, we thus obtain a most intense deposit, consisting of the original quantity of silver *plus* that extracted from the solution employed in darkening it.

The addition of metal thus brought about differs entirely from that arising from the ordinary method cf silver intensification, inasmuch as the latter is deposited entirely on the surface of the film, with comparatively little discrimination between lights and half-tones. In the other case, however, it is formed in the film by chemical means, and bears a strict proportion to the quantity of metal already present to form the different grades of the picture. Practically, then, the only limit to the density obtainable rests on the capability of the collodion film of containing or holding the metal, added by successive operations without busting or splitting. It is not probable, however, that, except in the case of a very weak negative, the necessity will ever arise for a second application of the treatment, but, rather, it will be desirable to modify the excessive action in the case of negatives in half-tone.

The simplest means of reducing the excessive density consists, as we have previously shown, in decreasing the strength of the silver solution. If a solution be used of the strength of sixty or one hundred grains to the ounce, as first recommended by Captain Abney, the darkening of the image is so rapid and complete that the result is only capable of being utilised for subjects devoid of half-tone, and even then the transparent portion of the negative must be absolutely free from the slightest trace of deposit to start with. But by considerably reducing the strength of the silver the action is very much slower and to a great extent under control, and, as the colour of the deposit is of a highly non-actinic character, it is possible to stay it when it is judged that the density is sufficient without allowing the full reduction to take place. We are unable to speak as to the stability or otherwise of each of the images, which, it must be remembered, are composed partly of bromide of silver, and not metallic silver as in ordinary cases. The darkening which we might be led to expect under the action of light, slight though it may be, would no doubt prove injurious in a half-tone subject, though perfectly harmless in a negative on black and white; for, if the latter has unsuccessfully withstood the searching test of the previous operations, there will be no deposit in the lines to darken or fill up.

This uncertainty is, however, removed in the method we are about to describe, and which is put forward only for a special purpose and not for general work, as its effect is far too pronounced. Most of our readers who have experimented to any extent with rapid emulsions will have discovered that it is a matter of the greatest ease to obtain a preparation which, while possessing extreme sensitiveness and the capability of rendering the feeblest details, is quite beyond the power of all ordinary methods of intensification. The image produced is remarkably clean and delicate, and will stand any degree of intensification in reason *without fogging*, but appears to be wholly devoid of some element essential to the production of density. With plates prepared from such an emulsion we have succeeded, by means of bromide of copper, in producing negatives of full printing density combined with perfect gradations of light and shade, and equal in every respect to the ordinary standard of alkaline-developed plates. It is scarcely necessary to say that the original image must possess (however feeble it may be) the basis upon which to build up the picture. A plate showing transparent glass where there should be detail will be perfectly useless.

The solutions required are as follow:—The bromide of copper solution is prepared by mixing equivalent parts of sulphate of copper and bromide of potassium (in hot saturated solutions), and after the mixture has stood for an hour or two it is decanted or filtered off from the sediment, and diluted to the required strength. A working solution of the right strength may be made by dissolving thirty grains of sulphate of copper in one ounce of hot water, and then adding an equal quantity of bromide of potassium, but as this rapidly becomes too weak it is preferable to keep the strong solution and dilute it when required. The nitrate of silver solution should be of the strength of from ten to twenty grains to the ounce, according to circumstances, and must be neutral or very slightly alkaline, as the presence of free acid appears to interfere with the reduction. In addition to these we require ordinary alkaline pyro. or ferrous oxalate of full strength.

After fixing and well washing the plate, it is flooded with the bromide solution for a longer or shorter time according to the increase of density required. If the image be extremely thin the bleaching action may be complete, but it must be borne in mind that this will lead to such an accession of strength as few instances will require, and if once overdone the case can scarcely be remedied. We prefer to proceed by only partially bleaching the image by flooding the plate with the solution, and allowing it to remain until a certain change is seen to be produced upon the surface colour, and then, after a very thorough washing, to apply the silver nitrate, allowing it to act until it produces no further darkening. At this stage of the operation a tolerably accurate idea may be formed of the ultimate result; in many cases the density will now be sufficient, but the image will be liable to the suspicion of instability, and the same may be said if the further degree of strength necessary is attained by only a partial reduction with *weak* alkaline pyro. or ferrous oxalate.

Experience alone will enable the operator to judge how far to carry the bleaching action and what strength of silver to use, but these should be adjusted so as to allow the full action of a strong developer subsequently. It is far better to err on the side of a too short application of the bromide or a too weak solution of silver, as if the first result be insufficient it can be repeated, the only point of importance to be observed being the thorough washing of the film between the different operations. The process may seem a roundabout and troublesome one on paper, involving, as it does, three separate stages, but it is not really so in practice, and, moreover, it is only recommended as a *dernier ressort* when all else fails. It has proved the means in one case of rendering available a considerable quantity of emulsion otherwise useless, but from which we are now able to produce most satisfactory results. The colour of the negative is a rich warm brown, and the printing qualities excellent.

In operating upon films which have been dried the bromide solution will be found to act very slowly and irregularly, unless special precautions be adopted to reopen the pores of the collodion. Moistening with dilute alcohol proves insufficient. It is necessary to use it warm and of full strength; that is to say, undiluted methylated spirit. Finally: we recommend that the image be not exposed to light (even unprotected gaslight) after bleaching, as this seems to lead to irregularity, though in what manner we are not now prepared to say. Insufficient washing, though it may not actually produce stains, has a similar effect.

PAPER FOR CARBON PRINTING.

The value of uniformity is nowhere seen to greater advantage than in photography. Photographers use glass plates for their negatives, printing-frames for holding them, carriers for the dark slide, mounts, matts, frames, and a hundred other articles of apparatus and fittings of one uniform regular size, with the effect of being able to purchase them at a fraction of the price that would be necessary in the case of a single instrument or piece of apparatus made specially. Anyone may soon see the force of our remarks if he has to get made any article of however trivial a kind, which is at all "out of the usual rut." He will have to wait a very long time for it, and when he has obtained it he will most likely be astonished at its cost, though there may really be no overcharge whatever.

It is the same with our chemicals. We can buy the usual dark room supply at reasonable prices and with great ease; but the moment we want any variation all kinds of difficulties are placed in our way. If we require a sample of gun-cotton of any special character we must, practically, make it ourselves.

And so it is with the fabric which forms the basis of ninety-nine per cent. of all the photographs in existence—the paper—whether albumenised or gelatinised. Thus, for albumenised paper we are practically limited to two sorts—one manufactured in France and the other in Germany. We are aware that the limited choice is owing to the fact of the papers we specify being of particular excellence; but their peculiarities have been sought out, and the chief element of value—the sizing—analysed, and the paper generally examined, till we know exactly how to make it. More than that: manufacturers in England have been asked to produce a similar product, but in vain. They know their business, and they know that to make a special article would involve more outlay and trouble than would be compensated for by any possible profit.

With carbon printing we shall, without care, drift in the same groove; thus at present there is in the market little, if any, kind of paper beyond a smooth sort of hard texture, faced, as it may be termed, with either shellac or gelatine and chrome alum, the proportions of the latter varying according to the purpose required—single or double transfer. Let anyone visit any exhibition of importance and note the water-colour pictures exhibited there. He will find every variety of surface and texture of paper, from the smoothest hot-pressed to the rough-surfaced, coarse-looking material apparently more adapted for making packing bags than anything else. On the other hand, let a visit be taken to the next Photographic Exhibition, and what a contrast! Thanks to the better art education that now obtains we get plenty of artistic excellence but an excessive similarity of texture. Boldness of lighting, accompanied by the veriest nauseating smoothness of surface and miniature-like delicacy of effect, and all in the same material so far as surface texture is concerned.

And yet this need not be, in carbon in particular; for it lends itself with particular ease to a far greater variety and pliability of treatment than silver printing, owing, in one direction, to the ease with which considerable alterations may be made by careful use of hot water. Our readers will say that they cannot purchase anything but the smooth kind of prepared paper that we speak of. We know they cannot, and that is the reason of our writing as we do; but it is a matter of the greatest ease to prepare their own paper, and, being independent of the manufacturers to that extent, their pictures will have the more originality and consequent value if technically good.

We shall be understood as not desiring to support any further variety in the manufacture of the paper itself, but only the adoption into general practice of a greater number of the existing varieties, as we know is done in a few isolated cases.

Thus, let us take a life-size head vignetted. What can look more effeminate than such a picture put on smooth, single transfer paper, no matter how white it may be by the addition of barytes to the gelatine? But print the same negative on to a piece of Whatman's paper (say), and it at once becomes an artistic production—all the better for needing little or no aid from the retoucher—and, if a few touches are deftly put in with black chalk and a stump, we have a highly-telling work of real merit. This is only one of many cases; we do not suggest life-size heads as forming the *ultima thule* of effort in this direction. Smaller heads may be placed on paper not so coarse, but still far removed from glossy tameness. Landscapes offer special scope for such treatment, and yet while we have a return to the textures given by the old waxed-paper negatives recommended we have no reference to any but the accustomed support, which might seem almost to be part and parcel of photography.

For those who are unaccustomed to the use of textured paper every information could be obtained from a respectable artists' colourman, who would be the most likely person at present from whom to obtain any necessary variety.

There is a quality sold more than any other made by the well-known manufacturers, Messrs. Whatman, and it is always called at the stationers' and artists' colourmen "Whatman's drawing-paper." It is made of various thicknesses, classified as of so many pounds to the ream, and can be obtained either hot pressed, not hot pressed, and extra rough. The hot pressed is only suitable for smaller work from the smooth surface the hot pressing gives, a good portion, however, of which disappears after wetting. The purchaser should be careful, if desiring to use large pieces, to ask for the seamless. It is a little dearer, but is free from a permanent crease across its breadth which disfigures the other kind.

These would be enough to start with, and afterwards the photographer wanting still more variety could try the various kinds of Hollingworth's paper, the tinted paper, and the imitation Creswick paper, &c. The real old Creswick paper is considered so valuable that we knew of a "find" of half-a-ream in a country stationer's shop being discovered by an artist, who bought it all up cheap and sold it at several shillings per sheet. Of course such paper would not have any more value than new paper for photographic use. When experiments with tinted paper are made we would caution our readers to employ not the "machine-made" but the "hand-made" paper, the former being too woolly or rotten to withstand the necessary handling in hot water.

THE LATE THOMAS GRUBB, F.R.S.

At the mature age of seventy-eight years, Mr. Thomas Grubb, F.R.S., died at his residence, Rathmines, Dublin, on the 19th instant.

It is now over twenty-three years since Mr. Grubb appeared in a prominent manner before the photographic world. The late Mr. Sutton had written in advocacy of landscape lenses of small dimensions, which elicited a masterly rejoinder from Mr. Grubb, whose acumen as an optician was thereby immediately recognised. At this time Mr. Grubb was Honorary Secretary of the Dublin Photographic Society (of which he was the founder), as well as the editor of its journal, which was soon afterwards discontinued.

Several papers of the highest importance in photographic optics were afterwards published by Mr. Grubb, among these being the following:—*On the Properties of Landscape Lenses; On Lunar Photography; On Some of the Optical Principles Involved in the Construction of Photographic Lenses; On a Screw Adjustment for Stereoscopic Lenses; On Proposed Standard Rules for the Dimensions of Lenses; On the Value of a Stop to a View Lens; On the Angular Field of a Lens; On the Effects Produced by Enlarging the Aperture of the Photographic Lens; On the Aplanatic Lens; On Comparative Trials of Photographic Lenses; On Lenses of Rock Crystal; On the Optical Centre; On the Equivalent Focus of Photographic Lenses, and on the Angle of Subjects Included; On Displacement and Distortion; On Intensity and Quickness of Lenses; A Simple Method of Ascertaining the Equivalent Focus of a Photographic Compound; On the Equalisation of the Photographic Image in Fields of Large Angle Projected upon a Flat Surface;* and *On the Relative Transparency to Actinic Rays of Glass and other Media.*

These are the titles of the leading communications on optical subjects made to the public, either through the instrumentality of the photographic societies of London and Dublin, or of THE BRITISH JOURNAL OF PHOTOGRAPHY and other channels. Such communications were not, however, exclusively confined to optical topics, for among other contributions to photographic literature we find one—*On a Large-sized Portable Camera, and Stand for the Same*, together with another, which we believe was the last he wrote, entitled—*A Camera for Dry-Plate Work.*

The invention of his "aplanatic" lens, in 1858, gave an impetus to the perfecting of landscape and group lenses; nor must we omit mentioning his services to the magic lantern by the invention, several years ago, of an achromatic condenser for that instrument, by means of which a wide angle of light may be condensed to a point sufficiently small to serve for illuminating a microscopic object. Mr. Grubb was also the inventor of the ingenious system of lens supports made use of by Lord Rosse in supporting his mirrors.

Notwithstanding Mr. Grubb's great talents as an optician we do not know how far we can strictly speak of him as one by *profession.* It is quite true that he created what has since developed into very large and important optical works; but several years ago, owing to his genius as a mechanician, he received the appointment of Engineer to the Bank of Ireland, when the optical business he had created we had occasion to speak only a few weeks ago, by whom the business has been exclusively conducted during the past ten years.

Originally intended for the mercantile profession, the mechanical tastes of the late Mr. Grubb were too strong to allow him to continue as he began; accordingly he threw himself with ardour into the higher departments of mechanics and optics, producing both refracting and reflecting astronomical telescopes of great magnitude and world-wide renown, the great Melbourne telescope being among the last executed under his own personal supervision. Mr. Grubb also invented and manufactured magnetic instruments which were supplied to more than forty British stations. When in Dublin a few weeks ago, attending the meeting of the British Association, we, along with many others, were permitted to see in operation, at the Bank of Ireland, the wonderful machinery invented by Mr. Grubb for printing bank notes from steel plates, the machinery for engraving these plates and for renovating them when worn, together with the machine by which they are numbered, and which is of such an automatic nature as to resent any omission of routine duty on the part of the attendants by refusing to proceed with its work until all manual requirements have been complied with.

Of the optical establishment at Rathmines we shall say nothing at present, reserving our remarks for a subsequent article, in which we propose embodying some further notes we made during our recent visit to Ireland.

Mr. Grubb was a man of a singularly kind and unobtrusive disposition, and was much beloved by all who enjoyed the pleasure of his acquaintance. Although he had been confined to his bed for a considerable time previous to his death, he retained his intense love for mechanical pursuits to the very last. A swing bench had been devised and erected so as to turn over his bed, and here he had his vice and other tools. Often after working for hours would he be seen to have fallen asleep with the tools in his hand, as in the act of filing or adjusting some piece of mechanism. He died "in harness." Thus has passed away another of those veterans to whom photography has been so much indebted.

THE question has often been raised as to the possibililty of dispensing with the spirit varnish, now ordinarily used as a protection to the negative, and substituting for it some other medium affording equal security without the inconveniences which attend the present system. A few months ago there was a rumour that we were shortly to have a new varnish possessing all the good qualities and none of the bad ones of the best varnishes now in use, with the additional advantage that it required no heat for its application; but, whether the promised boon is to be made public or not, there can be no doubt that varnishing the negative forms one of the minor troubles of the photographer. With a large choice of materials ready to hand it is somewhat surprising that so few really good varnishes are in the market, or that those which are obtainable are not of a more uniform quality, for it is no uncommon occurrence upon opening a new bottle of varnish of a "brand" which has worked admirably for a length of time, to find that the fresh sample is entirely different from what has gone before. Whatever may be the reason of this want of uniformity, it is certain that a large body of photographers would welcome anything which came in the shape of an efficient substitute, and, pending the arrival of that desirable consummation, several we know have seriously taken into consideration the possibility or advisability of making use of such makeshifts as albumen, gelatine, gum arabic, *et hoc genus.* We are scarcely inclined to counsel the adoption of such substitutes as the permanent protection of the negative, though they may, especially the first, answer well enough for temporary purposes. All are easily attacked by damp or moisture, which is a deadly foe to the permanency of negatives even when protected by a resinous varnish, and must be much more so when the protective coating is itself liable to decomposition, to say nothing of the danger arising from a piece of damp paper becoming permanently fixed to the negative during printing. But in cases where only one or two prints are required from a negative, or where it is desired to test its soon afterwards passed into the hands of his son, the present eminent optician of that name, concerning whose factory and large telescopes printing qualities previous to varnishing, a temporary coating of gum or albumen forms a sufficient protection, and obviates the trouble which would arise from the ordinary negative varnish. Albumen, however, though forming an admirable protecting film, is not so well adapted for use in the case of negatives which may require re-intensification, as it does not appear to soak into the pores of the film sufficiently, or, if it do, its subsequent removal is a matter of some difficulty even with a strongly-alkaline solution. Gum arabic is easy of removal and leaves the film in a sufficiently porous condition, but it is easily scratched and liable to crack in drying, while gelatine is open to the charge of raising blisters. We have recently tried a temporary coating, recommended by a friend, which answers admirably, combining the hardness of the albumen film with the ease of removal of gum. It consists of the white of one egg with sixty grains of dextrine in five ounces of water, mixed *secundum artem*, and filtered; it is poured on the wet collodion film, allowed to soak for a minute, then drained and dried. No alcohol should be used in remoistening.

PARIS INTERNATIONAL EXHIBITION.

In addition to the list of medal awards which we published last week we have received from our Paris correspondent the following

Supplementary List of Awards.

Gold Medal.—Howard Grubb.

Bronze Medals.—Alfred S. Fisk, W. H. Wheeler, — Unwins.

Honourable Mention.—Adolphe Beau, Godbold and Basebe, Lemere and Co., Lombardi and Co., W. F. Maltby, Carl Norman and Co., Herbert Watkins, Matthew Whiting.

To the photographic exhibitors of the United States of America the following awards have been made:—

Gold Medal.—N. Sarony.

Silver Medals.—Continental Photographic Company, F. Gutekunst, — Lundy, Joshua Smith (Chicago).

Bronze Medals.—Thomas Gubelman (Jersey City), — Guerin (St. Louis), Lafayette Seavey.

Honourable Mention.—J. H. Beal (New York), E. Gurney (New York).

NOTES FROM THE NORTH.

For the past six months the north, so far at least as I have been concerned, has been left to look after itself; but the readers of The British Journal of Photography have not lost much, as nothing of great interest seems to have occurred, except, perhaps, the discovery by Mr. J. G. Tunny of the tendency of certain samples of transfer paper to darken on exposure to light, and that has received, and is still receiving, a satisfactory share of attention.

In the early part of this year I mentioned in these *Notes* the fact that, notwithstanding the dulness of trade, several new photographic establishments were to be opened in and around Edinburgh, and as I recently had an opportunity of spending some time in one of the most important of them a brief account of the visit may not be without interest.

It is well known, in this part of the country at least, that a good many of the "well-to-do" Glasgow folks take up their abode in the picturesque and beautiful homes on the banks of the Clyde, and that many more are in the habit of spending the summer months "doon the water." In consequence of this the various towns along the river banks, and for some distance inland, offer such a fair field for the professional photographer as to have attracted some of the best and most successful men in the kingdom, and there is probably no better work done in any part of the country than on the banks of the Clyde.

Of those photographers one of the best known and most successful, both from an art and a commercial point of view, is Mr. McKenzie, late of Paisley. Anxious, probably, to enjoy the advantages of a residence in or near the Scottish metropolis, and having faith in the fact that good work will attract good customers to almost any locality, instead of selecting a situation in a fashionable thoroughfare—where at the best he would have been cramped for room, and where his patrons would have had probably several stairs to climb—he looked about for a suitable place in the country but within an easy drive of the city. This he was fortunate enough to find in "Willow Bank," which happened then to be in the market, and, both in itself and its surroundings, is one of the most lovely places within a five-mile circuit of Edinburgh.

Willow Bank lies on the northern slope of Arthur's Seat, about two miles from the city, and consists of a fine commodious mansion house, surrounded by a beautifully-kept garden and finely-wooded grounds. Mr. McKenzie's original intention was to have occupied a part of the house as a private residence, but, like most of those who took to the art in its early days, he is evidently an enthusiast in it, and, I think wisely, came to the conclusion that for the proper enjoyment of domestic life it is desirable that the studio and the dark room should be separated as far as convenient from the home. Acting on this conviction he has taken up his abode in another suburb of the city, distant at least five miles from Willow Bank, and, as that place is therefore altogether devoted to photography, it affords probably the most magnificent suite of reception and dressing rooms to be found in any establishment in the kingdom.

Mr. McKenzie's faith in his work is not only shown in having selected a place at a considerable distance from town, but also in the fact that it does not obtrude itself on public sight. It must be looked for by those who want it, as it is not even on one of the main roads that lead to or from the city, but on a kind of side road—what in England would be called a lane—going from Piershill toll to the Portobello and Duddington road, and on which the traffic is of the most limited description. Entering the grounds by one of two gates that open on this road, the visitor is led by a winding carriage drive to the principal entrance, where a flight of a few steps leads into the hall, and the eye is at once attracted by several paintings by one of Mr. McKenzie's sons, which give promise of no mean power in that direction. To the right and left respectively are what were the drawing and dining-rooms of the mansion, but now converted into noble-looking reception and waiting-rooms, and containing many beautiful art objects and some exquisite specimens of photography.

I do not know whether the feeling is general, but with me it is almost always present on entering the receptions rooms of most photographers—that they altogether overdo the exhibition of specimens. As a rule they are littered everywhere—from floor to ceiling, on tables and in cases, and occasionally strewed about the floor as well. There is hardly a vacant spot on which the eye can rest, and, even where the specimens are all of high-class work, the mind can with difficulty carry away an impression of any one picture in particular, and is more likely to retain only a confused jumble of what has passed before it. Mr. McKenzie has wisely avoided this, and places before his visitors one or two albums and about a couple of dozens of his cabinet portraits, all of which may be not only seen but carefully studied during the short time usually devoted to such employment; and the specimens thus shown are well worth studying, whether by those who love to look at high-class work for its own sake and for the pleasure it gives them, or those who are anxious to decide as to the style in which they themselves should be taken, or by those photographers who are willing to be students, and on the outlook for such inspiration as shall guide them in their striving after perfection.

A hasty survey of Mr. McKenzie's pictures conveys the idea that he is strongly "Rembrandtish" in his style, but a more careful examination shows qualities attained by few who aim at that class of effects. The high lights and deep shadows are there, and pretty much in the proportions seen in the best specimens of so-called "Rembrandt" work; but the lights are nowhere obtrusive, the shadows are full of most exquisite detail, and the two are so gradually and delicately blended as to produce a harmony that I do not think could be obtained except by the peculiar method of lighting which he employs.

The entrance to the studio is through the window of the north reception-room, and is reached by a flight of maroon-covered steps. It is about twenty-five feet square, seven feet from the floor to the "easing," and ridge roofed for about two-thirds from the wall against which it is built. The rest of the roof and south end is octagonal in form, or rather like the half of an octagonal building. It is glazed down to the floor with corrugated glass of a slightly-greenish tint, and utterly destitute of curtains, blinds, or shades of any kind; in fact, a casual observer would come to the conclusion that the designer of the studio had set before himself the problem of how closely he could imitate the conditions of open-air portraiture, and had succeeded admirably. In a studio of such a form of course the sitter may be placed in almost any part of it, and Mr. McKenzie says that perhaps the most beautiful effects are got in full sunlight, the angles of the corrugated glass so effectually breaking up the direct rays as to give them the character of simply a flood of diffused light.

At the time of my visit the sitter was placed equidistant between the north and south ends of the studio, and about six feet from the east side. The background, fitted with castors, was maroon, stretched on a frame about eight feet square and faced west by north, and, preconceived notions regarding the necessity for shade overhead and blinds notwithstanding, the effect was simply perfect.

A door out of this studio led into another of about the same size, with lop-sided ridge roof standing east and west, and glazed with plain glass. It was divided into two equal parts by a north and south partition so as to make two small studios to be used for children or rapid exposures, and, like the principal one, had neither blinds nor shades.

The system of lighting that I have tried to indicate may be more general than I think, but, if not, it is well worthy of a fair trial, as the negatives I saw in the printing-frames at Willow Bank were as perfect as anything could well be, and that without any aid from the art of the retoucher, beyond the mere stopping out of mechanica blemishes, The printing department is altogether separate from the other branches. The former proprietor of the place had been fond of hunting, and built an extensive kennel about fifty yards from the house. This has been fitted up with a series of washing troughs, sensitising, toning, and fixing apparatus, and a portion of the exercising court covered with glass, under which printing may be done on rainy days. Altogether the establishment is fitted up in a most substantial and convenient way, and is capable of affording accommodation for a very large business. At present the printing is confined to silver, but Mr. McKenzie intends shortly to adopt carbon printing also, and, as such enterprise as he has shown deserves a fair reward, I hope to see Willow Bank become one of the photographic institutions of Scotland.

John Nicol, Ph.D.

PHYSICS IN PHOTOGRAPHY.*

We must suppose that we have at hand a perfect emulsion, a film of which will give a bright image on development after exposure in the camera. Let half-a-dozen plates be prepared with such an emulsion by simply flowing it over glass plates and allowing the films to dry; and then let these be exposed in the camera for the time necessary to give a strong image on development. Let the plates be immersed respectively after exposure in a weak solution of nitric acid, of potassium permanganate, potassium bichromate, nitrous acid, hydroxyl, iodine or bromine vapour, or be exposed to the action of ozone, it will be found that the image impressed by light will steadily refuse to develope, however much it may be exposed; or, again, if another half-dozen plates be prepared and be exposed to light external to the camera, we know if exposed to the lenticular image after such treatment that we might obtain an image on development, but that it would be obliterated by the veil induced by the preliminary exposure. If between the preliminary exposure and exposure in the camera the plates be treated with any of the above solutions or vapours, and be then washed, we should find the impressions of light in the camera would yield images perfectly free from the veil. In other words the treatment of the film with any of these solutions will destroy the effect of the action of light. Now, as we have already shown, the image is formed of silver sub-bromide; hence we may say that the treatment has changed the sub-bromide to an undevelopable compound. When exposed to iodine or bromine the sub-salt will naturally become converted into the primitive salt; but when we look at the nature of the other destructives we cannot but be struck with the fact that they are either solvents of metallic silver or oxidising agents. In the first case we may presume that the loose atom of the silver of the sub-bromide (Ag_2Br) is dissolved away and converted into some other form of silver, leaving behind the half molecule of bromide, and in the other we may presume that the sub-bromide is oxidised to form an oxy-bromide of silver.

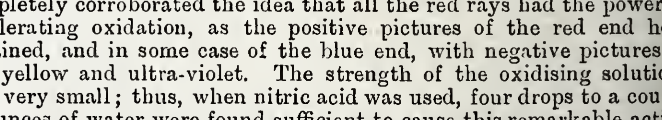
With this fact as a starting-point it appeared probable that the elimination of a veil due to an emulsion ought to be effected by the same agents as if the veil occurred through the action of light. It was well known that, in order to get an emulsion perfectly free from this enemy, chlorine, bromine, iodine, or some diad chloride or bromide were necessary to be added to the washed emulsion if the silver nitrate was in excess at first, and that nitric acid had the same effect if added to the emulsion with the silver nitrate. Here, then, seemed to be the roof of what was wanted; but another link was still required to make the reasoning complete. In making an emulsion, if the soluble bromide was in excess none of these agencies were required. The question then arose as to why this was the case. To clear this up a fair hypothesis was taken, viz., that no soluble bromide was absolutely free from contamination. If the bromide were of the alkalies, or some of the metals such as zinc, it was probably contaminated with the oxide, whilst with other diad metals it was probably of the lower form of bromide. Thus, cupric bromide was probably contaminated with cuprous, and cobaltic with the cobaltous, though in infinitesimally small quantities. Now the former impurity would cause the formation of silver oxide, and the latter of silver sub-bromide (argentous bromide). Experiment showed that the former would act as a nucleus on which the metallic silver, reduced by development, would be deposited, whilst the latter would have the same composition as the latent image, and thus induce the objectionable veil. The same reasoning applied to the chlorides, but the whole explanation was still incomplete. Experiment showed, however, that the order of formation of the different compounds of silver was as follows:—Argentic bromide formed first, next argentic chloride, then argentous bromide and chloride, and finally the oxide. If, then, there was but little of the impurity present in the soluble bromide used in forming the emulsion, pure silver bromide would alone be formed, leaving the impurity in solution, and in a state to be washed out. The whole subject of the fog-giving properties of emulsion was thus cleared up, and the correction necessary for it was apparent.

All practical photographers are aware that in the ordinary dry-plate processes there is a deterioration of the image if plates be kept a long time before exposure and development, and if sufficiently long time elapse that the image will almost refuse to develope at all. The question arises why this obliteration of a developable photographic image takes place. We have seen how an image can be destroyed artificially by the use of oxidising agents, and we might naturally infer that the same destructive agency might obliterate the image even when the oxidising agent is merely ordinary air, and after considerable experimental proof we are compelled to come to the conclusion that this is the case, more especially when it is found that any readily-oxidisible matter, such as gallic acid, if applied in solution and dried in contact with the sensitive film, preserves the image for a longer period than if this precaution be omitted. The oxidisable matter has to be oxidised before the image itself is attacked, for we may assume that the image itself is not as readily oxidisable as such bodies as that mentioned, and many others. The fact that the image can be oxidised and thus destroyed, seems to disprove the once-held opinion that the undeveloped image was formed of metallic silver—a body which will tarnish but not oxidise, the pure oxides being unstable.

As a sequence to the destruction of the photographic image by oxidation, the hitherto unexplained results which Draper obtained when photographing the spectrum were examined. Briefly it may be stated he found that if a spectrum was allowed to fall on a sensitised daguerreotype plate which had received a preliminary exposure to white light a remarkable phenomenon took place—a phenomenon which was also observable if weak white light were allowed to fall on the plate during its exposure to the solar spectrum. In developing such an image with mercury vapour, the blue, or most refrangible, end of the spectrum was impressed in the usual way—that is to say, the Fraunhofer lines showed as dark lines on a lighter background. At the red or least refrangible end of the spectrum, however, the Fraunhofer lines were seen as light on a darker background; in other words, the photographic action was reversed, the neutral point of no action lying somewhere in the yellow. On studying a picture taken by this means it was observed that in all cases the darkest Fraunhofer lines had the same tint, and that effect of light lines upon a dark background, or dark lines upon a light background, were caused by alteration in tint of the background itself. Could this effect have anything to do with the oxidation? If it had it would indicate that the rays in the least refrangible end of the spectrum must *accelerate oxidation*: for it must be remembered that the plates had received an exposure to white light either before or during exposure to the spectrum, and that the red rays prevented the development of the effect of the white light.

Now Draper had failed to get the same result on films of collodion containing the sensitive silver compounds, though he had obtained the reversal of the least refrangible end of the spectrum on such plates. If the theory of oxidation held good for daguerreotype plates it ought also to hold good for the collodion films, and experiment decided once again in favour of the theory. Collodion films, which held *in situ* the blue form of silver bromide already alluded to, and which had been proved to be sensitive to the red end of the spectrum in the ordinary sense of the word (*i.e.*, that a proper negative picture of it could be obtained as it could of the blue end), were the subjects of experiment. It is evident, if the red rays were accelerators of oxidation, that in order to get a positive picture of the red end (*i.e.*, one answering to the reversal of the Fraunhofer lines in Draper's daguerreotype plates) the films should be exposed to the spectrum whilst in some oxidising medium, weak enough by itself, not totally to obliterate during the time of exposure to the spectrum any preliminary exposure which should be given to them, and yet strong enough to do so, and to destroy the reducing action of the red rays, if these latter possessed a power of accelerating oxidation. Ozone, hydroxyl, nitric acid, and other oxidising agents completely corroborated the idea that all the red rays had the power of accelerating oxidation, as the positive pictures of the red end here obtained, and in some case of the blue end, with negative pictures of the yellow and ultra-violet. The strength of the oxidising solutions was very small; thus, when nitric acid was used, four drops to a couple of ounces of water were found sufficient to cause this remarkable action to take place, whilst if the nitric acid was reduced in quantity, or omitted altogether, the effect of the ordinary negative picture was obtained in that part of the spectrum (*figs.* 3 and 4). On the other hand, when the strength was increased, the image disappeared altogether.

FIG. 3.



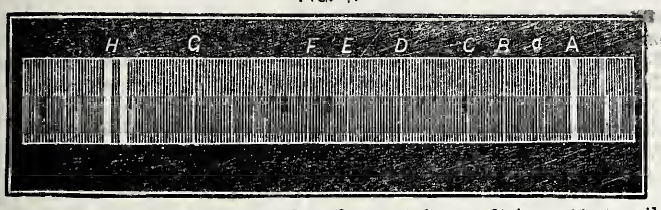
Figs. 3 and 4 show the results indicated above; the shaded portions show where the spectrum was photographed in the usual way, and the white portions indicate where the reversed action took place.

We are not sure but we believe that Draper used silver iodide as his sensitive salt in the experiments with collodion, in which he failed to obtain these phenomena. The iodide is insensitive to the red end of the spectrum under ordinary conditions of exposure, being usually exposed in the presence of a solution of silver nitrate which clings to it after taking it out of the bath. It was found, however, if this free

* Continued from page 140.

silver nitrate were washed away, and if the exposure to the spectrum took place in the oxidising medium, after a preliminary exposure to white light, that this reversing action, as it is called, of the red end of

FIG. 4.



the spectrum was obtained; and under certain conditions, if the silver nitrate were removed, that the same results could be obtained even when the plate was not exposed in this oxidising medium.

Now regarding the reversal in the blue indicated above, how can it be accounted for? By the very same theory, only an abandonment of the hypothesis that the least refrangible end of the spectrum *alone* is an accelerator of oxidation becomes necessary. In all comparative experiments made with the daguerreotype plate and the collodion film the difference of these conditions must be remembered. In the former the halogen liberated by the action of the light on the iodide combines immediately with the metallic plate, forming fresh sensitive compound; in the latter the thickness of the sensitive compound has a limit, and much of it is altogether inoperative, the outside of the particles alone being available for the reducing action of light, and the halogen has to escape or be absorbed as best it may. In a collodion film it is manifest that the reduction of all the sensitive compound available must take place after a time, and when this is the case, if the same rays which effect reduction likewise accelerate oxidation, that the latter effect of the rays will have unimpeded action. So much for the theory. Does experiment prove or disprove it? It is evident, if the hypothesis be correct, that a film which is exposed to the action of light in a medium free from oxygen, or in one which is an absorbent of oxygen, should be incapable, on development, of showing this reversal of the ordinary action of light.

The results again showed that the theory was borne out, for it was found impossible to obtain a reversal of the image when so exposed. Here, then, we have a probable explanation of the phenomenon known as solarisation, to which allusion has already been made; it seems to be an oxidation of the undeveloped image.

THE REACTIONS OF CHROMIC ACID AND CHROMATES UPON SUBSTANCES OF ORGANIC ORIGIN, CONSIDERED WITH REFERENCE TO THEIR USES IN PHOTOGRAPHY.*

It is generally sufficient to hang up the paper or glass coated with bichromated gelatine to dry spontaneously in a dark room or in a well-ventilated box, where they will be protected from the light. It is easily understood that the time required for drying depends principally upon the amount of water held by the air. When the pressure of moisture is slight and the atmosphere is far from being saturated the gelatine dries rapidly; when the opposite is the case it remains moist for a long time. In order to obtain positive data as to the influence of moisture in the atmosphere I made a long series of observations with an August's psychrometer. The psychrometer, as you are doubtless aware, consists of two thermometers divided into tenths, one of which has a wet bulb and the other a dry bulb[1]. From the difference of temperature registered by these two thermometers one can calculate the absolute degree of moisture contained in the air; that is to say, from the continuous evaporation of the water as well as the relative moisture, which shows the maximum percentage of water vapour contained in the atmosphere at that particular time and temperature[2].

The less moisture contained in the air the more rapid the evaporation; but if the air contain a great quantity of moisture it is often not advisable to dry bichromated gelatine in it (as may be ascertained by watching the psychrometer), as the drying would proceed too slowly. I found that the temperature of the air of the drying-room should not sink lower than from about 20° to 25° [the temperature given here applies more particularly to lichtdruck and galvanoplastic plates; carbon tissue dries more readily, and for it the temperature may with advantage be lowered to 15° C.], and that the difference between the readings of the wet and the dry bulbs should not be less than 5° or 6° C. The moisture contained in the air will then represent some 45 to 55 per cent., and the pressure will be equal to from 8·0 to 15·7 millemetres; while in winter, in consequence of the low temperature of the air, the moisture contents of the atmosphere are small, the dry air being warmed when the room is heated is relatively much drier, and accelerates evaporation much more rapidly than an equally warm summer atmosphere usually does. Thus it is that the drying of gelatine films in a room is undertaken under much more favourable circumstances in winter than in summer—a statement which at first sight seems scarcely believable, but which is nevertheless perfectly correct. The use and constant observation of a hygrometer in the drying-room would seem from the foregoing to be no useless "fad," even were the computation of the moisture contained in the air found to be at first a work of difficulty. In our drying-room an August's psychrometer has a permanent place and is in constant use. More convenient but much less exact are the *hair-hygrometers*, about which one may learn by consulting Kämtz[1] or Schübler[2]. In the drying-room one of these hair-hygrometers should never indicate more than 60° to 70°.

* Continued from page 426.

[1] Poggendorff's *Annalen*, vol. v., pp. 69 and 325; vol. xiv., p. 137.

[2] Suhl's tables are very convenient. They appeared in *Jelinek's Anleitung zur Anstellung Meteorologitcher Beobachtungen*. Vienna, 1869.

I have mentioned that under certain atmospheric conditions the required quick drying of the bichromated gelatine may proceed in free air. When in consequence of being loaded with moisture the atmospheric conditions are unfavourable, and when one cannot remedy matters, as in winter, by heating, one must have recourse to artificial means; the need for this occurs much more frequently in summer than in winter. The superfluous moisture must then be abstracted from the air by chemical means. For this purpose calcic chloride is especially worthy of recommendation, and has been used by Swan,[3] Scamoni,[4] Woodbury,[5] and Despaquis[6] for drying bichromated gelatine, the latter being placed in a tightly-closed vessel the bottom of which is strewn with *calcic chloride*. When in time, owing to the quantity of moisture it has absorbed, the salt has completely melted it may always be renovated by heating and evaporation, and in this it offers an advantage over the equally-effective drying medium, *sulphuric acid*,[7] which has also been recommended for use in photography.[8]

In this way the gelatine dries rapidly (the thicker films in about twenty-four hours) without losing its solubility in hot water. Swan[9] has, indeed, observed that bichromated gelatine dried over chloride of calcium sometimes becomes insoluble; but this must surely be of rare occurrence. I at least have never remarked it, except in so far as that the film does not remain long moist. The counsel to use *burnt lime*[10] for drying is not to be commended, owing to the slowness of its action.

Artificial methods of drying are almost exclusively used for thick bichromated gelatine films, mostly those upon glass, such as photo. relief druck, and, above all, photogalvanoplastic plates. Lichtdruck plates, on account of the granulation required, may, with advantage, be dried at a higher temperature. Carbon tissue, which is sensitised by floating upon a potassium bichromate solution, dries very quickly when hung up in free air, so that the formerly-recommended[11] drying over calcic chloride may be dispensed with in this case.

Instead of drawing the moisture from the air of the drying-room at an ordinary temperature, and by that means hastening the drying, it is open to one to increase greatly the temperature of a special oven. This is a very useful expedient and less costly than the calcium chloride. In many cases, however, it is not permissible to raise the temperature above the melting-point of the swollen gelatine (as, for example, carbon tissues, the gelatine of which would run); in other cases (lichtdruck, &c.) it can without injury be raised to the melting-point of the gelatine and kept there until the film be quite dry, though even here the temperature should not be too high, because the bichromated gelatine generally remains exposed to it for hours before becoming dry.

The temperature of the drying oven should never rise higher than 60° C. Here, again, I must repeat the warning that those bichromated gelatines which must absolutely retain the whole of their solubility in hot water during the process of developing the picture demand careful treatment and a lower temperature when drying—somewhere about 40° C.; while lichtdruck plates can even be dried at 70° C.[12]. To make matters sure one would be safe to get a temperature between 50° and 60°; the films would then require from three to ten hours to dry perfectly. At from 25° to 30° C. some sixteen to twenty hours are required; at 70° C. they are ready in from one to two hours. Of course these numbers vary with the thickness of the films on the glass plates. It is worthy of remark that the gelatine films when quickly dried can withstand great mechanical pressure, while slowly-dried

[12] The bichromated gelatine film of photogalvanoplastic plates is, as is well known, thicker than that of lichtdruck plates, and should, according to Leipold, be always dried at a higher temperature. Too great heat induces the formation of stripes across the plates.

plates are soft and friable.[1] Too quick drying causes bands to form across the plate, which show later when the pictures are printed.[2] The quickly-dried films have a matt surface, while the slowly-dried ones are glossy.

The opinions of photographers seem to be pretty unanimous on this point. Scamoni[3] dries his heliographic plates and Vidal[4] his lichtdruck plates at 30° to 31° C.; Abney[5] dries heliotype films at 24° C.; Pretsch[6] photogalvanographic plates at 36° C.; and Geymet[7] at 40° to 60° C. Courten[8] dries lichtdruck plates at 55° to 65° C. Husnik[9] gives more exact directions for lichtdruck plates, for he says—"At a temperature of from 35° to 38° C. lichtdruck plates do not get a sufficient grain. The best temperature is about 55° C.; 65° C. is too high, as the film then becomes insoluble."[10] Albert,[11] Markl,[12] and Voigt[13] all dry their lichtdruck films at about 50° C. The temperatures of 75° C. given by Reich,[14] and 100° C. given by Towler,[15] for drying lichtdruck plates is decidedly too high. The bichromated gelatine might easily be thereby rendered partly insoluble.

In the attempt to dry quickly one should not choose too high a temperature. Rapid drying at a low temperature are the conditions after which one ought to strive. While the one requirement so far limits the other, it must be remembered that it can only do so to a certain degree, which cannot be overstepped with impunity. J. M. EDER, M.D.

(To be continued.)

MILITARY BALLOONING.

THE matter of ballooning for military purposes appears to be once more attracting attention in this country. In France they have now a properly-organised service under the command of a colonel of the National Engineers, who considers all novelties and proposals as they arise, and who sees, moreover, that the state has always a body of skilled aëronauts at its disposal. At the end of the Paris siege the postal department, it may be remembered, possessed a large number of balloons, and these, being handed over to the French war minister, constituted the *matériel* necessary in the formation of a military balloon service. Colonel Laussedat—whose name as an energetic officer of the French Topographical Department is well known—was placed in command, and he at once secured the services of one of the Messrs. Goddard to put the whole of the apparatus in a fit condition for service. Since that day ballooning in France has been considered as much a duty of the engineers of the army as telegraphing and surveying, and classes both for officers and men are held for instruction. Lately, by the resignation of Colonel Laussedat, the French balloon service has lost its chief support; but his place has just been supplied by General Farr, who will, no doubt, take measures to maintain the high efficiency which has been attained by his predecessor.

In France, as in this country, the balloon is chiefly regarded by military men as an important means of reconnoitering. The Paris photographer and aëronaut, Nadar, was successful on several occasions in securing photographic records from balloons, but he never published his *modus operandi;* and the problem of balloon photography is one which still excites a good deal of attention. Mr. Walter Woodbury, the well-known inventor of Woodburytype—the only practical photo-engraving process we know—submitted, during the last war, to the Russian government a very ingenious method of securing pictures at an altitude. By his plan no one ascends with the balloon at all, and therefore the latter may be of very limited dimensions. It is captive, and twisted into the tethering rope are insulated wires in connection with the camera. The camera is weighted and hung upon a pivot so as to be always horizontal, and a fan attached to the balloon prevents the same from gyrating. It is easy to understand how a lens may be capped and uncapped from below with the aid of an electric current, and the photographs are secured—for a series may be taken at one ascent—upon a length of sensitive tissue which is unrolled for use through the medium of clockwork. The sensitive tissue and roller arrangement is that of Mr. Warnerke, which is known to all dry-plate workers, and which permits of securing pictures without glass. Mr. Woodbury's invention has, so far, been tested only in respect to its photographic properties; but in cases where an aëronaut would run too much risk, or where a large supply of gas is not available, the apparatus would be well worthy of trial.

It is the difficulty of securing a sufficiency of gas for inflation that at present stands in the way of employing balloons in the field. The French balloons are all large ones, for they were constructed most of them for postal service during the siege, and, besides the mails and aëronaut, sometimes carried three passengers. With the exception of half-a-dozen, all the balloons which left Paris had a uniform capacity of 2,000 cubic metres, while one, in which M. de Fonvielle and three other persons travelled from Paris to Louvain, measured 3,000 metres. Such bulky balloons as these are unsuited for the field, where the problem is to send a single observer aloft with the minimum amount of time and trouble. The smallest balloon and the lightest gas for the purpose are what the soldier seems to require, and it is towards these two points that attention has lately been directed by Captain Templar and the other officers who are just now occupied in the study of aërial navigation in this country. Naturally enough, hydrogen holds out the most promising features as a lifting medium, and it is with this gas that experiments are once more to be made. As our readers remember, the weight of hydrogen is calculated to be 2·14 grains per 100 cubic inches, while air, on the other hand, weighs thirty-one grains; and, as the lifting power is represented by the difference between these numbers, it stands to reason that theoretically a balloon, if filled with hydrogen, need be of but comparatively very small dimensions. Unfortunately, in a practical affair like ballooning, a lot of accidental matters require to be taken into consideration, and two of these are the facts that it is difficult to secure pure hydrogen, and more difficult still to keep it in the balloon envelope when secured. Captain Templar is sanguine that a 10,000 cubic feet balloon is quite capable of lifting an observer high enough for reconnoitering purposes, if filled with hydrogen, and wellnigh proved his case the other day when he overcame gravity, if he did not rise, with the aid of a light coal gas with which this small balloon was filled. The coal gas, specially manufactured for his balloon, had a lifting power of fifty pounds per thousand feet, so that a total of 500 pounds was here at his disposal. As we have said, this was insufficient for an ascent, for besides the weight of the aëronaut there are, it must be remembered, envelope, car, tackle, cable, and ballast to be taken into consideration. Instead of 500 pounds, hydrogen of the same volume would have supplied a lifting power of 700 pounds, and this, of course, would have been ample and to spare for an ascent.

To make this hydrogen recourse will be had, as in previous experiments undertaken by our military authorities, to the decomposition of water in the form of steam. The latter is to be passed through tubes filled with iron filings or turnings, and these, in becoming oxidised, set free the hydrogen. Unfortunately the hydrogen obtained in this way is impregnated with moisture, and unless submitted to the action of some desiccating agent like quicklime, for instance, is of little good for ballooning. The hydrogen it is proposed to obtain in the field, at anyrate, in this fashion, and it remains to be proved whether Captain Templar and his colleagues can secure it sufficiently pure and in proper quantity under these practical conditions. Although hydrogen is given off fast enough at the onset, previous experimenters have found the supply to fall off rapidly, for as soon as the surface of the particles becomes oxidised the decomposition of the steam ceases.

But perhaps the most interesting feature of the present ballooning experiment will be the trial of compressed gas. As our readers know very well, compressed gases are now a commercial article in this country, and you may purchase cylinders of oxygen or hydrogen at twenty atmospheres pressure. As our Royal Engineers carry about with them in the field such unwieldy things as pontoons they can hardly grumble at a wagon load of hydrogen tubes, and with these it is suggested to fill a balloon just wherever a reconnaissance is to be made. On nearing the enemy the first convenient spot will be chosen for the manufacture of the hydrogen, and this will then be compressed, with the assistance of suitable apparatus, into the tubes, to be drawn off again when the ascent is to be made. In this way there is always to be gas at hand, not only to fill the balloon but to keep up a constant supply for a limited period, since hydrogen, under the most favourable circumstances, rapidly exudes from a balloon envelope.

A military balloon, it appears to be decided, must be a captive one, and opportunity would of course be taken to place the observer in electrical communication with the earth through the medium of insulated wires twisted round the rope in the same way as in Mr. Woodbury's photo.-aërial apparatus above described. H. BADEN PRITCHARD.
—*Nature.*

HOW TO SIT FOR YOUR PORTRAIT.

THIS is the title of a thoroughly-practical sheet of instructions to intending sitters with which we are favoured by Mr. F. W. Bannister, of Manchester, who has prepared the same for the benefit of his own clients. Mr. Bannister has very kindly allowed us to reproduce it for the use of our professional readers, to some of whom it may at least afford a hint:—

At the Show Room.—It is impossible that the artist can attend here. All business matters must be settled with the bookkeeper only. Give

[15] Dingler's *Polytechnic Journal*, vol. ccvi., p. 203.

all orders carefully, clearly, and decisively, so that alterations may not be required in the studio; and, if doubtful on this point, see the book-keeper again, who will give all information as to when ready, how sent by post or otherwise. Be particular in giving accurate name and address, as we are not responsible for loss by post. Here select the size, style, or kind of portrait required, or if you prefer any particular view of your face, or to match any other portrait, so that you may be ready for the

Dressing Room.—Arrange your toilet and dress carefully, and if your face be much freckled or rough apply a little violet powder, and slightly pencil your eyebrows if very light. Be not prejudiced against any position that you may have had badly taken elsewhere, it might be the only good pose of your face when properly lighted and artistically taken. Promises of unbounded patronage if well taken will make no difference in the production; the artist takes *all* and *every portrait* to the very best of his ability, which is to his own as well as to your interest. Have no feeling of mistrust on this point, because it is very likely to give a bad expression. Good-mannered people need not be told to treat the artist with becoming respect and confidence, and with attention to his instructions, nor find fault with his necessary apparatus; by so doing, sitting for your likeness will be a pleasure instead of a trying and disagreeable ordeal. Throw cares, troubles, anxieties, and business aside, and be on the best terms with yourself.

The Studio.—No one except the sitter can be admitted. It takes many years of anxious study to do what accompanists suppose they can do in a minute, but a very little interference may make it impossible to do afterwards, viz., pose the figure. Here the artist cannot attend to any other business except likeness-taking. Here he will give you every instruction to carry out your wishes in producing the kind of portrait you have previously fixed upon, as far as the art of portraiture and science of photography and its appliances will permit of. He may have to alter considerably from the exact position, to secure the best form and most artistic portrait, and will advise you for the best. It is too late to make changes or alterations after the pose has been fixed upon. Be ready for the prepared plate, as it will not keep very long. Be not annoyed if spoken to sharply, as it might and does occur occasionally by mistake. Sitters move the eyes from one point to another, and if not spoken to promptly a very few seconds might spoil the whole preparations as often as repeated. Winking has no bad effect, but looking from one point to another has.

The pose has to be got little by little, thus:—Place your hand so and *keep it there,* while the other is *placed so,* and do not *alter* any other part while I correct your cuffs, or any other portion of dress; nor try to assist in doing so, because your movements in so doing may throw other parts wrong. The artist will attend to all without you asking is this hand or the other right, which would give you a careworn expression. Have full confidence in his abilities, or do not be pourtrayed by him.

Children under Seven Years should be accompanied by their best loved friend if possible, who should be ready to assist at the least hint, but do no more than is requested. Never threaten them if they do not sit still, nor tell them not to cry, because if you do they are sure to do it; do not give or promise them cakes or sweets. The conversation should not be about *taking them;* it should be about ponies, pussies, doggies, birds, or any varieties of toys most suited to their tastes. In groups the parents are generally so anxious about their little ones that they themselves are the most difficult to take. Do not talk to or attempt to assist others in the group while being posed, let each one attend to his own instructions only. A giddy or inattentive person in a group is a nuisance to all concerned.

Examples of Colours as Produced by Photography.—Pure white is too light, bluish white is better, yellowish or brownish white is best. Honiton or Maltese lace, of an open pattern, over black or grey, is a beautiful quiet white. Tints in juxtaposition—thus black and grey joining give greater apparent depth to the one and lightness to the other; light blue is nearly white; dark blue, mauve, &c., about half lighter than they appear to be; light pink up to dark red about the same scale as light bluish grey up to bluish black; brown as reddish grey up to reddish or the deepest black obtainable.

The face, to a true rendering of nature, requires the correcting pencil of the most skilful artist in modulation, on account of confliction of juxta contrasts of reds, blues, browns, yellows, pimples, freckles, vulgarities, &c., &c., causing disagreeable and uneven spottiness not always observable in nature. A tasteful display of almost any variety of dress, well broken up with lace, ribbons, jewellery, &c., avoiding violent contrasts, is always pleasing in photographic portraiture.

Conditions.—The rules, prices, and management of this establishment are not guided by that of any other. Neither is any work done on approval but to order and to the best of the artist's ability, who has had daily experience with every class of society for over a quarter of a century, and has given unbounded satisfaction wherever art portraiture is known, the very small minority of grumblers being those who do not know it, or that they are incapable of being any better posed, according to the style which they have selected and insisted upon. Sending by post, &c., at your own risk. Fees, postage, &c.—One dozen *cartes*, &c., or under, per book post, each parcel, 3d.; under cover, 6d. Send stamped directed envelope for all replies. Not accountable for any works or photographs left after three months.

ON THINGS IN GENERAL.

A very ingenious gentleman, whose effrontery was equal to his command of language, used—and for aught I know to the contrary may still—to go about the country under the name of "Parallax" to deliver a series of lectures to prove that the earth is not a globe, as infatuated philosophers contend, but is as flat as a pancake.

Among his proofs was the following:—A vessel gradually disappearing in the offing is supposed to get lost to sight by reason of the rotundity of the earth hiding it from view, but, said "Parallax," if you get a telescope it will all come into view again, and when lost to sight in that telescope a more powerful one would bring it back again, and so on. Surely Mr. Gresham, of New York—who by means of his "phantasmograph" expects to be able to see an artificial cloud about a mile high and a thousand miles away—should take lessons from the philosopher I have named, so as to induce the seafaring public to believe that his notion is of any value. There has been a deal of wonderful arguments to prove or disprove the possibility of carrying out Mr. Gresham's idea, but I am afraid the difficulty I have raised is the toughest of the heap. But inventors are a sanguine race; their ardour is unquenchable. Rarely, though, is there so sad a result as has recently been recorded in the fatal accident that befel a chemist who had invented a new mode of rendering cyanide of potassium harmless. He paid the forfeit of his life through over confidence in his discovery.

There is no fear that his example will be followed with regard to his own method, at anyrate. I find, I must confess, great difficulty in believing that it was an accident at all, for surely he must have been aware that, long years ago, prussic acid had been swallowed in public, immediately followed by a suitable antidote, with no evil effect whatever occurring. I speak of the ordinary prussic acid of the shops, such as the *Daily News* states is used for killing dogs, &c., but which, instead of being of the strength of a drop to a quarter of a pint according to that authority, is more like a drop to a quarter of a teaspoonful of water.

Really, the inventive faculty is about the only thing there is no dearth of at present, even in newspaper paragraphs. I find again that photographers are once more recommended to be taxed through their *cartes de visite,* because, forsooth, the sale of such portraits panders to snobbery and caddishness—this, too, in a paper belonging to a class whose only *raison d'être* is the retailing of nasty matter to those whose walk in life does not bring them within reach of a personal knowledge of such doings and the doers.

The newest inventor would seem to be one against whom we really have cause of complaint for his tardy appearance. Just as in mathematical science the circle-square turns up periodically, so in our case we look for the genius who is to produce stereoscopic effect by means of a single picture, and we might as vainly hope to convince the circular philosopher as the stereoscopic of the error of his views. What a wonderful thing is the indestructibility of error! One would have thought that enough had been written to prevent any resuscitation of this absurd proposition!

I was much interested in reading the Dublin notes that were recently given in these pages; but I certainly was not prepared to find a very old style of exhibiting photographs very popular with a large Liverpool firm described as a novelty. I can also endorse the writer's views on the Cadett's pneumatic shutter, but I think Dublin is by far from being the only place where the foot is used for compressing the india-rubber ball. "Necessity is the mother of invention," and no one who once had to squeeze the ball tight for a long exposure of (say) a minute would risk bringing on cramp by so laborious a muscular exertion, and the pedal pressure would be the most natural way out of the difficulty.

There has been quite a long roll of inventors posing before the photographic world the last few weeks. I cannot close my month's record without alluding to the brilliant method of Herr Brandt, of Bayreuth. I give his name, &c., in full, that inquiries may be made regarding possible patents. He recommends that a couple of drops of glycerine be rubbed on the back lens of the portrait combination in order to produce more artistic effect. Doubtless he is a man of artistic feeling and æsthetic longings, who has seen with disgust the hard, sharp pictures so much in vogue among so many photographers, and he has invented a method to obviate any such crudeness in the future of our art, and, thanks to him, there are to be no more hard outlines, sharply-defined features, and the materialistic realisation of textures and surroundings. A disciple of the higher art he will introduce a vague and more mysterious indication of external objects, and give to his own and his disciples a greater and purer spiritual appreciation.

THE PERILS OF SCIENTIFIC EXPERIMENT.

[Observer.]

A most unfortunate accident which has occurred at Prague recals in many of its details and circumstances the quaint traditions that were once prevalent with regard to the mediæval alchemists. Professor Fischer, of the Prague gymnasium, a young man, only twenty-five years of age, and of the highest eminence in his profession—that of chemistry—has come to an untimely end, under the most melancholy circumstances. No one needs to be told that cyanide of potassium—a drug largely used in photography—is a poison of the most deadly character. Its active ingredient is prussic acid. Prussic acid in its pure, or—as chemists would term it—"anhydrous," form is a substance too dangerous to be kept, or even manufactured. If a glass capsule containing a wineglassful of pure prussic acid were broken in the pit of a theatre those amongst the audience who were nearest the doors might perhaps escape, but the great majority would be killed upon the spot. The prussic acid ordinarily sold, and occasionally used for killing dogs and cats, contains about a drop of the pure acid to a quarter of a pint of water. Pure prussic acid no chemist dare keep. He might as well compress a ton of dynamite into a single cartridge—supposing such package to be possible—and then leave the deadly parcel lying loose upon his table. Cyanide of potassium is not, like prussic acid, volatile. It is a white powder, rather resembling flour or chalk. It is, however, so poisonous that a mere pinch of it sprinkled over an open wound or sore will cause almost instantaneous death; that a fragment almost imperceptible to the eye will, if swallowed, prove equally fatal; and that its mere smell has before now produced immediate death. It was, it seems, the ambition of Professor Fischer to discover some means of rendering cyanide of potassium harmless. We can do this with gunpowder—although the analogy is not strictly exact, the means employed with gunpowder being mechanical, while those for which Professor Fischer sought were chemical. We know what happens if a light is applied to a keg of gunpowder. If, however, we mix the powder with four or five times its bulk of sawdust a torch may be held to it with impunity. The mechanical resistance of the sawdust makes it impossible for the explosion to at once spread to the whole mass, and the consequence is that a sort of splutter ensues, like that of a squib or blue light. Professor Fischer's idea was that if cyanide of potassium were thoroughly mixed with sal ammoniac it would be as harmless as gunpowder mixed with sawdust, but would still remain equally available for all those purposes of photography for which it is at present absolutely indispensable.

In the course of his researches Professor Fischer made a mixture of which in his own mind he felt assured would meet the conditions of his problem. He compounded the cyanide with some other substance, and then—turning to his laboratory assistant—said, "Science has now so far advanced as to be even able to render harmless so dangerous an agent as cyanide of potassium." With these words he tasted the mixture, and was almost in an instant seized with the most violent and excruciating agonies. He at once implored his assistant to send for medical aid. Cyanogen, however—whether as prussic acid or as cyanide of potassium—kills almost instantaneously. In a few seconds Professor Fischer was beyond help. We are told that there is no possible reason to suppose that a deliberate suicide had been planned and carried out under the mask of an experiment. On the contrary, there is every reason to believe that the professor has met the fate which befel only too many of the early chemists and their predecessors, the alchemists. We know, now, what will happen to any experimentalist if he dips blotting-paper in nitric acid, washes it, dries it, and then incautiously treads upon it. What happened to the man who is believed—for his records perished with him—to have first discovered fulminate of silver is matter of scientific record. That he was engaged in researches upon the fulminates, and, more especially, upon the fulminates of the higher metals, was well known. How it precisely came about that he disappeared as he did will always remain matter of conjecture. There came one day a puff, a slight shock, and a smart noise as if some one had inflated a paper bag and then burst it between his hands. Of the professor himself, of his laboratory, of his apparatus, and of much else within the radius of some yards, not a vestige or trace was left. So it used to be with the alchemists—the heritors of the hidden wisdom of Böhme, Roger Bacon, and Albertus Magnus. They were always blowing themselves up, or asphyxiating themselves with some noxious vapour. For a man who knows nothing, or next to nothing, of chemistry it is a very dangerous game indeed to mix together a couple of substances of which he knows nothing, and then bray them in a mortar. Common sulphur is harmless stuff enough, so is charcoal, so is nitre; but let an ignorant man mix the three and apply a light to them and the result will much astonish him. When, of old, an alchemist was reduced to fragments in this fashion our ancestors had an easy explanation. He was a magician—they used to say—and the devil had come suddenly and carried him off. There was a time, between the days of Roger Bacon and those of Davy, Black, and Cavendish, when the foul fiend was thus always carrying off alchemists. We know now how it happened. If a man goes into a chemical laboratory and takes up a big beaker, and pours into it the contents of the first two bottles that are ready to his hand, the probabilities that he will be reduced to atoms on the spot are sufficiently serious to call for his careful consideration.

Apart from the sad fact that a young man with a bright and indeed brilliant future before him should be thus suddenly cut off, the death of Professor Fischer has another moral. Chemistry—whatever Mr. Lowe may have to say in praise of civil engineering—is the science of the world and of the future. The bridge which it takes the engineer years upon years to construct the chemist can in as many sixtieths of a second reduce to atoms. Chemistry has given us the balloon; it has put into our hands gunpowder, nitro-glycerine, dynamite, and, above all, fulminate of gold—an explosive so terrible that if an ounce of it be left in a stoppered bottle, its grains, falling amongst themselves by their own weight, will create a convulsion sufficient to lay all London in ruins. It has given us poisons so subtle that, were we to resolve to employ such means of warfare, we could sail in a balloon over the camp of the enemy and drop upon it a shell, the bursting of which would kill every human being a mile within its range. Then, too, chemistry has given us disinfectants. To the chemist we owe carbolic acid, chloride of lime, and permanganate of potash. Chemists have taught us to disinfect our sewers and drains, to ventilate our houses, to burn gas instead of oil, and to light our streets with what is more powerful than even gas itself—the electric light. It is to chemistry, indeed, that we owe almost all the comforts of everyday life. But, on the other hand, the possibilities of chemistry are almost too terrible to be contemplated. As the science at present stands any student can, if he have access to a well-stored laboratory, carry away with him in a pill-box matter sufficient to lay London in ruins, or to poison the whole community of its inhabitants. The chemist can—as every schoolboy knows—convert water into ice in the centre of a red-hot crucible. He can construct a shell the size of a cricket ball which will explode the moment it touches the water, and overwhelm in flames a hostile fleet. Indeed, the chemist reduces the world to its original and primal elements. For him, even more than for the engineer, nothing is impossible. And yet his power—vast as it is—is limited. He can more easily destroy than construct. He can take life, but he cannot give it. He can level a city with the plain, but he cannot build it again. He can create prussic acid, but he is ignorant of its antidote. He is like the fisherman who rashly opened the vessel sealed with the ring of Suleiman Ben' Daoud. The forces at his control are beyond his command; the powers he can evoke he cannot lay. It is the old story of Cornelius Agrippa—those who trifle with Nature's secrets do so at their peril.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
October 2	Edinburgh	Hall, 5, St. Andrew-square.
,, 2	Bristol Amateur (Ann. Meeting)	Museum, Queen's-road.
,, 2	Photographers' Benevolent	160a, Aldersgate-street.
,, 3	South London	John-street, Adelphi.

OUTDOOR MEETING OF THE MANCHESTER PHOTOGRAPHIC SOCIETY AND THE LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

On Saturday last, the 21st instant, the above-named societies met together at Hawarden, the residence of the Right Hon. W. E. Gladstone, who had kindly given permission to photograph the old and new castles and other views in the beautifully-situated park. On arriving at Hawarden they were welcomed by Mr. Gladstone, who informed them of the most likely points of interest where views and "bits" might be taken.

A more charming day for photography could not have been chosen, and, though the afternoon was a little cloudy and the light rather poor, the morning was all that a landscape photographer could desire, giving an opportunity seldom to be had of securing views with beautiful trees and foliage perfectly motionless.

The old castle, being a morning view, and surrounded with ivy and light-foliaged trees, was one of the principal subjects for the camera.

Hawarden at the conquest was held by Barons of Monthault (now Mold), under Hugh Lupus, Earl of Chester. It then fell to the Stanleys, but after the execution of James, Earl of Derby, in 1651, it was forfeited and sold to Serjeant Glynne, Lord Chief Justice, and one of Cromwell's Privy Council. The present castle was built by Sir John Glynne, in 1752.

Several excellent views were obtained of the new castle, and here a group was taken by Mr. L. W. Weber and Mr. J. H. T. Ellerbeck, with the castle for a background.

Soon after four the party mustered at the Glynne Arms Hotel, where about thirty sat down and did ample justice to a substantial tea. The President of the Manchester Photographic Society, Mr. Alfred Brothers, F.R.A.S., in the chair. After tea another group was taken by Mr. Potter and Mr. Ellerbeck, and then a start was made to the railway station for home. The group taken by Mr. Potter on a collodio-bromide plate, and the one by Mr. Weber on a Kennett emulsion plate, proved exceedingly successful.

On counting up the results of the day twenty-two cameras had been used and one hundred and ten negatives taken, almost every dry process of the present day being represented, besides which several members had been engaged in sketching and painting.

It was agreed on all sides that a most pleasant day had been spent and that another reunion of the two societies should be arranged.

In order to avoid any complaints of too short notice, the Secretaries of the respective societies desire to announce that it is intended to have a joint excursion to Miller's Dale in June next.

Correspondence.

PROTECTION FOR THE HANDS.

To the Editors.

Gentlemen,—I observe that in the last Journal you recommend gloves. May I add to your suggestion that of putting on to the left hand a gauntlet of the same material, which I have used for many years with good effect, as protecting the dress when developing large plates. I procured mine and that for my pupils at Messrs. Cow, Hill and Co., 46, Cheapside, E.C.—I am, yours, &c.,

Duffield, near Derby, W. Harding Warner.
September 23, 1878.

RE SWAN'S PLATES.

To the Editors.

Gentlemen,—Will you allow me to correct a mistake which has arisen somehow between the Secretary of our Manchester Photographic Society and yourselves? At the last meeting of that Society your report says:—"Mr. W. J. Chadwick showed some results on Swan's plates. One of the negatives represeuted Mr. Chadwick holding a wax vesta, by the light of which it was taken." It should have said—*a transparency* printed from a negative (portrait of himself) by the light of a wax vesta.—I am, yours, &c., W. J. Chadwick.

Manchester, September 24, 1878.

STEREOSCOPIC TRANSPARENCIES.

To the Editors.

Gentlemen,—It appears by your article of the 13th instant, referring to my criticisms on Mr. Brooks's paper, I must have expressed myself badly. You say—"We do not catch Mr. Oakes's meaning with regard to extreme sharpness or the reverse, especially when we look back at his preceding sentence, in which he speaks of the desirability of sharpness." What I intended to convey to your mind is this:—That for my own part I look upon extreme sharpness in a stereoscopic transparency as desirable, but in case Mr. Brooks or any one else choose to make a virtue of the fact that any degree of what you are pleased to term "woolliness" may be obtained in contact printing, I claim the supposed advantage in camera printing as well.

Where gradation is required from a dark to a light tint, or *vice versâ*, as is the case in printing from mask negatives for combination transparencies, there is a decided advantage in producing a certain degree of woolliness or softening of the edge, so that the combined pictures may blend into one another at the edge where the combination takes place.

As this may not be clear to many of your readers I must ask you to let me explain that in combination printing there are a number of mask negatives required. These negatives are for various purposes, but the main idea of using them is, as their name implies, to shut out one portion of the negative while the other portion is being printed. Supposing, for instance, you had a beautiful cloud negative that you wished to combine with a landscape negative, in which the sky and clouds have been sacrificed for the purpose of giving a suitable exposure to the landscape. You would first print the landscape in the camera, masking out the sky; then on another glass you would print the clouds and sky, masking out the portion to be occupied in the finished transparency by the landscape, so that when the pictures are plaeed face to face and mounted no one could tell on looking at the picture by transmitted light that any "dodging" had been resorted to. In a transparency of this kind the landscape portion is printed on the back of the front glass, and the sky aud clouds on the front of the back glass, so that when the two glasses are brought together *in situ* the two pictures occupy as nearly as possible the same plane. This is managed in the printing, and will be explained in my forthcoming paper.

I grant there is a decided objection to camera printing on the score of the length of exposure required in a poor light, and this is the only real objection that can be brought forward against printing in the camera. However, amateurs and others who are content with the ordinary results of contact printing are at liberty to continue that method, but I am writing, as you remark in your article, for those who wish to go in for high-class stereoscopic work, and to produce an endless variety of effects equal and, if possible, better than those done by the late Mr. Breese.

I should like to suggest, by the way, that as speed in production is a *sine quâ non* with professional photographers, or, rather, with manufacturers and publishers of stereoscopic work, there is no reason why a combined negative should not be made and printed either in the camera or by contact for the market, instead of printing each transparency in the camera, which necessitates two or sometimes three printings for each slide.

With reference to what I said as to "anything in the shape of apparatus at all coupled with the smallest modicum of ingenuity" would suffice to produce high-class work, I can only say that I wish the remark to be repeated with, if possible, more emphasis than before; for I suppose I am justified in concluding that any one who is going in for stereoscopic work possesses at least a small stereo. camera and a pair of single or double-combination lenses. Well, such a person may (with the addition to his camera of some arrangement to bring the lenses together or separate them at will), as I said before, with the smallest modicum of ingenuity make all the rest of the apparatus required for a few shillings—say half-a-guinea, at the most—and I may add that my own apparatus made after the model of Mr. Breese's, and with improvements not included in his (because I had all the advantage of his experience to guide me in constructing it), did not cost me as much.—I am, yours, &c., S. H. Ashley Oakes.

16, *Silverwell-street, Bolton, September* 20, 1878.

Miscellanea.

South London Photographic Society.—The first meeting of this Society for the session will take place on Thursday next, October 3, in the Rooms of the Society of Arts, Adelphi, when Mr. E. Dunmore will read a paper on *Varieties*, and Mr. F. York will narrate some of his experiences in Paris.

Trade Catalogue.—We have received from Messrs. George Matland and Co., 180, Commercial-road, their catalogue of photographic apparatus, chemicals, aud materials, which is replete with everything that photographers can require. It includes lenses, cameras, head-rests, and all the materials for producing negatives and prints, the department of *mounts* being unusually well represented. We here also acknowledge the receipt of samples of *carte* and cabinet mounts, which appear to be of excellent quality.

The "Crossed Swords" Albumenised Paper.—Messrs. Neustadt aud Co., 25, Mincing-lane, have sent us a sample of this well-known paper, the trade mark of which is doubtless familiar to all. Having given it a careful trial we have to speak in very high terms of its excellence, the surface being faultless and the tones and brilliance of the resulting prints unexceptionable. We do not know what toning bath has by others been found to give the finest prints when used in connection with the "crossed swords" paper, but in our experiments we made use of the following:—

Chloride of gold	1 grain.
Acetate of soda	30 grains.
Water	8 ounces.

The above formula, it will be observed, is one of those given in our Almanac as being always good and reliable.

The Recent Thames Disaster.—The staff of photographers at the War Department has been busily engaged in obtaining photographs of the wreck of the *Princess Alice*, as it lies on the foreshore at Plumstead, and partly within the Arsenal boundary. When beached, the two portions of the vessel were placed with their open ends next the river, in order that the water which entered with the rising tide should drain off at the ebb; but this has rendered the examination of the fractued parts a matter of difficulty, and the task of photographing those parts more difficult still. The work, however, has been surmounted by means of rafts, and, by taking advantage of dead low water, some very good negatives have been obtained, from which prints will be taken for the Coroner's jury and the Board of Trade inquiry. It is said that the last time the *Princess Alice* was photographed was the occasion when she was painted, gilded, and decorated for the conveyance of the Shah of Persia through the Pool and the docks, crowded with shipping, to Greenwich Hospital and back to Westminster, in memory of which service she has been known on the river ever since as "the Shah's yacht."

Photographic Recollections.—She said she "never could get a good picture, though she had tried a great many times—such horrid, ugly looking things, her friends would never put them in their albums." *She* didn't care, of course, for *herself*, if she could only satisfy others. "Some people never do *take well*, and I think I am one of them. I don't know what it is—suppose they look like me; but somehow or other they are not what I want to give my friends. My husband says I am expecting too much, and that I ought not to blame the artist. He says the first proofs look just like me, but I don't consider him a good judge. Now I have brought one that I had taken a long while since; let me see, ten or twelve years since. I don't know but it may be nearer fifteen; any way it was before Charley was born, and he is thirteen in March. Of course the dress is out of style; but just see, Mr. Artist, the *difference* in the way the face is taken." We smiled as we saw the difference and patiently went to work to repair the ravages which time, decay, and the dentist had made in the once rotund and rosy features of our sensitive customer. 'Twas *retouching* did the business, and relatives and friends marvelled at its *restorative* power.

"It smoothed away the lines of care,
And wrote new youth and beauty there."

——Sometimes people are unreasonable. We had done our level best to photograph an ambrotype, all that was left to the memory of a sainted mother. It was to be four-four, ink finish, and framed as per contract. Our work was done in time for the day of delivery, and the only surviving daughter, under whose order we executed the deed, came to procure and pay for the same. We noticed it did not seem to please her, and awaited the result. She said "it was not natural—didn't look as she did; never should know it was mother." We inquired mildly if it was not a true copy of the ambrotype from which it was taken. She said, "that may be, but *nobody ever thought that resembled mother at all;* and that was why I had it copied, so as to have something that would sort of look like her when she was living."—— He was a *freshman*—had never yet been "taken." His girl was with him, but not for a group. She "slicked" his hair and with loving fingers adjusted his "tie;" then retired to the reception room till the operation was over. We "posed" him, bid him be happy, keep perfectly still, *look directly here* (pointing to the camera), and removing the cap, we stepped quietly aside to wait the half minute exposure. Our sitter had left his chair and obedient to orders was gazing intently *into* the camera, his eye winkers fairly brushing a Dallmeyer that was aimed at him. When we intimated that we thought he had *moved*, he wanted to know if it would hurt the picture—*Anthony's Bulletin.*

Photography in Court.—At the Westminster County Court, on Tuesday, the 24th instant, the case of Richmond *v.* Artis was heard before the presiding judge, in which the plaintiff, a lady residing in Sutherland-street, Pimlico, sought to recover the sum of £2 which she had paid to the defendant, a photographer carrying on business at Brixton, for the purpose of photographing the tomb of her sister, who had been burried at Kensal Green Cemetry a year ago. The plaintiff, for whom Mr. Lewis appeared as solicitor, stated that she called upon the defendant and requested him to photograph the tomb in question, and that the portrait was to be of a size similar to that produced in court, instead of which he had executed one of a smaller size, and which, instead of being an accurate representation of the grave, was indistinct and out of perspective, and, besides, it contained the impression of other graves. In reply to his honour the plaintiff said there was no contract in writing, and that she paid the money because the plaintiff had guaranteed that the work should be done in a superior manner, and, further, that the defendant said that in the case of strangers it was customary to pay when the order was given. This being the plaintiff's case, the defendant said the plaintiff called on him and required the work in question done, and he told her that as he had to go a considerable distance his charge would be five guineas, to which she consented, and paid £2 merely as a deposit. He had never been able to get the balance, but when he threatened to proceed against her she, after having retained the proofs nearly five months without paying the balance due, now actually had the impudence to sue for the deposit paid on account. The learned judge at this stage of the case considered this an action which should never have been brought, and gave judgment in favour of the defendant with costs, who intimated in court that he would now sue the plaintiff for the balance remaining due. His honour considered the defendant justified in doing so, and the case terminated.

ANSWERS TO CORRESPONDENTS.

Photographs Registered—

W. G. Helsby, Denbigh.—*Portrait of Mrs. E. Jon*

J. Owen, Newtown, North Wales.—*Six Views at Berriew, Montgomeryshire.*

☞ *Correspondents should never write on both sides of the paper.*

Notice.—Each correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a *nom de plume* as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

A. Brothers.—Received. Will be immediately attended to.

Aspirant.—A kit-cat portrait measures three feet six inches by two feet four inches.

G. S. Innes.—By employing a more diffused light the texture of the paper will not be so strongly reproduced.

P. R. P.—You are quite right in the surmise; but the subject is one which is necessarily unsuited for discussing in these pages. Another reason has been given, but we think it untenable.

J. Beringer.—We do not know whether Mr. Harrison, of Falmouth, gives instructions in carbon printing; if not, we advise you to come to London and obtain lessons from the Autotype Company.

F.B.S.—1. We are unable to state the price of the book.—2. By reducing the proportion of the borax the toning bath will act more energetically; but we much prefer the acetate or carbonate toning baths.

Thos. Harrison.—Both *a* and *b* are excellent specimens of window portraiture; but they would have been improved by a darker background. The face of *c* is rather flat, but the detail leaves nothing to be desired.

F. Harrington.—To produce magic-lantern slides use dry plates and superposition. If you have a copying camera the wet process may be employed.—2. The slide carrier may be obtained at the establishment of the Sciopticon Company, Great Portland-street.—3. Two hours, if it be treated carefully.

Greentype Photographer.—There *are* processes for producing blocks for illustrating periodicals without requiring the services of a skilled engraver. These can be printed along with ordinary type. Some of these processes are patented, others have long been open to the public. For further particulars see our Almanac for 1876.

A. R. J.—Place the lens in lukewarm water, the temperature of which must afterwards be raised until the balsam by which the lenses are cemented becomes softened. Now separate the lenses by sliding one of them over the other. Clean the surfaces with a little turpentine, benzole, or collodion, and then re-cement them by means of fresh Canada balsam.

J. H. Lloyd.—Unless we saw a negative we could scarcely indicate the cause of the greenish colour. Presuming that you use the wet collodion process and develope with iron, fixing with cyanide of potassium, it is possible that a trace of iron may have been left in the film, which would be acted on by the cyanide, producing a blue colour. If we are wrong in this assumption you must supply further particulars.

Country Parson.—Stains on the hands caused by alkaline development are, indeed, difficult to remove. They resist the solvent action of strong cyanide of potassium, but they yield to iodide of nitrogen—an exceedingly dangerous compound, and one the employment of which we cannot recommend owing to its explosive nature. The method we now invariably adopt is a simple and successful one, and consists in friction with a lump of pumice stone, using soap and water as a lubricant. The liability to stain the fingers will be greatly reduced by making use of a flat dish for developing. These are now extensively used, and may be either easily made or procured from any dealer in photographic materials.

A Ferrotyper.—Yes; we are quite familiar with the subject of developing collodion positives so as to give them a metallic lustre; but we do not carry our admiration of them so far as you seem to do. The effect may be produced by the addition of sulphuric acid to the developer, but it is so long since we tried it that we are unable to state the proportions we found best. The way to ascertain this is to divide a twelve-grain iron developer into two portions, adding to one of them a few drops of the acid, and to the other about twice as much. Next, develope pictures with both and compare the results. Thus, by increasing or decreasing the proportion of acid, you can obtain any degree of metallic sheen that is desired.

Major Gubbins.—1. We cannot suggest any better remedy for "oyster-shell" markings on the surface of the plate than prolonged draining after the removal of the plate from the bath. This must be done in a damp atmosphere. Transfer the plate to a damp box on the bottom of which is placed a pad of blotting-paper, and allow it to drain for at least ten minutes. New and horny collodions are more liable to this defect than old and porous samples; the addition of a few drops of water to a horny collodion frequently proves a remedy.—2. The last traces of acid may be eliminated by the direct addition of carbonate of soda—of course previously dissolved in water.—3. We have never tried the sample of collodion mentioned. It may probably be improved by the addition of a little iodide of ammonium.—4. In all probability the cause of the difficulty in obtaining the photograph you desire of the distant plains will be found in the state of the atmosphere, caused by the ascending currents of heated air. You are well aware of the perturbations of the atmosphere immediately over any heated object, such as a brazier of burning coke or charcoal, and your difficulty, we imagine, has a strict relationship to this phenomenon. Select a time for exposing the plate when the ground is cool and the atmosphere warm.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician.

For the two Weeks ending September 25, 1878.

These Observations are Taken at 8.30 a.m.

JOURNAL OF PHOTOGRAPHY.

No. 961. Vol. XXV.—OCTOBER 4, 1878.

CHEMICAL TESTS FOR TRANSFER PAPER.

The darkening action of light on certain varieties of paper is a matter of interest not only to the photographer but to all those who practise the various graphic and reproductive arts. The engraver, typographic printer, lithographer, and more especially the chromo-lithographer, may have their results considerably modified by a change of tint in connection with the paper employed as the basis of his work.

It is, however, satisfactory to find that two independent experimentalists, recently writing in our columns, have come to the conclusion that a rag paper, when properly made and so far bleached as to require no tinting, may safely be employed for the manufacture of transfer paper, as a paper of this kind undergoes no alteration by a reasonable exposure to the action of light. Manufacturers are thus placed in a position to secure themselves from mischief by employing a thoroughly good rag paper for the preparation of anything intended to permanently receive the carbon picture.

Notwithstanding all this it appears to be a well-established fact that most vegetable fibres can be so thoroughly purified as to resist the action of light; but, at the same time, it is well to bear in mind that this is seldom the case in actual practice, as the paper-maker is usually satisfied if he produce an article which is white when sent out of his manufactory. The method of testing fibre with sulphuric or nitric acid is likely to prove useful to manufacturers of transfer paper, as this test, if carefully conducted, is not likely to allow a bad sample of paper to pass muster, it being more likely to condemn a reasonably satisfactory sample than to allow a bad one to pass.

In conducting this test care should be taken that the samples are dry when immersed in the acids, otherwise sufficient heat might be generated by the combination of the moisture with the acid to cause a darkening in cases where no change of tint would have occurred had the test been conducted with sufficient care. An error on this score is naturally more liable to happen when sulphuric acid is employed than when nitric acid is used, as much more heat is evolved by the combination of the former with water than by the action of water on the latter. The tint assumed by vegetable fibre when immersed in nitric acid is often indicative of the source of the fibre. For example: ordinary hemp acquires a yellowish tint, New Zealand hemp becomes reddish, while wood fibre generally becomes brownish, and esparto takes a lighter brown tint. It is premised that, in each case, the fibre has been partially cleansed and sufficiently bleached to appear fairly white, but that it has not been so far treated with detergents as to remove the whole of the incrusting matter.

At the present time the most important paper-making materials, other than rags, are esparto and wood—the wood being generally derived from coniferous trees, and in the majority of cases from pine or fir. Now it so happens that there are several more or less characteristic and very easy tests by which imperfectly-cleaned pine or fir wood may be detected in paper; but such tests are naturally of small practical value to the maker of transfer paper, as a negative result does not by any means afford him a guarantee that he may safely employ the sample, and a positive result merely indicates that the particular batch tested is unsuitable for use as the basis of a photographic picture. One of the best known of these tests depends on the action of an aniline salt on the incrusting matter of the fibre, and this test is easily applied either to sized or unsized paper.

A convenient solution for testing paper may be prepared by treating an ounce of commercial aniline with two ounces of hydrochloric acid, and then adding forty ounces of water. When this solution is filtered it is nearly colourless and is ready for use. A piece of pine or fir wood moistened with it rapidly acquires a bright yellow colour; and all ordinary commercial papers containing wood fibre acquire a similar tint if the hydrochloride of aniline solution is allowed to remain on them for a few minutes. This yellow colouration is more intense as the purification of the wood fibre has been less perfect; and in the case of the greyish "wood middles," which are sold for making the insides of cardboards, the colouration is almost immediate and very intense.

We amused ourselves the other day by tearing small samples of paper from the margin of ten English books, ten French books, and ten German books—all of which had been published during the last three years. Each of these samples was tested with the above-described solution of hydrochloride of aniline. The result was that out of the ten English samples only two showed signs of a yellow colour after a period of five minutes; four of the French specimens acquired a yellow tint in the same time; while of the German papers no fewer than eight out of the ten showed signs of containing wood fibre. These results show that extreme caution should be exercised in the selection of papers for making transfer paper, especially when the article is manufactured abroad and it is difficult to obtain much information concerning its origin.

ON NITRO-GLUCOSE AND ITS USES IN PHOTOGRAPHY.

The practice of emulsion photography having now been firmly established, not only in France but also in Belgium and Germany, our continental *confrères* have commenced the exploration of some of the collateral branches of photo-chemistry, which have long since been identified with emulsion work in this country. At a recent meeting of the Brussels Section of the Belgian Photographic Association M. de Pitteurs read a lengthy communication on the subject of nitro-glucose and its uses in photography, but more especially in emulsion work; and in the discussion which followed a part was taken by Dr. van Monckhoven, who, as our readers are aware, was one of the first to bring this substance before the notice of photographers.

We have ourselves experimented largely with nitro-glucose, not only in connection with emulsions but also in collodion for bath purposes, as well as in printing; and while we, in common with many others, have recognised advantages in its use under some circumstances, we have at times found it perfectly inoperative, if not actually injurious, and we propose to say a few words on the subject of this uncertainty, as we are aware that in some quarters considerable disappointment has accrued from the failure of the brilliant hopes held out from its use.

We may at once express a very strong opinion that the chief error has been in looking upon nitro-glucose as a substance of a certain fixed and uniform composition, whereas in reality there is every reason to suppose that it is at least as variable in its nature as pyroxyline. We all know—at least those of us do who have systematically attempted the manufacture of pyroxyline for special purposes—how slight a variation in the conditions of manipulation suffice to entirely upset the standard of the product obtained, even when employing different portions of the same materials; but when it is borne in mind how much more exigeant in the matter of niceties of temperature and of the strength of acids the nitro-glucose is, it is scarcely to be wondered at if equal variety of result be obtained.

Then, again, the nature or quality of the raw cotton or other material employed in the manufacture of pyroxyline is supposed—and with good reason, no doubt—to exercise an important influence on the character of the result. In its purest form the material acted upon is supposed to be cellulose, but who shall say what is the exact nature of the resinous and gummy impurities which are present in different samples of the raw article? And who, again, turning to sugar, is to stand sponsor for the quality or identity of composition of the different forms of sugar which find their way into the market from various sources? This is no overstrained view of the matter, as we have in our own experience met with samples of so-called "refined" sugar which absolutely refused to give a product at all answering to the general characteristics of nitro-glucose, though submitted to precisely the same treatment as another sample possessing no apparent difference in quality or appearance.

But the physical differences actually noticeable in the product itself, whether arising from variation in the composition of the material employed or in the manner of its treatment, are certainly sufficient alone to raise the suspicion of at least some variation in its chemical behaviour. Thus the colour of the newly-prepared nitro-glucose frequently exhibits a noticeable difference, varying from a pure white to a more or less pronounced grey, or from a feeble greenish tint to a decided yellow. It is always more or less coloured previous to its removal from the acid mixture; but the tint is then due to the presence of nitric fumes, the colours we have mentioned remaining permanently after the complete elimination of the acid. When the product is colourless, or presents a greyish, satiny tinge it is usually found to be more stable in character than when it is either green or yellow. It gives no precipitate or cloudiness with silver nitrate when newly prepared, whereas the yellow description takes a milky tinge almost immediately after solution if brought into contact with silver in the dark.

The operation of freeing the pasty mass from acid by kneading it under water is one of great tediousness, and it is questionable whether the desired result is ever thoroughly attained under such circumstances. So great is the persistence with which the acid clings to the solid mass that it may be kneaded with powdered chalk, and left in this condition for hours, and still retain a strongly-acid reaction. The only effective means of thoroughly neutralising it is in the state of solution, and this is best performed as recommended by Dr. van Monckhoven, we believe. The nitro-glucose, after being freed as far as possible from acid by washing in water, is dissolved in alcohol, and the mixture shaken up with powdered chalk until, on testing with blue litmus-paper, it is shown to be free of acid. It is then filtered clear of the insoluble salts of lime and poured in a fine stream into a quantity of cold water, when it will be precipitated almost in the state of powder. After changing the water several times to remove the soluble lime salts it may be again kneaded into a mass, which will be free from acidity as well as from colour.

When thus prepared it will be found much harder and more porcelain-like than the coloured product which is merely washed, and its action in the presence of silver, as well as on the density of an emulsion, is scarcely less noticable; in fact, it is necessary, before it can be utilised as a source of density, to submit it to a slightly-elevated temperature for a few days in the state of solution as recommended by Dr. Monckhoven, or for a more prolonged period at ordinary temperature, whereas the yellow or green product will, in the majority of cases, require no such treatment. If two samples—one purified as above described, the other in the crude state—be enclosed in carefully-corked bottles in the dry state and placed in a dark cupboard, as far removed as possible from all disturbing influences of heat and light, it will be found that after the lapse of some time, varying from a few days to three or four weeks or possibly a little more, the unwashed sample will have undergone a peculiar sort of decomposition; instead of presenting the appearance of a solid lump of hard enamel it will be found to have swelled up into a soft, frothy mass, the evolution of acid fumes being evident in the discolouration and corrosion of the cork. The washed sample will probably at this time be found unchanged, or, at the most, there will be but a slight action upon the cork, showing that decomposition has commenced, but is proceeding far more slowly than in the other case; it is, however, only a matter of time. If the pasty mass be washed in lukewarm water, in order to remove the liberated acid, its former hard consistency returns, and if stored under water the decomposition proceeds much more slowly, and does reach such violence as to produce frothing.

Now there seems to be a direct connection between the decomposition of the nitro-glucose and its power of conferring density; and we are inclined to attribute its action in that direction solely to the rapidity of its decomposition, which we look upon as strictly analogous to the more tardy "ageing" of pyroxyline or collodion. M. de Pitteurs attributes the effect of extra density to a decomposition set up by light upon the nitro-gluco-argentic compomnd, which in turn produces a substance capable of reducing the silver forming the sensitive film. Without disputing the possibility of some such reducing action under a sufficiently prolonged exposure as in printing, we cannot think it exists in the case of an emulsion, or we think it would be accompanied by the phenomenon of self-development—at anyrate in the high lights of the picture. This, however, we have never found to be the case. We think the action is much more easily explained. The instability of the nitro-glucose favours the formation of a lower nitro-silver compound similar to, though possibly not identical with, the *nitrite*, which is known to favour density, and that a similar result ensues from the "ageing" of collodion, or from the employment of a "high-temperature" (and less stable or partially-decomposed) sample of pyroxyline.

M. de Pitteurs and others seem to infer that the peculiar properties of high-temperature cotton are due to the presence of nitro-glucose; but we fail to find any warrant that such is the case in respective conditions which have to be observed in the preparation of such pyroxyline and nitro-glucose respectively. High temperature and comparatively weak acids are necessary in the one case, the lowest temperature and the strongest possible acids in the other—conditions which cannot easily be made to assimilate.

MINERAL ACIDS IN THE IRON DEVELOPER.

It would be difficult to point out an exact time from which to date the change from pyrogallic acid to sulphate of iron for the development of negatives. Already a younger generation of photographers has arisen which has never had to do with the old pyro. development, with its intense blacks and transparent shadows, and that beautiful "bloom" upon the high lights which was so much prized; hence they cannot so fully appreciate the radical nature of the change that was effected when pyro. was finally banished for wet-plate negatives. They have received the iron developer from their teachers, and, owing, it may be, to there being less of the spirit of experimentalism among them than among the pioneers of the art, they seem, as far as present practice may show, likely to transmit it unaltered to posterity. We do not assert that there is a certainty of the present formulæ being supplemented by others; but we do think that various modifications might be introduced with benefit, and that without any variation from the principles involved in the present accepted mode of development.

At the present time a solution of sulphate of iron of all strengths with varying proportions of glacial acetic acid, from half-a-grain to two grains to each grain of iron, together with a little spirit, forms the stock solution used by ninety-nine out of a hundred photographers. It is occasionally varied by the substitution of iron and ammonia sulphate, and more rarely still by the addition of such organic matter as sugar, gelatine, &c.; but that is the full extent of the change.

We have been led to these reflections, and to the experiments we are about to detail, by a reference to an old formula given to us as a great secret years ago by a very expert operator when the value of iron for negatives was beginning to be spoken of. It was made by dissolving fifteen grains of iron, together with half-a-drachm of glacial acetic acid, in an ounce of water for one solution, and three grains of pyro. and the same quantity of glacial acetic acid as in the iron solution for a second solution. In developing, ten drops of the second solution were mixed with half-an-ounce of the first; and for intensification ten drops of the iron solution were mixed with half-an-ounce of the pyro. mixture, and silver nitrate as usual—a very curious mixture, our readers will say; but we do not hesitate to assert that there were negatives produced by its aid which are unsurpassed at the present day.

Our next notes referred to the formula employed by one of the foremost professional men of a dozen or two years ago. The formula was—

Sulphate of iron	6 grains.
Glacial acetic acid	10 minims.
Sulphuric acid	2 drops.

The gentleman referred to was *facile princeps* of *carte* workers in his time, and his negatives were marvels of cleanliness of working and of gradation in the shadows. But who at the present time ever hears of the employment of sulphuric acid except for ferrotypes, *et hoc genus omnes ?*

As we further could not call to mind any exhaustive accounts of trials of the mineral acids to entirely replace the acetic, we determined to make a series of experiments to ascertain what, if any, disadvantages would be shown in their employment for wet collodion negatives.

The character of the precipitate in a test glass when nitrate of silver is added to a solution of iron varies, as is well known, according to the restraining acid present. With acetic acid it partakes of a brownish cast; with sulphuric acid the hue is lighter; and with nitric acid it is very decidedly whiter. This character, however, refers to the colour of the image by reflected light, and it will be found that their indications are not always comparable with those produced in a negative and examined by transmitted light.

Our trials with negatives were with varying proportions of nitric acid and sulphuric acid, with different strengths of iron solution and no acetic acid whatever. We made some score or two negatives, and we unhesitatingly state that the exposure required was not any more than would have been needed with the ordinary-accepted solution, and the character of the negative was very little different. The chief difference discernible was in the direction of density, the acetic acid developer giving a stronger negative than either the nitric or sulphuric acid; but the difference was not great, and no difficulty whatever was experienced in obtaining as much density as was required with the usual pyro. intensifier. We call attention to this—not on any account as a defect, but merely to put our readers on their guard against disappointment if they should feel inclined to try the new developer.

If we were asked what advantages the mineral acid developer possesses, we would reply that it is cheaper, and for travelling less bulky, and for comfort in working it is beyond comparison superior to the acetic developer, the pungent smell of which in a tent or in a close dark room being at times most offensive, while some samples of glacial acetic possess an irritating property which occasionally gives rise to most uncomfortable sensations.

It is our intention to continue our trials with this developer, and ascertain with repeated practice whether it may not be expected to possess such qualities as may justify the banishment of glacial acetic acid entirely from the practice of wet-plate development; and if, as we think likely, this happens we shall have one smell less in the dark room.

To those who do not care to employ a developer which does not give a full amount of density at the first application we would recommend the addition of half-a-grain of sugar or of a small quantity of gelatine, as described in a previous article a few months ago. By this means almost any amount of intensity may be obtained. If overmuch be not added we are inclined to think that the exposure will not be to any appreciable extent protracted.

We close our article by giving the two formulæ we employed with success:—

Sulphate of iron	20 grains.
Nitric acid	5 minims.
Methylated spirits of wine	20 „

Sulphate of iron	20 grains.
Sulphuric acid	5 minims.
Spirits of wine	20 „

These were used precisely in the manner that the ordinary developer with acetic acid is employed.

RECENT PATENTS.

No. XVI.—HUGHES'S TRIPLEXICON.

When last we drew attention to the improvements introduced by Mr. W. C. Hughes into the magic lantern, by which he has been enabled to produce a light of extraordinary purity and intensity, we intimated our intention of returning to the subject as soon as by the publication of the specification of his patent we should be placed in a position to describe in detail the means employed in effecting such intensity of illumination. Speaking on this subject in general terms, we attach great importance to such improvements as those introduced by Mr. Hughes, because every effort to supersede the oxyhydrogen light in the magic lantern is deserving of the highest commendation. When such efforts are attended by the degree of success we have seen achieved by Mr. Hughes then there is the greater cause for congratulation. With these prefatory observations we allow Mr. Hughes to speak for himself through the medium of his completed specification:—

The triplexicon lantern lamp is a new and improved form of lamp, having three distinct wicks and separate racks and pinions, arranged in such a manner and having such dimensions in construction and shape as to cause proper and perfect combustion, both for magic lanterns, the public streets, rooms, halls, ships, lighthouses, &c.

It has long since become apparent that to get the proper combustion of three separate wicks, so as to make them burn with anything like certainty and effect, would require a vast amount of ingenuity and skill. This, however, is done by regulating to a nicety the admission of the proper amount of air in such quantities as to support combustion without losing any of the whiteness of the light or flame. I am enabled, however, by my arrangements to produce such great intensity of light for the purposes above mentioned.

In speaking of its application, in this my final specification, to the magic lantern it is proper to explain very clearly the reasons for my various regulations, plans, shapes, and dimensions, as well as the construction of the "triplexicon" lamp itself, as hereafter described.

In the first place, it is very essential that the wicks for magic lanterns and the orifice of the wick tubes should be shaped and arranged in certain positions so as to be compatible with the absorbing power of a lantern condenser, so that few rays of light may be lost by it. It has been the aim of magic lantern manufacturers generally for years past to obtain a properly-illuminated and bright disc on the screen. One of the essential features for the accomplishment of this object is the size of the flames themselves, and the position and shape the wicks should necessarily occupy. For example, there may be placed at the back or front of a lantern condenser ever so concentrated a light, at either the top, bottom, or sides, and still scarcely any result will be perceptible; but adjust the same light at a proper focal distance and in the centre, then nearly all the rays are absorbed, provided the flame or flames are placed in straight lines, or partially curved from the lens. What is meant is this:—Suppose a flat flame is placed strictly parallel with the condenser, only that portion of the flame which comes immediately within the absorbing radius of the same will produce any advantageous result, because it is only the centre part of the lens that collects really the rays of light. But reverse the lamp, by presenting the edges of the flames to the condenser, and you get quite a different effect. Thus the condenser absorbs more light longitudinally than in a parallel direction. Therefore in a lamp of this kind it is very essential to study these points. This ultimatum has been obtained by the introduction of wicks placed in straight lines to the condenser, as in the "sciopticon" and lamps of similar construction.

In the application of three wicks for the same purpose the like principle is to be adopted; but to obtain in this case the concentrated light, the width of the wicks, as well as their various shapes, together with their proper combustion, must be of vital importance.

If three wicks are placed very close together, no matter in what position, a very poor light would be obtained, on account of sufficient air not being allowed to pass between the wicks, because of their closeness to each other; and, on the other hand, if placed too wide apart they would certainly lose their power for transmitting light to the screen, a large quantity of the outside rays being lost.

Suppose a large argand burner (say two inches in diameter) is placed in a magic lantern, a great deal of heat would be generated, adding but very little more light to the screen, on account of the light from the front and back being caught by the lens, while the greater part of it on the lateral sides would be lost, and on the whole give but little more brilliancy to the screen than a one-inch argand burner. Hence it is that the oxyhydrogen lime light is so valuable, because of the concentration of the light at a given point in magic lantern use.

Next comes the relation of these three wicks to each other, and to the condenser itself.

The object I have in view is to get the greatest amount of light possible. This can alone be obtained from the width of the burning edges of the wicks being placed in suitable positions, and having such internal and external arrangements as to carry off the hot air as much as possible. Therefore the width of the wicks for magic lanterns of three-and-a-half or four-inch condensers should not be less than one inch and five-eighths, but more if necessary, up to eight or ten inches.

In a magic lantern with three-and-a-half or four-inch condensers my standard size of the wicks is not less than two inches wide, although I claim to use them as low as one inch and five-eighths in condensers three and a-half to four inches in diameter, and wider if necessary.

It is evident that a condenser absorbs more rays of light when placed in such a position as to catch them edgeways, therefore the wider the wicks (consistent with the other arrangements) the greater must be the intensity of the light, and a more brilliantly-lit-up disc will be the consequence. The condenser at the focal distance will absorb or take in any amount of concentrated light. If three wicks are arranged (say three-quarters of an inch wide) for use in a magic lantern, what would be the result? No more effect than an ordinary light would give. But make them two inches, and you get a wonderfully-increased light, and so on, if larger, *cæteris paribus*. In this part of my invention I adhere strictly to this point, viz., that no three-wick magic lantern lamp should have wicks less than one inch and five-eighths wide, and increased if necessary to eight or ten inches, according (as before mentioned) to the size of the magic lantern condenser; but in streets, rooms, halls, shops, lighthouses, &c., they, when curved or bent (one or more of them), may be used in sizes varying from half-an-inch to eight or ten inches wide.

The wicks should be placed in the following positions in relation to the condenser, so that it absorbs as much of the light as possible, as well as to produce a properly-illuminated disc without aberration or shadow:—

In the first place, to produce these results the wicks should be situated thus, namely:—The centre wick straight, while the two side ones curve, as shown in *fig.* 10 of the drawings.

In the second place, the centre wick is straight and the two side ones each at an angle, as shown in *fig.* 11.

In the third place, the centre wick is straight, the side ones forming part of a circle or egg shape (as in *fig.* 12), also arranged in divisions, according to the various widths given in the drawings.

Either of the three triple-shaped wicks, shown by *figs.* 10, 11, and 12, will produce the same effect on the screen. Now, although the wick tubes take the above shape at their orifice for magic lantern purposes, as before mentioned, they are equally as powerful for rooms, streets, lighthouses, &c.

The whiteness and intensity of the flame is also determined by the proper and well-regulated amount of air being admitted, and by the proper arrangements underneath, between and above the perforated plates and that which surrounds the flames. This is very important, and the brilliancy of light produced by the arrangement of parts as to size and dimensions of the various fittings and parts forming the lamp, as shown by the drawings. As it is absolutely necessary to have properly-arranged air-draughts underneath the flames, it is also imperative to have the required quantity of air admitted round about and above them. This is done externally by the size of the combustion chambers, which are shaped by my invention in more forms than one suitable to the various sizes of the flames. For instance: if a set of wicks two inches wide will take a chamber four inches in diameter, a wick three inches wide will take one six inches in diameter, the same standard being observed with regard to the size of the fittings, and soforth, provided they have the arrangements I have made for their proper combustion. The flames, too, must rise steadily to a proper height and burn with great whiteness, which can only be guaranteed by my calculated constructions, as before described. In the combustion chambers, covering the flames of the ordinary two-wick lamps on the "sciopticon" principle, they have at either end two glass plates. These chambers are made of metal, and form part of the chimney by which the hot air escapes.

In my invention for covering the three wicks I place at each end, instead of glass, very finely-cut plates of mica or talc, or the condenser itself at one end, if necessary. My reason for so doing is that the ordinary window glass will not stand the heat, which has always been a serious defect even in the two-wick lamps, and would be much more so in lamps of three wicks; but I do not confine myself to the use of this form of chamber when the lamps are used in magic lanterns, but to the other parts of my invention which apply to its use in the streets, shops, halls, rooms, lighthouses, &c. The combustion chamber consists of an annealed glass, square, circular, conical, polygonal, or other convenient shape suitable for the purpose for which it is required; but I prefer for present use the conical annealed glass chamber, four inches in diameter at the bottom, three inches and one-eighth at the top, and three inches and three-quarters deep, and hollow right through like a cylinder, the bottom of which rests on the ground plate (*figs.* 13 and 15), and is covered over by a metal conical-shaped frame or cap (as in *fig.* 9), the glass cylinder fitting loosely inside the same and with the long metal chimney (D, *fig.* 3), which fits round the collar of the metal cap and forms an entire and complete chamber. Two openings (*fig.* 9), back and front, allow the light to pass out at either side; a silver reflector (C, *fig.* 14), with movable piece A, is attached to the cover or top plate of lamp, and reflects the light to the condenser. This cap or metal frame rests entirely on the ground plate, and can be removed as a separate piece. The glass chamber (*fig.* 16) should be made of annealed blower glass of any of the shapes and sizes before mentioned. The outside frame or cap fitting to correspond with it may have as many openings as required to admit of light passing out in any direction; or in place thereof a metal cap resting on the top of the glass chamber may be applied, so proportioned and arranged as to leave a large area for light to pass out without any interruption, so as to support the chimney hereinbefore described.

The ground plate (*fig.* 13), which is circular, and on which rests the metal frame and glass chamber, has an arrangement (*fig.* 15) for letting in minimum quantities of air, if necessary, to feed the flames. The plan of this portion of my invention will be more fully described hereafter with reference to the drawings.

As before mentioned, common window glass will crack under ordinary circumstances, because it cannot be got very readily and properly annealed, and when placed, as it has to be, in direct communication with the heat coming from the three flames, two inches wide, scarcely a minute will pass without its being shattered; hence it is the blown annealed glass chambers will survive any amount of heat that may be brought to bear upon them during the combustion of the same. Moreover, in this form of chamber and connected chimney the hot air escapes without any intervention, which is of great moment when the lamp is placed in a confined space, while in the metal combustion chamber it collects and remains intensified, much to the detriment of surroundings.

(To be concluded in our next.)

It may be a moot point as to which has done the most towards the advancement of photography—photographic journalism or the formation of photographic societies; but there can be no two opinions that, but for these two forces, our art-science would not occupy the position it does today. Perseverance, if backed up by other necessary qualities, can do much; but genius, plodding on alone, is apt to travel in a groove which, except by accident, it cannot leave. Niepce and Daguerre formed examples of this. Talbot, more favoured by circumstances, widened his particular course until it became merged in the broader stream of general science, and nowadays processes are built up more by the association of different ideas than by the single efforts of individuals. *Tot homines, tot sententiæ* may be true enough; but even with societies we find a tendency on the part of the different members to run in one general groove, until the society as a body acquires much, if not all, of the character of an individual. Two of our leading provincial societies have, however, instituted a new order of things. In our last number we published a brief account of a joint excursion of the Manchester and Liverpool photographic societies, and now that the ice has been fairly broken we trust that the experiment will become an established system. Our metropolitan societies necessarily partake more of the cosmopolitan character than those in the provinces, no matter what may be the size and importance of the towns in which the latter may be located; but it is worthy of notice that each of the two we have mentioned—belonging, as they do, to the two principal commercial "centres" of the country—has acquired for itself a character of "individuality" scarcely equalled by any other similar body, however small. The representatives respectively of collodio-albumen and of collodio-bromide have, however, resolved on an attempt at mutual benefit, in which we heartily wish them success, and should like to see the same principle extended in other directions. Photographic societies are not all so fortunately situated locally as these two, and a day excursion is all too short for the purpose in view; still, we think, the obstacles in the way are not insurmountable. Few, we imagine, of real photographers do not allow themselves a few days "out with the camera" in the course of the year; and we think it not impossible that, by preconcerted arrangement, a large number of *individuals* from all parts of the country could find it convenient to meet at some picturesque centre, and devote a few days or a week to mutual improvement and pleasure combined. The communication of practical ideas is what we want and what we cannot get at the formal meetings of societies; while a national "conference" for purely scientific discussion is to our idea not only unnecessary but worse than useless. The socialising influence of companionable intercourse, untrammelled by any formality and aided by the pleasurable excitement of the holiday, would conduce more to the genial interchange of ideas than all the "ordinary meetings" of a session, to say nothing of the additional pleasure to be derived from personal acquaintances or friendships thus formed.

PRACTICAL INSTRUCTIONS IN MODERN PHOTO-MECHANICAL PRINTING METHODS.

Part I.—PHOTOLITHOGRAPHY.

I. Making the Negative.—One of the most important points in connection with the successful practice of photolithography is to secure a suitable negative, for without this no amount of careful manipulation will lead to satisfactory results. A negative for photolithography should possess only two grades; and the more nearly these approach to absolute opacity on the one hand and perfect transparency on the other hand so much easier will be the work of making a transfer. When a drawing or engraving consists of lines which are intense, all about equal in width, and not separated from each other by very fine white spaces, it is generally easy to obtain a satisfactory negative, notwithstanding the fact that the lines for reproduction may be very fine.

Let us take a more difficult case, and suppose that we have to reproduce a moderately-fine engraving containing not only clear, open lines, but also fine greyish lines, closely clustered together.

If the engraving have become stained, or have acquired a yellow tint from age, it may be necessary to clean and bleach it, and it is generally advisable to do this unless the yellowness or tint is very evenly spread over the surface of the paper. If, however, the tint on the engraving appear uniform to the eye, and a preliminary trial with a small collodionised plate shows that it is photographically uniform, it is generally better not to bleach the print before proceeding to take a negative of it. If, on the other hand, it be resolved to clean and bleach the engraving, it should first be soaked in slightly warm water for a few minutes, in order to soften the paper and to remove any products of decomposition which may be soluble in warm water. This having been done, it should be put into a mixture of one part of commercial hydrochloric acid and forty parts of water, and when the acid has had time to thoroughly penetrate the print it should be laid on a sheet of plate glass and well rinsed with the acid, which must be poured on it over and over again. During this rinsing with dilute hydrochloric acid a very gentle friction may be cautiously applied to the surface of the print by means of a camel's-hair brush. After a thorough rinsing in water the engraving is next placed in a dish containing a solution of the so-called chloride of lime, prepared by dissolving one part of the commercial article (bleaching powder) in one hundred parts of water, and filtering the solution. As soon as this liquor has thoroughly penetrated the paper, gradual additions of hydrochloric acid may be made in order to liberate the energetically-bleaching oxides of chlorine. These additions of acid should be made carefully—not more than a few drops of acid being added at a time—and the acid be thoroughly mixed with the bath before the engraving is reimmersed. It is very much better to bleach the print slowly than to hasten matters by an undue addition of acid to the bleaching bath. The print having been sufficiently whitened or bleached, it must next be washed in three or four changes of water; but this washing is generally insufficient to remove all traces of the bleaching agent from the fibres of the paper, and as any remaining traces of free chlorine or free oxides of chlorine would lead to the destruction of the paper it is important to give the bleached engraving a final soaking in a solution of sodium hyposulphite containing about one per cent. of the salt. Sodium hyposulphite is a most energetic "antichlor," and is largely used for removing the last traces of chlorine from bleached goods, as silver printers find to their cost when they use mounts which contain this salt. The photo-mechanical printer has no reason to fear sodium hyposulphite, although to the silver printer it is a very sword of Damocles.

Having thus cleaned and bleached the engraving, the next thing is to mount it on a piece of thin patent glass plate. In order to do this select a piece of glass free from defects and a little larger than the print; put this into a dish of clean water, and then immerse the engraving, face downwards, taking care to avoid air-bubbles. Now adjust the engraving to the middle of the glass plate, and, while keeping it in position with the fingers, lift out the plate with the print on it. If this be properly done, the glass and the face of the engraving will only be separated by a thin layer of water free from air-bubbles, and this layer of water is next removed as follows:—The glass bearing the engraving having been placed on a horizontal board a sheet of wet paper is laid over all, and the water is forced out by scraping the surface with the india-rubber edge of a squeegee, this useful instrument consisting of a strip of india-rubber mounted between two strips of wood not quite so broad as the india-rubber. The excess of water having been thus removed the next step is to strip off the outer layer of paper, which was only intended to protect the back of the engraving from the slight grinding action of the squeegee. This is done by turning back one corner of the paper until it is nearly parallel with the rest of the sheet, and gently stripping it off by a steady pull. Under these circumstances the print remains adherent to the glass, where it should be allowed to dry slowly. Generally it remains on the glass when dry, and when this is the case it is in the best possible condition for copying, being perfectly flat and free from folds; if, on the other hand, it should separate from the glass on drying, it is still in good condition for copying, it being in this case merely necessary to clamp it between two glass plates.

It is generally advisable to mount any engraving which is to be copied on a glass plate as described above, as it is impossible to obtain a good copy of any printed matter unless perfect flatness be secured. The glass plate bearing the engraving can now be fixed to the black board of the copying camera by means of drawing-pins placed round its edge, and immediately behind the engraving should be placed a sheet of white paper, in order to prevent any possible degradation of tint from a partial transparentness of the engraving; but this paper doublet should not be larger than the print to be copied.

Care must be taken to illuminate the object as uniformly as possible, and it is generally easiest to do this out of doors. In order to prevent any possibility of light being reflected from the surface of the glass cover into the lens, a screen rather larger than the object to be copied should be placed immediately in front of the camera, and the lens must look through a hole cut in this screen. It is scarcely necessary to remark that the axis of the lens should be at right angles to the print and sensitive plate, otherwise an unsightly distortion will result; but, generally speaking, the mechanical arrangements of the copying camera provide for this.

The most convenient lens to employ is the portable symmetrical, as it gives a very evenly-illuminated field together with straight lines, and it covers a large field in proportion to its focus, thus avoiding an inordinate length of the copying camera.

In copying photolithography one will naturally use a bath which is free from any tendency to fog, and a collodion which has been iodised some time; but a very old and degenerated collodion must be avoided, or the film may become granular during intensification with mercury. A full exposure must be given, otherwise the fine lines will be lost; and after development with a weak iron developer the negative should be fixed with cyanide and then well washed by soaking in several changes of water.

At this stage a careful examination of the negative should be made. In the first place, notice whether the lighting of the subject has been uniform, and whether the deposit of silver on those parts which correspond to the whites of the original is fairly equal all over. If there be any fault in either of these respects it is best not to waste any more time over the plate, but to take another negative at once.

Next place a black cloth behind the negative, and carefully examine the lines to ascertain how far they are free from deposited silver. If the broad and clearly-defined lines of the engraving are not perfectly free from every trace of cloudiness reject the negative; but in taking another do not so reduce the exposure as to lose the fine lines, it being generally better to lower the strength of the developer than to unduly lessen the exposure. In most cases the finest lines of the engraving will not be represented in the negative by perfectly clear glass, neither will the fine spaces between these lines be as dense as the general ground of the negative. Several causes tend to this result. In the first place, it is seldom that the very fine lines of an engraving are clear and intense, an inspection with a magnifying glass generally showing them as greyish, broken, and ill-defined; moreover, the whites between these lines are in most cases tinted by the ink, and are consequently less pure than the general ground of the engraving. Any slight vibration on the part of the camera tells most on these fine lines and their intervening spaces, tending to mar the transparency of the former and to reduce the opacity of the latter. The evil effects of vibration may be, to a great extent, got rid of by suspending the camera and copying-frame (these being, of course, firmly united together) by means of cords, which should radiate outwards towards the roof of the building so as to lessen the tendency of the apparatus to swing.

When the best possible negative has been obtained and has been fixed with cyanide of potassium it must be intensified. In the case of a negative from a fine engraving this is best done by immersing it in a saturated solution of corrosive sublimate (mercuric chloride), where it should remain until the deposit becomes quite white, a period of five or ten minutes being usually sufficient for this. After a rinse in water it is next transferred to a solution of potassium iodide containing one grain of the salt to each ounce. Here the whitened deposit becomes rapidly yellow, and when the yellow tint has penetrated the film the negative is removed, rinsed, dried, and varnished.

If the negative be used in its present state for making a photo-lithographic transfer it will be found that an exposure which is sufficient for the broad clear lines is insufficient for those which are slightly veiled or fogged; and in order to render it practicable to secure the whole of the subject the negative must be shaded in the transparent parts. This is best done by fixing a sheet of fine tracing-paper on the back of the negative and shading on this with black-lead applied by means of a stump. Before fixing the tracing-paper on the negative it is best to damp it by laying it between moist sheets of blotting-paper, and when slightly damped in this way it is applied to the back of the negative, which should have been gummed round the edges. As the paper dries it becomes quite tense, and when dry it should be placed on an easel and shaded with the blacklead until all the lines appear about equal in transparency.

The success of this operation is best tested by exposing a piece of ordinary sensitive albumenised paper under the prepared negative, and noticing if the whole of the subject prints equally and simultaneously. If any part print more rapidly than the rest it must be shaded accordingly, and if any part be noticed to be slow in printing a little varnish should be applied to the tracing-paper at the back of this part, or in some cases a piece of the tracing-paper may be cut out with a knife. The foregoing, or some other method of shading the negative, originally advocated by Professor Husnik, should never be neglected when fine engravings have to be reproduced by photo-lithography. Coarse subjects—such as ordinary typographic matter reproduced the same size—do not require this treatment, as it is easy to obtain negatives of these that shall be perfectly clear in the transparent parts and possess any required density in the opaque parts. In such cases it is generally best to intensify with pyro. and silver after fixing, and then to treat with mercuric chloride, so as to obtain an extreme degree of density. The yellow negatives obtained by mercuric intensification become rather lighter in colour by exposure to light; so it is best to put them away in a shaded place. The short exposures required for making transfers do not injure them.

The negative having been thus secured, the next operation is to obtain a transfer or print in fatty ink by the method to be described in the next chapter. T. Bolas, F.C.S.

NOTES ON PASSING EVENTS.

By a Peripatetic Photographer.

In common, doubtless, with many readers of The British Journal of Photography, I have been much shocked at the account given, on the authority of the *Observer*, of the death of Professor Fischer from having incautiously tasted a mixture of cyanide of potassium (in solution, apparently) and chloride of ammonia, or some other substance with which the poisonous body was diluted. But upon reading the details very carefully I am rather inclined to think that there has been some misstatement made in connection with the alleged event. I have manufactured a good deal of cyanide of potassium during my life, and I have purchased samples of almost every kind offered for sale, at prices ranging from fourteenpence to six shillings per pound, and I assert that it is *not* "a white powder resembling flour or chalk," that a fragment "almost imperceptible to the eye" will *not* cause "instantaneous death," and that cyanide of potassium, contrary to the statement in the *Observer*, *is* volatile in the sense of its giving off deadly emanations. I incline to the belief that Professor Fischer could not possibly have acted in such an indiscreet manner as to taste, himself, a solution of medicated cyanide in order to demonstrate to an assistant its innocent nature. If he had done so he would have furnished an instance of foolhardiness such as the world has never before heard of. But cyanide of potassium does *not* kill instantaneously, the *Observer* notwithstanding; and even if the Professor had taken a much larger quantity than he could have imbibed in the manner described, he, chemist as he was, must have known that there are several antidotes to this poison which, if the event really did occur in his laboratory, must have been stored in plenty on shelves beside him. If he found that he was really "in for it" and was desirous of escaping from the consequences, he would have lost no time in swallowing an infallible antidote with which he, as an experimentalist in the toxological effects of cyanide, must have been quite familiar, and which is present in every laboratory. I allude to protosulphate of iron, which, with the addition of a little persulphate, immediately converts the cyanide of potassium in the stomach into Prussian blue, which is a harmless compound. I do not desire to insinuate that Professor Fischer was not poisoned accidentally; but, as the writer in the *Observer* has made loose statements in some matters connected with the unfortunate event, it is not impossible that his statements may be equally untrustworthy as regards the principal facts.

The death of Mr. Thomas Grubb is another reminder of the passing away of the veterans in what has been so well designated the "art-science" of photography. Mr. Grubb's forte lay in writing most lucidly upon photographic optics—a branch in which he was singularly well calculated to assume a high position as an exponent. I recollect spending an evening in his company when he last visited London, and was struck by the facile manner in which he conversed upon those particular departments of photographic optics known respectively as the oblique pencil and depth of definition—subjects which, it need scarcely be observed, are not connected with each other. Of all those (and they were numerous) who had occasion to take to task the late Mr. Sutton for errors of diction there was no one who did it with such weight as Mr. Grubb, and the weight was none the less felt because its administration was gently made.

Observing that the subject of stereoscopic transparencies is ever and anon coming up to the surface, I would suggest, to such of my brethren as possess the knowledge, how very desirable it would be if some competent writer would give us an exhaustive article on the method of producing transparencies by the negative albumen process. Such an article would be read with great avidity. There is in the transparencies of Ferrier and Soulier and their successors a certain charm which in a measure takes captive the senses of the spectator. There is transparence even in the deepest shadows, and this, coupled with the peculiarly rich tone they possess, renders them so much finer than collodion pictures that it is no wonder some connoisseurs prefer giving half-a-guinea for one such work of art than half-a-crown for a collodion picture. It is said—and I believe with some truth—that notwithstanding all that has been written on the albumen process the real method of its application to the production of transparencies has been closely guarded as a secret. I am aware of one gentleman under whose eye these lines will fall, and who is quite conversant with the details of the Ferrier method. Perhaps he will kindly respond to the hint I have here so plainly given.

Speaking to a friend lately concerning the recent meeting of the British Association in Dublin, he told me that his daughter was present in the Geographical Section for nearly an hour during the reading of Captain Waterhouse's paper, and she put it down as exceedingly "dry." From her point of view this is no doubt correct, just as the discussion of a topic connected with millinery or the making of costumes, *et hoc genus omne*, by a lady would be "dry" to one of the sterner sex. Speaking, however, as one to whom the subject treated is not quite unknown, I must place on record the great satisfaction with which I read from week to week Captain Waterhouse's valuable compendium of cartographic processes, which, taken in connection with what he has already written on the same subject, is by far the most valuable work of the kind that has yet appeared. However, I am still bound to admit that there is every excuse for a young lady thinking such a subject a rather dry one.

(To be continued.)

NOTES FROM AMERICA.

A Cure for Blistered Paper.—Regulating the Light in Studios.—Burnishing Prints.—The English Photographs in the French Exhibition.

Only a fortnight has elapsed since we spoke of the connection between blisters and a very dry condition of the albumenised paper upon which such blisters appeared. Some observations by Mr. A. Hesler, in the last number of the *Philadelphia Photographer*, tend to confirm what we then said. Mr. Hesler, however, goes farther back with regard to the preparation of paper than we did. We recommended the placing of the paper in a rather damp atmosphere previous to exciting it; he, on the other hand, recommends similar treatment in connection with its being albumenised. Taking the liberty of suppressing a liberal rendering of italics in Mr. Hesler's remarks we give them as follow:—

In looking over our valued friend Vogel's letter in your July number, his remarks on blisters remind me of what I said on that point in last *Mosaics*. His remarks confirm what I then said, viz., that the main cause of blisters—those damaging blisters—lies at the door of the albumenisers; and I refer to it now in hope that their attention may be forcibly called to the matter. I do know that to take plain paper (have it very dry and hard) and lay it on the albumen just long enough to make a coating on the said paper, will give to the poor photographer a paper that will blister in spite of all the blister-cures ever invented. I think I hear a smile come from friend Clemons, or the famous S. & M., across the briny deep, as they say, "Teach your granna how to take snuff, will you?" Yet I do not know that albumen applied to paper previously dampened, and allowed to lie on the albumen sufficiently long as to absorb the albumen into the fibre, that such paper will stand almost any kind of treatment and not blister. Try it, ye albumenisers, and aid in removing one of the damaging trials of us poor photographers.

The same writer has some remarks in reply to a question in which the experience of those who use tracing-cloth in excluding the light from studios is asked for. He says:—

I am using such screens, attached to spring rollers at the upper edge of the skylight, and find them just the thing. Under these I have blue opaque curtains. The upper ones keep out the sun, and are rolled up or down in a moment. The blue opaque cuts off the light from any part I choose. My skylight room is thirty-five feet long, east and west, by twenty wide. The light is nineteen feet long, east and west, by fourteen wide, facing north; lower edge seven and a-half feet from floor, with side light three and a-half feet wide by nineteen long, on which the top light rests. The upper side of the light is fourteen feet from the floor. Under this light I make children's pictures in less time than you can say "scat," and groups as soon as you can say "Jack Robinson."

Mr. Irving Saunders, in the same journal, imparts as follows, his experience in the burnishing of prints:—

About two years since I was very much troubled with very fine scratches in burnishing, different from those caused by roughness of the burnishing tool. Another proof that the cause lay outside of the burnisher was that two or three, perhaps, would burnish all right, then one scratched badly, next all right, and so on through the lot. I asked several the cause, Mr. Bass among the number, but none gave me any satisfactory reason. I finally found the cause to be that the prints were allowed to get too dry before burnishing, and the remedy I used was as follows:—After mounting, the moisture should not get off the prints before burnishing. As soon as the prints begin to curl toward the picture I pack them one upon another. My first plan was to place them in the cellar until ready to spot; while doing this I only expose one print at a time, keeping them packed. After spotting, lubricate with soap and alcohol (I find wax, spermaceti, &c., to give, in my experience, a veiled appearance), and spread out in the cellar upon something clean. I use a cloth stretched upon a small frame, where they should remain until ready to burnish. A superior burnish will result if they can remain twelve hours after lubricating, as directed, spread in the cellar. I have since made another improvement, substituting for the cellar a tight tin box, which I had made large enough to hold my prints flat. Care must be taken not to have the prints too damp. I run them through, lightly, twice across the burnishing tool, until all are through, then run about four times again, commencing with the first. I run the first thin.

It is always well that we should "see oursels as others see us." To this end we shall give what has been said of the English and other departments of the International Exhibition now open in Paris by a correspondent of the *Philadelphia Photographer*. He says:—

The English exhibition I think I have seen beaten in Conduit-street, London. Messrs. Elliott and Fry's enlargements; Mr. Vanderweyde's pictures by electric light; Mr. Bedford's views; Mr. Vernon Heath's large landscapes, 36 × 39 inches; Mr. Robinson's always attractive pictures; Mr. Warnerke's excellent film-pictures on fabrics; Mr. Slingsby's one exquisite interior view of a room; Mr. England's always fine views; some others from Brighton (where Mayor Mayall lives), by Mr. Boucher; some very fine productions in carbon by the Autotype Company (strange there were no other such from London), and a few others, made up the disappointing British exhibition—not forgetting, however, that king of landscape photographers, Payne Jennings. His work is superb, and if landscaping was more in vogue he would go up on our shoulders, as Salomon did ten years ago. He is an artist in every sense. Each one of his 10 × 12 views is a wondrous masterpiece. Hare and Ross and Dallmeyer look after the apparatus and optical departments. Notman, of Montreal, exhibits a few of his compositions—new here, perhaps, but not to us. No one else seems to do much in them. Norway, Sweden, Spain, Italy, and a few other foreign countries made a feeble attempt to exhibit, but I saw no novelties among them. The Italian Government exhibited about one hundred very pretty views of buildings, which made me sigh to see Italy again. Some Hungarian pictures are superb. And now we come to the United States department. What is shown here is not large in quantity, but generally is equal in quality to any photography on exhibition from any part of the world.

SWITZERLAND FROM A PHOTOGRAPHIC POINT OF VIEW.

[A communication to the Liverpool Amateur Photographic Association.]

Applications are occasionally made to me for information on the subject of Switzerland, with special reference to the needs and requirements of amateur photographers. Having lately returned from my twelfth visit to the Alps with my camera, I have thought that possibly the jotting down of a few notes by the way may be of use to others, and not entirely devoid of interest for our meeting tonight.

In the first place, a few words on the subject of preliminary preparations. It is hardly necessary to say that the all-important matter here is the production of the films and plates upon which those exquisite negatives which fond fancy imagines are to be developed. In this respect my misfortunes of this year have taught me very emphatically an exceedingly obvious, but nevertheless useful, lesson, viz., never to attempt a process with which, in all its details, one is not thoroughly acquainted. I had determined to take with me three cameras, and to use collodio-bromide plates in the larger of the three, my own films in the scenograph, and gelatino-beer in the quarter-plate camera. Accordingly I invested in a large bottle of collodio-bromide emulsion, and coated three dozen 9 × 7 plates. On trying a couple of these (the first and last of the batch) I found them hopelessly infected with an ailment which I had before become acquainted with in some commercial dry plates, and which an adept, whom I then consulted, informed me betokened "something wrong with the pyroxyline." The surface was covered with a mottled appearance, which ruined the picture, and left me no resource but to wash off all the films and try something else.

There next recurred to my memory a glowing description I had read somewhere of the beauty and perfection of an adaptation of the coffee process to the special requirements of Alpine scenery. Accordingly, having a large Winchester of bath solution which was worn out, and gave streaks in the direction of the dip, I sent this to the refiners', and ordered a new bath in its place. On the arrival of the latter I found myself within three days of starting, and therefore I worked hard and prepared a most promising batch of plates by this admirable process. The next morning I hastened to realise the value of my treasures. Alas! however, I speedily found that my friend the tradesman had merely filtered my old bath and returned it to me in its original condition. Every plate was hopelessly streaked with my old enemies.

There was nothing for it now but to wash the glass once more, and fall back upon a process upon which I could depend. The weather was too hot and the time too short to enable me to make a gelatine emulsion, so I telegraphed to Mr. Kennett for pellicle. I received a supply next morning, and by nightfall had all preparations completed once again for the next day's start. My films and small plates had been ready for weeks, and, with the exception of the former, fully sustained the character of the gelatine process for reliability. One hundred and thirty-nine plates were exposed on this tour, and one hundred and thirty-seven good negatives were the result, two having been spoilt by careless double exposures.

"How shall we get there?" is a question full of interest to every would-be Swiss tourist, and specially so to the photographer. My own practice and advice to others is to get the dreadful journey over as soon as possible, and make as few halts as convenient upon the way. Nothing, I think, in the way of scenery should tempt the traveller to unpack his cameras until he reaches his goal, unless both time and the supply of plates are unusually abundant. But the sturdiest and most ardent of photographers would hardly feel equal to one fell swoop upon the Alps from the point of touching the shores of the continent, and therefore a convenient resting-place, for one night at least, is a desideratum. The choice should, I think, fall upon a town in which there are good architectural subjects to be found for an early morning campaign; and when Belgium is selected as the point of departure for the long journey, Cologne, Frankfort, or Heidelberg are equally convenient as resting-places, and equally full of subjects of the right kind.

The best and cheapest route of all is that to Bale direct, by way of Antwerp, Brussels, Luxemburg, Metz, and Strasburg. As a midway halting-place by this route Treves occurs very conveniently. It is close to Luxemburg, and abounds with Roman remains of the greatest magnificence. The Porta Nigra, the ruined baths, and the superb Basilica will all prove irresistible temptations, and the town and banks of the Moselle are so full of pictures *in posse* as to render it difficult to avoid a constant employment of the camera in order to secure them *in esse.* My advice, however, to any who care to follow it would be—to arrive in Antwerp early in the morning, and secure negatives, *ad libitum*, of the Cathedral, the quaint old houses in the square, and just one canal scene near the quay. The one o'clock train gives time in Brussels for dinner and the exposure of a few plates upon the Town Hall, and, possibly, St. Gudule. But the latter is not a good subject, from the fact that the ground slopes rapidly down from the platform upon which the church stands.

Some of the people in Brussels exhibit a marked partiality for cameras. A half-plate apparatus of mine, with six double dark slides, was deposited for a few minutes on the platform, and disappeared mysteriously. Twelve beautiful plates were thus lost to me, and I much fear that their present owner will either fail to appreciate their value, or else be somewhat deficient in his knowledge of the requirements of gelatine plates.

At seven o'clock, p.m., a train leaves for Bale; and, if a good day's work has been done with the camera, and a good dinner devoured in the evening, the traveller will fall cosily to sleep, and, in spite of a few interruptions for the inspection of tickets, will "sleep the sleep of the just," and wake up for breakfast at nine a.m. in Bale. Six plates will prove an ample allowance here in the dark slide, though, possibly, not so on the breakfast table at the Trois Rois. The bridge and Rhine, the Cathedral front and terrace, and an old gateway tower will wellnigh exhaust the subjects of the first class.

From Bale decidedly the best route for those who are eager for pictures is a short detour to Neuhausen and the falls of the Rhine, and so to Lucerne. Although the height of the fall is only ninety feet, it is certainly the most impressive fall in Europe. There is a rock in the very centre of the boiling surges on the brink of the final plunge of the water to which there is safe and easy access from below. This position, however, is not a favourable one for a dry process, since both the photographer and his plates become unmistakably "wet" in a very few minutes. A point can be reached on the Schaffhausen side, from which a view may be taken of the rapids above and of the water on the verge of its descent, and a very fine picture it makes. The visitor to Lucerne ought not to be content with the ordinary stereotyped views of the place and neighbourhood. He should penetrate into the back streets and along the water side in the old town, and he will find many an old house reflected in the stream, which will amply repay him for his trouble.

My object this year was to get away from the rushing flood of tourists, and yet find myself in the midst of scenes which would yield me fine pictures. Accordingly, I determined to explore the Val d'Anniviers—one of the lateral valleys stretching southwards towards Italy from the valley of the Rhone. We halted for a day at Fribourg, as being conveniently midway between Bale and our destination. The town with its gorges, bridges, and organ delighted us all exceedingly. A compensating discomfort occurred in the extravagance of the charges in the bill at the Zahringer Hof; but I found Fribourg exceedingly rich in subjects for negatives, and obtained many good pictures. A short stay at Chillon was made with satisfactory photographic results, and then a journey—tedious only from the lazy crawling of the train—took us past the bridge of St. Maurice (said to be the finest view in the world), past Martigny and its routes to Chamounix and St. Bernard, to Sierre. Here we packed our baggage in a narrow cart and trudged along to Vissoie, the capital of the Val d'Anniviers. The road gently ascends for a mile or two along the Rhone valley heights, affording magnificent views of the Bernese Oberland and the valleys leading up to the Gemmi and the Diablerets.

On turning the corner, at a considerable height above the Rhone, the whole extent of the Val d'Anniviers, as far as Vissoie, lay before us. At our feet was an inaccessible gorge, through which the Navisanche finds its way to the Rhone; thence the valley stretched up between the mountains, closed in at its upper end by the magnificent Lo Besso and its snowy neighbours, the Gabel Horn and the Dent Blanche. The walk to Vissoie is about ten miles, along an excellent but very narrow road, at every turn of which some new glory of rock, or peak, or cascade, presented itself in maiden beauty to the camera. The gorge of the Pontis on this road reminded me of the Via Mala on the Splugen. It is quite as startling in the glory of its precipices and the abundance of its tunnelled galleries and foaming waterfalls. I had ordered the carrier to halt with the large camera at what he considered the finest "bit" on the road. Accordingly I got a good picture of one of the Pontis scenes.

We found Vissoie the very perfection of a resting-place. The village is high up on the mountains, the hotel most comfortable and most primitive in prices, the village exceedingly quaint and Swiss, and the scenery on all sides requiring adjectives of the most superlative degree to describe it. There were only two drawbacks to our complete felicity at Vissoie—one, that the bread came from the Rhone valley but once a week, and on the second day became sour and uneatable; the other that the landlord had but one joke, which he administered to us daily at dinner. The valley extends beyond Vissoie to a little village eight miles off—Zinal by name. At this place the happy photographer may live most enjoyably for four francs fifty centimes per day, and has within easy reach glacier scenery and alpine peaks and passes of the highest order of difficulty and danger. The best points of view here are from the Arpitetta Alp, over the slopes of the Weisshorn; from the Caban at Mountet, commanding the superb Zinal glazier, with a wondrous amphitheatre of snow-peaks; and the Roc-Noir, opposite to the strange but stupendous pyramid of black granite, Lo Besso.

At Zinal I found inscribed in the visitors' book the name of a member of our society, Mr. Pendlebury; but I do not think he can have had his photographic *impedimenta* with him when he made his visit, judging from the excitement which mine created among the natives, and from the careful skill with which my porter thrice dropped my heaviest camera from his shoulder to the stones.

Several passes descend into the Val d'Anniviers, near Vissoie. By one of these we had intended crossing into the Turtman Thal, after ascending Bella Tola, but the extent and depth of the snow rendered this out of the question, and we therefore retraced our steps to the Rhone Valley, and proceeded thence by Visp and St. Niklaus to Zermatt.

I have mentioned all these particulars of Vissoie and its neighbourhood in the hope that I may persuade some brother photographers to explore its glories, and gladden the heart of mine host of the hotel by their purses and presence.

There are three classes of subjects in which Swiss scenery excels, viz., snow and ice, picturesque *châlets* and villages, and rocks and rivulets. Now these are all readily obtainable in the Val d'Anniviers; and, on the other hand, there are no beggars, no *chamois-showmen*, no performers upon those marvellously-excruciating instruments which one comes across so often in the Oberland, and no demands are made for "baksheesh." You may rouse a thousand echoes everywhere by merely lifting your voice, but no cannon will startle you into deafness or extract from your pocket the grudged half-franc.

I have not reaped the full benefit I expected from the use of my films. The slide and focussing-screen answered admirably as regards portability and trustworthiness; but my batch was unsatisfactory, and I brought home but few pictures compared with the number of those upon glass. The focussing-slide gave me useful evidence of its superiority to glass. Especially was this the case on the Gorner Grat—some ten thousand feet above the nearest glacier. The slide rolled down over a small precipice (as focussing slides usually do under such circumstances) just when I was about to focus Monte Rosa, and it would have been dashed to atoms had it been of glass. I recovered it uninjured, save that it had fallen upon some snow which melted in the sun and dissolved a patch or two of the film. It has been serviceable, however, for several months since, notwithstanding the damage it sustained.

Zermatt afforded me some very fine negatives this year, and I venture to call your attention to the enlargement of the Matterhorn from a quarter-plate negative up to 25 × 17. This particular picture gave me the secret of success with this description of subject. It has always been a considerable difficulty with me to obtain a satisfactory negative when the background consists of snow peaks. The only reliable plan seemed to be to expose twice—briefly for the mountains, and the ordinary time for middle distance and foreground. I found, however, that in the early morning the light-power is more evenly diffused, and with the usual exposure of thirty seconds at 7.30 on a bright July morning I obtained a very perfect picture from this most difficult character of subject. I am trying an experiment in the case of a double exposure upon the Matterhorn, which I believe will be successful. I propose to print a single transparency from the two negatives by dint of careful masking, and then from the resulting transparency I hope to obtain a negative which shall combine harmoniously the foreground and the background.

Gelatine-film negatives have proved excellent in one respect—they never blur. Now, this immunity from the bane of dry plates has suggested to me the notion that if glass makers would supply us with plates of the peculiar yellowish tinge of the gelatine film we should then abolish the nuisance of blurring, and the equal nuisance of backing, entirely. This could easily be accomplished, I should think, without enhancing the price of the glass, and I am confident that the result would be the abolition of the backing and the consequent freedom of our negatives from most of their spots and streaks.

The photographer's route homeward will necessarily be largely influenced by the condition of his purse and his plate-box. It is usual to leave Paris as a *bonne bouche* for the last, and a most enjoyable route thither will be found by way of Strasbourg to Metz, thence to Rheims, and so to Paris. If the cathedrals of these three cities still leave some unexposed plates, and supposing that Paris is to be avoided, a most interesting route to Boulogne may be taken by way of Laon and Amiens. I once journeyed to Switzerland by this route, and was rewarded with the sight of four of the finest cathedrals in Europe. It may possibly yet be of interest to some to know that the stories of the necessary expensiveness of the Paris of the present have been much exaggerated. We lived sumptuously at a new hotel in the Avenue de l'Opera for ten francs per diem, and that in the full height of exhibition prices.

I must not trespass further upon your patience this evening, but will ask you to look upon the prints I have laid upon the table, and will then proceed to show you a few specimens of the scenery of the Val d'Anniviers in the lantern. H. J. PALMER, M.A.

FOREIGN NOTES AND NEWS.

Dr. Richard on the Elimination of the Chromates from the Carbon Print.—The late International Paper Exhibition at Berlin.—A New Portable Preparation of Collodion Cotton.

In the *Photographische Correspondenz* Dr. Richard has an article on the elimination of the chromates from carbon prints. Quite lately a number of carbon prints fell into Dr. Richard's hands which, though only two years' old, had already become lemon-yellow. This, Dr. Richard thought, was scarcely a proof of the boasted permanency of carbon, so he determined to discover the cause of the yellowing, and the result of experiments convinced him that he had found it in the defective elimination of the chromates, which in the course of time turn yellow.

An important condition in the permanency of carbon pictures is that all the chromates absorbed by sensitising, and not acted upon by the light during the exposure, should be completely removed either by the subsequent shaking or by the development. He thinks that this does not often take place, and that if some of the chromate, or rather bichromate, be not removed, owing to the prints having been left to soak too short a time before being laid upon the transfer paper, it will be enclosed between the upper and under surface, and, being pressed in by the squeegee, it may happen that the developing water does not remove it all, especially if the temperature of the water be not gradually raised.

Dr. Richard is also of opinion that the yellowing of prints is more likely to be prevented by the use of a chromate bath which is free from ammonia than by one containing a large quantity of ammonia, as the latter makes the film more horny and takes greater possession of the gelatine, especially when the tissue is floated for a long time on the sensitising bath, than when a neutral chromate solution is employed.

The *Photographische Mittheilungen* says that though the Germans have, as a rule, held aloof from the Paris exhibition, still they have had a bad attack of exhibition fever, which has broken out in various localities within the bounds of the empire. During the last few months only there has been a Hanoverian exhibition, a Schleswig-Holsteiner exhibition, an exhibition at Erfurt, and now the international paper exhibition at Berlin has just closed. It was expected that many of the exhibits at this exhibition would have been of a nature to interest photographers as such, but not so. For instance, Trapp and Münch and the Dresden photographic paper manufacturers were "conspicuous by their absence." Albumenised paper was only shown by Martin, of Dresden. Nor were photographic mounts much better represented, the only exhibitors being three Berlin firms. Steinbach and Co., however, showed both single and double raw paper as well as photographic roll paper, the width of which was equal to twice the length of an ordinary sheet. The only novelty was frames for photographs made of pressed paper-pulp, exhibited by Stavocky and Haring, of Henschdorf (Silesia). These are coloured matt, and imitate carved wood frames, than which they are much cheaper, though unfortunately the specimens exhibited were far from tasteful. Some paper with artistic watermarks, apparently printed from heliographic plates, was also shown, as were also asphalte pictures, chromolithographs, and photographs proper. There were few samples of bookbinding, and none of the preparation of albumen for photographic purposes.

In consequence of the agitation which has been going on for some time back in Austria and Germany for the freer transmission of collodion cotton, a well-known Berlin firm has patented a new preparation of the raw material of collodion, under the name of "celloïdin." This firm formerly prepared what it called "celloïdin cotton," which was a perfectly pure collodion cotton, quite free from all organic substances, such as dextrine, xyloidine, &c.

Celloïdin is prepared in the form of almost transparent sheets, like gelatine, and is neither inflammable nor explosive; when lighted it burns like paper without exploding, and carbonises slowly when heated in a test-tube. These properties allow of its being safely sent either by post, rail, or sea; but its greatest advantage is that from this celloïdin in sheets, by cutting down the sheet into small pieces and simply dissolving it in any desired quantity of ether and alcohol, a perfectly clear collodion, free from all sediment, is at once obtained and may be used immediately.

Every tablet of celloïdin having a gross weight of about 200 grammes, even allowing for a slight shrinkage owing to the drying-in of the tablet, should contain about forty grammes of pure celloïdin cotton; and to prepare a two-per-cent. collodion take one sheet of celloïdin and add as much ether and alcohol as shall increase the total weight of the collodion to 2,000 grammes, for a three-per-cent. collodion to 1,500 grammes, and for a four-per-cent. collodion to 1,000 grammes.

The celloïdon dissolves with ease, and as soon as solution has taken place the collodion is ready to be iodised. As already mentioned, the gross weight of a tablet may vary slightly owing to evaporation of part of its moisture, but the cotton contents still remain the same.

ON NITRO-GLUCOSE.

[A communication to the Brussels Section of the Belgian Photographic Association.]

For several years my attention has been drawn to a singular body called "nitro-glucose," which accompanies pyroxylines prepared at a high temperature, and which confers upon collodion the property of furnishing images of great intensity, and, at the same time, renders it eminently suitable for dry processes. In addition to this, emulsions of bromide of silver, in order that the best results of which they are susceptible may be derived from them, require, as you know, the employment of high-temperature pyroxyline. In view of the difficulty, frequently considerable, of procuring pyroxyline of this character, its relatively high price, as well as the numerous chances of failure which attend its preparation, from the fact that the strength of the acids—their respective proportions, as well as of the water added—require to be nicely adjusted to the quality of the cotton and the elevated temperature to which it has to be submitted, I have sought to utilise the properties of *nitrated sugar*, and have put the question in this form.

If it be true that it is to the presence of nitro-glucose that high-temperature pyroxylines owe their property of giving a very intense collodion, we ought to be able to attain a like result by the direct addition of a certain quantity of that substance to a collodion prepared from low-temperature pyroxyline. The experiments to which I have devoted myself have amply justified my view of the question, and the object of this communication is to make you acquainted with the results I have obtained. But, first of all, what is nitro-glucose?

As its name implies it belongs to a family of compounds, very numerous at the present day, endowed with more or less explosive properties, and some of which—such as nitro-cellulose or pyroxyline, nitro-glycerine and nitro-benzine—are familiar to you. All these bodies have their origin in a special action of nitric acid, known in chemistry under the name of "nitro-substitution," and which consists in the replacement of one or more atoms of hydrogen by an equal number of molecules of hypo-nitric acid; thus, under the influence of nitric acid, cellulose is converted into fulminating cotton according to the following equation:—

$$\underset{\text{Cellulose.}}{C^6\,H^{10}\,O^5} + \underset{\text{Nitric acid.}}{3\,N\,HO^3} = C^6\,H^7\,(NO^2)^3\,O^5 + 3\,H^3\,O.$$

As it is important to fix the water thus formed—otherwise the nitric acid would set up *oxidation* in place of *substitution*—it is necessary to add a certain proportion of concentrated sulphuric acid. According to the degree of concentration of the acids, and the temperature employed, we are enabled to vary the substitution compound; thus, by employing a weaker nitric acid and a higher temperature we obtain *photographic* pyroxyline, $C^6\,H^8\,(NO^2)^2\,O^5$, in which two atoms of hydrogen are replaced by two molecules of hypo-nitric acid. An entirely similar action is no doubt produced in the preparation of nitro-glucose; and though, as far as I am aware, no formula has been published,* it seems to me that, on the basis of analogy, the composition of this body may be expressed by $C^6\,H^9\,(NO^2)^3\,O^6$, the formula of glucose being $C^6\,H^{12}\,O^8$.

The Preparation of Nitro-Glucose.—The method of preparing nitro-glucose is in every way similar to that of pyroxyline, save that in place of nitric acid of density 1·4 it is necessary to employ the monohydrated acid having a density of 1·5, and known under the name of "fuming nitric acid;" it is also indispensable, as in the case of fulminating cotton, to cool the mixture of fuming nitric acid and of monohydrated sulphuric acid (the density of which is 1·842 or 66° Baumé). For one part of nitric acid we take one to two parts of sulphuric acid, and as soon as the temperature has descended to (say) 10° or 15° C. we add, gradually, by small spoonsful, ordinary refined sugar reduced to a very

* The *Traité de Chimie*, of Schwarts, vol. ii., p. 353, gives the formula $C^{12}\,H^{18}\,(NO^8)^4\,O^{11}$.

fine powder, taking care to stir the mixture thoroughly with a glass rod. As soon as the sugar comes in contact with the acid mixture it assumes the form of viscous clots, which remain suspended in the liquid or become attached to the sides of the vessel. It is difficult to fix the exact proportion of sugar which can be thus converted into nitro-glucose, as the quantity will always depend upon the degree of cooling obtained, &c.; and, though some writers assert that for three or four parts of the acid mixture one part of sugar may be used, I find it better to cease adding the sugar as soon as by the formation of water the temperature rises to 30° C.

In the course of preparation red vapours of hypo-nitric acid are sometimes evolved, but the formation of these may frequently be arrested by stirring the mixture vigorously with the glass rod. Although the transformation of the sugar into nitro-glucose proceeds rapidly, it is convenient to prolong the action of the acids for four or five minutes. The acid mixture is then poured into a large porcelain basin containing ordinary water, in which the nitro-glucose, being insoluble, forms itself into small, pasty lumps, settling rapidly to the bottom of the basin or adhering strongly to its sides, permitting the acid to be decanted and replaced by water, which may be again replaced by a fresh quantity of the acid mixture if needful; so that by successive precipitations and decantations the whole quantity of nitro-glucose may be collected at the bottom of the basin. With a rod or small plate of glass the viscid mass is detached from the vessel, having a greyish white appearance, sometimes slightly reddish from the presence of hypo-nitric acid, and kneaded into a solid mass, which is immediately submitted to washing. This operation, long and tedious from the pasty nature of the substance, can only be effected by treatment similar to that to which butter is submitted, only that in place of using the hands we have recourse to a pestle and mortar, with which the mass is kneaded, changing the water frequently until it exhibits not the slightest acid reaction to blue litmus-paper. It is finally washed in distilled water until a small quantity of this water filtered gives no cloudiness with solution of nitrate of silver.

The nitro-glucose may be preserved under distilled water in a wide-mouthed, stoppered bottle. Notwithstanding the most careful washing, nitro-glucose thus kept under water disengages within a short time of its preparation, slowly but continuously, nitric acid.

Physical Properties.—Nitro-glucose presents the form of a pasty, sticky substance, white, sometimes slightly grey, plastic and adhering to the fingers, and capable of being drawn out into long, white threads of a silky lustre. Dried in the cold it becomes hard and brittle; left in water it again becomes soft and sticky. Without taste or smell, it behaves in the presence of solvents after the manner of a resin; it softens under the action of heat, and explodes at a higher temperature. In the same manner as glucose it acts upon polarised light, turning to the right the plane of polarisation.

Chemical Properties.—Nitro-glucose is insoluble in water, soluble in ether as well as in alcohol, though it does not dissolve rapidly except in boiling alcohol. The hot saturated solution allowed to cool deposits a certain quantity of nitro-glucose, which a fresh quantity of alcohol again dissolves. I have found in this way that one part of moist nitro-glucose requires seven to eight parts of alcohol of 96° for its complete solution at ordinary temperatures. The alcoholic solution poured into water gives a white precipitate of nitro-glucose in a state of very fine division, which does not settle to the bottom of the vessel for several days. A solution of caustic potash poured into alcoholic solution of nitro-glucose produces rapid decomposition even at ordinary temperatures; the liquid discolours, and the products of the decomposition are, without doubt, identical with those obtained in the case of glucose. It is also decomposed by solution of cuprous chloride, and it is probable the same occurs with stannous chloride and ferrous sulphate, which, as we know, decompose pyroxyline.

Alcoholic solution of silver nitrate poured into a similar solution of nitro-glucose produces a cloudiness, or even a precipitate, more or less considerable. The precipitate which remains white in the dark discolours rapidly in daylight, and deposits a blackish powder, which consists of reduced silver. This powder, collected on a filter and carefully washed, is dissolved by nitric acid with evolution of ruddy vapours; and hydrochloric acid produces with it a precipitate soluble in ammonia. Glucose exercises on silver nitrate a still greater reducing action, as it manifests itself even in the dark. When a little ammonia is added to the mixed solutions of silver nitrate and nitro-glucose, or of silver nitrate and glucose, the reducing action is considerably increased. According to Hardwich, the intensity of collodions prepared from high-temperature pyroxyline is due to the combination which takes place between the silver nitrate and the nitro-glucose. Such is not the opinion of Dr. van Monckhoven, who holds that it is not with this latter body that the combination takes place, but with a compound arising from its decomposition. According to that gentleman an alcoholic solution of recently-prepared nitro-glucose is not clouded by the addition of silver nitrate; but if this solution be several days' old the nitrate of silver produces an abundant white precipitate very sensitive to light. My experience, on the other hand, agrees with Hardwich's view; for I have always found that newly-prepared nitro-glucose, as well as that kept several weeks in the state of alcoholic solution, is clouded by silver nitrate when the solution of nitro-glucose is sufficiently concentrated; otherwise it only produces an opalescence more or less pronounced. A further proof that the combination of the silver salt takes place with the nitro-glucose itself, and not with a body resulting from its decomposition, is found in the fact that an alcoholic solution recently prepared and added at once to collodion gives, in the state of emulsion, the same density as is obtained with a solution which has been kept several weeks.

M. DE PITTEURS.

(To be continued.)

Our Editorial Table.

ANTHONY'S SOLUBLE COTTON.

Liverpool: J. J. ATKINSON.

MANNERS and customs in trades and professions, as well as in social life, vary according to the different countries in which these are practised. For example: in our own country few photographers ever make the collodion they use, preferring to purchase it ready prepared. They rightly believe that those who devote much of their time to the production of any specific article are much more likely to succeed in its proper manufacture than he who does so in perhaps a *dilettanti* manner at occasional intervals. In America, on the contrary, it appears to be the custom of photographers to prepare their own collodion, in the same way as they prepare the baths, developers, and other compounds employed.

Readers of the American journals, or of such extracts as we present of them from time to time, will have noticed that when a photographer indicates his method of working he almost invariably sets out by giving the formula by which his collodion has been prepared—a fact corroborating our remark as to the universality of the practise of the home manufacture of this indispensable production. But, while preparing their own *collodion*, American photographers very wisely draw the line at the preparation of the pyroxyline, or "soluble cotton," as our transatlantic brethren prefer to term it.

The soluble cotton manufactured by Messrs. E. and H. T. Anthony and Co., of Broadway, New York, has for a long period enjoyed a very high reputation, the process by which it is manufactured having been patented five years since in America. Had a patent been obtained for England we should have been enabled to communicate to our readers all about its method of preparation; but, under present circumstances, it is only left for us to review the sample that has been placed at our service by Mr. John J. Atkinson, of Liverpool. Upon placing a portion of it in a mixture of ether and alcohol it dissolved in the most perfect manner, without leaving even a trace of residue. When it was afterwards iodised it yielded a collodion of admirable quality, and which possessed every advantage that could be desired. The formula by which it was iodised is that which is given on page 210 of THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for the present year.

We embrace this opportunity of acknowledging the receipt of some samples of collodion, ready iodised, which were handed to us by Mr. E. B. Barker, of the firm of Messrs. Anthony and Co., when that gentleman last visited London. This collodion gave most charming results, a peculiarity in its working being that with a weak iron developer full printing density was at once obtained, without the necessity for the employment of any intensifier afterwards. We presume it was made from pyroxyline similar to that to which we have above referred. Perfect transparence, freedom from crapiness, sensitiveness, and excellent half-tone are its characteristics. The "soluble cotton" is well adapted for emulsion processes, although it does not appear to have been prepared with this end in view.

THE UNIVERSITY MAGAZINE.

London: HURST AND BLACKETT.

FOR the reason given when noticing a previous number of this *Magazine*, we much prefer the portraits which form the illustrations when they are printed from negatives taken by Messrs. Lock and Whitfield. The lighting, gradation, and intensity of their negatives are such as to render them specially adapted for printing by the Woodbury process.

The noble portrait of Professor Max Müller, with which the October number is illustrated, is one of the finest that has yet graced the pages of the *University Magazine*. The eminent occupant of the chair of Comparative Philology at Oxford is represented in profile. From the biographical sketch accompanying the portrait we learn that Professor Max Müller was born at Dessau on the 6th December, 1823, and was educated at Leipzig. He came to England in 1846 to collate the manuscripts belonging to the East India Company and those of the Bodleian Library, with a view to the publication of the "Rig Veda," the earliest sacred hymns of the Brahmins. Literary honours were soon showered thick upon him, and he is now recognised as one of the most profound Sanskrit scholars in the world. The portrait, by Messrs. Lock and Whitfield, is an excellent one, and is admirably printed by the Woodbury process. The other articles in the magazine are of the usual high type.

GIHON'S PHOTOGRAPHIC COLOURISTS' GUIDE.
Philadelphia: EDWARD L. WILSON.

IN this manual Mr. John L. Gihon, with whose name our readers are familiar, haa embodied his own experience, together with the suggestions and useful items received from many artistic friends. In addition to remarks on India-ink work the author treats of water colours, oil paints, pastels, negative retouching, and rudimentary perspective. The work is written in a pleasing style and contains much useful information. For these reasons it is certain to find much favour among photographers. Its publication is confined to America.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
October 7	West Riding of Yorkshire......	Oddfellows' Hall, Bradford.
,, 9	Glasgow	172, Buchanan-street.
,, 9	Cheltenham Amateur..........	Savings' Bank.
,, 10	Manchester (Annual Meeting) ..	Memorial Hall, Albert-square.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE usual monthly meeting of this Association was held on Thursday, the 26th ult., at the Free Library, William Brown Street,—Mr. H. A. Wharmby, President, occupying the chair. Being the first meeting after the summer recess there was a very good attendance.

The minutes of the last indoor and the two outdoor meetings having been read and passed, Messrs. R. H. Forman and F. W. Birchall were elected members.

A resolution, proposed by the Chairman and seconded by Mr. J. A. Forrest, was passed, conveying a vote of thanks to Miss Watt, of Speke Hall, by whose kind permission the Association held an outdoor meeting on 25th July, in the grounds.

The following resolution, proposed by Mr. T. Clarke, seconded by Mr. E. Whalley, and supported by Mr. J. A. Forrest, was also passed:—"That this Society tenders to the Right Hounourable W. E. Gladstone its best thanks for his kindness in permittiug the members of the Manchester Photographic Society and the Liverpool Amateur Photographic Association to photograph in Hawarden Park on Saturday last, and also to express its appreciation of the friendly manner in which he personally tendered information as to the most desirable views and points of interest in the park."

The Secretary *(pro tem.)* was instructed to transmit both the above resolutions to the proper quarters.

The pictures produced at Speke Hall were then passed round. The prize—a beautiful album, given by Mr. J. A. Forrest—was adjudicated by Mr. Sayce to Mr. Potter, for the best picture taken on the day of the excursion, for an exceedingly beautiful view of Speke Hall.

Mr. Houlgrave exhibited several fine pictures taken from negatives on collodion and gelatine plates for purposes of comparison. The results were certainly much in favour of collodion.

Mr. J. H. T. Ellerbeck explained that he had by mistake exposed a "Bennett" plate for half-an-hour aud a "Pollitt" plate for half-a-minute, the curious result being that the usual development produced a decided transparency on the "Bennett" plate instead of an over-exposed negative, while even on the "Pollitt" plate an image was produced, although the plate was utterly spoiled for printing purposes owing to the large amount of carbonate of soda used.

Messrs. Weber, Potter, Kirkby, Boothroyd, and Clarke brought a large quantity of very fine results from gelatine and collodion emulsion and other plates, all of which proved a great advance on those of former summers.

The Rev. H. J. Palmer spoke of developiug gelatine plates with the ferrous oxalate, the results being very satisfactory, no toning being required for transparencies. Much pleasure was expressed in examining a very good enlargement 24 × 18 from one of his recent gelatine negatives—a view of the Matterhorn. He (Mr. Palmer) then read a paper on *Switzerland from a Photographic Point of View* [see page 473], illustrated with views taken during his summer trip to Switzerland, and which, from their number and quality, prove him to be a most careful and indefatigable worker.

Owing to the lateness of the hour and the large amount of interest already before the meeting the lantern exhibition was postponed for a future evening, and, after a vote of thanks to Mr. Palmer and other contributors, the meeting was then adjourned to the 31st inst.

THE BRUSSELS SECTION OF THE BELGIAN PHOTOGRAPHIC ASSOCIATION.

AT the June meeting of the above Section a communication was made by M. de Pitteurs, of St. Trond, on the subject of nitro-glucose, the disscussion of which formed the only business of the meeting. After the reading of the communication, the first portion of which will be found on page 475,

Dr. VAN MONCKHOVEN remarked that the practical importance of the addition of nitro-glucose to the collodion for emulsion purposes could not remain in doubt after an examination of the negatives exhibited by M. de Pitteurs. Some years ago he had prepared large quantities of nitro-glucose, and he had found great want of unformity in the products obtained. He had been in the habit of purifying the nitro-glucose by dissolving it in alcohol and reprecipitating it in water, and he thought it would be well if M. de Pitteurs would describe very particularly his method of preparation in order that others might be enabled to attain identical results. He said he had frequently observed that the addition of silver nitrate to a fresh solution of nitro-glucose produced no immediate precipitation, whilst old solutions invariably gave a precipitate, as is also the case with old non-iodised collodions, which are said to give great intensity; he considered it very possible, however, that his solutions were not sufficiently concentrated. He further expressed his opinion that none of the nitro-substitution compounds combined directly with nitrate of silver. According to his view considerable importance was erroneously attached to the temperature in the preparation of pyroxyline. He believed that the differences observed arose from the presence of resinous matter in the cotton, and he had found that cotton previously washed in soda gave the same results when prepared at a high or low temperature. For dry plates, by employing very resinous cotton great density was obtained. He inquired whether M. de Pitteurs could state what was the colour of his bromide films by transmitted light.

M. DE PITTEURS replied that he had not paid any special attention to that point, but he believed that the colour was orange.

Dr. MONCKHOVEN said it would be extremely interesting to try whether such films were sensitive to the red or orange rays of the spectrum.

M. ROMMELAERE announced his intention of undertaking a series of photo-spectroscopic researches, and of repeating some of the important experiments of Captain Abney iu that direction.

Dr. MONCKHOVEN said that, looking at the recent experiments of Captain Abney, Vogel, and others, we were not far from attaining a process which would enable us to prepare plates sensitive to the green rays. This would be of the greatest utility, not only in landscape work but also to the professional photographer in the studio, and for the reproduction of paintings, &c.; for, if the plates be sensitive to the green, it is probable they will be so also to the red and yellow rays, aud thus we should be no louger subject to the defect inherent to existing processes, by which deep colours—as blue and indigo—are rendered lighter, whilst light colours—yellow and red—are reproduced darker, than in nature.

A vote of thanks was passed to M. de Pitteurs for his communication, which it was resolved to publish in the *Bulletin* of the Association.

PHOTOGRAPHIC SOCIETY OF VIENNA.

AT the May meeting of this Society the chair was taken by Herr Melingo, in the absence of Dr. Hornig.

Business was commenced by the admission of three new members. A letter was then read thanking the Society for the laurel wreath which had been placed, in its uame, upon the grave of the late Herr von Voigtländer. Captain Tóth was elected a member of the managing committee of the Society in the room of Dr. Eder, resigned.

The Secretary laid on the table some samples of Berthold's paper substitute for liuen plate polishers, and a copy of *I Moderni Processi di Stampa Fotografica del Luigi Borlinette*, richly illustrated by specimens of carbon printing, lichtdruck, zincography, and heliography, after which he read au article from the *Wiener Medicinischen Blätter* upon the quivering of the eyes of the sitter when being photographed.

Dr. Székely showed a drying oven of the construction recommended by Professor Husuik, as well as some specimens of the results obtained by the dusting-on method of multiplying the negative described in the work of the latter.

To the question as to whether any gentleman present had obtained good results with the dusting-on process,

Herr HAACK said he used to dabble with that process, but his results were never all that could be wished. The principal drawback he had to contend with was that the copy negative always appeared over-exposed in the lights or shadows—in short, that he could not secure the proper proportionate distribution of light and shade given by the original negative.

The Secretary then read an extract from the *Neuen Freien Presse*, of the 6th March, which had been placed in the question-box, accompanied by an inquiry as to the correctness of its statements, the name of the learned Frenchman, wherein his process consisted, and how far The British Journal of Photography was justified in its remarks. The article was headed *Telegraphic Photography*. It has been said that a French *savant* had found a practical way of transmitting photographs to a distance by means of the telegraph, and that the French police propose to utilise it for the detection and arrest of criminals. The British Journal of Photography gives an exact description of the method, which is based on the same principle as the Bonelli-Hipp writing telegraph. "As in the latter the writing remains white on specially-prepared paper, while the portions of the paper unwritten upon are coloured blue by strokes of the telegraphic pencil placed close beside each other, so in like manner the photograph is reproduced, though somewhat coarsely."

After receiving the above questions Herr Quidde had communicated with Herr Wimpfen, the inspector-general of Austrian telegraphs, who informed him that as yet it had not been found possible to reproduce a photograph exactly by telegraph, though it might be done with approximate precision when, as in Baird's apparatus, the portrait is first transferred to a sheet of metal and then drawn in strokes of various thickness, which allow of isolation. Still, even with an apparatus like the medallion Guillochir machine, in which the Woodburytype metal plate of a portrait is placed, and the movements of a lever passing over the surface of the plate are transmitted by telegraph, an exact reproduced portrait with all the half-tones is not to be expected.

Baron Schwarz said that ten years ago he had seen an apparatus working between Paris and Lyons which telegraphed handwriting and outline portraits, but from its cost, as well as from technical objections, it could not be generally employed.

Herr Silas remarked that on account of its enormous cost Caselli's pendulum telegraph had not been employed for this purpose, though well adapted to it.

A specimen of mastic was exhibited and the reason of its non-solubility in benzine was asked, to which Herr Haack replied that the person who put the question had evidently bought an adulterated powdery sample of mastic, and advised him in future to buy it only in small lumps, when it ought to dissolve readily in benzine. The meeting was shortly afterwards adjourned.

Correspondence.

REMOVING PYROGALLIC STAINS FROM THE HANDS.

To the Editors.

Gentlemen,—I notice in your "Answers to Correspondents" (in reply to a query from a "Country Parson"), that you recommend friction with a piece of pumice stone, using soap as a lubricant, for removing stains from the hands. It is very good; but I think you will find the method I send you quite as good and much more pleasant to use. It is as follows:—

I have a bottle filled with silver sand placed on the washstand, or where the hands are generally washed. Get a good lather of soap on the hands first; put the piece of soap out of the way, and then shake from the bottle some sand into the palm of the hand, and proceed to rub over the hands, especially where stained. It is surprising how quick the stains are removed, and how pleasant and soft the hands feel after the above treatment. Of course wash off with clean water.

Keep the sand away from the piece of soap, or it will make the soap very disagreeable to use.—I am, yours, &c., Richd. Crowe.

25, *Williamson-street, Liverpool, September* 30, 1878.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

☞ With reference to the series of articles on *Photomechanical Printing Methods* by Mr. Thomas Bolas, F.C.S., the first of which appears this week, the author will be happy to reply, in our "Answers to Correspondents" column, to such queries respecting the subject as may be forwarded to him through us.

Erratum.—We regret that an error occurred in the "making up" of the formes of our last number, whereby the two lines which should have followed those terminating the first column, page 458, have been transferred—not to the column immediately succeeding this, but to the first one on page 459. Will our readers kindly make a note of this?

R. Peers.—You must state what is required.

Dr. Liesegang.—Accept our thanks for your courtesy.

S. J.—For terms apply to the Autotype Company, Rathbone-place.

G. A. L. P.—One fertile source of yellow spots in prints on albumenised paper is the presence of minute metallic particles, mostly to be found in the back of the paper.

R. R. Brown.—There is a manual of the ferrotype process. We are not aware who is the publisher, but you will doubtless obtain it on application from some of the dealers in photographic materials.

Felix (Leeds).—Professor Husnik's method of preparing photolithographic transfer paper was published last year. It will be found in our Almanac for the present year, to which we refer you.

R. H. L.—The formula for the varnish will be quite as effective if the oil of lavender be omitted, but the odour will be unpleasant. Oil of spike and essence of lavender are not the same substance.

Old Hypo.—1. Let the mixture be composed of equal parts by weight of the uranium and ferridcyanide.—2. Persulphate of uranium costs from one shilling and ninepence to three shillings, according to circumstances.

C. T. P.—Instead of using carbonate of ammonia in the developer, try the effect of ordinary washing soda in the proportion of one drachm to each ounce of water—of course making use of bromide of potassium as a restraining agent.

Capt. B.—By addressing a note to Mr. A. J. Melhuish, who is the honorary secretary, you will receive all necessary information with respect to the Amateur Photographic Association, including the terms upon which members are admitted.

T. H. H. B.—Certainly; but, while oxygen may be produced by the process you describe, it is a very tedious and expensive one, and you will study your own comfort and interests by confining yourself to the method by chlorate of potash.

Geo. Hercus.—We tried the sample of pyroxyline you forwarded, but found that it was very bad, being quite unsuitable for collodion. We have no means of ascertaining to what the failure was owing. Try again, making use either of the same or of another formula.

Polaris.—The nitre-sulphur light enjoyed popularity for only a brief period. It seems now to have "gone out;" at anyrate we never hear it so much as spoken of. Such particulars as are known concerning it will be found in the numbers of this Journal published early in 1875.

Anglo-American.—Although a patent was applied for, the protection granted did not extend beyond six months; hence you are quite at liberty to practice the process, provided you imagine that it contains a germ of value. Our own opinion was published more than twelve months ago.

J. D. L.—Our thoughts and intentions have been running in parellel grooves. We shall communicate privately with you soon with a view to determining upon the best manner by which to enable the public to be participants in the advantages that would undoubtedly follow the selection proposed to be made.

A. S. F.—From your description of the iodide of ammonium it is quite evident that it has become decomposed. Try the effect of placing the whole of the contents of the bottle in an evaporating dish, adding two or more drops of sulphide of ammonium, and slowly applying such a degree of heat as to drive away the water.

Obliged Reader.—1. If you colour the slides with aniline preparations it will be a source of regret, as they will fade sooner or later.—2. The manual named appears to be a good one, but we can only judge of this from an edition published about twelve years ago. Possibly another edition has since that time been issued.

A. A. Campbell Swinton.—The address as given by you—that is, the name and the city—will prove sufficient to ensure a letter reaching the gentleman. Mr. Solomon, of Red Lion-square, is the only dealer in London by whom the article required used to be kept; it is possible that he may still have some of it or be able to procure it.

A. J. Jarman.—We are quite unable to inform you how to make chloroplatinate of potassium "readily," for this is not yet known, but by consulting *Fownes* you will discover the means by which it may be made, although these are not very simple. Ferric oxalate may be procured from Messrs. Hopkin and Williams. We shall be in a position to give further details concerning the platinotype.

E. T. Whitelow.—1. In reply to your query respecting the solubility of protosulphate of iron, the following will prove an excellent and instructive bit of chemical amusement:—Pour into an evaporating dish an ounce, by measure, of the solution of protosulphate of iron, and apply heat until the water has evaporated. By weighing the remaining crystals and allowing for their bulk in the solution you will have your query answered. We, like you, have found much diversity in the publications on this subject.—2. By inserting a slip of litmus-paper in the alcohol you will easily ascertain whether the acid was or was not added. It might even be ascertained in a more "rough-and-ready" manner by adding to a small portion of the solution a minute lump of chalk, which would cause an effernescense.

Sad End of a Photographer.—On Saturday last, the 28th ult., an inquest was held at the "Cape of Good Hope," Limehouse, touching the death of David Henry Poole, aged forty-four, of Robin Hood-lane, who had died under the following sad circumstances:—Deceased, a photographer, had long given way to habits of intoxication, and while in that condition was perfectly ungovernable. On Wednesday he had started drinking early in the morning, and at midday a brother photographer fetched him out of a public-house and took him home. After a great deal of trouble he induced him to lie down, and left him covered with a blanket in a sound sleep. His son coming in soon afterwards found him lying on the floor with a cut on his temple, evidently caused by falling out of the chair in which he had been placed. A doctor being sent for he was found to be quite dead. Dr. Brunton, who had made a *post-mortem* examination, attributed the death to hemorrhage into the brain—the combined result of his drinking and quarrelsome habits and the fall. A verdict to that effect was returned by the jury.

THE PHOTOGRAPHIC EXHIBITION.

Apart from the fact that the *conversazione* with which the Exhibition was inaugurated on Tuesday evening last was somewhat unpleasantly crowded, there was no doubt whatever as to the *soirée* having proved a genuine success. Everybody, too, seemed to consider that the pictorial display was also successful, with the exception, perhaps, of the time-honoured dissentients who, abstaining from being exhibitors themselves, therefore "knew all along it would prove a failure." Absentees notwithstanding, the Exhibition is a good one, and is fairly representative of the best class of what we shall designate "everyday photography" in contradistinction to special efforts made by those whose time, not less than their artistic ability, permits them to prepare works expressly for exhibition.

The walls of the room are well covered, and the hanging very artistically effected. While we this year miss the productions of such exhibitors as Colonel Stuart Wortley, Messrs. Robinson, Blanchard, Viles, Crawshay, York, Whiting, Fry, Beasley, Mawdsley, S. G. Payne, Mrs. Payne, and others who have contributed to previous exhibitions, we notice the names of several artists who have hitherto withheld their work from these annual displays. We are glad to find that the various dry processes at present in use—mainly emulsion processes—are well represented.

Contrary to the customary usage the medals have already been awarded.

In *genre* pictures we are much pleased to renew our acquaintance with the large dog of Mr. Geo. Nesbitt, who has obtained a medal for his picture entitled *Broken Leg* (No. 212), representing a girl and *the* dog. Of the other exhibits of this artist we shall speak by-and-by.

The two medals offered for "the picture or series of pictures which, in the opinion of the judges, shall display the greatest amount of excellence" have been withheld, none in *their* opinion being apparently worthy of such awards.

The medal offered for "the best landscape or series of landscapes" has been divided, so to speak, one medal having been awarded to The Military School of Engineering, Chatham, for a *View near Bettwys-y-Coed* (165), and another medal being given to Mr. Vernon Heath for a frame of four views, *The Hills of Skye* (11).

For "the best portrait or series of portraits" the promised medal has been withheld, none seemingly being thought deserving of such distinction. The same verdict applies in the case of the medal offered for "the best transparency," and also for "the best microphotograph or series of microphotographs." Let it be distinctly understood that we are not here recording *our own* opinion of the merits of the pictures, but only that of the judges.

One of the two medals promised for "the best photo-mechanical prints" has been withheld; the other has been awarded to the frame of prints entitled *Book Illustrations* (321), exhibited by the Woodbury Company.

For "the best single figure study" the medal has been awarded for one of the figures in *The Seven Ages of Man* (293), by Mr. Augustus W. Wilson.

The inventive skill of Mr. Cadett, whose ingenious pneumatic shutter we described a short time since, has been appreciated by the judges, who have awarded to this gentleman the medal "for apparatus."

It will be remembered that medals were placed at the disposal of the judges "for any novelty, or other form of excellence, in process or result." Acting under the discretionary powers thus conferred, the judges have awarded a medal to Mr. Payne Jennings, for a frame containing eight instantaneous effects, *Sea Studies* (199).

As in previous years, we will next week commence a systematic series of articles dealing critically with the pictures exhibited; meanwhile, we shall devote a brief space to the apparatus and the contents of the large table in the centre of the room.

This table is, indeed, very richly laden. In attempting to describe the various exhibits here displayed we shall commence with those we consider the most important. Agreeably with this intention we shall describe the imposing collection of apparatus sent by Mr. George Hare, of Calthorpe-street.

To the non-photographic visitors the two revolving albums of Mr. Hare proved the main source of attraction on the opening meeting; for, as the well-balanced body was rotated on its axis, displaying fresh pictures at each revolution, wonder and delight were apparent in the face of each spectator. The *connoisseur*, moreover, saw in these albums the most perfect finish capable of being put upon wood; while the professional photographer as certainly recognised in them an important addition to the attractions of the waiting-room connected with his establishment. For us, however, the newly-designed cameras of this maker possessed a greater degree of interest than even the most approved appliances for the mere exhibition of pictures; and we were pleased to have an opportunity of examining *facsimiles* of two of the cameras for which a medal has just been awarded to Mr. Hare at the Paris International Exhibition. So far as we could perceive, from a careful examination of one of these cameras adapted for 10 × 8 pictures, its leading features are comprised in the following:—Owing to a particular formation of the base-board it has a double range of extension and adjustment, one of these motions being, to employ microscopic language, "coarse," and the other "fine." The "coarse" adjustment is, however, one of extreme smoothness in itself, being effected by sliding back the body of the camera in appropriate slots in a light brass frame-work upon the main sliding base-board of the instrument. In this state it forms a camera of great utility, capable of producing nearly every description of picture required in ordinary practice where a lens having a moderate width of angle is employed. But by the operation of a rack and pinion the supplemental base-board, to which is affixed the the back of the camera, is made to slide out a considerable extent farther—so much so that it can be used as a copying camera. The back of the camera is so constructed that the photographer may at the last moment, and after focussing and arranging his subject, vary the direction of the plate from a horizontal to a vertical position. When packed up this camera occupies a marvellously small space. We have been thus particular in describing it inasmuch as it is the only English camera that received the distinction of a medal at the Paris exhibition.

Of the automatic changing-box exhibited by Mr. Hare we need not now speak, as it has already been described in our pages, and has taken its position as an almost indispensable piece of apparatus in connection with dry-plate work.

Only a brief period having elapsed since we had an article on the electric method of exposing, associated with the names of Messrs. Cowan and Cussons, we need here only say that one of the most recently-constructed electric shutters is to be seen on the table. It is in full action—a fact that may be immediately ascertained upon pressing the ivory button in the end of the pear-shaped wooden handle which forms the terminus of the cord.

Messrs. W. W. Rouch and Co. also exhibit two of their recently-patented cameras, of which we gave a detailed account in our issue for August 30th. [See page 408, *ante.*]

Here we must take leave of the apparatus for the present, promising to return to the subject next week. As in former years, we give such notices of the Exhibition as have appeared in the London daily press up to the present time. These will be found in another portion of the current number.

ON THE QUALITIES DESIRABLE IN A NEGATIVE.

We commence this article by asking the question, "What constitutes a good negative?" Probably if we took the suffrages of our readers we should obtain a wonderful variety of replies, each individual expressing an opinion based upon the standard of his own productions. In point of fact there exists no general standard of quality. We are in the habit of seeing prints of a more than ordinary degree of excellence, perhaps; and we find ourselves in a position to appreciate the beauty of the *tout ensemble*—possibly to pick out one or two points in which they excel the ordinary run of photographic work, but that is all. It never occurs to us to ask ourselves the question, "What sort of a negative was that produced from?" or to attempt to get at the real cause of its superiority. We are content to accept the final result as it is presented to us, and to look upon the negative as merely one step towards that result.

Thus it is that too many go groping, as it were, in the dark, turning out negatives of more or less excellence, and content if they come up to the standard of quality, *as negatives*, which they themselves have created, and never, perhaps, dreaming of judging them by the test of their printing qualities. How often do we hear remarks such as "This negative ought to give a much better print!" or "I never expected that negative to print so well!" In the first case, when, after repeated trials, the negative will *not* "give a better print" the blame falls upon the printing arrangements, and, possibly, some unfortunate albumeniser feels his "ears tingle" without knowing the reason why. The second result is set down as one of those lucky "flukes" which "*will* happen," but there is no attempt to discover the *raison d'être* of the unexpected excellence.

The fact is, the practice is too prevalent of judging the negative solely by its appearance, and "pretty" negatives have become the fashion, or are sought after, with an entire disregard of the ultimate purpose they are required to fulfil. It would, we think, be time profitably employed if our readers would devote some of their spare evening hours to a careful study of their negatives, comparing them with the prints therefrom, and noting the special character of negative which produced any uncommon effect in the print. It is not necessary for such an examination that the negative be a perfect one, or even a passable one as *a whole;* for it frequently happens that a picture spoilt by over- or under-exposure contains a tree or a mass of foliage, a foreground or a distance, which is rendered perfectly, though the rest of the plate is useless. Better still would it be if the examination could be extended to the work of others; for as every photographer possesses, to a certain extent, a style of his own, an opportunity would thus be afforded of studying a new class of effects, not, perhaps, found in the photographer's own works. In this manner the eye would be trained to a better perception of the printing value of the negative, and the operator would be taught the class of image to aim for in developing. Development, without doubt, is the most important step in the production of the picture, and, unless commenced with a clear understanding of what is expected from it, the quality of the sensitive film, the proper illumination of the subject, and the correct timing of the exposure, avail little or nothing.

We come back to the question, "What constitutes a good negative?" We recollect once hearing the question epigrammatically answered thus—"Density in the lights, detail in the shadows, half-tone throughout"—three most desirable qualities, nay, indispensable, for no negative will pass muster without them; but the description is incomplete. We have a negative before us as we write, the subject a rural one, consisting of a farmstead and outbuildings, with a grassy foreground and dense foliage for the background. In nine cases out of ten the verdict would be that the negative is all that could be desired, and we invite our readers to take an imaginary glance at it as we point out its salient features. The principal object, the farmhouse is a low, white, rough-cast building, with thatched roof—a difficult subject and highly unpicturesque, unless treated as Millais treats white satin—the outbuildings brick and dark stone, with here and there a patch of vegetation, the tiled roof almost hidden by vari-coloured lichens, and the surrounding foliage in the full luxuriance of summer.

Take a good look at the negative; you will see that though the white building is dense almost to opacity there is plenty of detail visible. Here on the front a patch of the "rough-cast" has fallen away and laid bare the bricks, which have been re-covered with whitewash. See! under the windows the rain has drained away from the sills, leaving dark streaks, and there on the gable end the drainings from the thatch have left traces which even the broad glare of sunshine has been unable to hide from the camera. Trace the courses of the stone in the masonry of the granary, and note the variations in the shades of colour of the different blocks; count the trees in that mass of foliage at the back; you can almost do it, so faithfully are they rendered and so complete in detail. Density, half-tone, detail everywhere, and, yes! under that wood-shed, where the sunshine is cut off sharply by the projecting roof, there is a patch of clear glass. Certainly the negative seems perfect in every respect; but let us examine the prints.

We have two here, but surely they do not come from the negative we have just examined. This darker one certainly renders the central object to perfection—thatch, whitewash, weather stains, and all; the granary, too, comes out well, and the roof of the cowhouse, with its covering of lichens, is admirable; but where is all the detail in the foliage? This other print renders the foliage well, but the outbuildings are feeble and poor in tone; the house *is* whitewash and nothing else, and whoever gave it its last coat appears to have projected his bucket over the roof of the cowshed as the readiest means of getting rid of it when done with. Ah! friend, we left one little item out of the formula given above: besides density, detail, and half-tone we want *harmony*, and *there* is just where the majority of negatives (dry-plate ones, at least) fail. The negative we have described is, no doubt, nearly perfect in its separate parts, but the parts do not fit into a perfect whole. It requires two or three separate printings to produce a harmonious print.

Here is another negative, which takes us away to the breezy mountains. We stand on the spur of a hill a couple of hundred feet above a valley which stretches away before us until it loses itself in the hills in the distance. There, at our feet it seems, runs a little river, which here and there flashes back gleams of sunshine; on the opposite side of the valley, half-a-mile or more away, rises abruptly a rocky slope partly covered with straggling bushes; to the right another hill juts out into the valley thickly clothed with dark pine and larch; and looking down the river we have range after range of hills losing themselves in the distance. Notice how you can pick out every shrub on the slope opposite, and trace the contour of each individual tree in the pine wood to the right! There is detail everywhere; even in the distance, three or four miles away, we can distinguish a shepherd's hut or structure of some sort. We turn to the print; all the detail is there certainly, but what a tame and spiritless transcript of the scene! The distant hills, the sombre pines, the heather in the foreground, are all rendered in almost the same tint; even the flashes of sunlight from the river come up with a subdued look as if they felt themselves out of place.

We have secured harmony here decidedly, but we have carried it too far. What we now want is *contrast;* and these two qualities are the Scylla and Charybdis, between which we have to steer in the production of an artistic result. Density, half-tone, and detail are absolutely necessary attributes in a *photograph;* but to obtain a *picture* we have to study those extra qualities. In other words, the one set are technical, the other artistic, qualities; and as a good negative must be both technically and artistically perfect we have arrived one step nearer a true definition.

But how are these special properties to be secured? We know that starting with a sensitive film in perfect condition, no matter by what process prepared, we are able to produce a result which, as far as mere manipulatory excellence goes, may be nearly perfect, by merely attending to the correct adjustment of the exposure and development, though, judged from an artistic point of view, it may be deficient in many qualities. The difference can only be made up by the most careful attention to other conditions, which not unfrequently are more or less beyond the control of the operator, or, at least, necessitate such an amount of patience and skill in their application that it is practically beyond the power of many, especially amateurs, to give much heed to them, and thus it is that though we see so many technically good negatives we meet with so few artistic prints. In another article we shall consider the various circumstances which operate for or against the production of artistic results, our space in the present number being exhausted.

PHOTOGRAPHING "STILL LIFE"—MACHINERY.

We do not exactly know why inanimate objects should have the term "life" applied to them, but there is scarcely a more expressive term in the slang of art than "still life" applied to all objects which are the reverse of living. There are many articles coming into this category to illustrate which photography is invaluable, and a considerable number of them require some amount of experience and the wrinkles acquired thereby in order to obtain satisfactory results. Not the least important among them is the production of photographs for the engineer and millwright—locomotives, tenders, waggons, stationary engines, castings, and similar objects—some hints upon photographs of which, we think, may be useful to a number of our readers.

An ordinary landscape outfit will be sufficient if it comprise a variety of lenses giving straight lines. It will not be sufficient to have merely a large assortment of lenses; they must form a regular series as regards their focus. We find far too many operators select their lenses for their variety of purpose instead of taking note more particularly of the focus. Thus we have many times met with photographers having a large collection of valuable instruments, but which did not enable them to master all varieties of enforced standpoints. In one instance five or six lenses for 12×10 pictures ranged in focus about ten inches and fifteen inches, the varieties being made up of wide angle, medium angle, so-called group and quick-acting lenses of various makers, which the owner had been recommended from time to time by various friends to purchase. Now, if he had chosen (say) a seven, eight, ten, twelve, fourteen, and sixteen-inch focus lens, choosing the quick-acting at either of the last two foci, he would have an assortment with which he could "go anywhere and do anything," and in nothing more than in machinery work would he have found the benefit of such a selection.

The camera should by all means be a double swing-back, with the vertical action working *both inwards and outwards*—a necessary precaution to name, as a reference to our columns recently would show. The use of a swing-back will be found in photographing large, unwieldy objects in cramped positions not over well illuminated; a judicious use of the swing-back under such conditions will allow the bringing into good focus of some important but awkwardly-situated portion of the object without the use of a small diaphragm, which would necessitate too long an exposure.

The various and, frequently, most awkward spots where the objects to be represented are placed will be found a constant source of difficulty; but they can generally be overcome, especially with the aid of short-focus lenses. Great care and forethought will, however, be needed to ensure sufficient prominence being given to some particular portion of the machine which, possibly, may have been the chief inducement in the maker to have it photographed.

The alterations in the appearance of an object when shown in perspective must be borne in mind, and especially the relative magnitude of the nearer and more distant objects. We have a lively remembrance of the annoyance felt by an operator at being requested to re-photograph an arrangement of a sort of cast-iron flooring studded with protuberances, and a block, somewhat like a capstan, which was connected with it. The latter came out large and prominent; but the studs of the floor, being represented in perspective, scarcely showed at all, with the consequences we have above narrated. We perhaps need scarcely point out the care which must be exercised in the use of the swing-back when objects of rectangular construction are being photographed. It may happen then that, so far from the swing-back being adjusted so as to facilitate the focussing, it may be needed for the purpose of preserving the geometrical form of the model, when in all probability it will have an opposite effect to that of equalising the focus—just as, in swinging the back of a tilted camera, when a lofty steeple is included the latter is thrown more out of focus, and a very small stop is needed.

When the piece of machinery is taken *in situ* in the upper story of a "machine shop" it will be found advisable to wait till the dinner hour before commencing to photograph, though, of course, the arranging of the camera, &c., had better be done before that time. The reason for this recommendation is that the vibration of the steam engine and machinery will, unless they are stopped, pretty effectually ruin any attempt at taking a negative. The utmost judgment must be shown in making the exposure, as it frequently occupies over half-an-hour, owing to the dim light which generally prevails in such places. It is often well to take a preliminary tentative negative to make sure of this point, as it will usually be impossible to get a second negative. We well remember a manufacturer who employed five or six hundred hands, when asked to allow the engine to be stopped for a few minutes, replying that it meant a loss of time amounting to five or ten pounds in value!

When large surfaces of rough ironwork have to be taken it will be found that they will come out most unevenly and irregularly. To avoid this defect it will be well to give it a coat of paint drying with a dull surface, such as is known among painters as "turpentine flatting." If the circumstances of the case do not permit the application of this permanent surface a temporary one may be obtained by mixing up dry colours with a little old ale, and applying with a brush as usual; a bucketful of water will take off the whole when the photographic operation has been completed. The colour best adapted for the purpose is a slate colour of medium depth.

So important are these matters of surface and colour that we are aware that in one of the large locomotive manufactories of the country it is made a special point to have their engines photographed before the final painting—a ground work of the dulled surface we have described, and of a uniform colour, being first purposely given and allowed to remain till it is photographed.

The chief trouble in pictures of this kind is the almost universal demand to have the backgrounds painted out, and those only who have attempted it know the trouble of such an operation. It is no unusual thing for a negative to take half-a-day's steady workin before it is effectually done, and on this subject we may have some further remarks to make on a future occasion.

We must conclude with some slight reference to the chemicals. All that is in the slightest degree necessary to specially attend to is to see that they are in clean working order. Quick-acting collodion and bath are, of course, most desirable when protracted exposures are given; but even this quality must give way to cleanliness of action of bath and collodion, the two not being very accordant *desiderata;* for the air is generally so full of floating particles, metallic and otherwise, that it is next to impossible to keep the plate out of the sphere of their influence.

We have before us a striking and practical illustration of the readiness with which very rapid plates suffer deterioration from slight errors of exposure; and, as it seems to have a special bearing upon the views we recently expressed on this subject, we need enter into no elaborate explanations in introducing it to our readers. The example consists of a negative, one of a series taken three or four weeks ago in testing the working powers of a lens, though it is only a day or two since the peculiarity we are about to describe came particularly under our notice. In closely examining the several negatives we found over one of them, at a distance of about an inch from one end of the plate, a sharp line running vertically across the picture, the density of the image on that side of the line nearest the end of the plate being considerably greater than on the other side. It was evident that the narrow strip of greater density had received a longer exposure than the remaining portion of the plate, and, carrying our memory back, we recollected that in exposing one of the plates we had commenced to draw the shutter of the dark slide before capping the lens. The knowledge of this *lapsus* came too late to altogether arrest the action, but we were able to quickly close the shutter before, as we thought, any harm was done, probably half-a-second being the exposure thus given to the end of the plate. We find by the memorandum scratched on one corner of the negative that the exposure subsequently given was three seconds with the full aperture of a rapid symmetrical, and this had proved amply sufficient to bring out the detail even in the immediate foreground. The extra exposure stands, it will be seen, in the proportion of 1 : 6 to the correct time—that is to say, the end of the plate received one-sixth more than it should have done; and the peculiarity we wish to point out is that, though in the negative the line can be traced right across the plate, in the print we have before us the difference is so slight in the foreground as to be quite indistinguishable, while in the distance it is sufficient to obliterate the detail, or, to speak more correctly, to obtain the detail in the over-exposed portion the rest of the picture would have to be sadly overdone. We think it must be palpable that, when the sensitiveness is so great that a slight error of this description produces such widely different results on different portions of the picture, something more than care is necessary in timing the exposure; and for ordinary outdoor purposes a reliable actinometer becomes an absolute necessity, to say nothing of the skill and experience necessary to form a correct judgment of the subject to be photographed.

PRACTICAL INSTRUCTIONS IN MODERN PHOTO-MECHANICAL PRINTING METHODS.

Part I.—PHOTOLITHOGRAPHY.

II. Preparing the Transfer.—Having obtained a satisfactory negative of the subject to be reproduced, the next step is to make a print in fatty ink, commonly called a transfer. Very many methods of doing this have been devised and have been worked successfully in the commercial practice of the art of photolithography; but it is quite unnecessary to describe, or even to mention, the greater part of these methods, as, in the case of each of them, success depends principally on the fact of the student thoroughly mastering its details, and making himself so familiar with its difficulties as to apply the antidote to each difficulty almost instinctively. Moreover, every process requires a series of small appliances, which must be ready to hand and in good order if success is to be attained. These circumstances point strongly to the necessity of the student confining himself to one process, where this is practicable; but in these articles it will be necessary to describe two processes, and it will be advisable for the student to employ one or the other of these—not regulating his choice by the dictates of fancy, but selecting that method which is best suited to the class of work he intends to do.

The first method to be considered is specially adapted for those line or dot subjects which are clear, sharp, and well-defined, being at the same time free from greyish lines or anything approximating to half-tone; while the second process is applicable to cases where the bad definition of the finer lines or dots would render their reproduction by the first process extremely difficult.

In order to form the base of the transfer we must select a fine, closely-woven paper which has no great tendency to buckle and pucker when one side is subjected to the action of hot liquids. Either Saxe paper or Rives paper is admirably suited for the purpose, but these papers are somewhat expensive. This, however, will be no great obstacle to the use of one of them for a first trial, and after some experience has been gained a cheaper paper may be substituted.

The paper must now be coated with a thin and uniform layer of gelatine; but it is in many cases a great advantage to cover the gelatinised paper with an extremely thin film of albumen, and this extra albumenous film is of special advantage when very fine subjects are to be reproduced. The solution for the gelatinisation of the paper is prepared as follows:—Six ounces of an easily-soluble gelatine—such as Cox's soup gelatine—are dissolved in twenty-five ounces of warm water, and the mixture is churned vigorously for about twenty minutes. At the end of this time seventy-five ounces of warm water are added, and the mixture is again churned for a few minutes in order to thoroughly mix the newly-added water with the gelatinous solution. While the mixture is being churned it is generally advisable to add three drops of carbolic acid and a quarter of an ounce of ammonia solution to it. The gelatine solution must next be strained through fine muslin, and poured into a flat porcelain dish; this being placed in a tin dish of hot water, which may, if necessary, be kept hot by means of a Bunsen's burner. Immediately before use the solution should be carefully skimmed with a folded strip of paper, long enough to extend right across the dish, and if necessary a second skimmer should be used in order to ensure the absence of any scum or air-bubbles. The solution having been thus made ready, a sheet of the paper is held by diagonally opposite corners and is gently placed on the surface of the solution, the corners by which it is held being lowered last; and it should be allowed to float on the gelatinous mixture for half-a-minute, after which it is hung up to dry. It is well to skim the gelatine solution after the coating of each sheet, as otherwise it will frequently happen that minute air-bells will cause bare places on the paper, and it is a clumsy and unsatisfactory proceeding to float a sheet a second time in order to cover these places.

When the operation of coating is commenced the solution should be tolerably hot—say about 90° Centigrade—and the paper coated under these circumstances will be very thinly coated with gelatine, it being under these circumstances specially suited for the reproduction of fine lines or dots. As the temperature of the gelatine solution falls, and it consequently becomes more viscous, a more thickly-coated paper will be obtained, which will be more suitable for the production of transfers from rather coarse line subjects, such as typographic matter reproduced the same size, or reproductions of manuscript. The operation of coating may be continued until the temperature falls as low as 35° or 30° Centigrade, and if a number be pencilled on each sheet *immediately before coating*, these numbers will indicate the order of floating and the relative thicknesses of the layers of gelatine. If a batch of paper be required to be uniform all through it is merely necessary to keep the temperature of the gelatinous solution uniform. The gelatinous paper must now be thoroughly dried, and it will then be ready either for storing away or for being coated with a thin film of albumen. If it should be decided to do this, the preparation for albumenising must be made as follows:—Six ounces of albumen having been beaten or churned to a white froth, by means of an American egg-beater, is mixed with fifteen ounces of water, and twenty drops of ammonia are added. This mixture is now allowed to subside for two or three days, when the clear part is poured off and carefully filtered into a flat dish. The sheets of gelatinised paper are now floated on the albumen solution, just as they were previously floated on the gelatine solution, and in drying special care should be taken to avoid dust.

The paper thus prepared, whether simply gelatinised or gelatinised and albumenised, will keep well if preserved in a dry place, and a stock should always be ready at hand for sensitising when required.

Professor Husnik has introduced into the market a double-coated photolithographic paper, similar to that described above, and many will prefer to purchase this instead of preparing their own, as Husnik's paper is very carefully coated, and gives admirable results.

For sensitising the photolithographic paper the most convenient preparation is the alkaline sensitiser recommended by Husnik, and prepared as follows:—One part of ammonium bichromate is dissolved in fifteen parts of water, and four parts of alcohol are added, after which sufficient ammonia must be mixed with the solution to give it a decidedly ammoniacal smell. This solution should be kept in the dark, and when required for use the clear portion should be poured off into a flat dish, care being taken not to disturb the deposit which forms in the liquid. The paper to be sensitised should then be held by two corners, and it must now be rapidly and steadily drawn through the solution, the coated face being uppermost; and in pinning it up to dry care will have to be taken to prevent any little streams of the solution running back over the face of the paper. Small pieces of blotting-paper should be next attached to the lower edge of the paper in order to absorb the drainings; and the drying ought to be conducted rapidly and in a current of air, the most advantageous position for the paper being a little distance above a horizontally-placed stove-pipe. It is scarcely necessary to add that during the sensitising and drying the greatest care should be taken to exclude actinic light, as a very slight exposure is sufficient to bring a host of troubles in its train.

The whole operation of sensitising and drying the transfer paper can easily be performed in an hour or an hour and a-half, and only just the quantity of paper which is required for immediate use should be sensitised at one time, as it rapidly deteriorates after sensitising, especially in hot weather.

Printing-frames for photolithographic work should be provided with screws rather than with springs, and if the bars which bear these screws can be moved to any required part of the frame so much the better, as the pressure is more subject to control under such circumstances. Care must be taken that the frames, negatives, pads, and everything else concerned in the printing are thoroughly dry when used, and if these appliances are slightly warm when used so much the better.

The prepared paper having been placed with its face in contact with the negative, a sheet of very thin patent plate, rather smaller than the negative, should be placed behind it. At the back of this the usual felt pad and a rigid back must be fixed down tightly by means of the screws. Matters being thus arranged an exposure of about two minutes in the sunlight or twenty in diffused light is required; but, of course, this exposure will vary much according to the state of the weather and the negative which is being employed. It is best to regulate the exposure by an actinometer, the most convenient form being the ordinary cube actinometer known as the "autotype" or "Johnson's" actinometer.

When the printing is conducted by diffused light it is well to fix the frames a little distance inside a window, so as to cut off the most oblique rays, and thus lessen the evil effects of any want of contact between the negative and the sensitive paper. The lime light, the electric light, or the light of burning magnesium may be employed with advantage when it is desired to make a transfer in the evening, the exposure, in either case, not being inordinately long. When the simply-gelatinised paper is employed a rather longer exposure is required than when the doubly-coated paper is used, especially when a very soluble gelatine has been employed for coating it.

The paper, having received the necessary exposure, is removed from the frame and carefully examined, in order to ascertain if any lines are not sharp in consequence of imperfect contact, when, if any lines should prove to be ill-defined, it is best to reject the transfer at once and to make another. But if, on the other hand, the whole subject should consist of well-defined and clear brown lines on a bright yellow ground, proceed to the inking of the transfer. For this purpose dissolve equal parts of typographic ink and middle lithographic varnish in sufficient oil of turpentine to make a mixture having the consistency of cream; and by fastening a piece of fine muslin over the mouth of the bottle containing this mixture a convenient filter is made, through which some drops of the mixture can be drained out on to a slab of plate glass or slate. Now take a dabber, which may either be made of rag or of the glue and treacle mixture used for typographic rollers, and spead the ink equally over the slab. When this has been done the next thing is to evenly coat the exposed surface to the transfer paper with a thin film of the ink. For this purpose it is convenient to clamp it down on a piece of plate glass by means of four strips of reglet and some American clips, and then to apply the dabber softly and patiently. No pains should be spared in using every endeavour to obtain a thin and uniform film of the fatty ink, and the progress of the operation can easily be watched by lifting up the plate glass and looking through it. Under these circumstances the film of ink should appear greyish and uniform, and any thick or uneven places must be treated with the dabber until they are made to range with the rest of the film. During this operation a few drops of turpentine may be worked up with the ink remaining on the slab, as occasion may require; or if the film of ink on the transfer appears very lumpy and uneven it may be cleaned off by means of a rag and a few drops of turpentine, and the operation of inking can then be recommenced. In doing all this, however, care must be taken that no ink reaches the back of the paper.

The face of the transfer being now coated with a thin and uniform film of ink, quite free from any dense patches, it is next removed from the plate glass and hung up in a warm place for a few minutes, in order to allow the remaining trace of oil of turpentine to evaporate; but all this time the transfer must be carefully screened from actinic light. After this the transfer should be placed in a dish of cold water, where it ought to remain for ten minutes, or longer, in order that it may become thoroughly softened and ready for development with the brush, and from this point the operations may be conducted in white light.

The transfer being now thoroughly softened it is laid, face upward, on a piece of plate glass, which inclines down into a dish of cold water, and it is then softly brushed with a broad camel's-hair brush, care being taken to keep an almost constant stream of water flowing on the paper, in order to prevent as much as possible actual contact between the hairs of the brush and the inked face of the transfer. During this operation the ink will become detached from the unexposed parts of the transfer, and some of this ink will tend to pile itself up on the broader, exposed lines, while the finer lines will just retain the amount of ink originally put on by the dabber. So it will be seen that in inking a transfer which is to be treated by the above-described method, one ought to put on just the amount of ink which is required by the fine lines, thus leaving the broader lines to become intensified during the development.

Under favourable circumstances the delicate operation of developing a photolithographic transfer may be completed in five or ten minutes; or it may require a much longer time, especially when those parts of the subject which consist of fine lines closely packed together require local treatment with a small camel's-hair brush. It may occasionally happen that it will be necessary to use slightly-warm water in order to soften the transfer sufficiently, especially when a simply-gelatinised paper is employed; but when this is done care should be taken not to use the water too hot, a long soaking in moderately-warm water being preferable to a shorter treatment with hotter water. When a careful examination shows that the transfer is satisfactorily developed, it should be well rinsed with abundance of water, in order to remove any loose particles of ink, and it should then be dried between folds of blotting-paper, care being taken not to put the rough side of the paper next the inked face of the transfer, nor to use too much pressure, lest fibres from the blotting-paper should adhere to the image and mar the solidity of the lines. After having been dried between folds of blotting-paper the transfer should be pinned up in order that it may become a little drier than the blotting-paper leaves it, and generally a period of five or ten minutes is sufficient for this; but the exact degree of dampness which it should possess when transferred to the stone is only to be learned by experience. The brushes employed for developing the transfers must be carefully cleaned with oil of turpentine immediately after they have been used, and the turpentine should be allowed to evaporate completely before the brush is employed for the development of a second transfer. Benzole is more convenient for cleaning the brush when it is required again immediately, as this solvent can be dried off in a few minutes.

Before entering into lithographic details, and describing the transference of the fatty image to a stone, it will be well to treat of the second method of making a transfer, this second method being especially adapted for use in those cases where the nature of the subject renders it impracticable to obtain a negative in which the fine lines are as vigorous and clearly defined as is desirable. Even when this second method of making a transfer is employed the shading at the back of the negative should be performed as already directed.

T. Bolas, F.C.S.

PHOTOGRAPHIC EXPERIENCES IN PARIS.

[A communication to the South London Photographic Society.]

Our worthy President has often reminded us that the proceedings of the South London Photographic Society are not so formal as those of the Parent Society, and which fact he characterises as the great element of our success, as it encourages those who feel somewhat diffident when addressing a meeting. Our indefatigable Secretary, always on the look-out for something to keep us alive, pounced on me, thinking I must have something to impart after my recent trip to Paris. I should not have appeared before you tonight had I not derived some little experience on a subject which appears to be absorbing much attention. I allude to the gelatino-emulsion process, which has now taken a fresh start. I am not an experimentalist, and possibly should not have adopted it had not circumstances compelled me to do so. I purpose showing you on the screen some of my results with both wet and dry plates, that you may form some idea of the comparative merits of both. Previous, however, to doing this I will give you my opinions of the best way to get to Paris, the arrangements for working there and in the Exhibition, and lastly show the views, which I hope may lead to an agreeable and useful discussion.

Routes.—For those who suffer from sea sickness the route *via* Dover and Calais is the best, the voyage being under an hour, and the steamers more commodious. The departures are always at fixed periods, and the arrival in Paris convenient for dinner. For returning I prefer the tidal service, *viâ* Boulogne and Folkstone, if the departure from Paris is about ten o'clock, a.m., as it enables you to get away more comfortably, and the later arrival home is not of so much consequence as in Paris, where there is some doubt of your getting the accommodation you anticipate, and being then obliged to accept what offers. By the route *viâ* Newhaven and Dieppe there is a tidal service, but on certain days the voyage is performed in three and a-half hours, and the whole journey about the same time as the Dover and Calais route. The new steamers are most commodious and rapid; second only to the Holyhead and Kingstown line. This route is always the most crowded during the summer season, being a little more than half the expense of the South-Eastern and London, Chatham, and Dover routes. A first-class return for a month is £2 15s. as against £4 15s. on the other lines. Let me advise you to avoid the cheap night service of eighteen hours by either route; and if you wish to be economical take a second-class ticket by the day service. I have tried various routes, viz., Southampton to Havre, by the Seine to Rouen, and from London Bridge to Boulogne, and thence per *diligence*. If any of our friends are bicyclists I cannot speak too favourably of the French roads—they are magnificent, being constructed for military purposes, and kept in splendid condition.

Advice.—Ask the guard which side you get out to embark, rush on board, and deposit your hand parcels on the most comfortable seat on the poop looking aft, and if you wish to go below secure a couch by depositing a parcel on it. Then you have time to look about, as passengers observe the arrangement of priority. Again: when you disembark inquire which is the gangway, collect your parcels, and rush to the train to secure a window seat. On arrival in Paris secure a cab the first thing, deposit your hand parcels in it, receive a ticket from the driver, who will fall into the rank whilst you return to look after your heavy baggage, which you ought to register, as it removes all anxiety *en route*, and the cost of which is one shilling. Cab fares during the day time are always the same—1*f.* 50*c.* for one having two seats, and two francs for one with four seats, with twenty-five centimes for *pour-boire* or "drink-money." There is but one charge, whatever the distance, inside the fortifications. When I travel in England I generally send foward my luggage per goods train, to avoid the trouble of looking after it. I did the same thing in going to Paris, which caused me an immense amount of trouble. There was first the delay of ten days, and again the loss of one day in passing it through the octroi. I consigned mine to a French house I do business with, and they endorsed the bill of lading, and sent one of their clerks with me. The first hitch was the omission to get the authority from the firm to make the declaration. When he returned he found business suspended for over an hour for *déjeuner*. We followed suit. The delay in getting my photographic apparatus from England enabled me to visit all the places I intended photographing, noting the best hour for that purpose, and getting the necessary permissions, which are numerous.

1. For street work you place yourself under the surveillance of the police.
2. For the national palaces and public works you must apply to the Minister of Public Works.
3. For the national fine art galleries you have to apply to the Minister of Fine Arts.
4. For the municipal parks and squares application is necessary to be made to the Prefect of the Seine.
5. For the churches to the *curés* or architects.

Photographic manipulation in Paris is much the same as here. There appears to be a much greater number of outdoor workers there than in London. Most of the best portrait photographers undertake outside work, and execute it themselves. The larger number of the houses have court yards; and, if there be a studio on the top, you will generally see a dark box on wheels at the bottom.

I cannot speak favourably of the Parisian apparatus. It is a common thing to see a studio stand and camera on the street, the lens fixed into a rigid front, and the camera cocked at such an elevation as would make an architect shudder when he saw the converging lines. This does not apply to all. The appliances of such houses as Braun, Levy, Lachenal, &c., are most complete. I have noticed most unique camera-stands eighteen feet high, the legs forming a ladder for going up to the camera.

The number of street workers being so great the prices are very low. Cards sell from ten to twenty-five centimes, and cabinets and stereos. at half-a-franc.

The regulations for street-working, since the Franco-Prussian war, are very complicated if enforced; strictly speaking, you are not allowed to photograph in any of the twenty-two *arrondissements* of Paris without the special permission of the four commissioners of each. I had a friend who was an old school-fellow of the Prefect of Police, and through him I got a general order for all, which saved me a large amount of trouble.

There are advantages connected with such disadvantages. You take up your position with the sanction of the police, and in a measure under their protection. I never ventured to rely on this to the extent that French photographers do, who I have seen leave their cameras in the middle of crowded thoroughfares whilst away developing. Many of you no doubt are familiar with the position of the Grand Opera House. To take a photograph of this it is necessary to place the camera exactly in the middle of the Avenue de l'Opera, which is about as crowded as Regent-street in the forenoon. When I was focussing for this view I was in dread of being run over, although beside me stood a large camera which a Frenchman was working with the greatest composure, leaving his camera uncared for during long intervals. I found him at work there, and left him with his large negatives on the pavement leaning against the wall of an unoccupied house. The Porte St. Denis is situated in a very crowded thoroughfare. I was taking it on a cloudy day, with occasional sunshine. After waiting some time the sun shone out, and I put the camera-back against the kerbstone whilst I went into the middle of the road to focus; but when I went to fetch it I found it open and the film partly rubbed off. I heartily wished the person who was so inquisitive had on white kids. I had to wait a long time before the sun shone out again, when I then succeeded in getting a nice negative. This was the most trying job I had.

The facilities for working in the streets are very great—wide pavements and low trees, giving room for the tent and shelter from the sun. The atmosphere is very clear, allowing subjects to be taken with much better effects of light and shade than in London, where the atmosphere is very perceptible if the sun be shining very much to the right or left of the subject to be photographed.

Red-tapeism is more rampant in France than here. A gentleman told me that he was taking a photograph of the July column, which is situated in a large open space. He had permission to work in the 4th *arrondissement*, but it was necessary for him to take it from the 12th—the other side of the boulevard—when he was stopt by the police, who would not allow it without an order from his chief. I had an order from the Minister of Fine Arts to do interiors at the Grand Trianon. The day being calm and favourable for outside views, I decided on doing these first, when I was stopt by the Registrar of the Palace, who said he could not allow it without an order from the Minister of Public Works. I went back to Versailles, hoping to find some one there at the public works department to endorse my order. I got it done by the Registrar of the Palace and returned, but it was no use. Monsieur Monavon was inexorable. He said he recognised no one but the Minister of Public Works. This was a great disappointment, as I wished to do it before the foliage got too heavy. The weather prevented my going again until the trees were fully out, and so prevented my taking many charming little "bits" I had looked out. I was working in the Bois de Boulogne when a heavy thunderstorm came on, which prevented my working for two hours. I set up the apparatus, and was just in the act of exposing when one of the park rangers came up and asked for my authority, which I produced. He stated that I must not work after twelve o'clock. I remonstrated, and told him that it was not so stated in the order. He said those were his instructions, and he would not allow me to expose until I had a special order from his chief to work later. This I had to do, which took half-an-hour; but in the meantime it had become overcast again, and I had to wait two hours longer for the sun to accomplish it.

I will not here attempt to describe the *modus operandi* of the emulsion plates; I will do that when using the screen. The cause of my being compelled to employ them arises from the dreadful mess made by French operators in copying the pictures in the Louvre by the wet process. M. Ferrier's operators did the same thing here at Windsor Castle and Buckingham Palace, which has almost shut out English photographers from obtaining permission to photograph in the royal palaces. When taking a photograph of the grounds and Trocadéro from the gallery of the Exhibition, which is reached by a staircase of about sixty steps, I once followed a French operator, and, noticing frequent droppings from his dark slide. I reckoned eleven drops in going that distance. I was often surprised at the messes made about the building being tolerated.

The great object of my going to Paris was the open privilege to work in the Exhibition, but as it was in such an unfinished state I resolved to do all the outside work first, and make this series the last. There was very little difficulty in obtaining permission to work until ten o'clock, but some trouble to get the time extended until five o'clock. I will not attempt to describe the beauties of the park and Trocadéro and grounds—the whole being magnificent. The exhibition building, for internal grandeur, is far behind our Crystal Palace, or the 1862 building with its grand nave and transepts. There was not a single place where a comprehensive view could be taken, so that the photographs bear no comparison to those of our 1862 exhibition. There were a great number of workers; I have reckoned as many as twelve at work in the Rue des Nations, this being the most favourite spot, and one where the police did not interfere. Their instructions were not to allow anything but general views to be taken without the written permission of the owner. Many very pretty views could be taken in the grounds. I will not allude much to these tonight, as the object of my appearing before you on this occasion is to talk about dry and not wet plates. All the work I did in the Exhibition was by the wet process. There were a number of dry-plate workers. One operator told me that he had exposed sixty tannin plates in a day.

I will now proceed to show the views on the screen; but, before doing so, I should like to remark that if we have our popular lantern evening at Christmas I shall be pleased to exhibit the whole Exhibition series. F. York.

NOTES ON PASSING EVENTS.*

By a Peripatetic Photographer.

If I were M. Liébert, of Paris, I would do two things in connection with his elaborate book, which, I observe, has recently been reviewed in these pages. First, I would lose no time in securing for the work a new title, and one which would convey a more accurate idea of the nature of the book than the misleading *La Photographie en Amerique*, that forms the leading feature in the name or title of the work, which is in reality, and as the second portion of its designation declares, *Traité Complet de Photographie Pratique*. I offer, therefore, as a suggestion given in all meekness, as becometh one who meddles in a matter with which he has nothing to do, that the "top-knot," the "scalping lock," as it were, of the title should be discarded, because it is not "American," but *European*, or even cosmopolitan, photography which is therein treated. What would be thought of Dr. Monckhoven were he to issue a new edition of his invaluable work on the optics of photography, under the title of *The Lenses I Saw Used in Little Pedlington, being a Complete Treatise, &c.?* Now, I do not for an instant seek to compare the Blankshire borough just named with the two of the *five* "quarters" of the globe which give a local interest to the title of M. Liébert's goodly volume; but it will be admitted that the principle is similar in both cases. My second proposal would be to publish the work in English, which is the language commonly spoken both in this country and in *North* America, to which portion of the new world M. Liébert's title makes special reference, I suppose.

In one of the ever-interesting "Answers to Correspondents" which are to be found in the pages of The British Journal of Photography occurs the following *dictum:*—"Gas-bags are destroyed quite as much by the chlorine present with the oxygen as by the oxygen itself." This reminds me of the rapid approach of the time in which gas-bags are made more use of than at any other period of the year. Those who possess lanterns, or, more properly, those who exhibit pictures by means of the lantern, may be divided into two classes, namely, those who do so at their own residences, and those who "itinerate." To the former I recommend most strongly the adoption of a metallic receiver instead of a gas-bag. It does not cost much more, if made of thin galvanised sheet iron; indeed, I have seen a most effective gas-holder made of common tinned ware, and it is in accordance with my experience that, after having been three years in more or less constant use, it is in apparently as good condition as when it was new. To preserve a gas-holder of this kind from the ravages of time and oxygen, accelerated by the moisture necessarily present, it must be carefully varnished. The best varnish, by far, for such a purpose is a thick solution of the etching-ground made use of by copper-plate engravers, applied as a paint to the metal, which should have previously been made slightly warm. For the itinerant exhibitor a gas-bag proves more handy than anything else. It is inconvenient to carry the bag full to any considerable distance, and it is often inexpedient to make the gas just previous to giving an entertainment; but by compressing a quantity, say six feet, of oxygen in a small tubular receiver, it may be easily carried about, and just before commencing the display of pictures may be discharged into the bag from which it is to be used. In spite of all that has been written on the advantages of using compressed oxygen direct from the reservoir many give the preference to bags, as being more manageable.

What, I wonder, is to be the nature of the technical examinations which photographic candidates for the supreme felicity of competing for a five-pound prize, given by the Society of Arts, have to undergo, and by whom is the examination to be conducted. I do not think it to be at all likely that the "Peripatetic Photographer" will be called upon to be examiner-in-chief; still, in these days of marvels, there is no saying what may happen. Hence I have taken time by the forelock, and have roughly jotted down a few of the queries which I, as technical examiner in photography, may put to the aspirants for honours and pounds sterling:—"What new properties does protosulphate of iron acquire by becoming oxidised by exposure to the air?"—"Mention the reaction that takes place when an iron developer is applied to an exposed plate upon which is a portion of solution of nitrate of silver."—"Explain the apparent contradiction in terms in speaking of alkaline pyrogallic acid."—"What would happen if three ounces of teriodide of nitrogen were pounded in a mortar with one ounce of iodide of potassium?"—"If a photographer accidentally swallowed bichloride of mercury, or was overcome by fumes of cyanogen, what steps ought he to pursue?"—"In what manner does hyposulphite of soda fix a print? and what are the grounds upon which its use is so much dreaded by photographers?"—"What is the effect of the impact of a ray of light upon a silver haloid?"—"Give a formula showing what takes place when a neutral negative bath becomes acid by continued use, owing to the employment of a collodion containing free iodine."—"Can you account for the insanity of those photographers who apply the term 'redeveloping' to the act of intensifying an image?"—"What is negative aberration in a lens? and is there any connection between it and polarisation of light?"—"Suppose a lens to be under-corrected for colour, how would you rectify it so as to make the chemical and visual foci coincide?"—"What are the lenticular conditions for securing freedom from distortion?"—"What is the precise degree of difference between ferric and ferrous oxalate? and *why* does the latter reduce the salts of platinum?"—"*Why* does red hair show so much darker in a photograph than it appears to the eye in nature?"—"If, when taking a portrait, your sitter insists upon dispensing with that horrid head-rest, when you know that otherwise she cannot keep her head motionless, what would you do?"——These afford a clue as to the kind of queries that *may* be put to the candidate who is being examined in photographic technology.

* Concluded from page 473.

VARIETIES.

[A communication to the South London Photographic Society.]

At the pressing request of our worthy Secretary to supply a paper for this evening (who seems, by-the-bye, to experience considerable difficulty in getting members to energetically respond to his invitations), I have endeavoured to prepare one, although I am afraid it will be somewhat of a desultory and mixed character, for the difficulty of selecting a subject that will, in addition to being interesting and practical, possess the charm of novelty, is a task more than I feel competent to perform; still, rather than our opening session should be entirely paperless, I have endeavoured to string together a few topics that may be suggestive, or provocative of discussion, if nothing more.

Well, then, to begin. This very difficulty of providing papers should certainly be a subject calculated to interest *every* member of this Society, and, instead of our Secretary being driven to his wits' end to get them, he ought to be supplied with not only one paper for an evening, but *several*, thus having others to fall back on in the event of the promised reader "not coming to the scratch." The paper question has, however, been much talked of amongst us, but, it seems, has not advanced a stage further than the discussion. I would therefore suggest, if papers *cannot* be obtained from members of the Society, a series of subjects should be selected by us, and a competent man outside our Society requested, for either love or money, to write a short paper, on a subject we name, that could be read by our Secretary in the event of none being provided by our own members; for I apprehend little or no interest can attach to our meetings if we have nothing special to listen to or discuss. The result will be that at no very distant date this, at present, flourishing Society will die of sheer inanition; but it is to be hoped, numbering, as we do, so many practical men amongst us, that such a fate will be postponed for many years. It will, however, require something more than a passive interest to sustain its vitality, and I hope to see in this session, upon which we this evening enter, many unmistakable signs of continued energy and usefulness, and that every member will do or say something to sustain its credit.

Now to change the topic. The blistering of prints on albumenised paper seems to have been more than usually prevalent in the past summer, and more than one well-known writer has suggested that it is caused by the excessive dryness of the paper previous to sensitising, and that if the paper be left some time exposed to a moist atmosphere the evil will disappear. I regret I am not able to coincide in this theory, as I have found that paper kept in a cool and slightly moist atmosphere will blister just as much as if it were dry. Having, as I have, to superintend the preparation of thousands of sheets monthly, I find no precaution will entirely prevent some samples of paper from blistering, although by observing certain regulations the evil can be mitigated. It is a mistake to think that if blisters disappear on drying the proofs are none the worse, as it will be found such proofs will become spotty and imperfect much sooner than those which have not been afflicted with this complaint. Whatever may be the cause it is evidently connected with the preparation or albumenising of the paper. It may be due to the sizing, or it may be that the albumenising is too rapidly conducted, the albumen not being allowed time to thoroughly attach itself to the surface of the paper before it is removed and hung up to dry; but whatever the cause, it is outside the processes to which it is subjected by the photographic printer, namely, sensitising, printing, toning, fixing, and washing. A certain remedy—but, unfortunately, rather impracticable when large quantities of work have to be done—is to pass the toned print through a bath of methylated spirit, which entirely removes the tendency to blister, without in any way injuring the proof.

Again, to change the topic. The alkaline toning bath is the toning bath, perhaps, more generally in use than any other. I allude to lime baths. I shall, perhaps, surprise some when I say that this so-called alkaline bath will work better if it has an acid reaction on litmus paper. It may not be generally known that the effect of very weak acid upon the colour of litmus paper is much more readily observed when the effect is watched by gaslight than by daylight, and litmus so slightly changed by acid as to be imperceptibly altered by daylight is quite pink when examined by gaslight; and I have found lime toning to progress much more satisfactorily if the solution will change litmus slightly pink when examined under these circumstances than if it be neutral or slightly alkaline.

Again, another topic—clean hands. It is much more easy to keep them from being stained than to remove stains when made. The remedy is—*care* and *dexterity* in manipulation. Some manipulators could not, I believe, if their very lives depended on it, avoid making themselves in a mess, or get through a day's work without having hands as black as if they had been intentionally dyed. I don't think they would be happy or think themselves photographers if they did not succeed in making themselves grimy and untidy. I would recommend the use of a pair of good dog's-skin gloves, well rubbed with warm wax or paraffine, as being comfortable to wear and effectually keeping the fingers clean. India-rubber gloves answer the purpose very well, but some are very unpleasant to wear. I mention this subject, not so much to call attention to appearances as to its affecting the health of the operators; especially now, as the cold weather is approaching, the skin becomes more hard and inelastic and more easily abraded than in warmer weather, when it is soft and pliant, and is consequently more likely to be injured by chemicals inducing dangerous or, at least, troublesome sores. I quite believe that the eruptions upon the hands we hear so much about might be entirely avoided if the operator were rather more imbued with the spirit of economy and manipulatory neatness. For my part, I always look on so many stains as so much wasted material, and if this feeling could be realised by those engaged in photographic operations it would be a general benefit both to employers and employed.

Once more to change the topic. Respecting landscape photography: in general landscape subjects no good results can be reasonably expected unless the sun shines. Sometimes a special view may, perhaps, be better taken on a dull day; but in the majority of instances plates exposed without sunshine are plates spoiled. I fancy, from the little experience I have had, this rule is especially applicable to slow dry plates, or plates several times slower than wet ones, the beauty of the photograph depending, as it does, less upon the beauty of the composition as seen with the naked eye than upon the illumination of it. One has only to watch the effect of the light on some subject with and without sunshine to at once realise the difference and importance of having the landscape well lighted. A weed, a bunch of leaves, or some trifling object that on a dull day is scarcely noticeable will, with a touch of sunlight, spring into importance and completely alter the character of the view. Photographic beauties lie hidden in the most unsuspected localities, and are systematically overlooked in the idea of the necessity of going to some place of artistic repute to be enabled to procure pictures worth the trouble of taking. How often such trips, made on the representation of a friend who has an eye for colour, end in a disappointing fashion to the photographer I need not say; therefore I would impress on all incipient photographers—and others, too, for the matter of that—to thoroughly acquaint themselves with the effects of light and shade before they indulge in landscape work, as it is quite as important to be understood in this department as by the portraitist. In these days a photographer who has no proper ideas of lighting the sitter would be laughed at, and his work properly despised; yet, I believe, lighting the landscape is by many little considered, or not at all. If the sun shine, that fact is held sufficient; as to where it shines, and what it lights up or casts into shadow, is hardly thought about so long as it does not shine into the lens. This is a happy-go-lucky style of working that occasionally makes a good picture by a fluke, but a great many bad ones; and, as the principle on which to go is not understood, the probability is that a special success could never be duplicated unless by a rare chance.

I have now arrived at the last item on my list, and, if I have said nothing new, the subjects I have touched upon more or less affect all photographers, and force themselves into prominence in the practice of all the disciples of the so-called "black art." I will therefore leave this collection of *Varities* to your consideration, and hope it will be sufficient to induce a discussion for the evening and papers for future ones, one of which I would suggest should be a practical exposition of the development of *over-exposed* and *under-exposed* dry plates, by some good dry-plate worker.

Edward Dunmore.

ON NITRO-GLUCOSE.*

The Employment of Nitro-Glucose by Direct Addition to the Collodion.—I now arrive at the most important point for the photographer—the use which may be made of nitro-glucose by mixing its alcoholic solution with collodion. According to my experiments, by adding one part of nitro-glucose to four parts of pyroxyline prepared at a low temperature we obtain an emulsion giving an image of extraordinary intensity; in certain cases it will perhaps be advisable to diminish slightly the proportion of nitrated sugar. Knowing the proportion of pyroxyline contained in the collodion, and also of nitro-glucose in a given volume of alcohol employed to dissolve it, it will be easy, by a simple calculation, to ascertain the number of minims of alcoholic solution corresponding to one grain of nitro-glucose. This quantity of solution must be added to the collodion a few drops at a time, shaking the bottle vigorously. This operation (which may be performed in full daylight) completed, we enter the dark room and add the nitrate of silver solution, then the bromide of zinc, and so on with the remaining operations appertaining to the preparation of an emulsion. I may make one important observation—that emulsions containing nitro-glucose, as well as those prepared from high-temperature cotton, require a less quantity of *aqua regia* in order to leave the same excess of silver as in an emulsion without nitro-glucose. Thus, for instance, I have found that in using the same collodion and the same proportions of silver nitrate and of zinc bromide that it was necessary, in order to leave a slight excess of silver nitrate, to add four c. c. of *aqua regia*, whereas with the addition of nitro-glucose the proportion of *aqua regia* was reduced to 3·2 c. c. or 3·3 c. c. With 4 c. c. I obtained an emulsion with excess of *aqua regia*, for the distilled water employed in precipitating it became clouded by the addition of solution of silver nitrate. This fact can only be explained, it seems to me, by supposing that the combination which the nitrate of silver added to the collodion contracts with the nitro-glucose is more intimate than is generally supposed, and that it is not destroyed, at least immediately, by the *aqua regia;* and, in fact, emulsions made with the preliminary addition of nitrated sugar, even though prepared with excess of *aqua regia* and subsequently washed, gave the same density as those prepared with excess of silver.

Better than any description, the negatives I lay before you will enable you, by a comparison of results, to appreciate the enormous difference in density which exists between the two halves of each plate representing the same view, with an exposure rigorously the same, the camera being a binocular. One half of each plate was coated with emulsion without nitro-glucose, the other with an emulsion in every way similar save that it received an addition of nitro-glucose in the proportion indicated. You will remark the almost total opacity of the sky, the vigour of the high lights, and the clearness of the details in the shadows, and this without the production of a hard negative. It is advisable always, when from the nature of the subject it is not desirable to obtain an image of great density, not to push the development too far, which enables us to obtain pictures of much greater purity and fineness than with emulsions containing no nitro-glucose. The pictures obtained with the latter emulsion, as you will remark, appear to be more harmonious,

* Concluded from page 476.

but it is easy to see that this is solely due to the want of intensity; and as we attempt to remedy this defect by prolonging the development or increasing the quantity of pyrogallic acid, the images obtained become less clear and delicate, presenting a flat appearance, and eventually commence to fog. In order to avoid this latter result several authors, notably Captain Abney, recommend the cessation of the alkaline development as soon as the details have made their appearance, to wash the plate, and then proceed to intensify with the ordinary mixture of pyrogallic, citric, and acetic acids and nitrate of silver. The use of nitro-glucose dispenses with this complication of the manipulations, which, besides, is far from producing uniformly the result expected from it.

The examination of this negative, one half of which is from an emulsion prepared with high-temperature cotton and the other with nitro-glucose emulsion—giving, as you see, an identical result—proves afresh that the intensity of collodion is really due to the presence of nitro-glucose.

Besides its *rôle* as an intensifying agent nitrated sugar also appears to confer upon newly-prepared emulsions many of the qualities they acquire by age, such as increased sensitiveness, detail in the heavy shadows, and images which develope more rapidly and are less subject to fog either by prolonged action of the alkaline developer or by over-exposure. With a view of showing you the influence which age exercises upon emulsions I submit to your notice another negative the respective halves of which were covered with emulsions prepared with identically the same materials and in the same proportions, but one was newly prepared, the other two months' old. It is easy to see that the image produced by the latter emulsion is more vigorous and more perfect in the shadows than the other.

The Functions of Nitro-Glucose.—Having regard to the probable composition of nitro-glucose, we cannot but suppose that, in connection with nitrate of silver, it plays the part of a reducing agent, and that, in fact, the nitro-gluco-argentic precipitate remains unaltered so long as it is preserved in darkness; but in the presence of light the reducing action is not long in making itself manifest. There is further reason to suppose that under the influence of actinic rays the nitrated sugar is decomposed, and that the product which comes of the decomposition reduces in its turn the salt of silver. What appears to me to confirm this view is that the nitro-gluco-argentic compound in the presence of ammonia produces a reduction of metallic silver even in the dark. Doubtless the first phase of the action of the ammonia is the decomposition of the nitro-glucose into a substance which in time reduces the silver. Be this as it may, the increased density produced by emulsions containing the nitro-gluco-argentic compound is evidently due to the combination of the silver reduced by the action of the alkaline developer upon the silver bromide with that arising from the reduction of the compound in question.

In conclusion, gentlemen, I take occasion to remark that I am not the first who has sought to utilise the properties of nitro-glucose. Many years ago Dr. Monckhoven endeavoured to apply it to the preparation of paper destined for enlargements in the solar camera. In his *Treatise on Photography* he attributes the decomposition which collodion undergoes by age, as well as the property it acquires of giving dense images, to the formation of a certain quantity of nitro-glucose. I believe him to be correct, and here is a fact which seems to confirm that view:—A short time ago the manager of one of our principal establishments for the sale of photographic materials showed me a substance he had obtained under the following circumstances:—Having noticed that a sample of cotton which had been kept for about a year hermetically closed in a stoppered bottle had become extremely powdery he thought to utilise it in the preparation of an emulsion; but, as the bottle was filled with red nitrous vapours, he considered it desirable to submit the cotton to a preliminary washing. Accordingly it was placed in a funnel and a stream of water poured upon it, when, to his astonishment, the pyroxyline was converted into a gummy liquid, which flowed through the neck of the funnel into the lower bottle. I recognised in this substance nitro-glucose, for in its reactions it exhibited all the characteristics of that substance. It is, then, an undoubted fact that pyroxyline undergoes by age, and under the influence of certain conditions, a change which converts it into nitro-glucose.

Capt. Abney, in his two treatises, has also a few words to say about this substance. He, too, conceived the idea of adding it to collodion, and found that the images obtained were of extraordinary density; but he adds that, so far, practice has not confirmed its use. In other portions of his works, too, he notices the addition of gelatine to the pyroxyline after the manner of Warnerke, or, better, to the washing water of emulsions recently precipitated by means of a strong solution of tannin or salicine, with a view of remedying their lack of intensity.

Though it is true that these two eminent writers have already drawn attention to the properties of nitro-glucose and the uses to which it may be put, I believe, at least, so far as emulsions are concerned, I am the first to attempt to introduce it into actual practice. Henceforth it will be no longer necessary to have recourse to high-temperature pyroxyline; any collodion prepared from ordinary low temperature cotton (provided it be of a nature to resist the precipitation and washing) will be invested, with the greatest ease, with all the valuable qualities of high-temperature cotton by the mere addition of a small quantity of nitro-glucose. In view of a result which has so important a bearing upon emulsion processes I thought the subject worthy of bringing under your notice.

M. DE PITTEURS.

OPINIONS OF THE LONDON DAILY PRESS ON THE PHOTOGRAPHIC EXHIBITION.

THE PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The annual Exhibition of this Society is to be opened today, a preliminary view having been held yesterday. The photographs, which are numerous and in most instances of a high class, are exhibited in the Gallery of the Society of Painters in Water-Colours, at 5A, Pall Mall East. Among the exhibitors of this year, who number about one hundred, are to be found some of the best landscape photographers, both professional and amateur. In fact, the Exhibition may be said to shine especially in landscape photography, which together with landscape art appears to have taken the first place in England, while the supremacy both of drawing and of photography of the figure have remained with the Continent. There are not a few examples, however, of figure photography which show a high order of merit. There are in the room many photographs of well-known personages, which in their clearness of outline, and also their softness and delicacy of shading, would be by no means contemptible beside some of the best results obtained in Vienna, St. Petersburg, or Paris. Some of the most noteworthy examples are in enlargements, albeit enlargements are held to be purely mechanical effects, and are not highly esteemed on that account in the photographic world. It cannot fail to be interesting to see what the small negative does in reality produce when the picture is transferred to a larger plate. The fidelity with which every minute detail is reflected is strikingly shown when the enlarging process is gone through; and no better example can be found than the comparison of some of the large photographs of animals with the small ones printed from the original negative. Some very excellent specimens of enlargements of portraits are to be seen in the portraits of Mrs. Langtry, Mr. Hook, R.A., Mr. Henry Irving, and Mr. H. J. Byron. It is in landscape, nevertheless, that the great merit of the Exhibition lies. Many very beautiful photographs are here to be seen which have been taken with the wet plate, but it is being admitted that this must eventually cede its position to the emulsion or dry plate; and, indeed, if any one needed actual proof of the superiority of the new process, it would be found in the exquisite photographs which have been produced by it. One important advantage connected with the dry plate is its capacity for use. An idea of this may be gained from the fact that one of the conditions for the prize of £50 offered by Mr. James Paget for a dry plate process is that sensitive films made by it shall remain without perceptible change for not less than four months after preparation, and must keep satisfactory for three months in any climate between exposure and development. The advantage in results can be seen by the examples at the Exhibition, especially in regard to the faithful idea of interval and the exact delineation of objects at a distance. It would, however, be unfair to the older process, which has served its purpose so long and so well, unduly to praise the other at its expense, particularly in face of the very fine photographs it has produced, which are to be seen in profusion at the Exhibition. In addition to the pictures which are sent for competition, and which forms the exhibition proper, is a curious and interesting collection of photographs collected by Mr. L. Warnerke in the leading establishments of Sweden and Russia, and lent by him to the Council of the Society. These, in addition to illustrating phases of Russian and Swedish life, throw some light upon foreign processes of photography, and are well worthy of examination.—*Daily News.*

PHOTOGRAPHIC SOCIETY.—The annual *soirée* of this institution took place yesterday in the Gallery of the Society of Painters in Water Colours in Pall-mall. The guests were received by the President, Mr. James Glashier, F.R.S., and other members of the Council. The display of landscapes was admirable; but the portraits, as usual, fell short of the excellence of results attained by the photographers who have devoted themselves to scenery. There was an exception, however, in the three exquisite pictures by Mr. Hemery, representing the ages of innocence, wisdom, and of beauty. Of instantaneous effects there were some excellent sea pictures by Mr. Payne Jennings. The very large landscapes of Mr. Vernon Heath and of the Autotype Company maintain in every way the well-earned reputation which both have long enjoyed, and the views of St. Owen and the cathedral at Rouen are most illustrious specimens of the value of such architectural records. The applications of photography to ceramic ware by Mr. Watson, and the transparencies of the Sciopticon Company, deserve both notice and praise. The stereoscopic views of the Paris Exhibition by Messrs. Murray and Heath are perfection for such scenic effects. The contributions of the School of Military Engineering take no mean rank in the present collection, where they are brought into direct competition with the works of such eminent artists as Mr. Bedford and Mr. England. The landscapes, too, of Mr. Conway and Mr. Dunmore are particularly noticeable for their brightness and artistic character. The exhibition will remain open to the public until November 12, evening admission being also arranged on the Mondays and Saturdays.—*Standard.*

Photographic Society of Great Britain.—Last night the annual Exhibition of this Society was inaugurated by a *soirée* at the rooms of the Society of Painters in Water Colours, 5a, Pall-mall East, when the members and their friends assembled in such numbers as to make the inspection of the various works a matter of some difficulty. The Exhibition is, perhaps, not the best that has been held by the Photographic Society. It presents, however, notwithstanding the absence, as exhibitors, of two or three of the leading members, features of more than ordinary interest, inasmuch as some of those who have hitherto ranked as second- or third-rate artists have boldly come to the front, and taken a position that, gratifying as it may be to themselves, must at the same time tend to elevate the Society and the art which they practise. In the field of landscape British photographers have no rivals. They have made it their own, having outdistanced their Continental *confrères* just as our landscape painters have excelled, and, as a rule, triumphed over those of all foreign countries. There is, too, a noticeable advance this year in landscape photography, the dry-plate process telling with excellent effect on the artistic value of the work produced. Formerly, in transcribing the beauties of natural scenery, the success of photography was partial and varying. Sometimes a foreground would be the acme of perfection, daylight and truth meeting with a clear dawn, but distant objects, so completely amenable to the painter, would be slurred and blurred, or it might be the reverse—a clear distance and a blotchy foreground; but with the dry-plate work each part of the picture bears its due and proper relation in gradation and tint to the whole. This is an improvement which, like many other developments of this beautiful art, has been brought about by gradual steps. It is none the less marked, however, and in nearly the whole of the landscapes exhibited in Pall-mall, we may behold "the bright countenance of truth" depicted in studies of delightful freshness. Amongst the finest specimens are those by Mr. William Bedford, of 326, Camden-road; but, owing to the fact that his father was one of the jurors, they were not entered for competition. Mr. Payne Jennings, West Dulwich, is another contributor whose works are entitled to the highest praise. A frame of views in Ireland, by Mr. Jennings, are exquisite specimens of the art. Mr. Vernon Heath has been awarded a medal for a frame of four views in the Isle of Skye, the famous Scour-na-Gillian having as much attraction for the photographer as for the painter. In these views Nature's own cunning hand, assisted by the magic of the camera, is unmistakably present. Bits of rock, jagged, broken, shapeless, lying in chaotic confusion, backed up by a weird towering eminence, sublimely and magnificently grand, stand out with delightful, almost startling, reality, exciting the imagination and leading it perforce from nature to the contemplation of nature's God. This is the province of pure art, its highest aim; and in these views—snatches of Nature, in her most evanescent mood—Mr. Vernon Heath has exalted the art of which he is so accomplished an exponent. The sea studies, instantaneous effects, by Mr. Payne Jennings, are also worthy of the highest commendation—rather, however, for the beauty and naturalness of the clouds than for the restless motion of the waves. There are many views of the Paris Exhibition and its adjuncts by Mr. William England, St. James's-square, Notting-hill, and views in Kent and North Wales by Mr. Edward Dunmore. Amongst the portraits and figure subjects, although there are some excellent examples, there is no marked advance on previous exhibitions. It would almost seem that in this domain the art was at a standstill, and admitted of no improvements; but in these days of scientific discovery it would be unwise to hazard such an opinion, and on a matter of this kind we cannot venture to speak *ex cathedra*. In applying strong *chiaroscuro* to portraiture, Mr. R. Slingsby, of Lincoln, has already won his laurels. His two examples, *Satisfaction*, and the portrait of a lady, are deep in tint without heaviness, and the lights are soft and natural without abruptness. There is commendable delicacy in the work of Mr. T. G. Hemery, Peckham, and the perfection of monochromatic art in the opal enlargements by Messrs. R. Faulkner and Co., Baker-street, Portman-square. In portraiture pure and simple Mons. A. Boucher, King's-road, Brighton, and Messrs. Lombardi and Co., Brighton and Pall-mall East, hold a foremost place, their productions being essentially lifelike and graceful. Mr. A. W. Wilson, De Beauvoir-road, Kingsland, is the exhibitor of a frame containing illustrative photographs of *The Seven Ages of Man*, very excellent; and Mr. H. Garrett Cocking, High-road, Lee, son of the esteemed assistant secretary, sends four character studies, of which the most difficult, and at the same time most meritorious, is a scene from *The Husband in Clover*, the grouping of the two figures, as well as the general arrangement of the accessories, being cleverly managed. *Miss Rose Hersee*, as Elvira, *in the "Rose of Castile,"* is a work of merit; and, as regards *La Gitana*, it would clearly be unfair not to award the praise between the artist and the sitter. Mr. Harry Pointer, Brighton, contributes a number of instantaneous photographs from life, principally of domestic pets, in all kinds of peaceful and warlike attitudes, the whole forming an amusing collection. The Woodbury Company and the Autotype Company are, as usual, exhibitors of their enlargements, which are now so well known; and the School of Military Engineering, Woolwich, are large contributors of landscape scenery. Last year the views taken by the Arctic Expedition under Sir George Nares formed a special feature of the Exhibition. This year, also, there is a special feature, and one that is likely to be rather popular. Mr. L. Warnerke, Peckham-rye, a photographer of repute and an inventive genius, who has been honoured by foreign societies of a cognate character, has been to St. Petersburg, where he was instrumental in founding a photographic society. In his travels he also visited Sweden, and during his foreign sojournings he naturally made many friends. An evidence of this is afforded by a loan collection of photographs given to him by the leading establishments in Sweden and Russia, which are exhibited on the screens, and will well repay examination. They are chiefly Russian, illustrative of every phase of society there, from that of the palace of the Emperor to the cottage of the peasant. Mr. W. Carrick, an English miniature painter, settled in St. Petersburg, becomes an exhibitor, through Mr. Warnerke, of pictures of Russian life, embracing no fewer than 192 studies of character, and for these the Society has awarded him a medal. Mr. Carrick is also represented by a series of views taken in various parts of Russia. Several process are exhibited by Mr. G. Scamoni, head of the Photographic Department of the Imperial State Paper Manufactory, St. Petersburg, and by Mr. Sapteff, of the War Department. Coloured photography is not admissible to the Society's gallery, and, therefore, it happens that the new process called poikilographic painting, for reproducing oil paintings, invented and patented by Messrs. Lombardi and Co., is relegated to a rather bad light on the staircase. The five examples of this beautiful art are, with one exception, copies from the old masters, and the very texture of the originals is reproduced. The process is equally applicable to studies from the life. A negative is taken in the usual way, then enlarged on thin translucent paper or canvas, and the colours—mineral colours only being used—are applied on the reverse side, and show through the surface. The effect, which is very wonderful, is infinitely superior to anything produced by the oleographic or chromolithographic processes. As large works can be reproduced with the same fidelity as small ones, there can be little doubt that poikilography will play an important part in the dissemination of exact *facsimiles* of the great masterpieces of art.—*Morning Advertiser.*

Meetings of Societies.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

The opening meeting of this Society for the winter session was held on Thursday, the 3rd inst.,—the Rev. F. F. Statham, M.A., President, in the chair.

Mr. E. Dunmore read a paper entitled *Varieties* [see page 485], which was followed by a brief conversation of a desultory character, in which Messrs. Foxlee, Pearsall, Bolas, and Ayres took part.

Mr. F. York then read a paper on *Photographic Experiences in Paris.* [See page 483.] Mr. York illustrated his paper by means of a number of pictures admirably exhibited by the magic lantern.

Votes of thanks having been awarded to Mr. Dunmore and Mr. York, the meeting was adjourned.

EDINBURGH PHOTOGRAPHIC SOCIETY.

The ordinary monthly meetings of this Society were resumed on Wednesday evening, the 2nd inst., the chair being occupied by Dr. Thomson.

In consequence of the unavoidable absence of the Secretary the minutes of the previous meeting were not read, and the business commenced by the admission of the following as ordinary members:—Messrs. C. Morrison, D. Greig, — Bell, D. Wilson, J. Rodger, S. Garland, P. F. Patrick, E. Gilbert, William Rae, Thomas Rae, and Dr. Jamieson.

The only paper in the billet was one by Dr. Nicol, entitled *A Month among American Photographers.*

Dr. Nicol began by saying he regretted that the members had not something more practical with which to commence the session, and, although he disliked exceedingly to offer any apology in connection with a public appearance before the Society, he was compelled to do so on that occasion, as the request to prepare the paper had only reached him late on Saturday night, and he had found it impossible, in the limited time thus placed at his disposal, to do more than look over the notes taken during his recent tour in the United States and Canada. He laboured under another difficulty in the fact that the notes had already been pretty fully exhausted for publication in one of the photographic journals, and had doubtless been read by most of those present. He (Dr. Nicol) then gave a brief sketch of his visits to one or more of the photographers in the principal towns through which he had passed in a tour from Philadelphia to Flint, in Michigan, and exhibited a large collection of photographs collected by the way. Probably the most interesting were several beautiful panoramic pictures printed from various negatives by Mr. Gutekunst, of Philadelphia, and some exquisitely-beautiful specimens of portraiture by the same hand. There was also a large collection of the well-known art-studies by Mr. Sarony, of New York, which, both technically and artistically, were little short of perfection. He (Dr. Nicol) went on to say that the sum of the observations that he had made was that the American "skylights," as a rule, were really skylights, as side lights, on the whole, were little used; that the best results he had seen, including most of those he had shown, were produced without the aid of screens or blinds, the artist trusting almost altogether for the desired distribution of light and shade to the position of his sitter relatively to the top light, which he preferred to employ; and, further, that notwithstanding the much-envied brilliant atmosphere, and other circumstances supposed to be so favourable to the practice of photography in America, the photographers of England and Scotland had nothing to fear in a fair competition in the matter of portraiture at least, as if, probably, half-a-dozen of the best men were excepted the work in the United States was on the whole inferior to that generally met with at home. With regard to landscape work it was somewhat different, so far, at least, as the amateur was concerned. He was inclined to think that American amateurs stood higher than their European brethren. They were, probably, less numerous, but were more enthusiastic; and, in spite of the high pressure at which commerce generally was pursued, they had more leisure, and leisure of more photographic value, because of the greater prevalence of brilliantly-fine weather. He (Dr. Nicol) concluded by saying that everywhere he went he met with a most hearty reception, and found that American photographers generally showed a deep interest in the photographic sayings and doings of the old country.

The Chairman said that he was sure the members present had listened with much interest to the observations made by Dr. Nicol, and he would be glad to hear a general expression of opinion on any of the matters touched upon. The question of the relative proportion of side and top light was one of considerable difficulty, and one which every photographer must settle for himself. Generally speaking, a man would succeed best with that which he was best accustomed to employ, and very fine work might be done with either or both.

Mr. W. Neilson, in moving a vote of thanks to Dr. Nicol, said he did not altogether sympathise with the favourable opinion expressed regarding plain backgrounds in preference to pictorial or artistic embellishments. Both, he thought, were best, as, when a photographer had to photograph an interesting and beautiful subject, the sitter required no adventitious aid; but where the model was neither interesting nor good-looking it was better to make a picture of the background, bringing in the figure merely as an accessory.

Mr. M. G. Dobbie, while thanking Dr. Nicol for the interesting *résumé* of his tour, thought the Society should guard itself against endorsing the statement that American portraiture was inferior to that of this country. Dr. Nicol had only been able to visit a limited portion of the United States, and he knew there were many cities in which high-class work was done that he had not visited.

Dr. Nicol quite agreed with the observations of Mr. Dobbie, and of course wished it to be thoroughly understood that what he stated was simply his own opinion founded on what he had seen in the limited portion of the country he had visited.

On the motion of Mr. Dobbie a vote of thanks was given to the Chairman, and the meeting was adjourned.

Correspondence.

ON THE PRODUCTION OF OPAL PICTURES.

To the Editors.

Gentlemen,—As we have a good deal of opal work to do, and as our operators are at variance respecting the best method of producing pictures of that description upon which to work with pigments, kindly favour us with replies to the following queries, and which replies we believe will be of general utility to the profession.

Premising that we have hitherto got most of our opalotypes printed by the wet collodion process and by one who works for the profession, and being aware that he obtains his fine tones by some peculiar process of first rendering the picture invisible and then applying a developer, we should esteem it a favour if you would, first, throw out a hint as to the nature of the developer and general treatment consequent upon the adoption of such a developer; and, secondly, state whether in your estimation the developing of an opalotype by such means will conduce to its permanence, for as we obtain high prices for our work we strongly desire that it shall be both permanent and beautiful.—We are, yours, &c., A. & B.

October 8th, 1878.

[Similar queries to the foregoing having been epidemic during the past four months, and as we cannot afford time to reply *privately* to further communications on this subject, we have taken the liberty of publishing the above letter, instead of sending a private reply, as requested, having first of all taken the precaution of suppressing the name and address of our correspondents, and appending instead the initials now attached. Let it, then, be understood that in what we are now about to write we shall not indicate what is, in our estimation, the best method of producing opal pictures having a warm tone, but what is the best method based upon the routine described in the foregoing letter. There are two methods by which a picture upon an opal plate may be rendered invisible, so as to be ready for after-development. Presuming the picture to have been taken by the wet collodion process, developed by any suitable agent, and fixed by cyanide of potassium, and the image to be vigorous and plucky, with good detail, the tone is almost certain to be bad. The solution by which the picture was made to appear was one or other of the following: either a solution of bichromate of potash to which had been added a few drops of hydrochloric acid, or a solution of bichloride of mercury. Here we may state that if a strong solution of this latter salt be wanted it should be dissolved to saturation in hydrochloric acid, the solution being afterwards diluted with water. A little of either of the above solutions applied to a picture upon opal glass will very speedily render it invisible. This it does by converting the metallic image into a substance of a white colour, which, when backed by the white opal plate, is, of course, practically invisible. Should it have been bleached by the former of these solutions, causing the image to be converted into chloride of silver, there are, as Mr. M. Carey Lea has pointed out, several methods by which it may be darkened. Of these we have found an exceedingly weak solution of Schlippe's salt, with the addition of a little ammonia, produce the best tone. We have some reason to believe that the most popular process made use of by those who produce opaltypes under the circumstances mentioned by our correspondents is that of bleaching by means of the mercury salt described, having first added to it about an eighth of its volume of alcohol. When this solution is applied the image will at first darken, but will afterwards grow white until it has ceased to be visible upon the white plate. It must now be *thoroughly* washed, after which it should be flooded with a weak solution of sulphide of ammonium in water. The ordinary sulphide of commerce diluted with about six times its volume of water will prove a suitable degree of strength. Instead of this latter application a solution of hyposulphite of soda may be employed. It produces a somewhat blacker tone than the sulphide of ammonium. As regards the permanence of opalotypes produced in this manner we are unable to speak favourably. Probably the finest examples of photographs toned by this process which have ever been seen were those exhibited as illustrations of the photocrayon process, and which made no small noise in the world in 1869, when they were first introduced. Upon examining some of the specimens then produced we find that they have changed colour in a sensible degree. Mr. A. L. Henderson, who has bestowed some study on this subject, believes that if a solution of chloride of gold were mixed with that of the bichloride of mercury no change will take place. The method he suggests is to apply to the picture a two-grain solution of chloride of gold to which has been added one-fourth its volume of a saturated solution of bichloride of mercury in plain water. After the picture has been washed and dried it is to be fumed with ammonia, by which its tone will be darkened. Apart from the permanence of the method proposed, we imagine the tone will be rather colder than that which is so much desired.—Eds.]

CORRECTION.

To the Editors.

Gentlemen,—Kindly allow me to plead with your printer for the preservation of a little pleasantry in my paper on Switzerland. I remarked, *apropos* of an incident on the Gorner Grat, that the focussing slide fell over a precipice ten thousand feet above the nearest *glazier*. Your printer has, however, substituted the word "glacier," and thus makes me guilty of a misstatement, which would be very palpable to any one acquainted with the point of view in question.—I am, yours, &c.,

October 9, 1878. H. J. Palmer.

ENAMELS IN THE FRENCH EXHIBITION.

To the Editors.

Gentlemen,—Possibly some of your readers may be aware that Mr. J. R. Sawyer has, in the pages of certain monthly notes issued by his firm, enunciated his opinion that the enamels exhibited by English artists are "far behind" as compared with those shown by foreigners, and that this has been copied into the pages of your contemporary in the face of the fact that I have received a medal award for the excellence of those I sent. Without further comment I beg to request you to publish the following letter I have sent to the editor of the *Auto. Notes* in reply to his strictures.—I am, yours, &c.,

A. L. Henderson.

[Copy.]

To J. R. Sawyer, Esq., Autotype Company.

Dear Sir,—On my return from a continental tour my attention has been called to an extract from one of your letters "On Enamels at the Paris Exhibition," and published in the *Photo. News*. As I know you are neither a giant nor a dwarf I presume you did not go prepared to kneel before my enamels or to use a ladder to examine them. Such, however, is the position of my best work. Nevertheless will you be surprised to learn that I have been awarded a bronze medal? My enamels are all untouched photographs.

I will feel greatly obliged if you will communicate these facts to the party who reproduced your remarks.—I remain, Sir, yours respectfully,

A. L. Henderson.

EXCHANGE COLUMN.

No charge is made for inserting these announcements; but in no case do we insert any article merely *offered for sale*, that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a *nom de plume* be thought desirable), otherwise the notice will not appear.

Dark tent on wheels for 10 × 8 plates, can be used without wheels when required, having extra tripod, cistern, bottles fitted in place, cupboard to carriage, locks and keys, beautifully made, and photo. sent; will exchange for Dallmeyer's 4D, 2B patent, or 1A.—Address, W. Dakin, Holly Bank, Nether Edge, Sheffield.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

Photographs Registered—

A. Brothers, Manchester.—*Figure Study entitled "Resignation."*

Edwards and Simonton, Dublin.—*Two Portraits of the Lord Bishop of Ossory, Ferns, and Leighlin.*

PHOTO-MECHANICAL CORRESPONDENCE.

☞ With reference to the series of articles on *Photomechanical Printing Methods*, by Mr. Thomas Bolas, F.C.S., the author will be happy to reply, in our "Answers to Correspondents" column, to such queries respecting the subject as may be forwarded to him through us.

R. V.—Its solubility may be increased by the addition of ammonium-chloride.

J. T. S.—The paper you refer to is largely employed by French lithographers under the name of "*Papier Vegetal*," and it is very well adapted for backing negatives, as it takes black lead very easily. You will probably be able to obtain it at the photographic stock houses, or at some of the lithographic material warehouses in London.

GENERAL CORRESPONDENCE.

R. F.—Received. Thanks.

W. Weaver (Runcorn).—Received.

A. J. Jarman.—We shall forward your letter to Mr. Willis.

J. B.—We regret to say that the gentleman about whom you inquire is dead.

R. Peers.—Your exchange is inadmissible in our exchange column; but it may be sent to the publisher as an advertisement.

Frederick Dougherty.—1. The oxycalcium burner, and a six feet bag.—2. Do not attempt to make the bags; you will obtain them cheaper and better ready made.

M. Shelley.—Build the studio of the full length required, the sitter to face the north. You will then have east and west light morning and evening, which you can use as required.

J. G. L.—Evaporate the bath to dryness, weigh the crystals, and use them as ordinary nitrate of silver, making a new bath with them. See that the strength be at least thirty-five grains to the ounce.

An Old Veteran (Whitehaven).—We should have liked to publish your letter, but we feel quite certain that the estimable firm so strongly eulogised would take serious umbrage were we to do so.

John E. Bliss (Cambridge).—This correspondent would feel obliged if any reader could inform him of the name of the photographer who took the portraits of the survivors of H.M. turret-ship *Captain*.

A. H. W. (Acton).—Try one of the following, viz., thin linen coated with wax or paraffine, thin paper, or ground glass. The last-named will undoubtedly answer your purpose best; but it would prove very expensive, owing to the large size required.

Rev. J. P. B.—Of the two lenses the half-plate portrait combination will prove the better objective for the lantern, provided that it is found necessary or expedient to have the screen at one end of the hall and the lantern at the other. But if, on the other hand, you decide upon placing the lantern in front of the audience—that is, between them and the screen—the quarter-plate lens will be the better of the two; but even it will be found to possess too long a focus. To meet such a case we suggest that you obtain a combination in which the back lens will be of two and a-quarter inches diameter, and possess a great amount of negative aberration, and that it be matched with a front lens of smaller diameter and short focus. Combinations of this kind are not kept in stock by opticians or dealers, but may be easily constructed to order.

David King.—The single-barrelled air-pump will answer quite well for withdrawing the moist air.

Paris.—So far as we can learn, the photographs of each nationality are exhibited in that nation's department; therefore, if you wish to examine (say) Italian photographs you must look in the Italian department, and so with the others, the photographs not being exhibited in one place.

E. S. D.—From an inspection of the picture we believe it to have been coloured by powder colours; but, after the colours have been applied, some particular kind of varnish must have been flowed over the surface in order to cause the pigments to adhere.

W. L. R.—1. Suitable orange-coloured material can be obtained at most upholsterers' establishments, under the name of "orange cambric."—2. You should consult any respectable dealer in india-rubber appliances.—3. Obtain an india-rubber stopper for the varnish bottle.

Cestrian.—The filtering-papers may be rendered quite free from the hyposulphite of soda by immersing them for some time in warm water. We strongly advise you to treat in this manner the whole of the package of filters; for by using them as they are you will inevitably experience much annoyance.

☞ **Editorial Communications should be addressed to "THE EDITORS"—Advertisements and Business Letters to "THE PUBLISHER"—at the Offices, 2, York Street, Covent Garden, London, W.C.**

Photographers' Benevolent Association.—The Board of Management held their usual meeting on Wednesday, the 2nd inst., at 160*a*. Aldersgate-street. The minutes of the previous meeting were read and confirmed. The following gentlemen were duly elected as ordinary members of the Association:—Messrs. E. Tear, R. Prewett, and W. T. Wilkinson. An application for relief was then entertained, and, after full consideration, the Board granted the necessary order to meet the applicant's case. After other minor business had been dealt with the meeting was adjourned till November 6th, at eight p.m.

A Yellow Varnish for the Dark Room Window.—The *Photographisches Wochenblatt* gives the following formula for the preparation of a yellow varnish for this purpose:—Digest for several days in a wide-necked bottle, placed in some warm room, five parts by weight of Xanthorhöa resin (also called "acaroïd resin") in five parts by weight of ninety-five per cent. alcohol. During digestion the mixture should be shaken up from time to time. The sort of Xanthorhöa resin which goes by the name of "black boy gum," and which is dark in colour, is to be preferred. As soon as the alcohol has absorbed all the soluble parts of the resin add one quarter, by weight, of copal balsam or castor oil, in order to prevent the varnish from tearing. If requisite the quantity of the last ingredient may be slightly increased. When poured, like collodion, over the glass to be used for the window, the varnish dries rapidly, leaving behind it a perfectly clear, orange-coloured film which does not transmit a trace of actinic light, and which has also the advantage of adding but little to the cost of the clear glass. When the varnish is thinned with spirit it becomes lighter in the colour. This varnish is said not to lose its yellow colour owing to the action of light. It may also be used in the production of gold lacquer, as it may be used cold, and is glossy and transparent like ordinary gold lacquer. It has been used to brighten up old gilt frames.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 963. Vol. XXV.—OCTOBER 18, 1878.

ON THE ARTISTIC QUALITIES OF NEGATIVES.

In taking up the thread of the subject we treated last week, we must warn our readers that it is beyond our power to point out a "royal road" to success in the production of artistic results. The technical departments of photography may, no doubt, be fully laid down upon paper in such a manner that any ordinarily-careful person may understand and master the details with comparatively little practice; but when we venture within the bounds of art the pen becomes a feeble exponent of the laws and requirements. It is a simple matter to give directions as to the mixing and blending of colours so as to produce certain secondary effects; but not all the volumes that were ever written would be sufficient to supply the power of uniting those colours into a faithful transcript of nature. So we propose to speak chiefly of the chemical and mechanical conditions of photography, and to point out in what respects they may be varied in order to aid as far as possible artistic requirements.

Perhaps, strictly speaking, exposure and development belong rather to the technical side of the question than to the artistic; for a negative must be photographically perfect before it can aspire to pictorial excellence, and this involves not only a due amount of care in exposure but an equally careful and suitable development. Still we may be permitted to refer to one or two points connected with these two operations, which bear, perhaps, as much upon the artistic as upon the technical quality of the result.

To a certain extent it may be said that the requirements of artistic and technical excellence do not necessarily run together. An artist's rendering of a given subject would be widely different from that of a mere mechanical draughtsman; and, though the respective productions might be, for their special purposes, perfect, each would present certain characteristics wholly at variance with the requirements of the other. So, in the production of certain pictorial effects photographically, it is occasionally necessary to depart from the strict rules applying to purely photographic results, as in the case of so-called "moonlight views," which, judged from a technical standard, are merely under-exposed pictures; but in adopting such a course as this it is needless to say that the departure from orthodox rules must be made with a full knowledge of the exact effect it is desired to produce, and not in a haphazard way, trusting to good fortune to bring about a satisfactory result.

It is a question whether such "tricks" can be legitimately considered artistic; but, on the principle that *ars est celare artem*, the artifice is, no doubt, justifiable so long as the result does not expose the fraud.

The chief difficulty in the matter of exposure consists, as we have pointed out, in securing harmony between the unequally-illuminated portions of the subject; and while this difficulty varies in degree with different processes, it is never, even under the most favourable circumstances, wholly absent. With certain classes of subjects—those presenting but little natural contrast—it may, perhaps, be ignored; but it must be remembered that subjects of this description very rarely afford material for pictorial results, and therefore the gain in the technical department is neutralised by the absence of those artistic qualities which it might otherwise supplement.

The difficulty we speak of is more or less natural to all processes, wet or dry, and arises from the incapacity of a uniformly-sensitive film to render, under identical exposure and development, the different degrees of actinic action produced by the rays transmitted from the various grades of the subject. The charm of a landscape depends upon its "atmosphere;" but, in the great majority of cases, if a sufficient exposure be given to secure a proper rendering of the foreground, objects at a greater distance will be overdone. The only obvious plan of combating the evil is to regulate either the development or the exposure to suit the varied degrees of illumination in the several portions of the picture. The first is practically impossible, but, by dint of a little care and judgment, considerable benefit is derivable from the use of masks or screens to shade the better-lighted portions of the image during a part of the exposure. Numerous contrivances have been described, under the name of "sky shades," by which the purpose may be effected; but, though there is no controverting the fact of their utility when applied with skill and judgment, there is a tendency to abuse the power thus acquired.

We have seen many landscapes by various operators in the production of which the sky shade has been utilised in order to modify the over-action of distant objects, and we have no hesitation in saying that in the greater number of them the power has been abused—the masking has, in fact, been pushed to such a degree that foreground and distance have received proportionately the same exposure, with the result that atmospheric effect is entirely annihilated, distant objects being as sharply and vigorously rendered as those in the immediate foreground. The only excuse that can be offered for this fault lies in the fact that a negative with a clear, sharp, *under-exposed* distance *looks* nice; and, difficult though it may be to eradicate the habit, we must repeat what we have already said in our previous article in reprobation of the practice of judging negatives by their appearance rather than by their printing value.

The development, we have said, affords no opportunity of locally modifying its action; but a great deal may be done in the production of different effects by varying the character of the development, with or without altering the exposure. But in drawing upon the capabilities of a modified development it is very necessary to distinguish between the effect required in a case of simple over- or under-exposure and one in which the aim is to secure harmony between the contrasting portions of the picture. The conditions presented are almost diametrically opposite, and, of course, necessitate very different treatment. Suppose, for instance, we have a plate which we know to have been much over-exposed. It would be proper in this case to apply a powerfully-restrained developing solution which would bring out the image slowly and place it more under control. But in addition to, and of more importance than this, the greatest action of the restraining agent is exercised upon the most feebly-impressed portions of the image; and thus, by holding the shadows in check, a degree of vigour and contrast is imparted to the picture which would not otherwise be obtained.

But when the object is to secure harmony we have, so to speak, to deal with both under- and over-exposure; for, viewed relatively, the foreground is under-exposed while the distance is overdone, and the task before us is to effect a compromise between the two. Applying the same argument with regard to the employment of a well-restrained developer: if it contain a sufficient proportion of the restraining agent to prove effective in checking the over-action in the distance the already existing deficiency in the foreground will be still further exaggerated; and, though the detail may not be totally obliterated, it will be so enfeebled that the treatment necessary to bring it to printing density will utterly ruin the distance.

The more correct course to adopt under these circumstances is to use a developer in which the restraining agent is reduced to the lowest possible proportion. Presuming the alkaline method to be in question, we should employ a weak solution of pyro. (not more than one grain to the ounce) with the faintest trace of alkali and *no* bromide, applying it to the film until a thin, flat image, showing every detail, becomes visible, then intensify carefully. There need be little fear (if the exposure has been well timed) of want of contrast, for the lights during intensification will be found to gain strength with much greater rapidity than the weaker portions; the only danger will arise from a too rapid or hasty intensification. Some operators prefer to commence the development with plain pyro.; and though this may answer with an evenly-illuminated subject, such will not be the case under the circumstances we speak of. The fact is that plain pyro., though effective enough with a full exposure, is little adapted to the production of faintly-impressed detail; and upon the addition of alkali in however small quantity, in order to bring out the detail, the image already developed commences to intensify, and goes on gaining density with much greater rapidity than if the alkali had been used from the first. In this manner the contrast is increased rather than diminished, while the harmony sought for is not found.

Another element which materially affects the general character of the result is the process employed. Now, though we fully agree with those who believe that *any* process is capable of producing first-class results provided it is carefully studied and mastered, there is no gainsaying the fact that certain processes give a larger proportion of results of high quality than others, from which it may be inferred that the former present fewer natural difficulties to be overcome—that, in fact, with a given amount of trouble they produce a better result. Up to a very few years ago it was the almost universal opinion that dry processes in general were far inferior in this respect to wet; indeed, we have frequently heard enthusiastic dry-plate men assert their belief that their films were, even under the most favourable conditions, incapable of equalling the best wet work. Now this is all changed, and there are those at the present day who assert that to produce the very highest class of results a dry process is necessary. Whence arises this change?

It certainly is not to attributed solely to our increased knowledge of dry-plate requirements, though that may account for some part of the improvement; for there were, ten years ago, dry-plate workers who were quite as far advanced in their acquaintance with these particular processes as we now are with more modern processes. The change evidentally comes from some alteration in the dry processes themselves, and that alteration we firmly believe to be simply the vastly greater degree of sensitiveness which is now attained. Mr. Charles Bennett has pointed out how this property operates in favour of a better quality of picture by rendering extremely feeble detail, which a slower plate, even with a relatively longer exposure, would fail to produce; and this forms the chief, if not only, argument in favour of rapid films for ordinary work. But, as we have attempted to show in previous articles, there is a counterbalancing disadvantage in the employment of these films in the increased amount of care necessary. The production of really high-class results of course involves a greater amount of care and patience under any circumstances, and in the matter of sensitiveness it will therefore remain for the operator to form his own judgment as to how far it is necessary to go in order to obtain films of the requisite quality.

Care, indeed, forms the keynote to success in this branch of photography, as in any other departure from the ordinary run of respectable mediocrity; and if, in addition to the extra amount of care, each operator would also devote some little attention to the intelligent study of the technical portions of his work in the directions we have indicated there would soon be an improvement in the character of his productions.

THE PHOTOGRAPHIC EXHIBITION.

[Second Notice.]

Resuming our description of what is displayed on the table: Mr. J. Lane exhibits a camera and other apparatus. One noteworthy feature in the camera is that it opens out to nineteen inches; but by means of a supplementary base-board the body can be extended five and a-half inches beyond this measurement, or twenty-four and a-half inches in all. As a landscape camera it is adapted for whole plates, and it possesses the means of allowing the back (which is a reversing one) to be taken out, and a repeating-back to be inserted. Both of these adjuncts are to be seen on the table beside the camera, which is also fitted with a vertical and horizontal swing adjustment. Mr. Lane's ingenious top for his camera-stand—in which adjustments can be made with great accuracy—will approve itself to everyone on account of the facility with which it can be brought to an accurate level.

Mr. John Harmer exhibits a series of twelve stereoscopic transparencies (332) executed quite *à la* Breese. The effects of moonlight are wonderful. These pictures excite much comment from connoisseurs.

Ceramic photographs are exhibited by Mr. W. Watson and Mr. Henry N. White. The latter show the application of this branch of photography to tiles, the former to cups and oval *plaques*.

The Woodbury Company exhibit many beautiful transparencies, perfect in gradation and charming in tone. These are also characteristic of a large collection of transparencies exhibited by the Sciopticon Company, which, being of smaller dimensions than the others to which we have just made reference, are capable of being displayed by means of the magic lantern. Of the quality of Mr. England's transparencies we have spoken so frequently before that we need only say that those in the present Exhibition are quite equal to the best of his productions seen by us previously.

A frame of cloud negatives is exhibited by Mr. W. Perry, to whom, we imagine, many photographers are not a little indebted for the skies of their landscapes.

Mr. Henry Whitfield exhibits several gelatino-bromide negatives of views in Devon and Somerset, and Mr. J. H. Ritchie demonstrates the keeping properties of plates prepared by the tannin process by exhibiting one which was thirteen years old when exposed.

A Winter Night (347), by Mr. Charles Bennett, represents a transparency from a gelatino-bromide negative taken at *night*, last February, by the ordinary illumination employed in villa residences in the country. Of this picture we have already given full details in this Journal.

These complete the exhibits on the table.

The eye rests with delight upon the sunny, atmospheric landscapes of Mr. Vernon Heath, whose *Vale of Festiniog* (10) may be cited as an example of high-class work, possessing fine gradations of distance. It is to the frame of four views in the Isle of Skye (11) for which the medal was awarded, and the pictures in this frame amply repay close study. Mr. Heath also contributes several autotype enlargements of great merit.

Messrs. A. and J. Bool's large direct picture, *An Old Farmstead* (9), shows that the difficulties of producing direct large works have been ably overcome by these artists. Mr. E. Brightman's picture, *A Devonshire Lane* (16), is an excellent example of that gentleman's work. The enlargement of *Ferns and Bluebells* (26), by Messrs. Marsh Brothers, is a highly-successful piece of work.

A pair of companion pictures, respectively *The Oak* (32) and *The Farm* (33), by Mr. J. Dudley Radcliffe, are good subjects nicely treated.

Eight views done in the inimitable style of Mr. William Bedford occupy a prominent position on the walls, and emphasise the presence of this master of landscape. Mr. Bedford's pictures are entered as "not for competition." His two views at Bettws-y-Coed are among the finest work that we have ever seen produced, even by Mr. Bedford himself.

Mr. T. G. Hemery contributes three portraits (40·1-2) on opal glass. The centre figure, an elderly man with a flowing beard, is very fine.

We have, whether rightly or wrongly, always been in the habit of associating Mr. Henry Cooper with the production of what we may designate "lane scenery"—that is, little artistic "bits" picked up during a ramble through rural scenery. In the reproduction of such views we know Mr. Cooper to be *facile princeps*. We do not find in his exhibits this year any examples of precisely this class of picture, but we find, instead, some scenery of another character selected with the æsthetic taste and executed with the ability of a skilled artist. These will be found on referring to Nos. 52-8.

Ruddier in tone, while equally faultless as regards their pictorial and technical treatment, are a series of landscapes by Mr. H. B. Berkeley, who, by the exhibition of such graphic works, shows the futility of an observation we once heard made by Sir David Brewster, to the effect that the faculty for scientific research was very seldom found associated in one individual with manipulative and artistic ability. Every reader of this Journal knows well how high Mr. Berkeley stands in the former category; the five frames of pictures (86 *et seq.*) prove the possession of the latter quality.

Several excellent pictures of river scenery are exhibited by Mr. H. A. H. Daniel—his *Mill Dam* (69) being a good example of his work.

What would a photographic exhibition be without the wonderful and charming examples of babyhood by Mr. R. Faulkner? His enlargements, on opal glass, of picture of this class are exquisite. Of the six opalotypes (75, &c.) we are unable to express a preference for any one specimen. *Held in Bondage* is, simply, perfection. Here a little girl clasps her kitten closely in her arms, both subjects being replete with life and character. The study of such works must be productive of good to photographers. In addition to these Mr. Faulkner has a frame (307) containing upwards of fifty small views of the same class. This able artist has aimed a blow at conventionalism by his adoption of a red tone in these prints, which are produced in permanent pigments.

STOPPING-OUT BACKGROUNDS.

Although the time has long gone by when a perfectly-stopped-out sky, printing clean and white, was considered a point of great importance in a landscape negative, there yet are many occasions when, for various purposes, the production of a white ground is a matter of importance, if not, indeed, of necessity.

Thus, in our last week's issue, we treated of the desirableness, from the manufacturer's point of view, of having objects, such as machinery, &c., represented without any of the usual surroundings or adjuncts of the workshop. Those only who have tried work of this kind are fully aware of the difficulty of the process; and for a restricted class of work a few hints upon the subject will not be out of season, our readers fully bearing in mind that our remarks are only intended to have a limited application, though we think it unlikely that anyone nowadays would endeavour to send out a white-skied landscape.

It is possible to attain the object in view by two methods—first, by the painting out upon the varnish of everything but the required subject or subjects; and, second, by cutting an opaque mask and placing it *in situ*.

Taking the first method under consideration: we may say that a most important matter is the obtaining of a suitable paint for the purpose. We often see recommended, as apparently on an even footing, Indian ink, gamboge, lampblack, black varnish, and almost every pigment of the artist's palette has in turn been suggested. For a small spot, or when the details to be obscured are of themselves not very thin, there will not be much difficulty; but when a case arises where the background to be obscured consists of every variety of depth—portions, perhaps, being clear glass—it will be found that very few materials will answer every requirement.

Take as the most readily obtainable and nearest to hand the cake or moist water colour. The latter in the body required for complete opacity to actinic rays will not dry sufficiently upon the glass, and is in consequence quite useless. The former—the cake colours—have usually so much gum in their composition that after a little while they crack, and, perhaps, bring a piece of the film away.

Gamboge is a useful material in some instances, but has not "body" to cover well when complete opacity is required. We have seen many negatives on which it has been tried, and frequently it had to be supplemented by another coat on the outside, *i.e.*, the glass side, of the negative. Next comes indian ink—a most useful material, but still very difficult to cover well unless special precaution be taken. The time and labour required to grind even a little down into paint is no small matter. If this material be chosen it must be used very thick—as thick as cream—or the work will have to be done over again, owing to a number of semi-transparent spots making their appearance when dry. Then, again, this remarkable pigment is of such a peculiar nature that, when it has been rubbed down and allowed to dry, it will not, when re-moistened and taken up into the brush, work like that newly prepared; it loses its covering power, and will not flow with anything like the same facility from the brush. And, finally, we have seen more negatives than one the films of which have cracked under the use of indian ink.

The best water-colour material we ever saw was, without exception, an experimental tube of moist colour which, by special request, the manufacturer had made without any extraneous substance beyond the pigment itself and the water it was ground in. The intention was that a variety of substances should be tried to discover the best medium which would bind the paint but not crack the film. Lampblack was the colour chosen; it covered splendidly, but of itself naturally has no cohesive power, and might almost be blown off the surface painted with it. Various binding materials were tried—gelatine, gum, albumen, &c., with a little glycerine, treacle, honey, sugar, &c.; but the gentleman by whom the experiments were made finally gave it up as involving too much trouble to "mess" with. At the time we speak of he had a very large number of machinery negatives in hand, and was almost at his wits' end to get them done well and *expeditiously*. Circular saws, he said, when every tooth had to be painted out from a most variegated background, were, beyond measure, troublesome.

We have placed last on our list the best. For all general purposes a good "black varnish," in our opinion, is preferable to anything we have named, provided only that the negative will not be required again in its pristine state. It is obvious, of course, that many cases will arise where the permanent blocking out of part of a negative is entirely out of the question; for, though it is possible to remove a coating of thin material unless it has hardened by being allowed to remain a long time before treatment, it is practically one of those operations which had better be left undone. When the use of the black varnish is contra-indicated we advise the employment of indian ink, carefully laid on, not too thick, with a little stippling in weak places when dry, and aided by a loose mask on the glass side of the negative, which will reduce the space necessary to be painted upon to the smallest area.

The black varnish to be used is not the "Brunswick black" or the "Japan black" of the shops, but one of the kind made for the use of the "ambrotypist"—the "positive" black varnish; indeed, we have scarcely met with a sample made for the use of photographers which did not answer well. The best for the purpose is that made with a benzole or naphtha solvent; it seems to have incorporated with it a pigment, in addition to the asphalte, which gives to it a surprising body or covering power. The first two we named do not possess sufficient body, and the latter of them is too long in drying. We will defer the treatment of the use of movable opaque masks till next week.

RECENT PATENTS.*

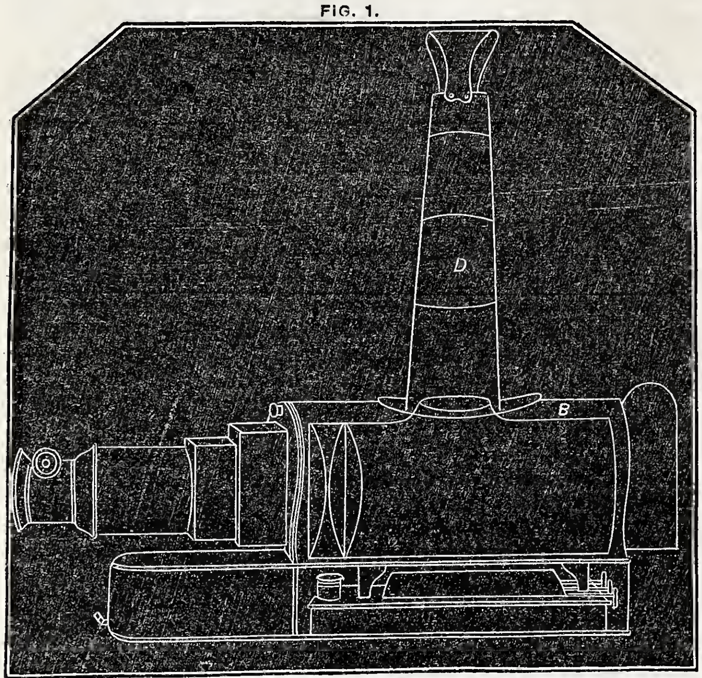
No. XVI.—HUGHES'S TRIPLEXICON.

Description of the Drawings (with Further Description of Details for Carrying my Invention into Practical Effect).—*Fig.* 1 shows

* Concluded from page 470.

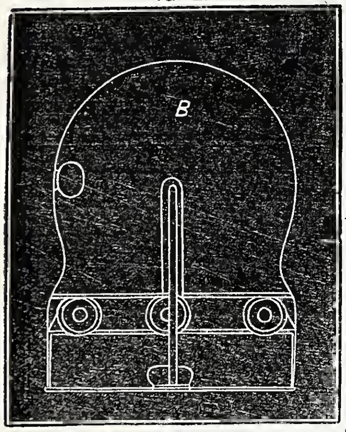
the form of the lantern body in elevation, same measuring (for three

FIG. 1.



and a-half or four-inch condensers) twelve and a-half inches from front to back, eight and a-quarter inches in height, and nine inches wide, and made larger if necessary, according to the size of the lantern condensers used. *Fig.* 2 is a back view of the lantern, showing exactly the form it assumes. *Figs.* 3 and 4 show the lamp in its entirety, and *figs.* 5 to 19 various sections of the same.

FIG. 2.



The lamp proper consists of an ordinary cistern or reservoir (B, *fig.* 3), which can be made any size to contain sufficient oil for the time the lamp is wanted to burn; on the top of this are wick tubes, three in number, through which the wicks pass, and are raised and depressed by three separate racks and pinions with milled heads. The centre wick holder is quite perpendicular, while the two side ones lean towards the centre one at the top (as shown by B, C, D, in

FIG. 3. FIG. 4.

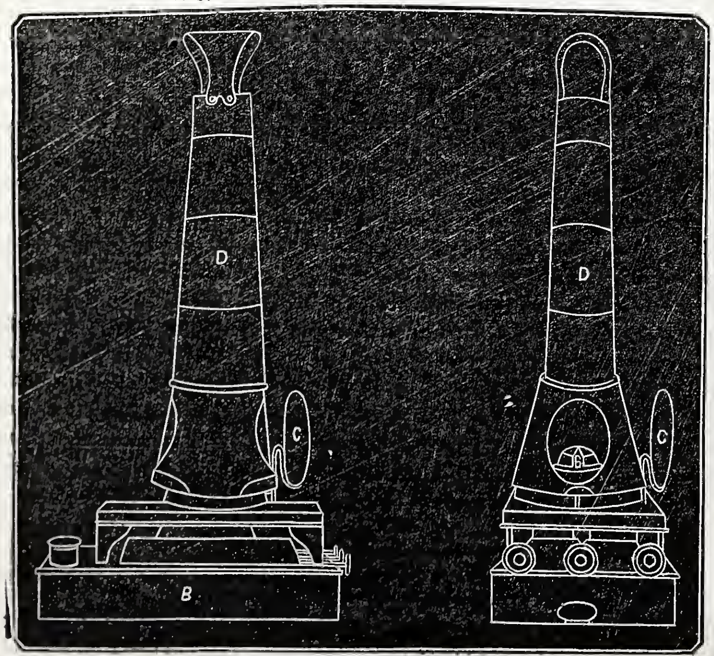


fig. 6), so that the three wicks may be enabled to assume the several shapes shown in *figs.* 10, 11, and 12. The two outside wicks in either case are more widely separated at some points than others from the centre wick (as shown at B, C, D, *fig.* 6), while at one point they are brought closer together, and are not wider apart in any position than half an inch and one-sixteenth, and not nearer together than a bare quarter of an inch in the narrowest part of the various curves, as shown in *figs.* 10, 11, and 12. There must be also between each wick holder (soldered near the bottom) perforated plates, as shown at A, B, C, *figs.* 10, 11, and 12. This is to prevent the air from rushing through too violently, and only to allow the proper quantity of air to pass between the flames for the proper combustion. The wick-holder is generally two inches and three-quarters in height. On account of the capillary attraction they should not be less, as sufficient amount of space must be allowed for the air to pass through in order to feed the flames.

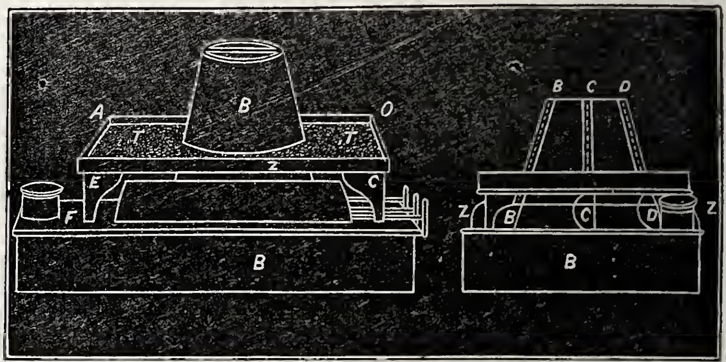
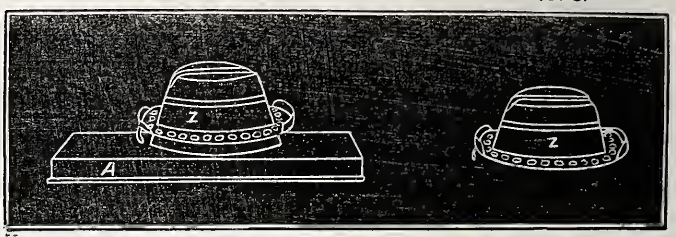
FIG. 5. FIG. 6.



Above the ground plate (F, *fig.* 5), and resting on four separate feet (A, E, C, O) barely one inch in height, is another plate (T) which is perforated with a number of small holes. This plate is about six and a-quarter inches long by four and a-quarter inches wide, having entirely around it a ledge *z*, three-eighths of an inch in depth. When the cover plate (*fig.* 7) is placed thereon the air penetrates through the cone *z*, and thence to the flames.

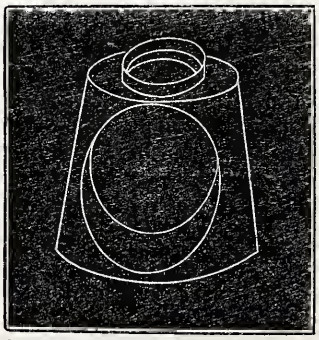
Between the perforated plate or platform, and on the top of cistern of the lamp, is placed a metal shield (see *fig.* 5) to prevent the heat from being thrown down direct upon the cistern containing oil. This is situated at both ends of the lamp, and is arched like a bridge (see *z*, *z*, *fig.* 6). On the cover plate (*fig.* 7) is fixed a bell-shaped

FIG. 7. FIG. 8.



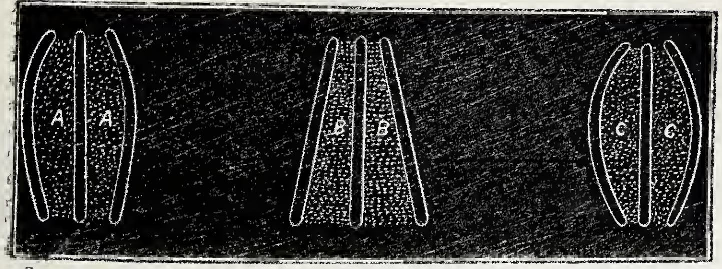
cone *z*, standing two inches in height, and in diameter at the bottom three inches and three-quarters. The extreme edge of same is turned back to allow of firmly soldering it to the ground plate of the cover underneath, the top part of the cone covering the wicks being two inches and three-quarters in diameter, down the centre of which a slot (B, *fig.* 13) is cut, of the size and shape to lie right above the curves of the two side wicks in either of the three positions before mentioned, and is raised above the two side wicks half-an-inch. The slot is carried in depth on the cone at either end half-an-inch (as at B, *fig.* 4). Between the cone and the wicks there is sufficient space to allow the air to efficiently do its work on any portion of the flames. It is, therefore, these dimensions and sizes of the various parts and fittings, together with the combustion chambers, that regulate this sized lamp suitable for magic lanterns with three and a-half or four-inch condensers.

FIG. 9.



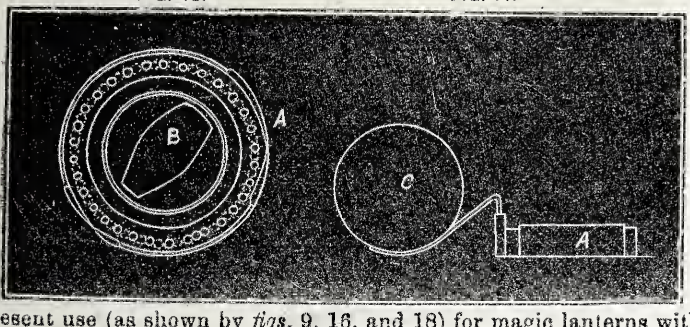
This lamp can be used for burning paraffine oils, but should colza oil require to be burned in it I can adapt an ordinary fountain cistern, but a little variation in sizes, either larger or smaller, will not prevent the desired and proper combustion of the flames; but to whiten the flames a proportionate quantity of fine wire gauze or muslin can be placed between the perforated plate (T, *fig.* 5) and the top plate (*fig.* 7).

FIG. 10. FIG. 11. FIG. 12.



The combustion chamber, as before mentioned, can be made of various shapes, but not larger in proportion than adopted by me for

FIG. 13. FIG. 14.



present use (as shown by *figs.* 9, 16, and 18) for magic lanterns with three and a-half or four-inch condensers.

FIG. 15. FIG. 16.

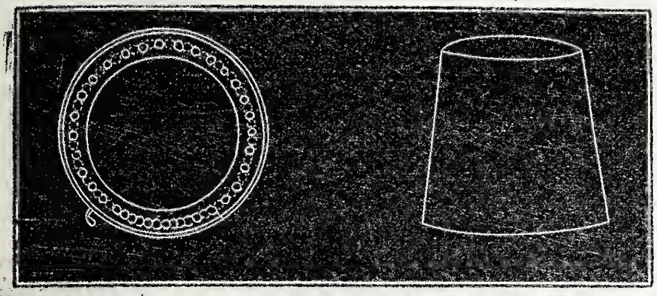


Fig. 16 is the glass chamber or cylinder (which must be made of blown annealed glass), about four inches in diameter at the bottom, three inches and one-eighth at the top, and three inches and three-quarters deep; the metal frame or cap (*fig.* 9) being just the size to cover the glass cylinder or chamber loosely, having openings back and front to let the light out. This, when the metal chimney (A, B, C, *fig.* 3) is attached, forms a complete combustion chamber.

Fig. 13 is the ground plate, which is circular and raised about midway up the bell-shaped cone (*z*, *fig.* 7), covering the flames, and securely fastened to the same, in order to hold the combustion chamber firmly. This ground plate is made in two separate pieces (as in *figs.* 13 and 15), but forming, when together, one platform. The top plate (*fig.* 13) has its inner and outer edges turned over on the underneath portion to form a frame, in which is placed the bottom plate (*fig.* 15), fitted moderately loose to allow it to revolve round either one way or the other. Both of these plates have a number of holes (say twenty-seven, for instance) at certain distances apart, and about one-eighth of an inch in diameter, the same being punched through the plates for the purpose of forming a vent for letting in the outside air to the combustion chamber should the glass chamber fit too tightly in the metal frames. By this arrangement the bottom piece is turned, and so covers and uncovers the holes situated on the top ground plate (the dotted lines in *figs.* 13 and 15 showing the position of the same). Attached to the perforated ground plate are two ledges, placed in such a position as to be back and front of the lamp (see A A, *fig.* 13, which shows their position). These ledges are placed for the purpose of retaining the combustion chamber firmly and securely in its place. D, *fig.* 3, is the connective metal chimney which forms part of the combustion chamber. C, *fig.* 14, is the reflector, which moves to and fro in a slide A, and is placed on the right side of the ground plate (*fig.* 7) covering the wicks. This is to enable the operator to adjust it in a proper position.

Fig. 18 is a metal cap or frame which rests on the glass chamber without resting on the ground plate, to which is attached the outside metal chimney, made in size according to the glass chamber.

Fig. 17 is an ordinary glass chimney, which can be used on the ground plate (*fig.* 13) if desired.

FIG. 17. FIG. 18. FIG. 19.

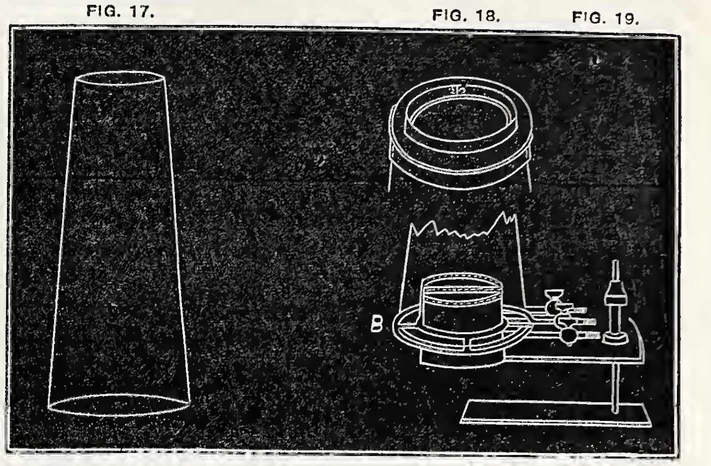

Fig. 19 is a gas burner having the same curves as the orifices in *figs.* 10, 11, and 12, but instead of pinions having three separate gas taps for adjusting the flames to a nicety; the width of the burners will vary in size from half-an-inch to eight or ten inches. They will also curve similarly to the wick tubes as used in the oil lamp. The cone *fig.* 8 will fit over them, and a metal platform (B, *fig.* 19) near the bottom will hold the cone and glass chimney or combustion chamber. This triple burner will assume the same positions, &c., as in the other portion of my invention relating to the "triplexicon" lamp.

The "triplexicon" lamp in its completeness can be made larger, the dimensions being of course in proportion with the size of the wicks, any part accordingly being made on a proportionate scale, which will ensure proper combustion.

Having now particularly described and ascertained the nature and object of the said invention, and in what manner the same is to be performed or carried out in practice, I hereby declare that I claim—

The new or improved form of lamp hereinbefore described, having three distinct wicks and separate racks and pinions, or equivalents therefor, arranged substantially in the manner hereinbefore set forth and described with the view to ensure proper and perfect combustion, whether for magic lanterns, streets, ships, halls, light-houses, &c.

Also the arrangement of the ground plate and of the combustion chambers, substantially as the same are hereinbefore set forth and described.

W. C. HUGHES.

We have only to add to the foregoing a remark to the effect that so intense is the light of the triplexicon in its present improved form that we have seen it successfully applied to the exhibition of objects by polarised light, as well as to the delineation of the larger microscopic objects hitherto shown by means of the oxyhydrogen microscope.

It is rather late in the day to speak of the necessity of cleanliness in photographic operations, and somewhat supererogatory on our part to impress upon our readers the desirability of keeping the various baths, dishes, and other utensils each to its special use as possible. This may not be convenient at all times; but when any departure is made from the rule it is needless to say that a thorough cleansing of the bath, dish, or bottle, as the case may be, should take place before applying it to its new use. We do not refer to a mere washing until the vessel *looks* clean. It should be *chemically* clean; and, when circumstances require it, strong measures should be resorted to. The utmost precaution, however, sometimes fails, as the case we are about to mention will show. We had submitted to us a few days ago a number of prints which were covered with a network of peculiar reticulated markings, which gave them the appearance of having been fitted together from a number of irregular pieces, after the manner of a child's "puzzle." The following information was vouchsafed as to the cause of the markings:—The prints, which passed successfully through the various operations of toning and fixing, were washed in two or three changes of water and left over-night in a porcelain dish to soak. The dish (an old one) had some time previously been used for sensitising paper, and when discarded for that purpose had absorbed, as porcelain will do, a considerable quantity of silver, which the cracks in the enamel plainly showed. Before applying it to a new purpose it was thoroughly scoured with fine sand, and then left for several weeks to the action of dilute nitric acid. This treatment had apparently removed all the silver, and after another thorough washing the first use it was put to was the soaking of the prints we mention, and the result showed too plainly how inadequate had been the cleansing. Porcelain is an abomination when silver solutions are used, and we should be glad to see it banished from the photographic laboratory if possible; but, so long as dishes of that material continue to be used, we would have our readers beware of the danger which is likely to arise from the indiscriminate use of one dish for different solutions. In the case we mention the effect was remarkable, and consisted of a faithful reproduction on the prints of every minute crack in the enamelled surface of the dish; and this not only on the print in immediate juxtaposition to the cracked surface, but through several as they lay one above the other in the water. In the whites of the print the markings were brown, and resembled ordinary hypo. stains; but where the image existed the tone was changed from a warm purple to a cold, slaty blue without any appearance of sulphurisation on the albumen side, though on the back of the print the lines were brown, as in the other portions.

SUBSTRATA AND BACKING.

There is, probably, no photographic process that has during any given time received more successful attention than that of collodio-bromide emulsions. Allowed to lie dormant for years after its first suggestion, the process was at length taken up with enthusiasm and prosecuted with such energy by most of our ablest experimentalists that one by one its difficulties were removed and its conditions understood, till at the present time, whether as regards simplicity of manipulation, certainty, or beauty of results, it is as nearly as may be perfect.

While, however, this is true as regards the nature and properties of the various more or less well-known varieties of the emulsion family, there are certain minor troubles with which the emulsion worker has to contend that have not received so much attention, and which ever and anon crop up to mar the otherwise even tenor of his way. Not the least troublesome of these is the difficulty in preventing the film made from certain samples of pyroxyline from slipping from the plate. Much has been written about the necessity for a suitable sample of pyroxyline for emulsion work, and I am aware that there is a general impression that the variety made with rather weak acids at a high temperature is most suitable for the purpose; but I think there is, in the results both of my own experiments and the practice of many of my friends, ample evidence that this is a mistake; that an excellent emulsion may be made from any good sample of pyroxyline; and that the variety best adapted for wet collodion is possibly also the most suitable for emulsion work. But there is one objection to such cotton which makes its use a source of vexation, namely, its tendency to slip from the plate, especially during the washing after fixing, which renders some kind of substratum, or other means of curing the evil, a necessity.

For this purpose the use of albumen has become very general, and no doubt it possesses many advantages; but for emulsion work it has the grave defect of, in too many cases, not answering the intended purpose. It is cheap, very easily applied, and secures a chemically-clean surface; but while, with all samples of collodion for the wet process, it holds the film perfectly, my experience leads me to say that most of the emulsions I have tried, whether made by myself or by others, slip almost as readily from it as from uncoated glass. In consequence of this I have for some time employed successfully an edging of rubber dissolved in chloroform, and find it all that those who have recommended the plan have claimed for it. It can be very neatly and rapidly applied by making a modified American clip so filed that the plate is gripped in a groove about a sixteenth of an inch in depth. This is lined with a strip of woollen cloth saturated with the solution, and the plates may be edged at the rate of a dozen in less than two minutes.

The two drawbacks to this method are the additional trouble in making the plates perfectly clean, and the fact that the solutions have a tendency to get between the film and the glass, which makes the complete removal of the hypo. a difficult matter, and consequently the coating of the entire plate with a suitable substratum is to be recommended.

This brings me to another of the minor troubles of emulsion workers, as, in conjunction with the substratum question, I have been trying to get rid of the evil in an easier and more satisfactory way than has yet been proposed. I allude to blurring, and the method of backing now generally adopted for its prevention. There are few emulsion workers who would not be glad to get rid of the trouble of smearing the backs of their plates with the sticky mess of sienna now employed, and of the disagreeable necessity of washing it off again previous to development. Mr. M. Carey Lea and others at one time recommended the staining of the emulsion itself with cochineal, aurine, &c.; but the system did not come into general use, mainly, I believe, because the action of the foreign matter considerably reduced the sensitiveness of the plate so prepared. The idea that I have been trying to work out is to combine the colouring matter with the substratum, and, so far, I have met with such a degree of success as to induce me to ask others to take the matter up, in the hope that some one will hit on the material most suitable for the purpose.

While satisfied with the rubber edging already alluded to, I got rid of the trouble of backing by applying a preliminary coating of collodion coloured with aurine. Such plates are easily prepared, and will of course keep indefinitely previous to the application of the emulsion, while there is not the same necessity for chemical cleanliness as where the emulsion is to be applied directly to the glass surface. A very pale tint effectually prevents reflection from the back surface of the plate, so rendering blurring from that cause impossible; and it is easily removed after its work has been accomplished, partly by the pre-development, moistening with dilute alcohol, and partly in the subsequent fixing and washing processes. But the desire to use a substratum over the whole plate led to the search for a different colouring matter—a search in which I have not yet been so successful as I hope to be. The substratum which at the present time I think is in every way most useful and convenient is a solution of india-rubber in benzole; but this latter, unfortunately, is a menstruum in which aurine is not soluble, although, probably, had it been so it would not have suited, as the rubber film is not easily penetrated by either alcoholic or aqueous solutions, and, consequently, its subsequent removal might have been attended with some difficulty.

What is wanted, then, is a colouring matter soluble in benzole and sufficiently unstable to be readily decomposed—*bleached*—by light. Of such substances the vegetable world includes a considerable number, although, as yet, I have only been able to experiment with a few. Of these, so far as I can see, the colouring matter of turmeric *(curcumæ)* offers the greatest chance of success. As the body of the film is necessarily thin the solution of colouring matter must be strong; and, probably, the easiest way to make it would be to moisten the coarse powder with the liquid and pack it closely, but not tightly, into the neck of a pretty large glass funnel. More of the liquid should then be poured into the funnel and allowed to percolate slowly through the turmeric, the colouring matter of which it will carry with it. In this way a very strong solution should be made, in which the necessary quantity of rubber may afterwards be dissolved. Plates coated with such a solution will be sufficiently deep in tint to prevent blurring; but it will resist the action of the various solutions used in development, and leave the finished negative slightly yellow in colour. To those who prefer to make thin negatives this tint will not only be unobjectionable but, while it lasts, a positive benefit, as it is pretty well known that such negatives print better in subdued light. In cases, however, where it would be objectionable it may readily be completely removed by a few hours' exposure to bright sunshine.

I do not, of course, present this as by any means the best material for the purpose; but, as I am strongly under the impression that there is a very decided advantage in the combination of the substratum and the blurring preventive, I am anxious to direct the attention of emulsion workers generally to the subject, in the hope that a perfect coloured substratum may soon be found.

John Nicol, Ph.D.

PRACTICAL INSTRUCTIONS IN MODERN PHOTO-MECHANICAL PRINTING METHODS.

Part I.—PHOTOLITHOGRAPHY.

III. Second Method of Preparing a Transfer.—The method of making a transfer which is now about to be described is a modification of a process due to Asser, of Amsterdam. Asser's process can be so far varied as to be rendered suitable for the reproduction of subjects in line or dot on one hand, or for the reproduction of half-tone subjects on the other hand; but in this latter case the reproduction takes the form of a grained or stippled picture. For the present let us pass over that modification of Asser's process which is adapted for reproducing half-tones, and consider how the method can be best applied to the reproduction of line or dot subjects. Now, it is well to bear in mind that, when the method is so used as to reproduce lines clearly and satisfactorily, there is still a tendency toward the reproduction of certain first approaches to half-tone, when these exist in the original. By taking advantage of this peculiarity of the process the adroit operator will often be enabled to obtain a satisfactory reproduction of subjects which are so ill-defined and grey in the finer parts as to defy the greatest skill and care of an operator employing the method already described. It generally happens that when the method which is about to be described is employed the lines are hardly so sharp and well defined as when the ordinary method is made use of; but this want of sharpness is so slight that it is scarcely noticeable unless a magnifying glass is made use of. In this case, as in many others, it is difficult to unite all desirable qualities in one process.

The quality of work producible by the method under consideration depends, to a very great extent, on the nature of the paper employed, as a clear and sharp definition of the lines can only be secured by the use of a paper having a smooth and even surface. It is imperative that this even surface shall be due to the natural quality of the paper, as a smoothness induced by heavy rolling is of no avail. Thin Rives paper is the most convenient material to employ, and a sheet of this having been placed in water, it becomes easy to distinguish the smooth side. This side being uppermost in the dish of water a piece of plate glass, which should be rather larger than the paper, is slid under the floating sheet, care being taken to avoid the inclusion of air-bubbles between the paper and the glass. The piece of plate-glass is next lifted out of the water with the paper on it, a slight grip on one or two points being sufficient to prevent the paper floating away. The next operation is to place the sheet of glass on a table, and by the application of a squeegee to remove the excess of water from between the paper and the sheet of glass. Before applying the squeegee it is well to cover the sheet of paper with a piece of waterproof cloth, or another sheet of paper, in order to prevent any damage to the surface of that paper which is about to be used for making a transfer.

The wet paper, thus fixed on a glass plate, must next be coated with a very weak flour paste, and this paste should be made by boiling together four parts of wheat flour and one hundred parts of water, care being taken to avoid lumps of unsoftened flour, and to strain the mixture carefully through muslin. The addition of a few drops of ammonia to the paste is an advantage, as even freshly-made paste is often slightly acid; and any acidity in organic materials which are to be rendered sensitive with bichromates is very undesirable. After the plate which bears the wet paper has been placed in an approximately level position its surface is flooded with the warm paste, about fourteen ounces of this being required for an ordinary sheet of demy paper. The plate must then be gently inclined, so as to run off the excess of paste at one corner. While the paste is being poured off it is as well to rock the plate just as one would do when collodion is being poured off in the operation of taking a negative. The plate carrying the pasted paper being now reared up on one edge to drain, a point will be noticed when the coating of paste tends to divide itself into little granular patches, which more or less resemble spinach seed. When this point is reached the pasted surface of the paper must be smoothed by means of a long-haired badger brush. This operation of smoothing the pasted surface requires some little practice in order to perform it satisfactorily. In doing this the brush should be held loosely in the hand, and the ends of the hairs should pass rapidly and lightly over the surface of the paper until an even surface is produced. The rocking motion given to the brush ought to start from the wrist, the arm being comparatively still. A satisfactory surface having been produced, the sheet of paper may either be stripped off the glass and hung up to dry, or it may be allowed to dry on the glass plate; but in this latter case it sometimes adheres unless the glass has been slightly waxed, as a trace of paste often penetrates the paper.

The dried paper may either be rendered sensitive by immersion in Husnik's alkaline sensitiser, already referred to, or it may be sensitised in a three and a-half per cent. solution of potassium bichromate to which a few drops of ammonia have been added; and after the paper has been soaked for a few minutes in either of these solutions it may be fixed up to dry in a warm place. When dry it should be exposed under a negative for about the same length of time as would be necessary in the case of a simply-gelatinised photolithographic paper; but, as the image produced on pasted or starched paper is very dark and vigorous, it is generally convenient to conduct the operation of printing in a frame provided with a jointed back, so that the progress of the operation can be watched from time to time. The exposure to light should be continued until the finest and faintest lines are distinctly impressed upon the paper. All examinations of the print must be made by non-actinic light, as a very short exposure to daylight would be prejudicial, and the hinged back of the pressure-frame should be so placed as to render it unnecessary to loosen more than a small fraction of the print when an examination is made. If this latter precaution were not taken there would be a considerable risk of losing the register of some of the lines, as exceedingly slight differences in hygrometric condition notably affect the dimensions of paper.

The exposure of the transfer having been finished, it is next placed in cold water in order to remove the free bichromate, and a few changes of the water are necessary. The transfer is then dried and placed between folds of paper, after which it is well ironed with a moderately-heated flat-iron. During this ironing those parts of the flour paste which have been made insoluble by the joint action of light and a bichromate acquire an increased degree of affinity for fatty matters and darken in colour, while those portions of the paste which were protected from the action of light are in no way altered by the heat of the flat-iron. After this ironing, the transfer is placed in cold water in order to soften the unaltered parts of the paste, and the next operation is to apply a fatty ink to the face of the wet transfer by means of a brush used after the manner of a dabber.

The kind of brush best adapted for this purpose is an ordinary small paint brush known at the oil shops as a "sash tool." Before this can be advantageously employed for inking the transfer it must, like a lithographic roller, undergo a preliminary preparation. The object of this preparation is not only to break up the tips of the hairs or bristles, but to so far saturate these bristles with fatty matter as to prevent any undue amount of water from penetrating them. The preparation of the brush is commenced by anointing it with printers' ink, and then beating the ends of the bristles on an anvil until the final eighth of an inch is battered and disorganised. More printers' ink having been applied, the brush is worked for a short time against a brick wall or some other rough surface, and, after a thorough cleaning with turpentine, it is ready for use. The ink is next prepared by mixing one part of ordinary letterpress ink with two parts of oil of turpentine, and fastening a piece of muslin over the neck of the bottle, so as to form a filter for the ink. Some drops of this having been shaken out on an inking slab, and well worked into the brush, a few minutes are allowed for a portion of the turpentine to evaporate. The wet transfer is then laid evenly on a slab of plate glass, and, after the excess of moisture has been removed by means of blotting-paper, the inking is commenced by gently dabbing the face of the paper with the inking-brush. This operation should be continued slowly and uniformly until every part of the transfer is charged with rather more ink than is required to remain on it, and if the whites become tinted it is of no consequence. Now free the brush from a superabundance of ink by working it on a clean part of the slab, and, after having flooded the transfer with water, resume the treatment with the inking brush; but in this case it is necessary to use a more rapid motion and a very light pressure. Under these circumstances the excess of fatty ink will become gradually cleared off, leaving the subject clearly defined. It often happens that some parts of the subject will require local treatment with the brush in order to do them justice, and it is just as well to have the original subject near at hand for reference during the clearing of the transfer. It is scarcely necessary to observe that those parts of the original which are formed of ill-defined, greyish lines should be reproduced in the same manner, otherwise the general effect of the original will be altogether lost. If the inking appear to be unsatisfactory the whole of the ink may be cleaned off with oil of turpentine, and the operation of inking can be recommenced.

Success in the operation of inking is only to be attained by a careful study of those conditions which lead to an abundant deposit of ink, and those conditions which lead to the deposition of a smaller proportion of ink, or which tend to remove the superabundance of ink from a highly-inked transfer. These may be classified as follow:—

Circumstances tending towards the deposition of much ink:—

1. Comparative dryness of the transfer.
2. The use of considerable pressure in applying the inking tool.
3. Thinness of the ink, or the presence of a considerable proportion of turpentine.
4. Slow movement of the inking brush.
5. A high temperature.
6. The use of a brush highly charged with ink.

Circumstances which tend towards the deposition of but little ink, or the removal of an excess:—

1. A flooding of the transfer with water or a solution of gum.
2. The use of but little pressure in applying the inking-tool.
3. The use of a stiff ink.
4. A rapid movement of the inking-tool.
5. A low temperature.
6. The use of a brush charged with but little ink.

In using the inking-brush it should be remembered that anything approaching to a brushing or dragging action should be carefully avoided, as this would certainly lead to the destruction of the coating of paste, and to the deposition of an unremovable film of ink on the unprotected paper. In dabbing the brush should always be brought down vertically on to the surface of the paper.

When all the lines are so inked that the transfer fairly represents the original engraving, it is merely necessary to remove the excess of moisture by the cautious use of blotting-paper, and then to hang up the transfer until its dampness is reduced sufficiently to fit it for transference to the lithographic stone.

It is important to bear in mind that transfers prepared with a quickly-drying ink, as directed above, very rapidly deteriorate by keeping, and they should, consequently, be transferred to the stone as soon as possible after they are made. When circumstances render it impracticable to put a transfer down on the stone within four hours after it is made a little tallow should be added to the ink employed, and when a short delay only is expected an addition of a tenth part of tallow to the ink will suffice; but if circumstances render it necessary to keep a transfer for a long time, or to send it abroad, it may be necessary to employ an ink containing a larger proportion of tallow, and this may amount to a fourth part of the ink, or a still larger proportion of tallow may be necessary in some cases. The addition of tallow should only be made when circumstances render it necessary, and even then the proportion added should be as small as possible.

The photo-mechanical student should bear in mind that many substances decompose certain bichromated organic matters just as light decomposes them, inducing insolubility in water and a tendency to adhere to fatty bodies. Among these deleterious substances may be mentioned the fumes of sulphuretted hydrogen and of sulphurous acid. The former of these often finds its way into the preparation-room in consequence of imperfect trapping of the drains, and the latter is a product of the combustion of coal gas containing sulphur. When coal gas is used in the photo-mechanical laboratory the greatest care should be taken to provide efficient means for ensuring the escape of the products of combustion. Many failures in photo-mechanical processes may be traced to the use of coal gas, and it is generally best to altogether avoid its use in rooms where bichromated gelatine or analogous products are dried, and, as a partial safeguard against the effects of any injurious vapours, it is well to sprinkle a few drops of ammonia on the floor.

In the next chapter the more especially lithographic details will be considered. T. Bolas, F.C.S.

THE PHOTOGRAPHIC EXHIBITION OF 1878.

May an old photographer who has seen many more exhibitions than he cares to acknowledge to venture once more to give his impressions? The present Exhibition, though small, is to my mind fully equal to any of its predecessors, and it has this great merit that there is a very much less proportion of inferior work than has hitherto found its way into these exhibitions. Whether this be due to a stern sense of impartial duty in rejections may be doubted, inasmuch as rumour points to a great lack of exhibitors coming forward; and this is corroborated by the evident filling up of space at the last moment, judging from the extent occupied by the collection of foreign work sent in by one well-known, ingenious artist. Be this, however, as it may, and although one misses many well-known names, there is work shown which has never been surpassed, though doubtless it may have been equalled on former occasions.

Photography would now seem to have arrived at a position in which farther advance can scarcely be imagined. Year by year it has progressed, and it would seem at the present time to have reached a high table-land of excellence. One thing may be noted—although this does not apply to the present year only—namely, the true introduction of clouds into the landscape. Doubtless, clouds have been taken before, and clouds have been introduced, but they have been more often rather as principals than as accessories. A change very much for the better has taken place, and the present Exhibition has numerous striking examples of their judicious and artistic introduction and treatment.

Looking at the landscape work shown it is impossible to conceive finer examples than those on the walls in Pall Mall. The painter may study them with advantage, and no longer look down on his brother photographer as a being to be despised. Light and shade, foreground and distance, foliage, and even water (till of late years a stumbling-block), aërial perspective, and that beautiful combination of detail with breadth—all read a lesson to the gentlemen of the brush which it would be well for them to study, instead of turning up their noses in disdain at what they are pleased to term "mechanical processes." Speaking of the landscapes: why does one of the foremost in this line persist in wilfully destroying the fine effect of his collection by jumbling them together in one black frame with thin divisions between each plate? In spite, however, of this injustice to his work its merit stands conspicuous. Separate frames—or, at all events, a thoroughly-marked division of one picture from another—would obviate that confused effect which the want of such treatment unfortunately engenders. The same evil genius spoiled his frame last year in a similar way, and his works in the French Exhibition are marred by the same inattention to effect.

The Exhibition of the present year has, in my mind, another great merit, viz., the absence of those patchwork photographs which have so often at previous exhibitions held prominent positions in the room, and in which the artist has with mistaken ambition aped the painter and endeavoured to effect by photography what he deemed the superior merit of a picture, whereas he only achieved a something which had all the necessary inherent defects of the hand and marred the wondrous special quality of the photograph. He, in effect, by his manipulation—however ingenious and laborious the process—only succeeded in thoroughly destroying the charm of the photograph by combining with it those very defects which are necessarily incident to the brush, and which the true artist would only be too glad to get rid of.

In portraiture, too, great results are achieved, though it must be admitted the enlarged "life-size" attempts in this branch are not of the happiest character. It is singular that the one figure selected for a medal from the clever illustrations of Shakespeare's *Seven Ages* should be deficient in the special characteristic attributed to him by the poet. Where is "the beard of formal cut?" The Justice has a carefully-shaved chin; why the omission? Photographers are sometimes careless in their selection or in the treatment of their models. A fisher girl seated on a rock netting has unfortunately forgotten to take off her gold and jewelled bracelets—somewhat incongruous adjuncts for a young woman engaged in such an occupation.

The enlargements in carbon of landscapes and interiors are worthy of every commendation, and the same may be said of the charming Woodburytype productions. Whilst on carbon printing it may be remarked that, with very few exceptions, there are no carbon prints in the Exhibition. Why is it that photographers will stick to the old more or less evanescent processes of silver when they have a permanent process at their command? A staunch conservatism seems to possess them, in spite of all that is done and written and the successful specimens shown. That carbon can equal silver is undoubted, and the manipulation is certainly as simple and easy as its rival.

There are some ingenious pieces of apparatus; but why in the electrical arrangement for effecting exposure adopt a shutter for covering and uncovering the lens, which is thoroughly faulty in principle, as it necessarily gives a longer exposure to one part of the other? In the pneumatic method a better arrangement is adopted; but neither of them effects anything like rapid or instantaneous exposure. There is no reason why this should be the case.

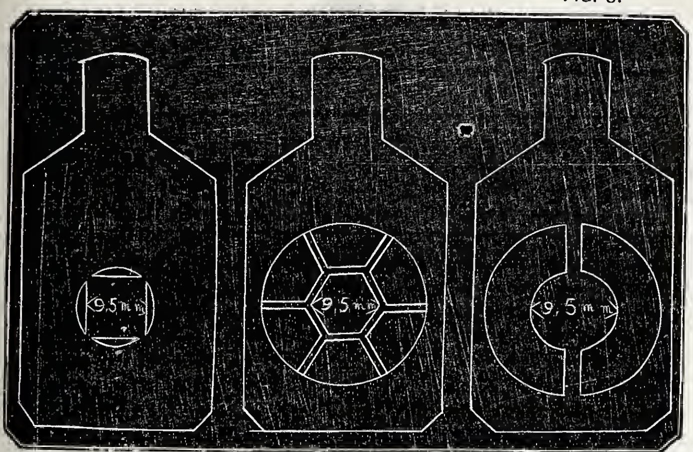
Taking it on the whole, the Exhibition is well worthy of more than one visit. An Old Photographer.

FOREIGN NOTES AND NEWS.

Another New Stop.—Dr. Vogel on Photography as an Art.—Polychrome-Autography.—Another Method of Drawing the Negative Off the Glass Plate.

In The British Journal of Photography for September 13th, under the heading of *Recent Patents*, will be found an account of the way in which Herr Lehmann proposes to take single photographs which he believes will possess stereoscopic relief. This patent has, it seems, attracted the attention of another inventor. Herr Paul Gliese writes to the *Photographisches Wochenblatt* that he was much astonished to see that the stops recommended by Herr Lehmann were, as from the illustration he could convince himself, the same as he formerly used to produce "plastic" pictures. Now, however, he uses the stops *figs.* 1, 2, and 3 in the following way:—In looking at an object one not only sees a little to the right and left of it, but also a little both above and below]; therefore with this stop he draws out the focussing-glass from its focus, so that the picture not only goes from right to left, but also up and down (?), and by focussing sharply he covers these pictures. Thus he obtains a circle round the object which enables him to get "plastic"

FIG. 1. FIG. 2. FIG. 3.



results. He then arranged the stops, *figs.* 2 and 3, with which he gets the same plastic results, and all three are, he says, preferable to the stops with two openings recommended by Herr Lehmann. The stops shown in the illustration belong to a Voigtländer euryscope, and the diameter of their centre is nine and a-half millimeters.

In Moll's *Notizen* Dr. Vogel discusses the question—"Is photography an art or not?"—which, when photography is understood to mean merely the physico-chemical process, he answers by "no." But, if all the points which a photographer must keep in view in the production of a beautiful picture—namely, tasteful posing, artistic lighting, and arrangement of the surroundings and well-judged retouching—be included, he would say that photography is at least partly an art. Still he is very far from admitting all photographs to be works of art, and with these and his subsequent remarks most candid photographers will agree. Thus, there are many photographers who think that when they have lighted a face *à la* Rembrandt they have produced a work of art, when they have merely produced a peculiar effect of light and shade, which is by no means necessarily a work of art.

Then, again: In placing photographs in competition with paintings the photographer's work is often rendered inartistic—not from any lack of artistic feeling in himself, but by the unadaptable and unidealisable (if it be permitted to coin such a word) nature of the materials he has to work with. For instance: a photographer may desire to pose a living model so as to suggest some well-known *genre* painting. Here the photographer has to contend with difficulties which do not beset the painter. Dr. Vogel instances Meyer's *Girl Reading.* The subject is a pretty child, of about twelve years of age, sitting at a window, with a large book in front of her, over the top of which she looks coquettishly at the spectator, the lighting being Rembrandtesque,. There is a photograph in the market, taken from a living model, posed after the manner of the painting, which, as far as the lighting, pose, and costume go, is exceedingly successful, corresponding almost exactly to Meyer's picture. Unfortunately the model has a somewhat indifferent and even *blasé* expression, instead of the smilling, coquettish look of Meyer's original; also the large hands distract the attention, and the white dress on the light side of the picture appears merely a white splash without any detail, while the corresponding part of Meyer's picture is painted in his most artistic manner. This is, then, one of the weak points of photography, considered as an art; for, as no one needs to be told, if Meyer's model have not naturally the exact expression he desired, he could idealise it. If her hands were too large he need not represent them at their full size. But the poor photographer is helpless.

In support of his theory that a photograph from a living model is seldom a perfect work of art, even with the best will and taste on the part of the arranger of the picture and the best of models—because in the few minutes taken to arrange things all imperfections cannot be taken in at a glance, and they are often not perceived until the photograph taken is examined at leisure—Dr. Vogel gives some other examples, one of which may be cited. A clever photographer of his acquaintance once wished to imitate Plockhorst's *John and Mary Returning from Christ's Grave.* The whole composition contained only two figures, dressed in brown drapery, with a daybreak sky background. The photographer found two suitable models and proceeded to arrange them, but in spite of all he could do the result was stiff. The two models were, as far as regards their heads, of the desired type, and the best that could be procured, but there their suitability ended. The female model was much too short for the *John,* and consequently could not group with him so as to suggest Plockhorst's picture, while she could not call up the desired expression of anguish for the Madonna's face. Then in the original the apostle was barefooted, and even that particular, though but a minor matter, it was found impossible to reproduce, owing to a malformation in the foot of the model. Verily the troubles that afflict the enterprising artistic photographer are many!

The *Papier Zeitung* says Herr Holtzmann has just invented and patented a process which he calls "polychrome-autography," by which a number of impressions can be taken from a drawing in one or more colours. The inventor supplies the prepared colours and papers, which are all that is required for the preparation of about twenty-four proofs. The drawing is made in the ordinary way with drawing pencils and brushes dipped in the prepared colours and upon the specially-prepared paper. The finished drawing is then laid, face downwards, upon a piece of previously slightly-moistened "negative paper." The impressions are got by laying this negative upon good, stout, white paper, also previously moistened, and rubbing it down with the hand, no other pressure being required.

The *Photographisches Wochenblatt* describes a method of drawing a negative off the glass plate:—The plate to be used is first cleansed from all greasy matter by washing, first, in a warm solution of soda, now soaking half-an-hour in a solution of one part of nitric acid to ten of water, then rinsed well under a tap, and, lastly, the still wet plate is rubbed with a rag and whiting until a thick paste is formed, which shows the lines of rubbing distinctly. Both sides of the glass having been so treated with the whiting the plate is allowed to become perfectly dry, and is then polished. The following solution is meantime prepared:—

Caoutchouc (cut in small pieces)	100 grammes.
Chloroform	250 ,,

Solution will have taken place in a couple of days, frequent and powerful shaking of the mixture being required. Of this solution of caoutchouc five grammes is added to 250 grammes of the purest benzine, and the whole is filtered through cotton wool, after which it is ready for use.

Pour a little of this last solution over the carefully-cleaned and dusted plate, and let the overplus run off upon a cotton filter. In about half-an-hour the film is dry; but the older the film the better it is, unless the plates are stored in an oven. The emulsion or, if the wet process be worked, the collodion is then poured over the plate, which is converted into a negative in the ordinary manner. When the latter is finished and sufficiently rinsed, place it for a few seconds in hot water, in order to warm it; now let it drip, and then coat it with the following solution, which has previously been filtered through muslin:—

Water..................................	100 grammes.
Gelatine..............................	6 to 8 ,,

In summer one gramme of glycerine may be added for every ten grammes of gelatine, and in hot climates this quantity may be slightly increased. Too little glycerine makes the gelatine film hard and brittle; too much makes it sticky. Before coating with the gelatine place the plate level on a tripod and spread the fluid with a glass rod. Dry in a *horizontal* position—preferably in a drying-box, which may be made perfectly level by means of adjustable screws, and in which it may be placed as soon as it has stiffened. The drying-box may be warmed by a spirit lamp for the first hour. When the gelatine film is perfectly dry varnish with retouching varnish, or, if the negative do not require to be retouched, coat it with thin raw collodion; then run a knife round the edges of the plate, and draw off in the usual way.

OPINIONS OF THE LONDON DAILY PRESS ON THE PHOTOGRAPHIC EXHIBITION.

Photography.—The Photographic Society of Great Britain has now opened its show for the year at the Gallery of the Society of Painters in Water-colours in Pall Mall East. In spite of the discoveries in the production of artificial light, which threaten to work a revolution in photogeny, the past year has been distinguished by no sensational developments in photography. The most interesting, perhaps, of the methods illustrated at the Photographic Exhibition is that by which a near approach to photographing in colours is secured. The Lombardi Art Company have applied with novel care and skill a method of representing colours which is called "poikilography." A photograph in monochrome is enlarged from a negative in the usual way and transferred to thin paper or canvas. Colours are laid on by the hand on the reverse side, and show through. The colours may be roughly applied, and are without shading. The most delicate shades are supplied by the photograph. The effect of paintings by Rubens, Holbein, and other old masters is admirably reproduced. A portrait from life (of Miss Curwen) taken according to this method appears to be pleasing so far as the very bad position given to the picture on the stairs enables it to be judged. This situation is allotted to the picture because the rules of the Society exclude hand colouring from the rooms of the show. The time, perhaps, will come when photographs in colours will be produced wholly by natural means. The prismatic spectrum has been reproduced on the daguerreotype plate, and also on specially-prepared paper, in colours which approached the original, although they were wanting both in truth and fixity. In the meanwhile such approximations as those of the Lombardi Art Company, or M. Vidal's variously-coloured gelatine films, are to be welcomed. The points most to be noticed in the methods of plain photography are the increasing use of dry plates, and the advantages gained by the processes of enlargement which the Autotype and Woodbury workshops have brought to perfection. A small photograph can be taken much more rapidly than a large one: and speed is obviously desirable in dealing with cloud and wave as well as with the mobile faces and attitudes of living beings. The Exhibition is full of examples of large pictures with unlimited wealth of detail produced from negatives in which the naked eye discerns only coarse masses of black or brown. The Society has adopted the practice of giving medals for the objects exhibited. The jury was compossd of Mr. Poynter, R.A., Mr. John Brett, Mr. James Glaisher, F.R.S., Messrs. F. Bedford, H. P. Robinson, E. Piercy, and H. White. The medal for the best landscape has been adjudged to the School of Military Engineering, Chatham. As it is in landscape that the Exhibition, in common with English photography in general, is peculiarly successful, the honour is the greater for the students of this military school, who are usually employed in photographing machinery, guns, and military positions, and only in their holiday time take the beautiful scenes such as that near Bettws, which has won for them the medal this year. The medal for the best series of landscapes is awarded to Mr. Vernon Heath. The views thus distinguished comprise the hills of Skye—Blaven, from Loch Hart of Corrie; Marscow, from the Red Burn; Blaven, from Scour-na-Gillian; Scour-na-Gillian, from the Red Burn, studies of stone-heaped fells with mountains in the background. In these a great difficulty of the photographer has been overcome. The distance and the foreground are rendered with equal success. The figure study distinguished with a medal by the judges is one of a series of enlarged illustrations to Shakspeare's Seven Ages in *As You Like It.* It is the figure of the Justice, "with eyes severe and beard of formal cut," by Mr. A. W. Wilson. The *genre* picture selected for a medal is *The Broken Leg*, a dog with his leg bandaged—the subject of the anxious solicitude of a little girl. The photographer who succeeded in obtaining quietude from these difficult subjects is Mr. George Nesbitt, of Bournemouth. The Woodbury Company gain the medal for the best photo-mechanical prints. By their remarkable process the thin films which form the light and shade of a photograph are pressed into a metal slab, which is thus excavated into an engraving block. The book illustrations shown for the medal are perfect in delicacy and distinctness of linear engraving. The medal for apparatus has been won by the well-known firm of Marion and Co. They exhibit Cadett's patent pneumatic photographic shutter. The object of this invention is to open and close rapidly access to the lens while the operator engages the attention of, for instance, a child who is being photographed. The photographer has merely to press an elastic ball like the handle of a pneumatic bell, and the pressure is conveyed by a slender india-rubber tube to the instrument. A little cap is by this means rapidly raised or lowered. The pneumatic apparatus is much more portable than its competitors worked by electricity. Additional medals were placed at the disposal of the judges for any novelty, or other form of excellence, in process or result. One of these was given to Mr. Payne Jennings for instantaneous effects in pictures of yachts in full sail upon the sea. The camera in these views comes as near to representing motion as is possible. In the 400 entries catalogued (many of them series of objects) there is much of interest besides the pictures or instruments for which medals are awarded. Mr. Warnerke has lent a large collection of Russian and Swedish photographs. Many of these were taken by the State establishments of the Russian Empire, and some are remarkable illustrations of the processes known as heliogravure, hyalotype, &c. There are several fine portraits in the Exhibition, but as specimens of pure photography some of the best were disqualified for the medal by having been improved by hand. Mr. Faulkner's work is peculiarly soft and pleasing. He transfers a photograph to opal glass and completes it with sepia. The portraits of Mrs. Alfred Morrison and of Miss Bertha Ellis are particularly noticeable. The portraits taken by M. Boucher should not be overlooked. Mr. Dixon's representations of the heroes of the Zoological Gardens, the views on Loch Morah, taken by Mr. W. J. A. Grant, of Arctic fame, Mr. England's valuable series of plates recording the buildings erected for a year on the slope of Trocadéro and on the Champ de Mars, Captain Abney's photographs of the Swiss Alps and the Welsh Hills, Mr. H. Garrett Cocking's *Gitana*, and other character sketches are among the many good pictures of the show. Messrs. Wratten and Wainwright's photographs, from negatives taken by the instantaneous gelatine plate exposure, will be interesting to photographers as examples of the increasing use of the dry-plate method. Mr. Bennett sends a transparency taken on a winter's night by candlelight and lamplight. The subject was entirely in still-life, and an hour's exposure explains the perfection of the picture. Ceramic photography has made less progress than could have been desired, but some pretty applications of photography to cups and saucers are to be found in the Exhibition.—*The Times.*

Meetings of Societies.

MANCHESTER PHOTOGRAPHIC SOCIETY.

The annual meeting was held at the Memorial Hall, on Thursday evening, the 10th inst.,—Mr. Alfred Brothers, F.R.A.S., President, in the chair.

After the minutes had been read and passed, the President read the

ANNUAL REPORT.

In the annual report of the past session your Council have the pleasure of stating that the Society is in a condition of full average prosperity. Members retire, but others enter, and the members at the annual meeting are tolerably even.

The attendance at the monthly meetings has been good, and the members have been liberal in the supply of interesting matter and objects for investigation and examination. Papers on set subjects, for some reason, appear to be going out of fashion; but as long as the interest of the meetings is sustained in other ways this need not be the subject of serious regret.

The Treasurer will inform you of the financial position of the Society. There are at present 72 members on the roll, against 70 at the last annual meeting.

The average monthly attendance has been 33, against 29½. The least number at any meeting was 29.

Four papers have been read before you as follow:—

On a Process of Reducing Silver Chloride to the Metallic State. By Mr. J. W. Leigh.

On Double Printing of Transparencies for the Stereoscope. By Mr. S. H. Ashley Oakes.

On the Gelatine Process, and the Preparation of Dried Pellicle. By Mr. T. Chilton.

Mr. W. J. Chadwick, in addition to many other interesting contributions, read a paper, by Mr. Woodbury, *On the Modern Magic Lantern.*

Mr. McCall, on behalf of Mr. F. York, exhibited a Keevil lantern, and demonstrated the capabilities of the instrument.

Mr. D. Young also exhibited one of Keevil's lanterns, perfected.

Many other interesting things, which it is not necessary to dwell upon in this report, have been brought under your notice, for which your Council beg to thank the several contributors.

The February meeting was a great success; an excellent supply of comfortable things enabled the unusually large company to practice the wet and dry processes to their entire satisfaction. You had on that occasion the pleasure of entertaining some of the leading members of the Liverpool Amateur Photographic Association.

As regards the proposed *soirée:* your Council were invited by the Peel Park Museum Committee, under exceptionally favourable and liberal conditions, to hold an exhibition of photographs in their building, in connection with the opening of the new wing for art purposes. The Secretary of your Society, however, received so little response to his applications for exhibits that the invitation had to be declined.

The only outdoor meeting of the season, to Hawarden, though late, was a real success as regards enjoyment, and probably so photographically. This meeting, as you are aware, was held jointly with the Liverpool Amateur Photographic Association.

Your Council, in conclusion, have to thank all the members who have contributed in the least degree to the success of the session; and they take this opportunity of tendering their acknowledgments to the Belgian Photographic Society for the periodical transmission of that Society's *Bulletin.*

The annual report received the confirmation of the meeting, and the election of officers and Council for the ensuing year was proceeded with, and resulted in the election of the following gentlemen:—*President:* Thomas Haywood, Esq.—*Vice-Presidents:* Mr. A. Brothers, F.R.A.S., Rev. Canon Beechey, M.A., G. T. Lund, M. Noton, and J. Wade.—*Council:* Messrs. Charles Adin, R. Atherton, J. J. Kershaw, J. W. Leigh, S. H. Ashley Oakes, J. C. Sewell, E. Woodward, J. Warburton, N. Wright, and James Young.—*Treasurer:* Mr. W. G. Coote.—*Honorary Secretary:* W. J. Chadwick, Prince's Bridge Iron Works, Salford.

A vote of thanks was passed to the ex-President, the ex-Secretary, and the Treasurer.

Some of the members who were present at the recent outdoor meeting exhibited the results of their day's work.

The meeting, which was thinly attended, was then adjourned.

THE RHENISH, WESTPHALIAN, AND FRANKFORT PHOTOGRAPHIC SOCIETIES.

The above Societies had a joint meeting, at Lorch am Rhin (half way between the two usual meeting places—Cologne and Frankfort-on-Maine), on the 30th August, on which occasion the whole day was devoted to the discussion of photographic matters. Photographers from many other parts of Germany were present, besides members of the two societies mentioned above.

On the chair being taken by Herr Baumann, who was elected President by acclamation, Dr. Schleussner was chosen Secretary, and the meeting proceeded to discuss the points set down in the order for the day.

I. The first subject discussed was the assistant and apprentice question. All the speakers were unanimous in deploring the dearth of capable assistants, and to bring about a better state of matters it was declared advisable that no master should engage an assistant who had not served a three years' apprenticeship, or who could not produce a certificate of discharge from his last employer.

Herr Criefelds thought that in this way masters would have things in their own power, though in large towns he would recommend that the apprentices who had finished their time and were desirous of being engaged as assistants should be examined by a committee of photographers.

The scarcity of skilled retouchers was then mentioned, and was attributed to the dearth of suitable technical schools.

Herr Rheinstädter thought that such schools should be placed in connection with a school of art, so that men who showed themselves to be possessed of considerable skill with the pencil, but of little or no talent for painting, might be induced to turn their attention to retouching. Their final practical training must, however, take place under the eye of a practical retoucher; and it was recommended that such a training school for retouchers should be under the direction of a committee of the best retouchers.

Herr Geldmacher's experience was that the best retouchers were not painters, nor were they trained at the academy of painting.

Herr Baumann wished to see it established as a principle that the number of apprentices should never exceed that of the journeymen assistants.

A committee of six was appointed to consider the matter and report.

II. Point two had reference to the price and quality of albumenised paper. Here it was resolved to put pressure on the manufacturers of paper to induce them to abate their prices, and a committee was appointed to consider the subject of the ways and means.

III. and IV. Points three and four were the transmission of collodion by rail and Boissonnas's extra-rapid process.

One of the speakers on the last-named subject said the extra-rapid process was called the "lightning process" in America; but there it was beaten by Ingles' (of Montreal) double-lightning process. In Montreal, for the sum of twenty dollars, one could obtain the right of buying the requisite collodion, silver bath, and developer.

Dr. Schleussner then showed two negatives taken, in one and two seconds respectively, by Dr. Richard's rapid process. The negatives in question were pronounced well brought out and very delicate in the details, but slightly fogged. No prints accompanied them.

Telegrams, expressing regret for enforced absence, were received from Herr Quidde on behalf of himself and several other members of the Berlin Association for the Cultivation of Photography, and from Herr Festige, of Erfurt.

It was resolved to have another conference next year, the meeting-place to be Cologne. The meeting was then closed, and was followed by a supper, which was in turn brought to a conclusion by those present drinking to the sentiment—"Till we meet again at Cologne."

Correspondence.

MR. HENDERSON AND HIS ENAMELS.

To the Editors.

Gentlemen,—I am at a loss to conceive what spirit of mischief whispered into the ear of Mr. A. L. Henderson the counsel to rush into print upon the subject of his enamels at the French Exhibition, and, moreover, for what reason Mr. Henderson ignores the ordinary courtesy of communicating to his correspondent the fact that he is going to publish his letter; however, matters of courtesy give way to matters of fact. Here are the facts. In our monthly *brochure—Autotype Notes—* I wrote the following:—"In enamels England is far behind. It is absolutely worth while for any one giving attention to this special branch to go over, if for nothing else than to see the splendid photographic enamels in the French department." Then follows a description of what I considered the most noticeable enamels exhibited by the French artists.

In the article itself I instituted, as far as my ability went, a comparison as to the progress made by various countries in the different branches of the photographic art; and I submit that in my treatment of the enamels there was nothing whatever to cause Mr. Henderson to feel aggrieved, for he was not even named. Why, then, take the cap and fit it so elaborately upon his own brows?

He tells us that the jury have awarded him a bronze medal. Well, they could only have done less by giving him "honourable mention." If he is satisfied with his "bronze" well and good; but I would just point out the fact that, whilst the jury gave him a bronze they gave M. Walery a *gold* medal, and the Comte de Roydeville and M. Deroche a *silver* medal each. It was the enamels of these three gentlemen that I especially named as being so exceedingly fine, and surpassing anything of the same kind shown in the English section.

Mr. Henderson asks if I shall be surprised to hear that he has got a bronze medal; by no means. I think the award is a very just one. I am sure that if he is satisfied I am satisfied; and in conclusion I will willingly forgive his want of courtesy, and promise him that whenever he exhibits his enamels he shall have the benefit of whatever critical acumen some thirty years of experience in photography has bestowed upon me.—I am, yours, &c., J. R. Sawyer.

Ealing Dene, October 15, 1878.

P.S.—Pray pardon a "P.S.;" but what does Mr. Henderson mean by saying I am "neither a giant nor a dwarf?" Is it meant for a joke?—J.R.S.

PHOTOGRAPHY BY ARTIFICIAL LIGHT.

To the Editors.

Gentlemen,—*Apropos* of the extended use of artificial light in photography: I do not think that photographers who desire to use electrical illumination will readily find a better system than the following:—Pull down the white blinds of the studio, light them by a source of light screened from the sitter, and—"fire away!"—I am, yours, &c., D.

October 16, 1878.

Serious Fire.—We have received the following note from Messrs. G. Matland & Co., 120, Commercial-road East:—"We regret to inform you that our stock and premises having been destroyed by fire we are compelled to suspend business until further notice; but all orders now in hand will be executed as soon as possible."

Obituary.—We regret to perceive, from *The St. Louis Practical Photographer*, that an announcement of the death of Mr. John L. Gihon, of Philadelphia, had been received just before going to press. Mr. Gihon was an artist of merit, and well known as an able writer as well as a practical manipulator. He died on board the schooner "Anita," on the 16th ult., on his way home from Venezuela, and was buried at sea.

Robberies.—At the Marylebone Police Court, on Tuesday last, Henry Turner, aged 23, of 15, Alasia-road, Kennington, photographic printer, was charged on remand with stealing, on the 5th inst., a photographic lens, value £7 10s., the property of Rowland Taylor, his master, a photographer, at 369, Edgware-road. —Detective-sergeant William Crane, X division, produced evidence of other robberies by the prisoner, and asked for a further remand, as it was believed that other cases could be found against him.—The application for a further remand was granted.

Suicide of a Photographer.—Mr. C. W. Holloway, photographer, of 107, Clarendon-road, Notting-hill, London, has committed suicide at Henley-on-Thames, under very extraordinary circumstances. It appeared from the evidence taken at the inquest on Thursday, the 10th instant, that on the previous Thursday the deceased arrived at Henley, and took lodgings at the Black Horse Inn, Friday-street; and although nothing strange was noticed about him at the time, it was soon apparent, from the curious questions he asked, that he was suffering from much mental anguish and aberration. A day or two afterwards, while out for a walk with the landlord of the house, he suddenly exclaimed that everybody was staring at him. Nothing further occurred, however, until the following morning, when, after he had finished a hearty breakfast, he asked for pen, ink, and paper, and went upstairs apparently with the intention of writing a letter. A quarter of an hour later he was found with his throat cut, and although medical aid was speedily obtained he expired within about an hour. In the room was found a paper, with the following written upon it in pencil:—"Believe me all, as I now go before my God, whom through Jesus Christ I believe I shall be saved, this hunting me I can see is a dreadful conspiracy to deprive me of my father's or mother's money. I will blame no one. I am perfectly innocent of any crime but drink." The jury returned a verdict of suicide while in a state of temporary insanity.

The Medal Awards at the French Exhibition.—We have received, from Mons. A. Liebert, of Paris, printed copies of letters addressed by him respectively to the President of the Jury of Class XII. and to his photographic *confrères*. In the latter of these he complains bitterly of the unfairness of the awards made in connection with Class XII. He says the Jury have finished their labours long ago, yet the list has not been officially published, but almost all interested know the results. He also complains that the Jury are either incapable or animated by sentiments of partiality, the awards being so unjustly distributed having caused so many complaints to be made to the President of the Jury, who, however, does not condescend to reply. He (M. Liebert) sent a letter on the 29th August, and which was published in several journals (a copy of which is on the second page of his circular), remains unanswered, proving, to his mind, that the Jury have no argument to justify their conduct. He would like his *confrères* to inform him of their opinion of the works exhibited in the Champ-de-Mars, and encloses a list of awards, so that they may judge of the merits. M. Liebert complains in his letter that other works similar to his own have received much higher rank, and protests against the judgment given in his case. He declares to the President of the Jury that he refuses to accept the silver medal awarded to him, giving the President permission to dispose of it in favour of somebody else, and refuses to have anything more to do with exhibitions.

Fatal Oxyhydrogen Explosion.—The numerous friends of Messrs. J. Wrench and Son, opticians, and well-known lantern manufacturers, Gray's Inn-road, will be shocked to learn that Mr. Edward Wrench was killed by an explosion on Wednesday afternoon last, under the following circumstances:—The report of a loud explosion at the time mentioned caused great alarm among the occupants of chambers in Gray's Inn. It was soon ascertained that something serious had happened at No. 30, Gray's Inn-road, occupied by Messrs. J. Wrench and Son, opticians and this having been reported to the fire brigade station in Holborn a curricle was soon in attendance from that depôt. At the time of the explosion Mr. Wrench, Sen., and his clerk were in the office on the ground floor, and both of them were greatly startled by its force. The other persons in the house were the son of the proprietor and two women—one named Elizabeth Gibson, and the other known as "Kate." They were all on the second floor, the two women being engaged in their ordinary occupation, whilst Mr. Edward Wrench was in the act of preparing some oxygen gas for the working of magic lanterns. The explosion of the retort, which has not yet been accounted for, was not preceded by any warning, and the escape of the two women with their lives is said to be marvellous. The moment the father had recovered from the shock he proceeded upstairs to ascertain the extent of the mischief, when he met his son staggering from the room in an unconscious state. He caught him in his arms, but the weight of the body being beyond his strength, he was obliged to let him fall on the floor. Dr. Taylor, of Gray's Inn-road, was immediately summoned, and he pronounced life extinct. The force of the explosion seemed to have caused portions of the retort to enter the young man's side and penetrate the lungs, and the injuries were otherwise severe. The deceased was only twenty-four years of age. The two women also sustained injuries about the face and hands. The room where the explosion occurred was greatly shattered, and the windows were forced out.

EXCHANGE COLUMN.

I will exchange a 15 × 12 mahogany studio camera with two fronts (little used) and table stand on castors for a good 12 × 12 field camera and tripod stand.—Address, W. Perry, Hythe, Kent.

I will exchange a brass-bound 10 × 8 Kinnear camera (leather bellows), two slides, and single lens, for 5 × 4 pocket camera and lens and three double and one single slides, or offers.—Address, Geo. Duncan, Tanfield, Edinburgh.

Wanted, a pair of stereo. lenses or lens and camera in exchange for bath for 10 × 8 plates, large tray (two inches deep) 14 × 12, and another; three volumes of *Photographic Journal*, 1875-6-7; other articles or cash adjustment.—Address, Wilkie, 13, Little Trinity-lane, Queenhithe.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

Photographs Registered—

Lewis and Co., Ranelagh-street, Liverpool.—*Portrait of Prince Bismarck.*

Alfred Pettitt, Keswick.—*Portrait of Alfred Scott Gatti, and Two Portraits of Madame Albani.*

PHOTO-MECHANICAL CORRESPONDENCE.

F. Carter.—Certainly not.

B. L.—The object of adding alcohol is twofold: it not only prevents the solution of the film of albumen, but it also accelerates the drying of the paper.

Litho.—The tint is quite arbitrary; but, having selected one which suits your eyesight, you had better adhere to it as far as practicable. Greater exactitude is generally attained by the use of a large number of light tints than by employing a small number of darker ones.

GENERAL CORRESPONDENCE.

Notice.—Each correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a *nom de plume* as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

Delighted Visitor.—The fine pictures to which you refer were all obtained by the wet collodion process.

P.—We shall make private inquiries, and if we are successful shall reply to your queries in a succeeding number.

Art.—The whole secret lies in the addition of bromide. Add nearly twice as much as you have hitherto been in the habit of doing.

Country Photo.—You have added by far too much sugar to the bath. Rectify this by the addition of an equal portion of solution not containing any.

A. R. R.—The focus of the lens is too long in the proportion of one-third. A *carte* lens possessing an equivalent focus of seven or eight inches will answer very well.

T. O. B.—To blacken the inside of the camera apply a mixture of spirit varnish and lampblack. For imparting a finish to the *outside* French polish stands unrivalled.

M. G. Haberer.—We are not acquainted with any other method by which sulphocyanide of mercury is made than that which is described in the various treatises on chemistry.

G. H. S. P. (Brixton).—If the strength of the silver bath be considerably reduced the bronzing of the shadows will disappear. Try the effect of sensitising a sheet of paper in the same manner as you have been accustomed to do of late, and then laying it down while quite wet upon a small quantity of distilled water contained in a flat vessel.

Joseph Greenwood.—After dissolving the chloride of strontium—the solution being somewhat strong—obtain a small piece of very clean sponge, charge it with the solution and apply to the glass in horizontal sweeps.

G. B. Baxter.—The gelatine may be very easily clarified by liquefying it at a low temperature, then incorporating white of egg very thoroughly with it, and finally raising the temperature until the albumen is coagulated.

Cynthia.—The number containing the article respecting which inquiry is made has been out of print for several years; but if you call at the Publishing Office of this Journal you will be afforded an opportunity of reading it.

W. T. P.—So far as we are aware everything requisite to be known in connection with this interesting invention has been published in our columns. If you will put your queries in a definite form we shall be glad to reply to them.

Amateur Photo.—Trim the prints previous to toning and fixing them; after washing them place them neatly one over the other in a pile and subject them to pressure. They are now ready for being mounted. After making a few trials the operation will become easy.

M. S.—When we state that as soon as an "answer" is written the letter calling it forth is thrown into the waste-paper basket and never more seen by us you will readily perceive the impossibility of our "referring back." Re-state the matter and embody the addenda contained in the present letter, and we shall endeavour to carry out your wishes.

C. T.—We cannot indicate any means by which you will obtain *fuller* information than those which we have so repeatedly given. We imagine from your query that you are not a regular reader of this Journal and our Almanac; but it would be foreign to the intention of this column of "Answers to Correspondents" to devote it to the republication of matter accessible to every reader.

F. Harrington.—1. The porous nature of the collodion will account for the water getting under it. To ensure its not obtaining access at the margin of the film, "edge" the surface of the plate with a substratum.—2. To secure enlargements on paper by means of the lime-light magic lantern make use of iodised paper excited by means of aceto-nitrate of silver. A warm solution of gallic acid is usually employed as the developer in such cases. The tone is controlled by the addition of silver.

Tyrol.—We must decline to offer any opinion respecting the merits of the burnishers mentioned, so far as regards the "validity-of-patent" point of observation. Any counsel who is conversant with patent law will give you an "opinion" for five guineas. You would derive much advantage by coming to London and making a rigorous inspection of the various patents for photographic burnishers, and also by studying carefully a set of the back volumes of The British Journal of Photography.

Ed. S. Wilkin.—The data at command is too imperfect yet to enable us to offer any opinion respecting the regular use of the electric light in the studio. While we have a strong conviction that the system of lighting will eventually be revolutionised by its means, we shall defer for a few weeks giving our ideas concerning the manner in which it can best be done. In the meantime we reiterate a statement we have several times previously made, namely, that it is possible to obtain quite as good portraits by artificial light as by natural light, provided due care be taken in the manner in which the light is directed upon the sitter.

Frederick Holt.—1. It is indeed exceedingly difficult to institute a series of systematic experiments under the circumstances in which you are placed, and if you obtain results different from those to which you have made reference you deserve much credit.—2. The principle upon which the Nicol's prism acts is this:—A ray enters a rhomb of Iceland spar, getting split up, or divided, into the "ordinary" and "extraordinary" elements of which it is composed. In direction these are divergent. Both fall upon the oblique central surfaces of the prism, which are cemented to each other by means of Canadian balsam, which, having an index of refraction intermediate between that of the spar for the ordinary and extraordinary rays, acts upon the elementary part of the ray which is most refracted as a totally reflecting mirror. By this means that ray is ejected through one side of the prism, allowing the other ray to be transmitted through the end.

An Inquirer into Spirit Photography.—Feeling it to be impossible to give, *seriatim*, replies to your numerous queries, we shall confine ourselves to a general reply based upon your letter. Buguet, the Parisian spirit photographer, was sentenced to one year's imprisonment on account of frauds practised upon the public, and when he was tried he confessed to these frauds. He yielded up to the French police the figures or marionettes from which he produced the "spirits" visible on the plates that were afterwards developed. Now, these are facts that stand attested in the history of crime, as recorded in the archives of the police courts. We have a perfect recollection of the statements prevalent at the time, to the effect that he acted in this matter as a mere spy and tool of the French police, who were desirous of obtaining evidence against M. Leymarie, the editor of *Le Revue Spirite*, and it was alleged that these officers of justice were not very particular as to the means by which such evidence was secured. Leymarie and Buguet stood in entirely different categories. The latter was a self-confessed impostor, the former was merely his dupe; and now that his incarceration has terminated Leymarie stands on the same footing among his friends that he previously did. For an answer to the query respecting the *present* state of spirit photography we must refer you to the *Spiritualist*, in which articles by Count Bullet and others on the subject have recently appeared.

BROMIDE OF COPPER: ITS PREPARATION AND PECULIARITIES.

Of the various bromides which find a place in the laboratory of the photographic experimentalist the most recently introduced is the bromide of copper; and, as it presents certain features which seem to promise for it a more extended sphere of utility, and as it is, moreover, a rare and somewhat expensive salt, we have considered it worth while to say a few words upon its uses and economical preparation.

The principal practical use to which it has hitherto been applied is, as our readers will be aware, in the process of intensification recently made the subject of careful study, and fully described in our columns, by Captain Abney, and which we have had occasion to refer to more than once as a useful addition to the already numerous list of methods for obtaining density under exceptional circumstances. Mr. Warnerke has also spoken of cupric bromide in connection with the preparation of emulsions, and claims for it, when employed in that capacity, a special advantage in securing the impression of very feebly-illuminated details. In this direction, however, we have not yet heard much of its use—very possibly on account of the difficulty in obtaining the salt.

Its application to the purposes of intensification depends upon its property of attacking or bleaching the developed image by converting the metallic silver to the state of bromide—a property which it shares in common with its fellow haloid, the chloride. Its action, however, is different from that of the latter; for, whereas the application of a solution of silver nitrate to the bleached image produced by the bromide invariably results in a very remarkable increase of density, the same course of treatment following the bleaching with chloride produces little or no effect under ordinary circumstances. There is, however, a certain amount of resemblance between the two salts in general chemical properties; but the bromide appears to be a much less stable compound than the chloride, bearing a strong analogy in this respect to zinc bromide. Like chlorine, bromine forms two compounds with copper, one of which contains twice as much of the halogens as the other. In the case of the chlorine compounds their composition is pretty accurately known, and they are formulated as $Cu\ Cl_2$, $Cu_2\ Cl_2$ respectively. But the bromides have received comparatively little study; hence we are not so certain of their composition, though the formulæ Cu Br and Cu Br are usually accepted.

Those of our readers who have had occasion to use the better-known cupric chloride, which is obtained in pure crystals, will be aware that commercial samples are almost invariably contaminated with traces of the *cuprous* salt, as evidenced by the presence of a white insoluble sediment in the solution of the crystals. The same sediment is formed if the solution be left exposed to the atmosphere, and is due to the loss of a portion of the halogen and consequent reduction of the chloride to the state of sub-chloride, and ultimately, in all probability, by the hydrated oxide. To similar reactions we may trace the formation of the insoluble matter found in all samples of zinc bromide—at least in *all* samples we have seen; and there is every reason to believe, though from the nature of the salt it is more difficult of recognition, that the same or similar changes occur in cupric bromide. On account of this instability or uncertainty of composition it is, therefore, advisable in using bromide of copper to keep it in alcoholic solution (as is customary with the zinc salt), the strength or combining value of which is ascertained by actual experiment.

The simplest and best way of preparing cupric bromide is, no doubt, by the double decomposition of cupric sulphate and baric bromide, the insoluble baric sulphate being easily filtered out, leaving a solution of pure cupric bromide. But bromide of barium is a rather expensive salt, its cost being at least four or five times that of bromide of potassium at retail rates; therefore by adopting the method we propose the substitution of the latter salt forms equally as simple and as effective a plan as the other. The method described for the preparation of the bleaching solution for intensifying consists in mixing hot saturated aqueous solutions of sulphate of copper and bromide of potassium respectively. This forms a solution of bromide of copper, out of which, upon cooling, a large proportion of the sulphate of potash which results from the interchange of elements crystallises, and the portion which remains in solution produces no ill effect when the solution is used for the purpose in question. In order to utilise the cupric bromide for emulsion purposes it becomes necessary to free it from the remaining traces of a potash salt and also to drive off the water, and this entails an amount of trouble which many would be loth to incur.

If we substitute alcohol for water the insolubility of the two salts in that menstruum forms an obstacle, though by placing them together in a bottle with alcohol a slow and imperfect interchange of parts takes place. To bring about a perfect decomposition we have adopted the following plan:—Weigh out equivalent proportions of the two salts, or, rather, one equivalent of sulphate of copper to two of bromide of potassium; these will represent nearly equal actual weights, or, to be as nearly exact as possible, fifty parts of the first to forty-eight of the second. Reduce them separately to a fine powder, and when this is effected let them be mixed intimately in a glass mortar. The pulverisation of the sulphate of copper almost entirely removes its blue colour, and, when added to the bromide of potassium, the mixture is at first nearly pure white; but as the two powders are worked together with the pestle the colour rapidly changes to a dirty brown, and the whole gradually loses its powdery character and assumes the form of a soft, coherent mass. The latter effect is due to the liberation of the water of crystallisation of the cupric sulphate, which forms nearly one-fifth of the total weight of the mass, and by its presence enables the two salts to react upon one another rapidly and completely. The soft, brown magma must be rubbed down with the pestle until it assumes a smooth, even appearance, and presents no white specks of undecomposed material. This will occupy four or five minutes, after which it may be set aside in a warm place for some time to drive off as much as possible of the moisture. If artificial heat be resorted to the temperature should not be raised above 180° to 200°, as at this stage the cupric bromide seems to be peculiarly liable to decomposition, as is proved by the strong odour of liberated bromine experienced if the temperature be raised only as high as 212°.

The mass now consists of a mixture of sulphate of potash and bromide of copper, and very probably also sub-bromide; for the faint odour of bromine, which is easily detected, shows that at least a partial decomposition of the $Cu\ Br^2$ has taken place. If a high temperature be applied the odour of bromine is much more powerful, whence it may be assumed that heat favours this decomposition. The bromide of copper has now to be freed from the useless potash salt. This cannot be satisfactorily performed by the amateur by crystallisation from an aqueous solution, though a large proportion of the sulphate may be removed in this manner in consequence of its low degree of solubility; and even to only partially purify the bromide in this manner entails, as we have shown, a good deal of unnecessary trouble. If instead of water we employ alcohol, or even ether, the difficulties are entirely removed; for the sulphate of potash, being perfectly insoluble in these two menstrua, merely requires separating by decantation or filtration, leaving the bromide in solution. Further: this solution, after its strength has been ascertained by volumetric analysis, may be used by direct addition to the collodion, and thus all necessity for evaporation is obviated.

This purification is best performed by shaking up the mass of mixed salts in a bottle with a small quantity of alcohol or ether, just sufficient to cover it, and, after a few minutes' rest, decanting the liquid portion and replacing it with fresh alcohol or ether. By repeating this operation a few times the whole of the bromide is extracted, leaving the sulphate of potash as a dirty, granular sediment. We prefer the use of successive small quantities of the solvent to a direct addition of a larger quantity. As a farther safeguard againt impurity—though we do not suppose the presence of a small quantity of sulphate of potash would work any great harm—the solution may be passed through filtering paper, and is then stored away in a well-stoppered bottle.

If it be considered preferable to obtain the product in the solid state it is an easy matter to evaporate it to dryness, but it is impossible to crystallise it. We are, perhaps, incorrect in saying even that it may be evaporated to dryness, for a very lengthened application of heat fails to do this, as the substance appears to pass directly from the state of *solution* to that of *fusion* in the same manner as zinc chloride under similar circumstances; and it is only when the heat is removed and it is allowed to cool that it becomes solid. The evaporation is conveniently performed over a water bath, and we should recommend the operation to be carried out in close proximity to a fireplace with a good draught, otherwise the combined fumes of methyl (we have employed methylated solvents) and the disengaged bromine produce a painfully-irritating effect upon the eyes, and this is especially the case when ether is employed.

A very handy means of temporising a water bath consists in removing the inner boiler of a glue kettle and placing an evaporating dish over the mouth of the outer casing. It is almost needless to warn our readers that the light must be removed from below the kettle before commencing the evaporation, or an explosion will be almost inevitable, especially in the case of ether. If the water in the kettle be raised to the point of ebullition sufficient heat will remain after removing the light to carry on the evaporation with rapidity and regularity. When the whole of the solvents have been driven off, the residue will present the appearance of a dark brown or black incrustation on the sides of the dish—to all appearance quite dry; but, if a glass rod be plunged into it, it will be found that a sort of skin has formed on the surface, while the under portions are still liquid. Upon cooling, however, it solidifies into a dark-coloured cake, or slag, which changes to various shades of brown and brownish yellow when powdered.

A very noticeable peculiarity of this dark-coloured product is the variety of colour it presents under different circumstances. Dissolved in alcohol, ether, or collodion it colours the solution a peculiar yellowish tint of brown. Dissolved in a considerable quantity of water it forms a bright green solution; but in a minimum quantity the colour is again brown, but of an entirely different tint to the alcoholic solution. If the weak aqueous solution be gradually evaporated a point is reached at which it becomes brown while hot, but regains its green colour upon cooling. So remarkable is this change of colour that if a porcelain basin be rinsed out with a solution so weak as to scarcely leave any perceptible trace of colour, and placed over a Bunsen burner or other source of heat, as it dries it will assume a deep brownish-black colour, and this in turn gives place, when the basin is allowed to cool, to a delicate lemon-yellow. Similar phenomena are common to many of the copper and other salts, and are due to the hydration and dehydration of the substance; but the exhibition of both classes of colour in the presence of water we do not recollect to have met before. Some further peculiarities in the working properties of this preparation we must postpone for a future article.

THE PHOTOGRAPHIC EXHIBITION.

[Third Notice.]

As respects composition, the two views in North Wales (81-2), by Lieut. Darwin, R.E., are all that can be desired; but we think that a mistake has been made as regards the manner in which they have been printed. They appear to have been cemented upon the back surface of a plate of glass, so as to ensure optical contact between the glass and the surface of the print, the result being that they have a flat, sunk-in appearance which, under ordinary treatment, they would not have had. These remarks apply also to several of the pictures exhibited by the Military School of Engineering, Chatham.

Among a number of excellent landscapes exhibited by Mr. T. M. Brownrigg, we may direct attention to his picture, *On the Wey* (104), and *A Spring Evening on the Blackwater* (124), as ably keeping up the reputation of this able photographer.

The interiors of Mr. Fred. Downer (122) are highly-successful examples of this class of photographs. The *Farm Studies* and *Harvest Studies* of Mr. J. Foster (108 and 127) will prove very useful to artists. Mr. J. Milman Brown's picture, *Shanklin Old Village* (93), is a subject which will be recognised by all who have been so fortunate as to have visited this village. It is, however, rather inferior to other pictures by the same artist—for example, to his work, *A Country Road* (148).

The enlargements (111) by Mr. Henry Dixon are very excellent. Produced from negatives two inches in dimensions, or even less, the texture and detail of the enlargements are most admirably rendered.

Mr. C. Bennett contributes a large number of fine cabinet-size pictures. Of these the hanging committee have consigned to a position far too low for comfortable examination a frame of views of *Guernsey Rocks* (102), by the collodio-bromide process. Others, such as the frame 118, are now favourably situated for careful scrutiny. The frame mentioned contains twelve charming views, entitled *Bits from Bettwys.* Here we may observe that the lovely Welsh village, Bettwys-y-coed, has, in conjuction with its picturesque surroundings, furnished themes for a greater number of pictures in this than in any previous exhibition. Bettwys is indeed a lovely spot, and one which is, and may well be, the delight of every lover of nature who has been privileged to vist this romantic district. Dull, indeed, must be the soul of the photographer who, located even temporarily amid such scenery, does not there find room for expansion, or, to descend to commonplace, subjects almost innumerable for his camera. From the pictures of Mr. Bennett it can easily be recognised that this artist is a gentleman of refined tastes and also a skilful photographer.

A series of *Views on Loch Morah* (134), of dimensions nearly similar to those just mentioned, reveal the fact that Mr. W. J. A. Grant has brought home several interesting mementoes of a visit to the north. Two large pictures, by Mr. W. Vanner, *On the Windrush* (131) and *The Pollards* (132), are successful and pleasing works, and the same remarks will apply to two frames (151 and 152) of attractive pictures by Mr. William Wainwright, Jun., representing *Views on the Thames*.

A large collection of noteworthy photographs taken in Paris transport the sympathetic observer to the Great International Exhibition now open in that city. The twenty-three views of various interesting scenes in the World's Fair, selected by Mr. England for exhibition, have been executed with all that care and skill for the possession of which Mr. England has obtained a world-wide reputation. Those who, on visiting the French Exhibition, have had to hurry past numerous beautiful architectural and other details are here enabled to revisit such scenes once more, pictorially, and dwell at leisure on the structural peculiarities of each.

The exhibits of such an arduous scientific investigator and writer as Capt. Abney necessarily command attention. His various pictures are able illustrations of the peculiar features to be discerned in the skilful working of such processes as the washed emulsion, both plain and in combination with a beer and albumen preservative, and these developed with both alkaline pyro. and with ferrous oxalate. Pictures of this description possess educational value for the photographer; and for a similar reason we also welcome a frame of views in Kent and North Wales, by Mr. Edward Dunmore (94), obtained by plates that were prepared according to a variety of modes of manufacture, such as the Liverpool ordinary and extra-sensitive, Colonel Stuart Wortley's dry plates, and those of the Uranium Dry-Plate Company. As regards the pictorial merits of Mr. Dunmore's works, their artistic qualities are abundantly apparent.

Mr. A. Boucher exhibits largely. The various faces are so beautifully worked up by the popular appliances of the retoucher's art that it would be a positive relief if some photographic firm of eminence would exhibit a collection of works in connection with this branch of our art that were quite untouched. A number of portraits by Mr. John Lamb suffer by being hung too low to admit of their being easily examined.

The pictures of Mr. F. N. Broderick, Jun., respectively *The Coast at Ventnor* (138) and *Wreck of the Eurydice* (139), are highly interesting. The latter could scarcely fail to be so under any circumstances.

The famous poikilographs, exhibited by Signor Lombardi, arrest the attention of those who pass upstairs on the way to the gallery. These have necessarily been relegated to the staircase, as it is one of the rules of the Exhibition that no coloured photographs are admitted inside the gallery. The pictures in question are, with one exception, reproductions in *facsimile* of paintings in the Dresden Gallery, and they arrest attention by their fine finish and apparent elaboration. We say "apparent," for it is now well known that these imposing pictures are merely photographs which have been rendered translucent and the pigments then applied to the back of the picture, the photograph itself supplying the drawing, detail, and lights and shadows. The appearance is that of a most carefully-executed painting in oil, and the effect is singularly excellent. One of the pictures is an ordinary photographic enlargement finished and coloured in the manner indicated, and its effect is exceedingly good.

We must postpone further critical notice of the present display till next week.

STOPPING-OUT BACKGROUNDS.

We left our subject last week after treating of opaque pigments as light obstructors; but it will be evident that many cases may arise in which the sole employment of such a method would entail loss of time and waste of material. Thus, when a very large space has to be entirely stopped out for temporary purposes, we should never cover the whole space with the pigment, as it will be found that a margin of half-an-inch painted on all round any object will prevent the light "printing under" if a brown-paper mask be placed on the back of the negative, and cut within a trifling distance of the contour of the object to be printed with its white margin.

Then, again, a combination of the two will often be useful in the case of a subject containing both broken curves and straight lines; for it is our experience and that of others that the painting of an absolutely straight line of several inches in length requires not merely a steady hand but an amount of skill that frequent practice alone can give. We first had our attention called to this in seeing some clever views of locomotive engines which had been taken for the manufacturer's purposes, and had consequently the background stopped out. They were perfect in execution, and, indeed, were some of the most effective examples of the usefulness of photography we ever saw. A few of them were not so clean-looking as regarded the outline of the boilers, and upon pointing it out we were informed that these few were entirely painted out by hand, while the others had the minuter details painted out, and the longer straight lines, such as those bounding the boiler, stopped out by a paper mask. This mask (placed, of course, on the film side) was, where possible, one solid piece, cut out in the necessary parts—not by scissors, but by a sharp penknife; but not infrequently it was found difficult to mask in that manner, and then strips of blackened sensitised paper were cut out with perfectly clean edges and cemented in their place.

Where masks, large or small, or any temporary obstructions have to be attached to the varnished side of a negative we have found that nothing surpasses a solution of india-rubber. It secures the mask most completely, sticking very pertinaciously and not cockling it at the point where it is smeared on, and, finally, permitting its easy removal if not allowed to remain on too long. If gum be employed it cockles the mask, and will prevent a large one ever registering true to the negative from which it is printed. Spirit varnish does not adhere firmly without trouble; paste is like gum, and both have a tendency to pull away portions of the film.

Where the use of a large paper mask to the almost entire exclusion of painting out is determined on it is usual to print a deep impression on plain paper. It will, however, be found a most difficult matter to fix it in its place after cutting, some portions refusing in the most provoking manner to cover the required space, though the whole of the other part of the paper may lie exactly over those parts of the negative through which they were printed. The inexperienced hand will be apt to think that this is caused by inexact cutting out. It is not so, however; it is mainly caused by a straining of the fibres of the paper during the cutting, so that the various portions are put "out of square." The effect is mostly produced when scissors are employed in the cutting, and hence those photographers who do a class of work requiring many of these masks almost universally employ a sharp-pointed penknife, cutting against a piece of zinc or cardboard.

One of the best methods of doing this is to print (on salted paper, albumenised paper cockling and twisting too much) of such a depth that every detail shows most plainly. Then before taking the print out of the frame a narrow edging of the caoutchouc solution is run round the top of the background, and the print pressed to and allowed to remain in the frame for a few minutes; the negative with the attached print is then taken out, and put aside for a few minutes to harden the cement, when it is ready for cutting the mask. To do this a piece of zinc or cardboard is put a short distance upon the edge of the negative with its attached mask; the latter is then turned over towards the operator, and sharply doubled down upon the zinc, &c., thus leaving the print to view. Everything that is required is then cut out with the knife, and when this is done it will be found upon turning the print back again in its place that, if it have not been pulled and fingered, it will be perfectly in register over every part of the negative.

We have dwelt at length upon this subject, as we have reason to believe that the photographing of such objects as we have named is a lucrative branch of photography, but one which, from its comparative infrequency, is found to present sundry difficulties to those who have not been trained to it.

It will be obvious that when pure landscapes are in question such a mode of masking is not to be tolerated for a moment. It would be impossible to prevent that most vicious of effects—a hard outline; and when a distant horizon was depicted it would simply ruin a picture. For landscapes, and all classes of pictures where the separation of parts at the masked edge would be at all prominent—such, for instance, as the junction of sky and earth—the masking must be most gentle and graduated. Fortunately, it generally happens that, as the sky of itself never comes out very dark in a picture, other dangers and difficulties are reduced to a minimum. All that is necessary, as a rule, is to cut a piece of brown paper roughly to shape, and move it a little during the printing (a cut-out silver print may be used, if preferred, of course on the back of the negative). When the clouds are to be printed in a similar method may be used to stop out the print, though this branch of the subject belongs more especially to the domain of double printing, of which it is not our intention now to treat.

RECENT PATENTS.

No. XVII.—MRS. DALE'S METHOD OF COLOURING PHOTOGRAPHS.

To produce the most effective picture by the minimum expenditure of time and skill is one of the problems which every photographer desires to be solved in his own professional practice. To what extent the invention of Mrs. Robert Dale aids in securing such a desirable consummation every intelligent reader will readily perceive from a perusal of her specification, which, having received provisional protection only, is now thrown open to the public:—

Inasmuch that heretofore coloured photographs have been produced either by the direct application of paint to the surface of the photograph, or by rendering by means of varnish, gelatine, siccative, or paraffine (all of which are liable to crack, discolour, or evaporate) the photograph transparent, and by then affixing the same face downwards on the glass, painting the back thereof.

According to the present invention coloured photographs of a more permanent nature are produced in a simpler and more effective manner, and at a cost much less than has heretofore been the case.

The process consists in mounting an ordinary paper photograph, which should be clearly photographed and rather darkly printed, face downwards, on a convex glass by means of a warm solution of starch or other adhesives of a gelatinous nature, and, after drying, laying the same in a bath of pure castor or linseed oil until the same has become perfectly transparent. The finer parts of the photograph are then painted on the back with pure oil colours without medium or varnish, the photograph supplying light and shade, and the colour showing through. A second convex glass is then placed over the back of the painted photograph, and on the back of this second glass is painted all the layer and heavier masses of colour necessary to render the photograph, when viewed from the front, a complete painting, combining an apparent delicacy of manipulation with a depth of tone and roundness of form not attainable by any other process. The glasses are then carefully closed at the edges by means of fusion, or the application of an impervious substance to the prevention of evaporation and the exclusion of air. A white or tinted card is then affixed to the back of the second glass, when the whole presents the appearance of a painting on porcelain.

It is necessary to mention that, in the case of photographs of still life, flat glasses are sometimes preferable to convex ones.

The advantages of this invention are simplicity in working, smaller cost of production, and greater permanency than has hitherto been attained by any other process.

From the foregoing specification it will be seen that excellent effects in colour may be obtained by adhering to the directions given. On the *novelty* of the invention we are not called to speak, seeing that there is now no restriction whatever upon its use.

No. XVIII.—VANDERWEYDE'S METHOD OF ILLUMINATING OBJECTS TO BE PHOTOGRAPHED.

It is one of the conditions upon which a patent is granted that within a period of six months from the date of application a complete specification shall have been filed. This Mr. Vanderweyde, from some cause or other to us unknown, has neglected to do; hence the public have now the full benefit of such invention as is set forth in the following specification, which is the provisional one, and which has been declared "void" for the reason just given.

The title of the invention is "An Improvement in Illuminating Objects to be Photographed, and the Interior of Public and other Buildings," and the specification is as follows:—

My invention relates to an improvement in illuminating the subject to be photographed, and the interior of buildings, by the electric or other powerful artificial light, and consists in an improved arrangement whereby the rays diverging from the source of light are collected into a parallel or converging beam of light, as required for the purpose of photography, without the aid of a lens as heretofore used, and the illumination is wholly or almost entirely obtained by reflected light, the direct rays from the source of light being completely or for the most part intercepted.

My invention consists in the employment in combination with the electric or other artificial light of a parabolic or other concave reflector of comparatively large size, in the focus of which the light is placed, and a shield or screen of opaque or semi-translucent material placed on the opposite side of the light to the reflector.

The shield or screen is made as small and placed as close to the light as possible, in order to intercept as little as possible of the reflected light, and the interior surface may be polished, and of flat, concave, or other form best adapted to reflect the rays of light which it intercepts towards the reflector.

In illuminating public buildings the reflector would be formed by the dome-shaped ceiling or roof, or by hangings of light-coloured blinds or curtains arranged in a convex form, the light being placed in the focus of the reflector, and the direct rays intercepted by a screen, as before described.

This system of illumination is not new, but it is the correct one. The effect is similar to that obtained when the sitter is illuminated by means of a white cloud, of which this is merely an artificial form.

No. XIX.—PRAGER'S METHOD OF TRANSFORMING PAPER PHOTOGRAPHS INTO OIL PAINTINGS UPON CANVAS, WOOD, &c.

This patent has been obtained by Mr. Adolf Prager, of Berlin, and relates to a new or improved process for transforming or converting photographs into oil paintings upon canvas, wood, metal, or any other suitable material. The patentee says:—

The albuminous coat which covers the photographic paper upon which the photographic image is received is detached from the paper, and represents a fine or thin pellicle or transparent skin, upon which is the photographic image.

This albuminous skin or pellicle being wet, is transferred to a glass table, and when it is dry I apply upon it the oil colours upon the image on the inverse side—that is to say, upon the side which was adherent to the paper.

In all the colours employed in my process I mix about one-tenth of tears of mastic finely powdered.

When the albuminous pellicle or skin has been painted as above described, and is completely dried, it is then transferred on to an ordinary picture canvas, or on to a wood panel, or on to a metallic plate which has been previously varnished with mastic varnish, and which varnish has been allowed to dry completely beforehand.

The canvas, the wood panel, or metallic plate, having the albuminous painted pellicle thereon, is placed between two metallic plates moderately heated and pressed in a powerful press until the two metallic plates have become cold.

I take the plates from the press, and the photographic image prepared by this process represents a perfect miniature upon canvas, wood, or metal, with which the thin albuminous coat forms the body by hot pressure. The colours being placed under the albuminous pellicle, are consequently not in contact with the atmosphere, and, being fixed by hot pressure, these miniatures are preserved for an indefinite time.

Having thus described the nature of my invention, and the manner of performing or carrying the same into practice, I would have it understood that I do not limit myself to the exact details hereinbefore described, so long as the main features of my invention are retained, neither do I claim any part of the process or appliances separately, previously well known, and in common use; but what I claim is the new or improved process or processes combined for converting, transforming, or transferring photographic pictures or images on paper into oil paintings upon canvas, wood, metal, or other suitable material, substantially in the manner hereinbefore fully described.

The process here described is merely a modification of that now well-known method of colouring a translucent or transparent photograph on the back and then pasting it down upon canvas or other support. The difficulties of the "patent" process greatly exceed those of the common method.

Dr. Nicol has made a valuable suggestion in his article last week in proposing a new method of preventing the defect known as "blurring." No one who has ever worked the old plan of backing the plate will be inclined to say much in its favour, beyond admitting that it is the only practical preventive at present known which does not act injuriously upon the sensitiveness of the film or the quality of the result. The use of coloured glass and some other devices no doubt prove effective in their action, and do not affect the photographic properties of the film; but they fail owing to being practically unsuitable to the requirements of dry-plate work. Colouring the film by various means has been proposed; but this, while doubtless perfectly effective in arresting as far as it is possible to do the tendency to blurring, gives rise to insensitiveness and irregularity, and has therefore secured no very great amount of recognition. Such being the facts it is not surprising that attention should be directed to the substratum, with the view of interposing a non-actinic film *between* the collodion and the glass. Such a proposal was indeed made some years ago; but Dr. Nicol is the first, we believe, who has come forward with a detailed and practical suggestion. It seems strange, however, that he should have selected the one of all the various substrata in common use which apparently presents the smallest chance of utility; for benzole as a solvent is far more limited in its application than water, alcohol, or ether. The two last are, of course, placed out of the competition where the object is to secure a coloured film which shall not be acted on or dissolved by the collodion; but why reject the first, which is *the* solvent *par excellence?* Albumen Dr. Nicol rejects as useless for the main purpose of a substratum—to cause the collodion to adhere to the glass—and justly, we think, now that alkaline development is so general; but gelatine, which is rapidly coming into favour, offers equal facilities as a vehicle for colouring matters soluble in water. So long as the colouring matter is insoluble in ether and alcohol there seems to be little danger of the collodion attacking it to any appreciable extent, and the only difficulties are in the selection of a substance answering to the necessary conditions and capable of easy removal when its function is complete. As a further suggestion in the direction of the choice of a suitable pigment we venture to ask is it necessary that it be soluble? We think that a sort of emulsion of some semi-opaque material would answer the purpose quite as well by intercepting the rays of light in their passage to and from the back surface of the glass. It would not interfere with the textural quality of the sensitive film, and many substances may be chosen which are soluble in either hypo. or some other easily-applied reagent, so that no difficulty need be experienced in their ultimate removal. The only objection likely to present itself lies in the thinness of the substratum and of the solution used in its formation; the latter condition would possibly operate against the production of a sufficiently dense film by its inability to hold a due quantity of the insoluble matter in suspension. It would be interesting to try the efficacy of a gelatine substratum containing *insensitive* iodide of silver. This should not only play the part of an interceptor of the light rays, but also aid in the production of a dense image.

PRACTICAL INSTRUCTIONS IN MODERN PHOTO-MECHANICAL PRINTING METHODS.

Part I.—PHOTOLITHOGRAPHY.

IV. Transferring the Fatty Image to a Lithographic Stone.—The transfer having been made, our subsequent operations are independent of daylight, as the photographic part of our operations is completed, and we have next to study and to practise the lithographic portion of the work.

There is no disguising the fact that, unless the student is prepared to be beaten and to be stopped short after a few experiments, he must set to work in good earnest and acquire a considerable practical knowledge of most of the operations incidental to lithographic printing. Not only this, but he must also carefully study the principal sources of failure, and to some extent compensate for his want of extensive experience by minute observation and thoughtful consideration. In all this his previous photographic training will aid him considerably, as in many respects there are points of analogy between the behaviour of a negative plate and that of the lithographic stone.

It is too much the practice, in treating of photolithography, to consider that the subject is practically exhausted as soon as the transfer is made; and the student is then recommended to seek the help of some practical lithographic printer, who will in a few minutes teach him all that it is now requisite for him to learn. Here lies, in all probability, the reason why so few photographers have carried out photolithography commercially, and added this process to the ordinary working operations of the studio and of the printing-room. The photographer makes his transfer successfully, thinks all difficulties are over, goes in rather an elated spirit to the nearest lithographic printer, and then difficulties commence. Perhaps the lithographer applied to has only been accustomed to a few branches of his business, and is as unprepared for difficulties incidental to the treatment of a photolithographic subject as many itinerant photographers would be if required to work the collodio-albumen process, or to make carbon transparencies. It is, in fact, in the lithographic part of the work in which photographers require special instruction; and in this branch of the subject they are most likely to meet with apparently incomprehensible failures, from which lithographic operations are by no means free. But the patient labours of such men as Engelmann, Hullmandel, Knecht, Lemercier, and of the immortal Senefelder, the discoverer of lithography, have placed the student of today in a position to meet these difficulties as they arise.

The first work of the beginner is to select some lithographic stones. Very much depends on the quality of these, and on their suitability for the kind of work which he intends to do; as an unsuitable stone, or one improperly prepared, will be a continual drag on the student's progress, and may even cause him to abandon further experiments in photolithography. In commencing lithography it is well to have nothing to do with second-hand lithographic stones, unless, indeed, they are to be made use of as inking slabs. A second-hand stone may be so saturated with gum on the one hand, or with fatty matters on the other, as to lead the novice into great difficulties. The presence of gum on the stone would render the adhesion of the fatty transfer imperfect; and the presence of fatty matter would give the stone a tendency to tint under the action of the inking roller. Either of these faults can only be remedied by a laborious grinding away of the surface of the stone until the entire removal of the contaminated portion has been effected.

Having entered a lithographic material warehouse the beginner ought to inquire where the Bavarian stones are kept, and he should then proceed to examine them very leisurely. Those which possess an uniform grey or buff tint, and on which no spots, veins, or markings can be detected, are most likely to repay the trouble of a further examination. A moist sponge should now be passed lightly over the face of each selected stone, provided, of course, that this useful article can either be smuggled into the warehouse or be borrowed there; and notice should be taken as to the rapidity with which the film of moisture sinks into the various stones. Those stones which absorb the water almost immediately are most suitable for the general run of work; but it is quite possible to have a stone inconveniently porous, while those stones which absorb the film of water with considerable slowness are unsuitable for the class of work which is at present under consideration. The most important point, however, is to select stones which are uniform in porosity all over the surface, as evidenced by an equal absorption of the film of water. When some parts of a stone absorb water readily, while other parts absorb it slowly, that stone is fit for no other purpose than for use as an inking slab, and it is not very good for that purpose unless its surface has been saturated with boiled linseed oil, and a sufficient time has been allowed for the oil to become indurated. The precaution of moistening the surface of each stone before finally selecting it should never be neglected when it is practicable to apply this test, as the moistened surface of the stone often shows defects which would otherwise escape observation. Some stones contain whitish, chalky spots which are much softer than the rest of the stone, and the presence of these spots constitutes a very serious defect. As these soft places often lie in strata parallel with the face of the stone, they sometimes do not show on the surface until the stone has been in work for some time; but a careful examination of the edge of the stone will often reveal their presence when they so exist. Iron stains, especially in the case of hard stones, are often unaccompanied by any want of uniformity as regards porosity; but it is best to avoid stones so marked, as these markings are liable to deceive one with regard to the relative intensity of the various parts of any subject which may be transferred to the stone. Exceedingly fine black lines like hairs are generally harmless, unless accompanied by an incipient fissure, and it very often happens that the best stones are so marked. Those stones which are composed of several strata, as seen by examining the sides, should be rejected, even when the face of the stone only cuts into one of these layers, as the repeated grinding of the stone will ultimately so far diminish its thickness as to bring the face down to the fresh layers. Care should be taken to select stones having both faces approximately parallel, as if the thickness of a stone be not uniform a considerable amount of time and labour has often to be expended in packing it up when on the press. The beginner will do well to select all his stones of an uniform size—say twelve inches by ten—as in grinding it is convenient to work the faces of similar stones together.

Lithographic stones, as usually supplied by the dealers, are only roughly dressed, and the first operation is to prepare the surface so as to fit the stone for work. Having placed one of the stones on a board placed in the sink, its surface should be flooded with water, and a little pit sand that has been passed through a sieve having twenty meshes to the linear inch must be sprinkled on it. The grinding operation is now commenced by placing a second and similar stone face downwards on the sanded surface, and then moving the top stone about in all directions on the lower one. By slightly pressing with the fingers on one corner of the upper stone a sufficient grip can be obtained to enable the operator to cause it to rotate on its vertical axis, and a little practice on the part of the operator will enable him to manage that the rotating axis shall so travel about on the lower stone as to describe lines parallel with its sides. In this way the upper stone is made not only to revolve on its axis, but also to travel round the centre of the lower stone at the same time. This operation must be varied by driving the top stone from each corner in succession, so as to equalise the grinding action as much as possible. After this, diagonally-opposite corners of the top stone are held, and a to-and-fro motion is communicated to it, the direction of this motion being continually changed, the hands being also occasionally shifted to the alternate angles of the upper stone. The more the upper stone overtops the lower one during the grinding so much greater will be the tendency of the top stone to become concave on the face, and of the bottom one to become convex; and it is well to counteract this tendency by occasionally changing the two stones, one against the other. During the whole of this grinding operation it will frequently be necessary to wash away the whitish mud which results from the grinding, and to charge the lower stone with a fresh supply of sand and water. When the surface of neither stone presents any scratches or indentations deeper than those caused by the sand the first surfacing is complete.

The stones are now very carefully freed from every trace of the coarse sand by a thorough rinsing, and the surfacing operation is repeated with fine graining sand which has been passed through a sieve having a hundred and twenty or a hundred and sixty meshes to a linear inch. In order to obtain the best surface which this fine sand is capable of giving it is advisable to move the upper stone in very small circles, and to avoid any movement in straight lines. As the grinding action of the fine sand is not great it is allowable to employ a small piece of lithographic stone or a zinc muller in the place of the upper stone. When the fine sand has smoothed the stone uniformly all over—and this is best ascertained by allowing the stone to dry—it must be carefully rinsed, and then polished with pumice-stone. A piece of pumice which is close in the grain, free from any large hollow places, and not unduly dense, should be selected, and a flat face must be worked up on it by friction against some *non-gritty* surface, such as the side or back of a lithographic stone. Having placed the lithographic stone on a table, and provided a basin of water near at hand, the pumice is dipped in the water and then worked backwards and forwards on the face of the stone until an uniformly-polished surface is produced. Every now and then it is necessary to dip the pumice into the water, in order to remove the mud, which tends to clog it. The stone having next been rinsed with water is wiped on the face with a glass cloth or piece of diaper perfectly free from any trace of fatty, saponaceous, or mucilaginous matter. This cloth should, in the first instance, be very carefully cleaned by boiling in weak soda solution, after which it should be thoroughly rinsed in clean water and dried. As much depends on the freedom of this cloth from traces of fatty matters, and more especially on its perfect freedom from anything of a gummy nature, it ought to be kept in a box or drawer by itself, and it should be locked up if careless people are likely to gain access to it.

The stone, being now dry, is placed on the bed of the press, and its surface is covered by several thicknesses of paper, care being taken that the sheet which is immediately next to the stone is perfectly clean. The pressure is now adjusted so as to give a moderate and uniform pinch on the stone. The uniformity of the pressure may be ascertained by placing a few narrow strips of paper between the sheets of paper which cover the stone and carefully examining the traces left by these strips when the carriage is passed through the press. When an uniform pressure cannot be produced by a proper adjustment of the roller or scraper of the press, it becomes necessary to pack up the stone by means of thick paper placed under those parts where the pressure is deficient; but this packing should be so graduated in thickness as to leave no part of the stone unsupported, otherwise a fracture might easily occur. Before proceeding farther it is well to see that all parts of the press work freely, that the leather tympan is tight, and that the carriage rides steadily under the roller or scraper. In the case of a scraper press see that the leather is well lubricated with a mixture of blacklead and tallow; but at the same time take care that all parts of the press which do not require lubricating are quite free from grease.

Let us now suppose that all adjustments of the press are made, and that the stone and the bed of the press are so marked that the same position of things can easily be re-established. The next thing is to see that the transfer is ready to hand and that it possesses the right degree of moisture. This may be adjusted either by the application of a damp sponge to its back on the one hand, or by fanning with a piece of cardboard on the other. The stone is now removed from the press and some pints of boiling water are poured over its face; after which it is drained for an instant and its prepared surface is quickly wiped with the especially clean cloth. The dry and slightly warm stone being now laid in its old position on the bed of the press, the damp transfer is laid face downwards in the required position, and it is covered by the sheets of paper which were employed to lay over the stone when the pressure was adjusted. The tympan being now shut down, and the carriage passed through the press with a steady movement, the transfer becomes adherent to the stone. The backing-paper is next shifted or turned round and another pressure is applied; and this shifting of the backing-paper and renewed application of pressure may be repeated five or six times, while it is well to add an extra sheet of paper to the backing before each renewed pressure, so as to gradually increase the pinch on the stone. It is also well to turn the stone round occasionally during the operation of transferring, in order to ensure a complete transference of the image; and a moist sponge may advantageously be passed over the back of the transfer, every now and then, not only with the view of replacing the moisture absorbed by the backing-paper, but also with the object of slightly increasing the dampness of the transfer as the operation progresses.

A sufficient number of pressures having been given the stone is removed to the sink, and the back of the transfer is sponged with water until it is so far softened as to render easy the stripping it off the stone. The transferred image should then appear clearly and sharply-defined on the stone, while the paper just removed should be almost entirely denuded of the fatty ink. The stone is now to be flooded with tepid water, and at the same time it must be rubbed with a broad camel's-hair brush, in order to remove any trace of gelatine which may be adherent to the surface of the stone. It is as well to spend a sufficient time over this operation, as any trace of gelatine remaining would not only tend to prevent the adhesion of any writing or retouching which may be put on the stone at this stage, but it would also hinder the penetration of the gum, and so render the whites liable to tint during the printing. The stone, being freed from all traces of gelatine and well rinsed with water, is now set up to dry, after which it is ready to receive any additions in the shape of border lines, title, and soforth. If any of the coarse lines of the transfer are defective they may be retouched at this stage; but the working up of any fine lines which may be defective had better be performed by a method to be described further on.

These additions and corrections are made by means of lithographic writing ink, which is sold in the solid state, and must be rubbed up with water when required for use. One end of the stick of ink is to be worked in a very few drops of water contained in a slightly-warm saucer until the water has dissolved sufficient ink to give it a consistency about equal to that of ordinary copying-ink. A few drops more water are now added and the rubbing up of the ink is resumed, this series of operations being continued until a sufficient quantity of the liquid ink has been obtained to half fill a small thimble, which instrument, if mounted in a small block of wood, makes an admirable inkstand. The special care required in rubbing up the writing ink arises from the fact that a large excess of water curdles and decomposes the ink, rendering it lumpy and unfit for use. The operation of writing on the stone is best performed with a fine pen of the kind usually sold for the purpose; and it is scarcely necessary to remark that the writing must be reversed in order that it may print correctly. If preferred, the titles may be written or printed on lithographic transfer paper, and the transfer thus obtained is then transferred to the stone just in the same way as the photographic transfer was put down on the stone. Border lines are best made with the ordinary ruling pen employed by draughtsmen, and any erasures may be readily made by scraping away the defective lines with a sharp penknife. During all these operations on the dry stone the greatest care must be taken to avoid its coming into contact with any greasy substance, and the prepared face of the stone should not be touched by the fingers or hand.

The image and additions being now fairly on the stone, and the writing-ink being dry, the next operation is to brush over the whole surface of the stone with a thick mucilage of gum, and then to place the stone aside until the gum is dry and the stone shall have become quite cold, if, indeed, any warmth remain after such a series of operations.

The subsequent treatment of the stone and the management of the inking-rollers will form the subject of the next chapter.

T. Bolas, F.C.S.

A NEW STUDIO.

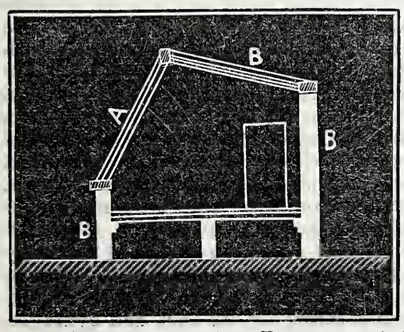
The columns of The British Journal of Photography for the 16th November, 1877, contained an account of the destruction of my studio (only erected two years previously) and business premises at Surbiton by fire. So complete was the loss that, with a very small exception, not an instrument, negative, or article of furniture of any description was saved, and nothing but a smoking pile of wet ashes remained. After a short period of confusion the business of settling with the fire insurance office was entered on, and occupied three months. It was impossible to make temporary arrangements for business, being winter time; thus the thread of every transaction was cut, and had to be recommenced afterwards.

It was determined, as the entire block of buildings was down, to rebuild on a much larger scale, and with every possible advantage in the lighting of the studio, &c. The following are a few of the considerations which guided me in designing a studio:—1. It must have the most rapid possible light without glare, and sufficient length to take large groups; also to permit the use of large lenses for small pictures. 2. No blinds must be required. 3. The situation ought to be such that the afternoon light should not be a slow one. A reference to the sectional sketch will show what I ultimately determined upon, and I have never regretted for a moment a single one of the dispositions made.

It is my belief that the studio is the most rapid that has ever been built, and by the most simple head and body screens the need for blinds is entirely obviated. The length of the studio (fifty feet) permits of making, practically, two rooms of it; and as the backgrounds are strained on frames and attached to movable stands on castors they can be wheeled about or turned to any angle in a moment. Shadow effects are obtained without the sitter moving from a central seat, and the camera can be wheeled round, and the background too, until the desired effect is seen.

The camera is covered by a light movable canopy lined with black, under which the operator stands, and by which the light can be effectually cut off from the lens.

The great feature of the studio is the arrangement by which the sashes, starting from two feet from the floor, slope inwards at an angle of 60° until a height of twelve feet six inches is reached, as in the annexed diagram. A is the glass, whilst all the B parts are



opaque. The part of the roof marked B is painted, inside, of a cool bluish, French grey, and, from the angle at which the light reaches it, reflects downwards a gentle actinic light of great value. The glass is continued right to the end of the studio.

I am aware that "it has been said by them of old time" that a space of five or six feet dark should be left at each end of the studio. I carefully went into this question and determined to carry the glass right to the end, for if it turned out wrong it could easily be stopped out. The light is very valuable from the end, and I recognise it as an advance.

It was objected very strongly by some competent judges who saw my plans before commencing that a great disadvantage would be found in the sloping main light, from being unable to get the sitter near enough to the light owing to want of headway. This is not so, as a six-foot person can stand at the side of the glass without touching it.

A very important matter on which I determined to make a decided change from the ordinary practice was in backgrounds. With a few exceptions I had hitherto had the usual rolling arrangement, with backgrounds fixed on brackets above. I have them now all strained on frames—one on each side of the frame. These fit against stands on castors, and they can thus be wheeled in any direction to suit varying lights or to introduce any desired part of the background.

Very little in the way of costly furniture, curtains, or similar accessories have been procured. Providentially the public taste has been directed in other and far more pleasing ways.

Samuel Fry.

PARIS INTERNATIONAL EXHIBITION, 1878.

COMPLETE LIST.

Class XII.—Photography.

Hors du Concours.

M. Davanne, Juror for France, President.
,, Luckhardt, Juror for Austria, Secretary.
,, England, Juror for Great Britain.
,, Frank de Villecholles, Supplementary Juror for France.
,, Alfred Chardon, Expert for Photo-engraving.

Decorations of the Legion of Honour.—M. Davanne, President of the Council of the French Photographic Society, Paris, for distinguished labours for many years in the advancement of the art and science of photography, author of several works on photography—*Chevalier*; M. Rousselon, director of the photographic establishment of Messrs. Goupil and Co., Asnières, France, remarkable for his splendid exhibition of photo-engravings—*Chevalier*; M. Dujardin, photo-engraving—*Chevalier*.

Grand Prizes.

Diplomas of Honour.—Direction General of Government Works of Geography (Photographic Section), Portugal; Imperial Fabrication of Paper for the State, Russia; French Society of Photography, France; Photographic Society of Vienna, Austria.

Collaborator—Grand Medal.—A. Poitevin, specially recommended to the Minister of Commerce by (1) the Imperial Fabrication of Paper for the State at St. Petersburg; (2) by the French Society of Photography at Paris, France; (3) by the Photographic Society of Vienna, Austria; (exceptional prize) France.

Diplomas of Gold Medals.—Janssen (member of the Institut), presented (1) by the Minister of Public Instruction, (2) by the French Society of Photography, France; Rodriguez, J. J. (Section Photographic of the General Direction of the National Works of Geodesy, Topography, Hydrography, and Geology, of Portugal.)

Diplomas of Silver Medals.—Scamoni, for the perfection of his heliographic plates and of different processes employed for photographic impressions in printing inks, Russia; Pinard Frères, photographers of the School of Medicine at Nantes, Ministry of Public Instruction, France; Capello, Director of the Observatory of the Enfant Don Luis de Portugal, Portugal; Lombard, chief of the photographic service at the Prefecture of Police, Paris, France.

Diplomas of Bronze Medals.—Bouche, *attaché* to the photographic service of the Prefecture of Police, Paris, France; Collard, photographer, of the city of Paris, Council Municipal, France; Emonds, photographer, of the city of Paris, Council Municipal, France; Gelbke, co-operator with M. Luckhardt, with eleven years of service, Vienna, Austria; Lissonde, *attaché* to the photographic service of the Prefect of Police at Paris, France; Marville, photographer to the City of Paris, Council Municipal, France; Merlet (Tony), co-operator with M. Walery, Comte d'Ostrorog, Paris, France; Rafray, missionary of the Ministry of Public Instruction, France; Schmidt (Otto), co-operator with the Maison Czihah, Vienna, Austria; Zotmann, co-operator with M. V. Angerer, Vienna, Austria.

Recall of Gold Medal awarded in 1867 *and again in* 1878.—Lafon de Camarsac, France.

Gold Medals.—Angerer, Austria; Bergamasco, Russia; Bechard, Egypt; Braun, France; Brusa, Italy; Cheri-Rousseau, France; Dallmeyer, England; Dujardin, France; Garnier, France; Gillot, France; Goupil and Co., France; Vernon Heath, England; Joliot, France; Karéline, Russia; Koller, Hungary; Levy and Co., France; Lumiere, France; Matheiu-Deroche, France; Mieczkowski, Russia; Nadar, France; Perlmutter, Austria; Quinsac, France; H. P. Robinson, England; Carlos Relvas, Portugal; Ross and Co., England; Sarony, United States; Sebastianutti, Austria; Leon Vidal, France; Victoire, France; Comte Ostrorog Walery, France.

Recall of Silver Medals awarded in 1867 *and again in* 1878.—Baldi and Würthle, Austria; Baldus, France; Berthier Paul, France; Darlot, France; Jeanrenaud, France; Negré, France; Reutliuger, France.

Silver Medals.—Allessandri Fratelli, Italy; Alinari Fratelli, Italy; Alviach, Spain; Ambrosetti, Italy; Arosa, France; Audra, France; Autotype Company, England; Bacard Fils, France; Balogny, France; William Bedford, England; Beernaert Freres, Belgium; Berthaud, France; Blaise and Rochas, France; Boissonnas, Switzerland; Brandel, Russia; Carette (Lille), France; Chambay, France; Chaumaux, Switzerland; Centennial Photographic Co., United States; Chaulnes (Duc de), France; Chute and Brooks, Uruguay; Dagron, France; Delton Photo. Hippique, France; Derogy, France; Deroux, France;

Duboscq, France; Ducos du Hauron, France; Elliott and Fry, England; Faulkner and Co., England; Fernique, France; Fleury Hermagis, France; Flormann, Sweden; Francais, France; Adelbert Franz, Austria; Garcin, Switzerland; Gernzet Freres, Belgium; Gugenheim and Forest, France; Gutekunst, United States; Henderson (Montreal), Canada; Holterman, N. S. Wales; Jaffé, Austria; Jocger, Sweden; Payne Jennings, England; Jonte, France; Klösz, Hungary; Kostka and Mulert, Russia; Kozmata, Hungary; Lochenal and Favre, France; Landy, United States; Laurent, Spain; Lawton, United States; Lacadre, France; Lemercier, France; A. Liébert, France; Linck, Switzerland; Löwy, Austria; Mieusement, France; Moräes, Portugal; Mulnier, France; Neurdein, France; Notman and Sandham, Canada; Penabert, France; Prazmowski, France; Provost, Pere and Fils, France; Puech, France; Achille Quinet, France; Ravet, France; Comte de Roydeville, France; Rupprecht, Hungary; Sebah, Egypt; Stillfried, Austria; Slingsby, England; Smith, United States; Szekely, Austria; Taeschler Freres, Switzerland; Tourtin and Co. (Emile), France; Turner and Henderson, Canada; Ultzmann, Austro-Hungary; Warnerke, England; Winter, Austria; Yves and Barret, France.

Bronze Medals.—Almagro, Spain; Alophe, France; Franz Antoine, Austria; Angiolini and Tuminello, Italy; Appert, France; Arenas; Spain; Asser, Holland; Bardoux, England; Beil, Portugal; Boggio. Italy; Bonfils, France; Dr. Borsos and Varsagh, Hungary; Boucher, England; Brownrigg, England; Bude, Austria; Carjat, France; Cayrol, France; Chamoin, France; Charconnet and Lavergne, France-Chauvigné, France; Christiano, C. Argentine; Cognacy, France; Collard, France; Czihah, Austria; Daintree, Queensland; Dandoy, Belgium; Davis, South Australia; Decagny, France; Delié, France; Delon, France; Otero Diaz, Spain; Dupont (Antwerp), Belgium; Dupont (Brussels), Belgium; Durandelle, France; Eder, Dr. J. M.. Austria; Espagnet, France; Fabre (Toulouse), France; Fiorillo, Egypt; Fisk, England; Freeman, South Australia; Samuel Fry, England; Garin, France; Geiser, Algeria; J. Girard, France; Gilles Freres, France; Godillot, Algeria; Gobelmann, United States; Guerin, France; Gugier, Austria; Gurney, United States; Hare, England; Harrison and Co., France; Hedges, England; Heid, Austria; Henderson (enamels), England; Houze (de l'Aulnay), Gabon; Hunter and Co., Canada; Hutinet, France; Janart and Guillot, France; Julia, Spain; Junior, C. Argentine; Just, Austria; Klary, France; Kozies, Hungary; Ladrey, France; Lampué, France; Lamy, France; Liverpool Dry Plate Company, England; Loudon Stereoscopic Company, England; Lönborg, Denmark; Loudet B., Argentine Confederation; MacLaughlin, Canada; Marché (du), France; Mariou, France; Mawson and Swan, England; Maunoury, France; Mezzara, France; Michaud, France; Minister of Public Works, Japan; Molteni, France; Mora, Mexico; Muller M., Austria; Nobas, Spain; Numa-Blanc (Scarborough and Nice), France; Nûnes, Portugal; Pacht, Denmark; Pector, France; Peignot, France; Pellet and Co., France; Petersen, Denmark; Pierre Petit, France; Pinel, de la Chardiere, France; Pont, France; Poullenc and Wittmann, France; Poujade, France; Raoul, Russia; Rechnitzer, Hungary; Richard; Robin de Lormel, Caladonie; Roechini, Portugal; Rhomaïdès Peres, Greece; Rossetti, Italy; Rothschild, France; Rottmayer, Austria; Ruckert, France; Salzj, France; Saunier, Reunion; Sauvager, France; Schaeffer, France; Seavey, United States; Skeen, Ceylon; Sherlock, England; Szubert, Austria; Terpereau, France; Thorsen, Norway; J. Ainé Tourton, France; Truchelut, France; Trompette, France; Trutat, France; Ungar, Austria; Unwin Brothers, England; W. H. Wheeler, England; Van der Weyde, England; Yermakoff, Russia; York, England.

Honourable Mention.—Abdullah Bey, Egypt; Alker and Chotteau, Belgium; Antonopouls, Russia; Atchison and Co., Cape of Good Hope; Aubert, Norway; Audouin, France; Aumont, France; Barnard, France; Barthelamy and Co., France; Bate and Co., Uruguay; Beal, United States; Adolphe Beau, England; Beer and Mayer, Austria; Besso (Vittorio), Italy; Billon (Daguerre), France; Boake, New South Wales; Boiarski, Russia; Borris B., Greece; Boscher, France; Boulanger, France; Brun, France; Bruton, Cape of Good Hope; Burato, Austria Bureaux Freres, France; Cardinali, France; Carette (Paris), France; Carleman, Sweden; Carré, France; Castillo, Peru; Couton, France; M. Danesi, Italy; Davelny, Belgium; David, France; Paul Delondre, France; Demaria, France; Deyrolle, France; Dubroni, France; Dufour, France; Eckert and Mullern, Austria; Ferrié, France; Fiorillo, France; Fleurquin and Co., Uruguay; Foucher, France; Fouquet and Guetant, France; Frattacci, Italy; Frossmaun, Cape of Good Hope; Fruchier, France; Gilbert, France; Goldbolt and Basebe, England; Gotz, Russia; Gouin, France; Greenfeld, New South Wales; Greiner, Holland; Guérin, Belgium; Guidi (St. Remo), Italy; Guidi (Florence), Italy; Guilleminot, France; Guler, Switzerland; Viscount Hainoque de St. Senoch, France; J. Pereire, France; Pedra, Algeria; George de la Personne, France; Person, France; Poole, Canada; Porgerin, France; Portier, Algeria; Pricam, Switzerland; Alexandre Guinet, France; Ravasz, Hungary; Raynaud, Belgium; F. de Reisinger, Austria; W. Roe, Cape of Good Hope; Roman, France; Romanet, France; Rubins, France; J. M. Santos, Portugal; Miss Schpakowski, Russia; D. Scott, New South Wales; Secretary of Native Affairs, Cape Town; Someliani, Guatemala; Staudenheim, Austria; Stephan, Switzerland; Stern, Hungary; G. W. Sweet, South Australia; Szaciuski, Norway; Piffereau, France; Tillge, Denmark; Tillot, France; De la Tombele, France; Vallette, France; Verryck, Belgium; Veysset, France; Watkins, England; Welti, Switzerland; Whiting, England; Widmayer, Switzerland; Wilz, France; Zamboni, Hungary.

CLASS XV.—INSTRUMENTS OF PRECISION AND OPTICS.

Jury.

M. Broch, Sweden and Norway, President.
Colonel Laussedat, France, Vice-President.
M. Cornu, France, Reporter.
Lord Lindsay, Great Britain.
G. Colombo, Italy.
De Fleischld, E., Austria.
L. Soret, Switzerland.
Vice-Admiral Mouchez, France.
Commandant Perrier, France, Secretary.
M. Bardoux, Sen., France.

Gold Medals to English Exhibitors.—J. H. Dallmeyer *(Rappel)*; Howard Grubb; A. Légé and Co.; Negretti and Zambra; T. Ross and Co. *(Rappel)*; Sir W. Thompson.

Silver Medals to English Exhibitors.—H. Crouch; G. B. Glover, China; Horne and Thornthwaite; M. Pillisher; J. Swift; S. Tisley and Co.

Bronze Medals to English Exhibitors.—Cetti and Co.; Royal Commission of Victoria; Dollond and Co.; Hearn and Harrison, Canada; Sir C. Layard, Ceylon.

Honourable Mention.—F. Darton and Co.; Charles Potter, Canada; A. E. Thomas.

W. HARRISON.

Asnières (Seine), October 19, 1878.

BALLOON PHOTOGRAPHY.

THE balloon experiments at Woolwich have, besides demonstrating the possibility of making military *reconnaissances* by means of balloons, opened an interesting field for an assault by the photographer's camera.

Captain Templar has succeeded in showing that a well-known laboratory experiment may be utilised in the field for the purposes of warfare, and has already raised military ballooning into an art that must not be neglected. Hydrogen, the lightest known gas, can be prepared by decomposing steam, and Captain Templar has demonstrated that it may be obtained in a rough-and-ready way fashion from materials that can easily be carried with the other *impedimenta* of an army. A supply of steam, a furnace, and an iron tube, with a quantity of iron turnings or shavings, are all that is necessary, and, as M. Giffard has proved that it is possible to construct a balloon that will retain hydrogen gas for apparently an indefinite time, the problem has been so far satisfactorily solved. Steam is passed through a tube containing red-hot iron; the oxygen of the steam is seized by the iron, and hydrogen is liberated, a few hours' working being sufficient to inflate a balloon capable of lifting 70lbs. for every 1000 cubic feet of hydrogen gas contained within its envelope.

Mr. Woodbury has taken advantage of these experiments to try some of his ideas in balloon photography, and we may soon expect to hear that he has been successful. Captain Templar proposes to elevate an observer with his balloon, who is to report what he sees; but Mr. Woodbury's idea is to send up a camera and to photograph the scenes exposed to view. The rope holding the balloon contains one or more electric wires, which, at the proper time, can be made to uncap the camera and so take a picture which will enable the commanding officer to ascertain the positions of the enemy without relying on the eye observations of an aëronaut. By a very simple arrangement—which, however, needs a battery—Mr. Woodbury proposes to take four negatives, which will give views of the surrounding country in four different directions if required, or take four pictures of any given spot; and it is said that he has succeeded in devising a method of preventing the balloon from gyrating—the great difficulty that has hitherto been found impossible to overcome in taking pictures without an operator near the camera. So far as we have heard no photographs have been taken from M. Giffard's captive balloon at Paris.; but Mr. Woodbury found on making application that the "right" had already been sold. It is presumed that those who have acquired the right have been unable to surmount the obvious difficulties, and the experiments at Woolwich are consequently studied with more than the average amount of interest.

Captain Templar is endeavouring to compress hydrogen and store it in steel bottles, so as to carry a supply in an ordinary military waggon into the field; but, if Mr. Woodbury can succeed in rendering his camera automatic in its action, it would facilitate the operations by rendering it unnecessary to inflate the balloon to such an extent as would be needed if an observer had to be carried in the car.—*Echo.*

NOTES FROM THE NORTH.

Little things go a great way both in giving comfort and contributing to success. As winter approaches a large number of photographers will doubtless, as usual, suffer from many of the ills incident to a low temperature. Here is a "wrinkle," cheap and efficient, by which the bath, at least, may be kept at such a temperature as to ensure immunity from many of these ills. I saw it in the laboratory of one of the most popular Edinburgh photographers a few days since, and he, I believe, copied it from Mr. Bruce, of Dunse.

The bath or baths, for there were several, were fixed at a suitable angle in a box with a tight-fitting lid. They were placed a few inches apart, and into the space so made was slipped an ordinary rubber hot-water bottle filled with water at a suitable temperature. This, of course, can easily be changed as often as may be necessary; but if the box were made double, with a space of an inch or two between the walls, and the space packed with a non-conducting material, such as the woollen shoddy sometimes used for stuffing cushions, a single supply of hot water would keep up an uniform temperature during the whole working hours of a winter's day.

Another wrinkle, in the direction of economy, I saw in the same studio, inspired, I think, from the same quarter. Everybody knows that the great bulk of the free silver on the surface of a wet collodion plate is reduced by the developer, and that in the majority of cases it is run into the sink, very few taking the trouble to recover it, although where much work is done such saving would amount to a good many pounds annually. In the dark room alluded to the hole in the bottom of the sink was plugged up, so that the only means by which the water could escape was by the overflow openings. The sink was, in consequence, always full, and the reduced silver settled at the bottom, ready for removal periodically. To prevent the sediment being disturbed by a too-sudden influx of the developer the sink was covered with a wooden tray a few inches in depth, the bottom sloping gradually to a hole in the centre. The solution when poured from the plate fell first into this and then flowed gently into the sink below, the reduced silver falling to the bottom, while the water and soluble salts ran out by the overflow. Those who have not considered the silver recoverable from the process of development worth the trouble which they suppose it entails would be surprised at the quantity of valuable metal they have hitherto wasted, as it must indeed be a small trade in which the cost of the saving apparatus would not be covered during the first month. I need hardly say that neither hypo. or cyanide should be allowed to enter the sink so prepared, but I presume most operators fix by immersion in a bath; and while, where convenient, it would be well to have a separate sink over which to do the washing after fixing, in the absence of such an arrangement it may be safely done over the depositing tray.

Photographers who are sufficiently acquainted with art to be able to do a little water-colour sketching, or who include in their staff an artist fairly competent, might extend their business by adopting an exceedingly attractive and effective style of animal portraiture, a specimen of which I saw recently in the reception-room of one of my friends. It was the portrait of a fine, large dog, lying in a state of repose, introduced into the foreground of a pretty sketch consisting of a lake or river and distant mountains. The portrait, although painted all over, possessed the true photographic fidelity which so few artists of the brush can produce; while the rest of the picture, although subservient to the principal figure, was so brought into relation with it as to make an exceedingly perfect whole. The *modus operandi*, as explained by the artist, was very simple. A suitable negative of the dog having been obtained, the background was stopped out and a print made in the proper place on a sheet of Whatman's drawing-paper. This having been worked upon with water-colour in the ordinary way, the landscape was then copied from a sketch previously selected. The effect was certainly very fine, and could not fail to attract attention wherever it might be exhibited—a union, in fact, of fine art and photography that is perfectly charming.

Amateurs whose convenience for the preparation and drying of plates are limited are not unacquainted with the annoyance of occasionally, from inadvertence, opening the dark room door while the lid of the dry ng-box is open, and so exposing the whole batch of plates to diffused white light. Such a momentary exposure has little effect on slow bath or emulsion plates; but on the more rapid gelatine varieties it most certainly induces fogging propensities, and, consequently, ought to be guarded against. Here is a self-acting arrangement I saw in operation in the dark room of an amateur a few days ago, and which is both simple and efficient:—The drying-box was a kind of cupboard in front of the work bench, having a number of shelves, some of which were carefully levelled so as to let the plates set previous to their being placed on edge to dry. To economise space the door or shutter was counterpoised and made to slide down to the level of the lowest shelf when plates were being taken out or put in. The door of the dark room was kept shut by a spring bolt, which could be opened by turning a knob on the inside. Fastened to the wall and a little to the right of, and in a line with, this knob there was a piece of wood in the form of a lever, one end of which was connected with the sliding shutter, while the other, when in a horizontal position, covered the knob. The arrangement was such that while the shutter was up and the plates covered the lever was down, leaving the knob uncovered; but while the shutter was down the lever so protected the knob that the door could not be opened till the drying-box was shut. Of course the details of such an arrangement will vary with the nature of the fittings of the dark rooms to which it may be applied; but here is the idea, and each operator may work it out for himself. John Nicol, Ph.D.

(To be concluded in our next.)

ON THINGS IN GENERAL.

The Battle of the Lights is coming on. The ground is being cleared, and very soon the people of this country will have a fair chance of judging for themselves the relative merits of gas and electricity. What a panic has seized the holders of gas shares! They seem to think the beginning of the end is already in sight, and they hasten to realise their cash ere their capital vanishes. Foolish shareholders! However, it is the old story of scientists *versus* the populace, and whatever the result photography cannot but be the gainer when electric lighting of some form and in some degree becomes realised in every town of importance, as is sure to be the case before very long—that is, if the lawyers do not stop it—for it is true that the process has got a footing in the country. It is already in Chancery.

I have been reading lately letters from well-known photographers recounting the churlishness of some provincial photographic nobodies who declined to allow the use of their dark room for changing a few dry plates. Perhaps one ought not to be too hard on them, for it is quite possible their dark rooms were in such a state of dirt and disorder that they were ashamed to let any one see them—a not unlikely supposition, judging from dark holes I have looked into in various places. I thought the old days of exclusiveness and want of fraternity among photographers had died a natural death; but so long as processes and process-mongers find buyers and victims one must expect ignorant secrecy to prevail in places.

There is certainly another side to the question. No one likes a rival to overhaul his premises, and these cases may also be explained on the grounds of fear of something of the kind. Thus, I know a well-authenticated case where the same man was treated in such a manner twice over. A vendor of apparatus gained admission to the studio of the photographer in question, making as many excuses as possible to get a good inspection of the place, and very shortly afterwards opened a studio within a quarter of a mile. The second case was still more gross.

I read the other day in one of the foreign journals an account of a case of adulteration of nitrate of silver. It turned out, as might be expected, a case of accidental substitution. My experience of nitrate of silver is that, in England at least, it is obtained in a remarkably pure form, and at a price which is a standing subject of marvel to me. I cannot, however, say the same of chloride of gold, as I have come across samples of that chemical not possessing one-half of the toning power of others.

I was much interested in reading Dr. Nicol's remarks upon side *versus* top lights in America. Doubtless there is a good deal in the question of necessity; but it is a very proper subject to have brought before any body of photographers who have not even got rid of the dogmatic dicta enunciated in the time of "the great Silvy"—that a large extent of side-light was an essential condition in obtaining good results, and that, indeed, most of the success attending M. Silvy's pictures was owing to his having seen and utilised the vast advantages of such a form of room.

In reading the report of the same meeting I was much amused with the remark of one gentleman who has contributed papers to photographic literature (if I do not mistake the name) well worth reading. He would have the pretty women put on a plain background, and the plain women on a pretty background, so that the latter would be the more prominent part of the—one cannot call it picture. I could not help calling to mind the advice of Lady Dorchester to the Queen when the latter suggested to King William that Sir Godfrey Kneller should paint the court beauties. "Madam," said the lady, "if the king were to ask for the portraits of all the wits in his court, would not the rest think he called them fools?" And so, Mr. Neilson, what would a lady say if her *carte* were sent home with an elaborate fancy background? Would she not very soon "take her custom away" from the man who wrote her down plain? Free Lance.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
October 31	Liverpool Amateur	Free Library, William Brown-st.
,, 31.	Oldham	Hare and Hounds, Yorkshire-st.

BRISTOL AND WEST OF ENGLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

The annual meeting of this Association was held at the residence of the Honorary Secretary, Mr. H. A. H. Daniel, on Friday, the 18th inst.,—Mr. T. Davey in the chair.

The minutes having been read and passed, Mr. Steevens was unanimously elected an ordinary member of the Association.

The Hon. Secretary then read the following—

ANNUAL REPORT.

In presenting the report for the past session your Council desires to state that, generally, the Association is steadily advancing, and making itself more widely known; nevertheless, there is considerable room for a greater amount of interest to be taken in the Association's proceedings, and more constant zeal in endeavouring to increase its roll of members.

The following communications and papers have been read before, and contributed at, the meetings:—

The Splitting of Negative Films. By Dr. Mantell.
Exhibition of Pyro. Hydrogen Light.
Trial of Lanterns.
Whims of a Landscape Photographer. By Mr. E. Brightman.

Your Council has pleasure in stating that the financial position of the Association is satisfactory, there being a balance in its favour.

There have been seven indoor and one excursion meetings during the session; and your Council is glad to find that the attendances have shown an improvement on the preceding session, with the exception of the excursion meeting, which, contrary to the general rule, was not so well attended. At the same time, every person present at the latter operated, which has not been the case previously.

Your Council, in concluding the report, desires with still greater emphasis to impress on the members generally the fact that *each one individually* is to a very *large* extent responsible for the success and usefulness of the Association, as by allowing one's interest in the meetings to vary, and one's attendance to be interfered with by anything not of the utmost importance, poor meetings result, thereby lessening the attractiveness of the meetings of the Association to the remaining and attending members.

Your Council is most desirous that the prosperity of the Association should increase rapidly and its usefulness be widely spread, and, therefore, urge on every member the great desirability of speaking of it and making it known as much as possible, and of recruiting for its ranks as many new members as possible in every way.

Lieutenant Lysaght proposed the adoption of the report, and remarked upon its generally satisfactory character. This was seconded by Mr. Brightman, and on being put to the meeting by the Chairman it was carried.

The accounts of the Association having been audited and found correct,

Mr. H. A. H. Daniel (Hon. Secretary) said there were one or two matters he desired to bring before the meeting. The first thing was to read a letter from the President, Mr. W. W. Stoddart, desiring that a fresh President should be elected, as he found that the number of things he now had in hand were too many, and his health, he feared, would not be able to stand the strain if continued. This communication he (the Secretary) knew would be heard with great regret by every member of the Association, as Mr. Stoddart's great scientific knowledge, and his most genial bearing and valuable contributions to the Association, when circumstances permitted him to be present, could not be overrated.

After some conversation on the subject it was decided to ask Mr. Stoddart to reconsider his determination, and to assist the Council in selecting a third vice-president for election by the Association.

The Chairman considered that the best course to pursue, as the present President was a gentleman whom the Association could ill afford to lose.

The Secretary then introduced a subject which claimed a certain amount of careful consideration, viz., the question of having a monthly journal, with full accounts of meetings, &c., circulated amongst the members, as proposed some little time since, in conversation, by Mr. Brightman. He (the Secretary) pointed out that it had been thought it would be a very acceptable arrangement to the corresponding members, as at present those who were almost always debarred from attending the meetings at all during the year seemed very isolated, and that if the proposed journal were instituted it was felt that this state of things would be very much improved.

After being discussed it was decided, on the motion of Mr. Brightman, seconded by Lieut. Lysaght, that a journal of the kind described be circulated each month, and that every member be supplied with an almanac at the end of the year.

Lieut. Lysaght detailed some of his experiences with Swan's dry plates, having been much pestered with blistering of the film and could not thoroughly account for it. The plates of his own make (also gelatine), when subjected to identically the same treatment, showed no signs of behaving similarly.

No one else present had experienced this, and

The Chairman handed round the first two of Swan's plates he had tried, which were thought to be quite a success; and, when compared with some collodion emulsion plates, even allowing for defects, seemed to be of a more delicate quality.

Mr. Brightman remarked upon the great sensitiveness of, and certainty in using, the plates in question.

Lieutenant Lysaght stated that he was making some rather important experiments in connection with the *making* of gelatine emulsions, and, if the results were what he expected, he would communicate the details to the Association.

The Secretary having made a few hopeful remarks as to the opening session, the meeting terminated.

An outdoor meeting of the above Association was held in August last, when the members journeyed by rail to Tintern, meeting some members of the Cheltenham Society, by pre-arrangement, at Chepstow. The total number present was not very large, but everyone came prepared to work, of which a good amount bid fair to be done, ranging from 10×8 to 7×5, by both wet and dry processes. However, hardly had everybody got fairly into harness and made a few negatives, when one of the "blue mists" which thunder weather generally spreads over the luxuriant verdure of Tintern, enveloped everything, and work was practically put an end to. The commissariat department was then carefully attended to at that most charmingly-situated little hotel "The Beaufort Arms;" after which all rejourneyed towards home, the "dry men" anxiously awaiting the results of "development" and the wet men thankful for the little they had.

Correspondence.

TRANSPARENCIES.

To the Editors.

Gentlemen,—I shall be glad if you will publish the few following remarks respecting my transparencies, to prevent anyone who may view them, while now in the Exhibition, from feeling disappointed with the process by which they were produced after, perhaps, having read so much in its favour.

The only time I had at liberty for the preparation of apparatus and accessories for use in, as well as for, these productions, was before half-past seven in the morning and after half-past six in the evening, most of the negatives, which are very simple in character, being secured by carrying out moist plates from my house as opportunities arose.

The object I had in view in exhibiting them was simply for the purpose of breaking the ice in this particular branch of our art-science once again, and not as specimens of art or photographic perfection, to expect which, under the above circumstances, would have only caused me much disappointment, many effects being quite outside the extremely limited time at my disposal.—I am, yours, &c., John Harmer.

Wick, near Arundel, October 18, 1878.

THE ENAMEL AWARDS AT THE PARIS EXHIBITION.

To the Editors.

Gentlemen,—Referring to the above and Mr. J. R. Sawyer's letter, also his remarks in The British Journal of Photography and *Autotype Notes:* in the first place allow me to correct the error Mr. Sawyer has made when he imputes "want of courtesy" to me, in consequence of my not informing him that I intended publishing the letter I sent him. Why! I asked him to inform the person who reproduced his *Autotype Notes* remarks. What is this but publication?

I am in the happy position of having no trade interests to respect. So my tongue is untied and I speak out fearlessly. One thing I do know—that the less Paris Exhibition medallists say regarding the way they have obtained their medals the better. Since the awards were made known "a little spirit of mischief" has just revealed the following facts, which require some elucidation:—

A certain English exhibitor, whose work no honest person could deny as surpassing all others in his branch, was asked by several jurors for examples of his work to take home to their respective countries, at the same time informing him that he must get the highest award. The artist complied with the request; but it is presumed some irregularity must have taken place in the distribution of the complimentary proofs, as the highest award was *not* granted. On making inquiry, one of the "knowing ones" informed him that "had he replied, and complied with the request, the award would have been otherwise."

Returning to enamels: I certainly object to any one criticising my work who is *un*able to tell the difference between highly-finished paintings and untouched enamels. Mr. Sawyer, with all his "thirty years' experience in ordinary photography," might as well judge of the quality of an autotype print after it has been painted all over as to give his opinion of ceramic photography at the Paris Exhibition. I am sorry for this state of things. What photographers require is a process that demands little or no artistic work, and anyone who has worked the "dusting-on" process knows what kind of plain enamels they are.

Some more strange rumours are afloat here regarding the awards, the particulars of which I will reserve for a future occasion.—I am, yours, &c., A. L. HENDERSON.

Grand Hôtel Bergère, Paris, October 22, 1878.

[While we can readily enough believe that the large French photo-enamels which obtained the highest awards may owe much, if not all, of their merit to the dexterous manipulations of the skilled retoucher on ceramic work, and that therefore they may in *technical* perfection be inferior to those exhibited by Mr. Henderson, we think that in the charge brought, on hearsay evidence, against the honour of the jurors in regard to the medal of the other exhibitor there must be a grave mistake. Jurors at photographic exhibitions have undoubtedly obtained an unpleasant amount of notoriety for alleged favouritism; but it is impossible that such a body of gentlemen as that of which the jurors in Class XII. at the Paris Exhibition is composed could have stooped to an act like that recorded merely because the exhibitor withheld the cheap bribe of a few prints; and we have no doubt that the jurors will themselves be more amused than angry at such an allegation.—EDS.]

Miscellanea.

HUSBAND'S PREFERENCE.—The following is an alarming evidence of the progress of the photographic art:—A lady, last week, had her likeness taken by a photographer; and he executed it so well that her husband prefers it to the original.

THE LATE FIRE.—Messrs. George Matland and Co. write:—"We have secured temporary premises at 163, Cannon Street-road, Commercial-road, where we shall resume business on Saturday next, during the rebuilding of our former establishment.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.—The annual Technical Exhibition meeting of this Society will take place on Thursday evening, November 14th, in the large room of the Society of Arts, Adelphi. Particulars may be known on application to the Hon. Sec., 57, Queen's-road, Peckham, S.E.

WEAVER'S EXPOSING SLIDE.—Mr. Weaver, of Runcorn, has forwarded to us a model showing a further improvement effected by him in his camera-shutter recently described in a sub-leader (page 434). Mr. Weaver has altered the form of construction while retaining the principle, the peculiarity of the alteration enabling anyone, however little skilled in mechanical ability he may be, to adapt the invention to his own camera. It is now applicable to any bellows-bodied or sliding camera without the necessity previously existing of cutting a slot in the camera. This shutter deserves to find favour on account of its simplicity and efficiency.

POTASSIC PERMANGANATE AND CAUSTIC SODA AS A TEST FOR HYPO.—In the *Deutschen Photographischen Notizen* Herr Fritz Haugk recommends potassic permanganate and caustic soda as a delicate and inexpensive test for hyposulphite of soda. As the test is very simple and likely to be very useful no excuse is required for giving Herr Haugk's words here at length. He says:—

"Potassic permanganate has long been known as a test for hyposulphite of soda; but by itself it can never rival starch and iodine in sensitiveness. Professor Böttcher, of Frankfort—a very skilful and learned experimentalist—finds that a solution of potassic permanganate becomes much more sensitive to hyposulphite of soda when a little caustic soda is added to it. Böttcher's formula is as follows:—Dissolve one decigramme of the purest potassic permanganate and one gramme of chemically-pure caustic soda (prepared from sodium) in half-a-litre of distilled water. The red fluid instantly loses its colour and becomes green on the addition of the slightest trace of hyposulphite, owing to the deoxidation of the permanganate. Unfortunately to most photographers these chemicals in the absolute degree of purity prescribed by Böttcher are not always accessible; I have therefore tried whether less pure chemicals could not be used with good results. Of course one would not expect to get such remarkable results with the less pure chemicals as with those that are perfectly pure, still the results obtained are sufficiently satisfactory for everyday work. For such work it is sufficient to dissolve a grain of potassic permanganate the size of the head of a pin in about 400 cubic centimetres of water, and to add to this solution from fifteen to twenty drops of caustic soda solution, such as may be bought from any chemist. If after standing some time a brown precipitate be deposited, decant carefully into a clean bottle. In no case should one try to remove the precipitate by filtration, as the solution would thereby be decomposed and its property as a test perfectly destroyed. It may, however, without injury be filtered through glass cotton. A solution of potassic permanganate prepared in this way is considerably more sensitive than starch and iodine. If about ten c. c. of it be poured into a test tube, and a similar quantity of 1 : 40,000 hyposulphite of soda solution be added, the cochineal red colour of the permanganate solution will instantly be changed into a bluish-green. If a similar quantity of 1 : 60,000 soda solution be added the permanganate solution will immediately become violet-blue. With a solution of 1 : 100,000 the permanganate solution becomes lilac; and with a still more dilute solution pale lilac. When perfectly pure chemicals are used, as prescribed by Böttcher, even the presence of a millionth part of hyposulphite of soda may be detected by a distinct change of colour."

THE FATAL EXPLOSION IN GRAY'S INN ROAD.—Dr Hardwicke held an inquest at the board-room of the offices of the Holborn Board of Works, Gray's Inn-road, on Friday last, the 18th. inst., relative to the death of Mr. Edward John Wrench, aged 24, optician, who was killed on Wednesday by the explosion of a gas retort on his premises, 37, Gray's Inn-road.—Edward Newstead, solicitor, Gracechurch-street, identified the body of deceased as that of his cousin. He was in conversation with Mr. Wrench, Sen., on Wednesday, about noon, when they heard a loud report. Mr. Wrench went upstairs. Witness followed, and met a woman on the landing, whose face was covered with blood. The deceased was then being carried downstairs by two workmen, insensible. He immediately obtained medical assistance, but in a few minutes Mr. Taylor pronounced his cousin to be dead. The window sashes were blown out, and the glass broken. The grate was blown into pieces, and the fireplace was a heap of bricks. He did not see any trace of the retort. Deceased was in the habit of making oxygen gas, and was generally most careful in the process.—Mr. Reginald Taylor, surgeon, Gray's Inn-road, said when he arrived at the scene of the accident deceased was lying on the second floor insensible, and in a state of collapse. He ordered brandy, but deceased could not swallow it, and only lived about ten minutes, the cause of death being collapse and loss of blood from severe wounds in various parts of the body.—Mrs. Elizabeth Gibson, who was led into court, her face enveloped in bandages and blind, said she was assisting deceased in making oxygen gas. The retort had been on the fire, but having turned on its side deceased set it right again. A few minutes afterwards it exploded, and the whole of the gas flew in her face and burnt her. She was then near the door, which suddenly closed. As she got into the passage deceased called out, "Oh, Mrs. Gibson!" She was then blind, and did not know what followed.—Wright, G 175, deposed that he saw the window sashes blown into the street, and going up into the room found it full of smoke.—Mr. Allardice deposed to finding the retort and the broken cup and tube.—Mr. W. Valjee Simons, 19, Langley-road, Kennington-park, analytical chemist, said, after hearing the evidence of Mrs. Gibson, he was able to account for the accident. He called the same afternoon on which it took place, and searched the room and found the retort and tube. The turning over of the retort into the fire would cause some of the oxygen mixture to fall into the cup, and thus choke the tube, causing the retort to explode, as the gas could not escape. He was told that the deceased had not put the whole of the oxygen mixture into the retort but had left some on the counter, but he could not find it. He sent for some to the place where deceased usually purchased it, and found it to be pure.—By a juror: I see that there is a screw over the cup; do you not think if there had been a valve in place of a screw the gas would have escaped, and thus averted the accident?—Witness: Yes, that is so. I usually put in a plug with white lead, so that if the retort gets too full of gas it blows the plug out, and no accident occurs. This retort is one of the strongest; indeed, it would have been better had it been weaker. I have known the plug to be frequently blown out of the retort when I was engaged making this gas.—The jury returned a verdict of accidental death.

EXCHANGE COLUMN.

Wanted, The British Journal of Photography, posted Mondays, in exchange for apparatus, &c.—Address, F. S., Whitley Brow, Melksham.

I have 200 negatives of actresses and celebrities, by Fradelle and Marshall, to exchange for anything useful.—Address, W. Slater, 166, Grange-road, London, S.E.

Wanted to exchange, a glass bath, 15 × 20, in box, for lantern photographic slides, or anything useful in photography.—Address, G. Schofield, Heaton Mersey, near Manchester.

Wanted Grubb's patent aplanatic lens, A_0, and good studio or field camera, in exchange for enlarging camera. 15 × 12, or field camera, 12 × 10; must be good.—Address, C. Watson, 4, Kirkgate, Ripon.

Mahogany expanding camera, with double combination *carte* lens, adapted for either portraits or views, with complete set of chemicals for wet plates, will be exchanged for scenograph with chemicals, or good pocket camera.—Address, J. B., Kirkfield Bank Post Office, Lanark—to be called for.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

PHOTO-MECHANICAL CORRESPONDENCE.

J. James.—Paraffine oil is an excellent fuel to employ, as the products of its combustion have not that injurious effect on bichromated gelatine which is known to frequently follow the use of coal gas. Very convenient stoves for burning paraffine oil can now be obtained for a small sum at many oil shops.

Stanley.—The addition of soap to the ink employed in making a photo-lithographic transfer is very objectionable, as traces of the soap often adhere to the whites of the paper, and this leads to a tinting of the corresponding parts of the stone. In making a transfer from an engraved plate an ink containing soap may be employed.

GENERAL CORRESPONDENCE.

W. X.—The spots are probably due to careless manipulation, as there are decided traces of finger-marks on the surface.

Calcium.—We have no knowledge of the special requirements of the bath you mention, but should imagine *any* good collodion would answer.

X. Y. Z —Let the sides be eight feet high, with a high ridge roof. Four feet may be left opaque at each end of the roof, but glaze the sides up to the end.

James C. Archer.—The mottled, yellow appearance of the prints is owing to their being fixed in a too weak or exhausted solution of hyposulphite of soda.

W. Wainwright.—Our correspondent asks if any reader can inform him of an apparatus for heating a small dark room, and which will not give off smoke or dust. He has no gas laid on.

D. C.—The only suggestion we can make is to stop out the background in the negative with Bates's black varnish, making use of a magnifying glass and an unlimited amount of patience.

B. Egginton.—1. Paper sensitised upon a bath containing a large proportion of citric acid will keep white for several weeks.—2. Negative retouching varnish is now a commercial article. [See advertisements.]

J. W. D.—The appearance of the negative indicates that the collodion contains too much iodising material for the strength of the bath. Try the effect of adding about a fourth part of *plain* collodion to that which you are now using.

George B. Fox.—To fuse the crystals of nitrate of silver place them in a porcelain dish and apply the required heat cautiously. Avoid the application of too great a degree of heat, as decomposition is caused thereby. When fusion has taken place pour out the molten mass upon a clean iron or marble slab.

John Tanton.—We cannot advise any better means of securing a fair average in the quality of your pyroxyline than by mixing the whole of the samples, and carding them together so thoroughly as to ensure any one tuft, pulled out at random from the mass, to be perfectly similar in quality to any other tuft obtained in a like manner.

S. F. R.—While we cannot inform you of the *cause* of the blistering of the gelatino-bromide film (unless its having been subjected to an unduly high temperature affords a clue), we are able to indicate a remedy for, or, more correctly, a preventive of, this evil. It consists in making use of *hard* water for the various solutions and washings to which the negative has to be subjected.

A Bath Photo.—We strongly disapprove of the method you adopt of poising the large plate upon the ends or points of the fingers during development, because of the tendency of the parts touched to become heated and thus to cause unequal development. It will prove a better method to sustain the plate upon a pyramidal block of wood, its motions being guided by a finger and thumb applied to one corner.

Rev. T. B.—Stir a teaspoonful of chloride of lime into a vessel containing three or four ounces of water, and then add a few drops of hydrochloric acid, by which chlorine will be disengaged. In this solution immerse an iodised collodion plate after it has been sensitised in the nitrate of silver bath, first taking the precaution to wash it well with water. The film will by this treatment be converted into one of chloride of silver.

L. D.—It is the iodide in the old negative baths that prevents them from answering well for printing. The easiest remedy is to precipitate the silver by the insertion of a strip of copper. Any iodide that may be precipitated can be removed by treatment with a weak solution of cyanide of potassium. Or you may try the effect of adding a solution of citric acid, neutralising it with carbonate of soda. This is said to answer the purpose of effecting the conversion of a negative bath into a printing bath.

M. D. T.—A simple method of photographing leaves consists in superposing them upon sensitive paper, covering with a glass plate, and then exposing to light for a period sufficient to have caused their details to be visible upon the paper. Next fix in hyposulphite of soda, and wash. Toning will not be necessary in this case. By proceeding in this manner you will afford your antipodean friend quite as good an opportunity of studying the venous formation of the leaves as by sending the specimens themselves.

J. H. B.—Apparent motion may be induced in a stereoscopic representation of a subject by taking one picture of a movable subject, such as a man wielding a hatchet when the instrument is raised to its height, and another after the blow has been given and the hatchet has fallen. When a picture prepared agreeably with this principle is placed in the stereoscope, and is examined under such circumstances, and by the aid of an oscillating shutter, as to cause each eye to see its respective picture in rapid rotation and the two not to be seen simultaneously, the arm will then seem to be rising and falling. The phenomenon of persistence of vision has something to do with this peculiar effect.

S. S. George.—Mr. Tilley's method of putting in backgrounds in negatives consists in first exposing the plate to the sitter with a *dark* background; then, while the sitter remains immovable, let the dark background be superseded by one of a white or, at anyrate, light colour, a transparency of any landscape desired as a background having been inserted immediately in front of the sensitive plate previous to and during a brief secondary exposure to the white ground. Upon developing the negative the pictorial background will be found admirably produced behind the sitter. The method is ingenious, and is capable of various applications. We are not aware whether Mr. Tilley's patent is or is not in force; but it is more than three years since the patent was obtained.

Ignoramus.—This correspondent wishes to know in what manner she is to proceed in order to obtain a blue tone upon her prints. She has hitherto, during her limited experience in photographic printing, been making use of paper purchased ready sensitised, and has been toning in the carbonate bath. While we think that the tone she has usually obtained—a rather brownish-violet—is much to be preferred to that to which she aspires, we yet give a hint by which the blue tone so much desired may be secured. It merely consists in allowing the prints to remain in the toning solution a much longer period than she has hitherto been doing. Immerse three prints in the toning solution at the same time, and let one be removed after they have acquired a violet tint, a second after that tint has become of a pronounced blue tint, the third not being removed until it has passed into a kind of bleached-blue stage. Let these be fixed, washed, and dried, and it is probable that the last of the three prints will be of the tint desired by our lady correspondent, although in our estimation it will not be the most agreeable tint.

Geo. S. P. O'Hara.—You will not experience much difficulty in ascertaining whether it is the bromide of cadmium or the nitrate of silver that is in excess in the emulsion if you proceed as follows:—Prepare two solutions, one of nitrate of silver and the other of bromide of cadmium, distilled water being the solvent. The degree of strength is immaterial. Now, having placed a small portion of the collodion emulsion in a measure, add sufficient distilled water to precipitate the pyroxyline, and decant the clear supernatant liquid, to a little of which add one or two drops of the nitrate of silver solution. If there be a turbidity or milkiness formed you may be sure that there is excess of soluble bromide in the emulsion; but if the liquid remain clear it is an indication that if there be any excess at all it is that of nitrate of silver. To verify this add a few drops of the bromide solution to a fresh sample of the supernatant liquid, and if milkiness ensue you may rest assured that the emulsion contains an excess of nitrate of silver. The remedy is suggested by a knowledge of the nature of the excess.

The Manual of Photographic Colouring (by Joseph Wake).—This comprehensive work will be published on Thursday next, the 31st instant. Our readers will find that this volume contains in a handy form all that is necessary to know about photographic colouring in its various branches. For particulars see page iv. of our advertising sheet.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician.
For the two Weeks ending October 23, 1878.
These Observations are Taken at 8.30 a.m.

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 965. Vol. XXV.—NOVEMBER 1, 1878.

FURTHER REMARKS ON THE USE OF BROMIDE OF COPPER.

It now remains for us to speak of bromide of copper on its practical application to emulsion purposes, for which use it has been specially recommended by Mr. Warnerke and others. We may first of all remark that, strictly speaking, the preparation we described last week is not perhaps absolutely pure; indeed abundant proof may be found that it is not, though it is quite sufficiently so for the uses to which it is proposed to apply it. If it be used in alcoholic or ethereal solution, as we have described, the sources of impurity are more numerous than if it be brought to the solid state. While in the first case the impurities may be of an injurious nature, in the latter they are preferably harmless chemically; the only inconvenience arising therefrom will be found in the necessity for determining the combining equivalent of each separate sample made.

We have spoken in our previous article of the liberation of bromine during the formation of the salt by the mutual decomposition of the bromide of potassium and sulphate of copper. This in itself would produce no further ill effect than the loss of a portion of the bromine by the formation of insoluble sub-bromide of copper, the liberated portion remaining in solution. But there is every reason to suppose that this free bromine in the presence of alcohol may result in the formation of *bromal*, which Captain Abney has stated to be a fog-producing element in emulsions; but, on the other hand, there is just cause to doubt the production of this substance—at least within the comparatively short time occupied in the sensitising of an emulsion—for we know that if bromine itself be substituted for a bromide in the collodion no such fogging results. In the case in question, however, the bromine and the alcohol are presented to one another under entirely different conditions, and it is, of course, quite possible that their reactions may therefore differ.

As proof that some abnormal formation does take place, it may be mentioned that, if the alcoholic or ethereal solution of copper bromide be kept for some time in a closed bottle without previous purification by evaporation, a peculiarly pungent and irritating odour is developed which differs totally from the well-known smell of bromine. It is less a "smell" than a suffocating exhalation, which has a painfully-irritating effect upon the eyes and upon the mucous membrane of the nostrils if accidentally inhaled. We have found that such a solution if long kept produces an undoubted tendency to fog when used in sensitising the emulsion, and even when comparatively fresh there is usually a slight tendency to veil the shadows, though not to such a degree as to prove of much importance. The dried product produces no such effect, even if redissolved and kept in solution for a considerable time. The reason of this is not far to seek, for it may readily be supposed that the impurities, if volatile, as they appear to be, are driven off in the act of evaporation, and that once got rid of there is no tendency to further decomposition of the bromide. We have tested the stability of the bromide produced in this manner by repeated solution and evaporation, using alcohol, ether, and water as the solvent, and so long as a temperature of about 200° Fahr. is not exceeded we have been able to notice no decomposition. If, however, the solution be evaporated over a naked flame instead of by the water bath a gradual disengagement of bromine occurs; but as far as we can see there is no formation of secondary products.

Perhaps the best test of purity we could apply is the combining equivalent of the salt. Five grains of the solid bromide of copper were dissolved in alcohol and tested with the volumetric silver solution. It was found that 6·8 grains of silver nitrate were necessary to complete the decomposition. Now, taking the formula $Cu\,Br_2$ and combining equivalent $\frac{223.4}{2}$ for cupric bromide, the theoretical quantity of silver nitrate necessary would be a trifle over 7·6 grains. But, working on the figures obtained in the experiment above, we arrive at an equivalent of 125; that is to say, 125 grains (one-half equivalent) would be necessary to decompose 170 grains (one equivalent) of silver nitrate instead of 111·7 grains—the theoretical quantity. This difference is sufficiently large to admit of the supposition that the bromide contained an equivalent of *combined* water; but a subsequent analysis proved this not to be the case.

Ten grains of the salt were dissolved in alcohol, and the solution passed through a small filter, previously thoroughly dried and accurately balanced. The filter was then washed by passing through it fresh alcohol until all traces of the colour of the bromide were removed; there then remained a somewhat bulky white powder. The filter, with the insoluble matter it contained, was then dried and re-weighed, and was found to have gained nearly one grain, though, from the bulky character of the precipitate, we had anticipated a wider difference. Ten grains of the substance tested contained then only nine of real bromide of copper, and working from that quantity the equivalent is reduced to 112·5, or so near to the theoretical figure as to leave no ground for supposing that the difference is anything beyond accidental or unavoidable error. A small portion of the powder ignited in the flame of a spirit-lamp imparted to it the characteristic bluish-green colour of copper, without any trace of the lilac or purple tinge peculiar to potash salts. The remainder dissolved completely in nitric acid, and ammonia in excess developed the well-known deep blue colour, showing the presence of copper. From this we may assume that the only impurity consists of sub-bromide of copper; if cuprous oxide were present the colour of the residue would be black, or nearly so.

The application of this "purified" salt to emulsion purposes is extremely easy; it is sufficiently soluble in alcohol at ordinary temperatures, forming a splendid deep ruby or port-wine-coloured solution. Here we notice another peculiarity of the chameleon-like salt, for under different conditions it presents a variety of colours, including black, brown, green, yellow, and crimson. In order to avoid subsequent trouble in the way of spots it will be well to dissolve the bromide in the alcohol, and to filter the solution before adding the pyroxyline and ether; this will present less inconvenience and loss than the filtration of a much stronger "bromising" solution to be added after dissolving the cotton. Moreover, under the latter circumstances, it would be necessary to employ hot alcohol in order to dissolve a sufficient quantity of the salt.

Forty grains of bromide of copper were dissolved in twelve drachms of alcohol and filtered—the filter being washed through with another two drachms of alcohol, to avoid, as far as possible, waste of bromide. Twenty grains of cotton and fourteen drachms of ether were then added, forming a collodion with much of the appearance of bottled stout, but with a slightly redder tinge by transmitted light. This was divided into two equal parts—one of which was sensitised with twenty-seven grains of silver nitrate, the other with thirty grains dissolved in the usual manner. The first emulsion was calculated to contain a very slight excess of bromide, while the other contained something under a grain and a-half of silver in excess in each ounce.

A remarkable fact is noticeable in the sensitising, and one which suggests the idea that the combination between the bromide and the silver in the emulsion takes place much more rapidly than is generally supposed. The colour of the collodion before sensitising is, as we have said, black, or nearly so; but immediately upon the addition of the silver the colour commences to disappear, and by the time the full quantity has been added the emulsion has acquired the ordinary appearance, and it is only by careful comparison with another, prepared by one of the usual salting formuæ, that the faint blue tinge imparted by the nitrate of copper can be detected. The change from the deep, dirty colour of the collodion to the delicate, creamy tinge of the emulsion is really surprising; and it is, perhaps, the suddenness of the metamorphosis that leads to an impression that the bromide is precipitated in a state of greater fineness than usual. Be this as it may, the emulsion does not differ in any material point as regards colour or general appearance from one prepared with cadmium or ammonium bromide.

In working qualities we find no distinctly-marked properties by which the bromide of copper emulsion can be distinguished from the ordinary ones we use, unless it be in the direction of cleanness of development and freedom from fog. In this respect all the samples we have prepared from what we term the "purified" bromide have been specially noticeable; but, as we had occasion to remark in the earlier portions of this article, there is occasionally a decided tendency to fog, and always a slight veil when the bromide is used without purification. The colour of the developed image also differs slightly from what we usually obtain, though this may be due rather to other conditions than to the bromide.

With regard to comparative sensitiveness we are not in a position to speak decidedly, as our opportunities for outdoor exposures have been very limited latterly; but, as far as exposures by artificial light under a negative may be taken as a test, we find the copper bromide to be about equal to cadmium and ammonium double salt, but with this difference—that the former gives under similar conditions a "pluckier" image. We cannot, however, offer any evidence in favour of the alleged advantage the cupric bromide is stated to possess in rendering feebly-lighted details, though it is true the circumstances under which our experiments have been made scarcely permit of our judging correctly what would be the effect produced in the camera. We find in transparency printing a wider contrast between the lights and shadows than would be the case with an ordinary emulsion; that, in fact, a flat negative gives a more vigorous print with the copper emulsion than is the case with one prepared from other bromides—a result which appears to be exactly opposite to the allegations mentioned above. If the advantage claimed were in the better rendering of subjects presenting *feeble contrasts* then we should be inclined to support it.

We have, however, to record two notable features in the behaviour of cupric bromide which seem to specially recommend it to our notice: we allude to the facility it affords for preserving an emulsion for a lengthened period in the presence of free silver, and also its favourable action upon the precipitation. With regard to the first, this is, we believe, the special function which Colonel Stuart Wortley claims for nitrate of uranium in his formula, and which Mr. M. Carey Lea some years ago stated to be common to most of the metallic nitrates, naming nitrate of copper as the one best adapted to the purpose. We may, therefore, in the present instance, attribute the effect to the nitrate of copper formed in the emulsion; and we may state that we have kept an emulsion containing an excess of a grain and a-half of silver to the ounce for forty-eight hours before precipitation without any restraining acid and without developing the slightest tendency to fog. This we have never been able to do with any of the bromides in ordinary use. Immediately before precipitation, however, we prefer to add one grain of citric acid to each ounce as a safeguard against accident.

The physical character of the precipitated emulsion, too, differs entirely from anything we have previously met with, partaking, as it does, neither of the powdery product obtained in some instances nor the hard, pellicle-like lumps which occur in others. The pyroxyline is precipitated in a fibrous mass like a bunch of moss, and when "pulled out" closely resembles tufts of wet tow, the fibres twisting and knotting together in a most peculiar way. In this form it presents every facility for thorough and rapid washing as well as for drying and re-solution, though inferior, perhaps, in this respect to the powdery precipitate. It is, however, easier to collect than the latter, and, more important, does not appear to suffer the same injurious action from the precipitation; indeed, there is very little to distinguish the image produced by the washed emulsion from that obtained after it has undergone that operation.

THE PHOTOGRAPHIC EXHIBITION.

[Fourth Notice.]

Poikilographs are not the only works of art exhibited by Messrs. Lombardi and Co., for this firm has also contributed a numerous collection of portraits varying in dimensions from cabinet size to enlargements. These pictures display graceful posing and excellent manipulation; but, as we remarked when critically noticing the works of another Brighton firm last week, we should like to have seen such a display of pictures free, to a much greater extent at anyrate, from the work of the retoucher.

The portraits exhibited by Messrs. Boning and Small are charming; among them a portrait of Miss Violet Cameron is singularly effective, the expression, posing, lighting, and manipulation being all alike good.—Mr. E. Fox must make friends with the hanging committee before he next sends pictures to the Exhibition, so as to prevent them from "skying" such a picture as his *Gulls* (21), which might with advantage have been made to change places with an enlargement suspended directly underneath. His other pictures possess an average degree of merit.

The exhibits of Mr. G. H. Dunmore prove the possession of great skill by this artist. His frame (331) contains several meritorious landscapes as well as good interiors.

The *Marian* (210) of Mr. W. M. Harrison is an ably-executed picture of large dimensions of a child, and the same must be said of *Popping the Question* (204). By some strange perversity on the part of the hangers these fine pictures are placed so high as to almost necessitate the use of a chair upon which to stand in order to examine their details, while two large direct heads, by the same artist, are placed on the line, whereas they should have been hung at least twelve inches higher.

Messrs. Chaffin and Son exhibit several large group and single-figure *genre* pictures. Of these *Visiting the Studio* (215) is probably the finest, as it certainly is the most imposing. An artist who has been painting a portrait, to be seen on the easel, is represented as showing it to a lady and gentleman who are presumably members of the family of the person represented on the canvas, and who are engaged in a close and critical inspection of the "counterfeit presentment" of their old friend. This picture is highly successful. Inferior to it is *Criticism* (203), by the same artists, owing to the introduction of the figure of a young lady seated on the right, her presence marring the effect of the artist—seen at work—and the lady critic who is looking over his shoulder. Upon the face of the former lady there is a sort of expression which might be embodied in the words "when pensive I thought on my love"—an expression admirable enough in itself, but scarcely in harmony with the general conception of the picture. Indeed if No. 203 were properly severed in two parts, each half would make an excellent picture; one portion being allowed to retain the title borne at present by the whole, while for the other half the designation *Day Dreams* would not be inapplicable. The *Meditation* (107), and *Expecting Jack Home To-day* (114), also by the same artists, are noble pictures, every way worthy of the reputation of Messrs. Chaffin and Son.

Mr. R. V. Harman's frame of views of Camden-place, Chislehurst, the residence of H.I.M. the Empress Eugenie, will receive a careful inspection on account of the interesting associations and memories which cluster around this regal residence; while the views of *Kentish Scenery* (302), also by Mr. Harman, will secure similar recognition, due to their intrinsic merits.

It is difficult to say which of Mr. A. G. Pettitt's nine large pictures of *English Lake Scenery* (316) is the finest; but it is probable that this pictorial *status* will be assigned to the *Study of Roadside Cottage* and to *Fisher Crag after a Shower*. These are excellent pictures.—The sunny land of Italy has furnished admirable subjects for the cameras of Captain Lyon and Mr. S. Thompson, while Mr. Andrew Pringle has, in a number of pictures contributed by him, confined himself mainly to Scottish landscapes; but among his exhibits, however, will be found a few cullings from Irish scenery.—Several nice woodland views are contributed by Corporal J. Miller, R.E.; and Mr. Greaves has two good enlargements of children.—Mr. H. Garrett Cocking exhibits several pictures, among which the portrait of *Madame Rose Hersee* (244) strikes the observer as being an excellent likeness of that eminent English *cantatrice*.

There is no intimation either in the catalogue or upon the work itself as to whether the noble photograph, *A Devonshire Mill* (49), by Mr. Henry Whitfield, is an enlargement or a direct photograph. In either case it is very successful, and it would have proved still more so if some of the "tricks of trade" had been resorted to in order to put more detail into the rushing stream on the right. Mr. Whitfield should lose no time in studying the great modern "art of sophistication."—Three large direct portraits by Mr. S. Wolstenholme evince great skill.—A charming and effective picture, entitled *Resignation* (228), is the sole illustration of the pictorial work of Mr. A. Brothers in the Exhibition; but even by this single exhibit he is most ably represented—no thanks, however, to the hanging committee, who have placed his picture by far too high.

THE SURFACES OF FILM SUPPORTS.

It is an unquestioned fact that the surface of the glass plate—which only we shall include in considering the bearings of our subject—has, though apparently perfectly pure and clean, under slightly-differing circumstances a most remarkable variety of states, capable of varying greatly in action; for, though in an article published some little time ago we pointed out the easy changeability, and indeed solubility, of the surface in a chemical aspect, the states we speak of may more properly be classed under the head of mechanical as opposed to chemical. The case of old plates with varnished films is one which obtrudes itself to a marked degree upon the photographic mind. How many hundreds of thousands, we might almost say, of such old negatives are there not at the present time waiting to be cleared off—the clearing being put off till the swelling heap of glass compels attention! Yet, of all these hundreds of thousands, how many when finished, every care being taken to make the surface as clean as possible, will the operator be able to use with confidence, and consider equal to new glass? And how many hundreds of negatives will be spoiled through using them? These are burning questions, for, to our knowledge, there lie in many photographic store-rooms, or other out-of-the-way places, glass plates that in quantity represent quite a little fortune, and yet which we do not hesitate to say the majority of the owners would willingly part with for half their cost, or for half the number of new plates.

A careful examination of the subject may lead to a practical acquaintance with the conditions governing the usefulness of various modes of cleaning glass surfaces and their consequent suitability for photographic operations.

We may better approach the subject by first ascertaining the grounds for believing that the conditions are mainly, if not entirely, of a mechanical nature, to draw a distinction which, if pushed to its limits, it might be very difficult to define, but which here may be described as the action of the glass itself as opposed to the action of imprisoned or surface-held chemical agents.

Continuing our examination of old plates in this light, the tendency to dirty pictures upon them is proverbial, and the explanation is that the glass is porous and retains a portion of the old image, which reacts upon the new, causing abnormal, or rather anomalous, deposition of silver between the film and the glass. The ease with which silver and many other insoluble formations are made to deposit upon apparently similar surfaces is well known, and has been well treated by Mr. Tomlinson in a variety of papers, published from time to time (and to these we would recommend any of our readers to refer who wish to take the subject up). It is therefore quite as reasonable to suppose that the uneven action of the developer is owing to a mechanically-altered surface and to the action of ingrained foreign matter.

We are so accustomed to look upon glass as an impenetrable solid—the saying, "smooth as glass," showing the popular estimation of the evenness of its surface—that it is difficult to believe that so smooth-looking a material can have pores upon its surface, and we must confess to a little scepticism on the point. It is one thing to have a comparatively soft or tender surface, and another to have one pierced with holes, so to speak. We have not seen any arguments advanced to prove that the exterior of a piece of glass, beyond this question of relative hardness, is in any way different from the interior; and if the whole texture of glass were full of these minute wells, or intersticial cavities, it would be almost opaque to light, or at least would present a milky hue quite different from the beautiful clearness that renders it so attractive an article in its decorative aspect.

We do not lose sight of the molecular constitution of matter, according to which theory all matter might be said to be porous; glass in particular is so, for there must be a multitude of cavities to permit of the presence of the ether through which the light vibrations travel. We speak of a coarser texture, as that is evidently the character assumed in those disquisitions on porosity which have been considered. But in surveying the subject from a chemical standpoint, it may be permissible to consider the molecular aggregation of its constituent elements.

An excellent argument in favour of the mechanical roughness of the surface is provided by the celebrated plane surfaces made by Mr. Whitworth. When put together they adhered most tenaciously, and for a time it was considered a satisfactory explanation to say that the pressure of the air was the cause. But it was found that theory did not account for several of the phenomena in question, and now it is explained that the surfaces adhere through the entanglement (if we may so term it), or the interlocking, of the particles composing the surface. Whether these are actual molecular particles or mere projections of larger size produced in the grinding may be open to doubt. We think, however, that the former is the more likely supposition, seeing that it is but reasonable to assume that the continual grinding would have taken off all projecting particles except such as were constituent and unchangeable or reduced to their smallest dimensions—that is, the final molecule.

We shall continue our consideration of the subject next week, and give the results of some interesting experiments we have made in connection with the photographic bearing of the question.

A NEW CURE FOR BLURRING.

At the October meeting of the Liverpool Amateur Photographic Association I stated that my experience during the past summer with my gelatine films had convinced me that their entire freedom from the nuisance of blurring was due to the slight yellowish tinge of these sheets. The idea naturally occurred to me that if we could obtain glass of this particular colour, for photographic purposes, from the manufacturers we should at once put an end to halation of all kinds. Since the meeting in question, the kindness of Mr. J. A. Forrest has enabled me to test my theory thoroughly; and the result of my experiments is, I am glad to say, a complete success. Mr. Forrest supplied me with specimens of glass of almost every variety of orange and yellow; but I selected for my purpose those only which were of that slight yellowish tinge with which all workers in gelatine are familiar, and of which an example readiest to hand may be found in a gelatine lozenge.

I coated my plates with gelatine emulsions of two kinds, viz., one which gave a very slow but dense film, and one made from Kennett's pellicle, which was moderately rapid. I chose a subject as a test which is infallibly productive of the evil with every kind of dry plate I have tried, and especially so with gelatine. This subject is the interior of a church, through the great east window of which a flood of light is poured, which usually obliterates all signs of mullions and tracery. The exposures were made under conditions of light and atmosphere which are invariably provocative of blurring in its worst form. The sun was shining brightly; but the wind was in the east, and the air filled with haze. In every case the test proved entirely satisfactory. The tracery and design of the window are visible in their minutest details, and not the slightest trace of halation exists anywhere in the picture.

This was conclusive, to my mind, and the only thing that still remained to be done was to ascertain if the yellow tinge of the glass would prove an impediment in the process of printing. This, however, was not the case, either as regards the time occupied in the process or in the brilliancy or excellence of the result. The prints were not more than a few seconds longer than those produced from negatives on ordinary glass, and the results seemed to me to be even better than would have been the case in dealing with a negative of similar density on a white glass plate.

The cost of these tinged glasses need not be greater than that of those in ordinary use, and I shall hope to find that some enterprising manufacturer will be found who will be willing to supply us with glass of this kind, and thus relieve us of all further trouble and difficulty in our efforts to get rid of the nuisance of blurring.

H. J. Palmer, M.A.

NOTES ON PASSING EVENTS.

By a Peripatetic Photographer.

There is a smart shower of snow falling as I write, which prompts me to inquire if many photographers do not commit a mistake in making the slope of the roofs of their studios too gentle to permit the snow being easily removable. Only a very slight angle of slope indeed is required in the case of rain, but after a snow shower it is of importance that the roof be cleaned without delay. The slope of the studio window described last week by Mr. Samuel Fry is such as to cause no grounds for the indulgence of this fear; but I am acquainted with another studio in which, previous to a recent alteration having been made, it was wellnigh impossible to operate during a severe winter owing to the almost perpetual lodgment of snow, which could not be easily removed. It is true that, as the proprietor informed me, very little business was done by him during the winter, and although the barrier of snow occasionally intercepted the light it consequently did but little harm; still, there are studios—in London, at least—in which from fifty to eighty negatives a day are taken even in winter, and in such cases the loss from a heavy fall of snow would be very severe were not proper measures taken to counteract the consequences.

The death of Mr. Edward J. Wrench, through the bursting of an oxygen retort, has caused a profound sensation in London lantern circles. As the oxygen mixture was pure, this fatal misadventure must be removed from the list of what I may designate "chemical" explosions, in contradistinction to "mechanical" explosions. By the former I mean the generating of a gas, such as hydrogen, along with the oxygen, and which forms with it an explosive mixture only requiring the presence of a spark or flame in order to give deadly effect to the compound. In the present instance the explosion was one of a *mechanical* kind; the outlet pipe was choked, and oxygen continued to be generated until the elastic force of the gas overcame the strength of the walls of the retort, when the latter gave way. I have been informed that no washing-bottle was employed on that occasion, but that the communication was direct between the bag and the retort. Such being the case, the chances of danger resulting from a stoppage of the outflow of the gas were infinitely increased; because, as there was no audible bubbling of the emergent gas, there consequently existed no means for knowing whether the gas was or was not being given off. The retort, I understand, was made of very strong wrought iron, being of a conical shape, with a rounded bottom, but, alas! it had *no safety valve* or other means by which the pressure upon it might be relieved when it had attained an abnormal degree of strength. When the accident is viewed in the light of the foregoing facts it is not difficult to account for it The moral is obvious to all who prepare oxygen, and need not here be mentioned.

No one can have perused the report of the last meeting of the Bristol and West of England Amateur Photographic Association without feeling admiration for the enterprise displayed by that band of black-fingered brothers in starting a journal of their own, in order that "full accounts of meetings, &c.," may be supplied to their corresponding and other members who are debarred from attending the meetings of the Society. As one of the public, and one who reads the transactions of all the societies, I perused this announcement with a certain feeling of regret, inasmuch as by this step I and the other readers of this Journal will have to bid goodbye to the Bristol Society, whose transactions will henceforth be a sealed book to all but its own members. But—from a patriotic point of view—is such exclusiveness wise? Would it not be better for that Society to publish their transactions as heretofore, or at anyrate in such a form as to make them open to the public? One would imagine, however, that the funds of the Bristolians must be in a most flourishing condition to enable them to indulge in the costly luxury of issuing a journal of their own proceedings. Its cost to the members must be nearly, if not altogether, in the same ratio with the gardening operations of the suburban Cockney who, when complimented on his peas by a Sunday-dinner visiting friend, replied cynically—"The peas ought to be good, for they were grown in my own garden, and I calculate that they have cost me at least sixpence each pod." Query: may not the Bristol Society's proposed journal be like the peas of our Cockney friend? and may not societies, like amateur gardeners, consult their pecuniary interests by purchasing their photographic "peas" from the market gardener? I know something about the expenses incurred in conducting the affairs of societies, and I should be sorry to see such an estimable brotherhood as that of Bristol running their heads against a stone wall.*

(To be continued.)

RETOUCHING.

The periodical display of photographs at the Exhibition of the Photographic Society of Great Britain in Pall Mall once more draws attention to the expediency of retouching. One regulation with regard to this Exhibition was that "coloured pictures would not be admitted." The question now suggests itself—What is a coloured picture? Is a slight framework of photography nearly, if not entirely, covered with pigment a coloured picture? And is a picture almost entirely consisting of hand work a photograph? An answer to these two questions is much needed, and relatively to them I will make a few remarks.

Untouched photographic portraits and figure subjects have for many years almost ceased to exist, so far as the principal portraitists are concerned; and those who do not practise it do so from motives of economy, and not because they consider it detrimental to the artistic qualities of the picture. I think I may safely assert that there is rarely—very rarely, indeed—a portrait taken that cannot be considerably improved by judicious retouching upon either the negative or print. That it is carried to a pernicious and ridiculous extent in some instances is patent to all. Still, it is evident from the popularity retouching has acquired that the public will never be again contented with the old style of untouched picture.

Retouching does not do away with the necessity for good photography as some assert, neither will a bad photograph become a good one by any amount of retouching; but, unless the picture under examination is a flagrant and bungling example, it is impossible to tell how much hand work has been applied, or which is retouching and which is genuine photography, without spoiling the picture to ascertain, and, also, having the negative to examine in the same condition it was when printed from.

These considerations show that any judgment upon the technical qualities of the photograph must be more or less of an unsatisfactory nature, and depending entirely on the skill of the retoucher to assimilate the character of his work with that of the genuine photograph. That portraits and figure subjects are especially improved by judicious hand labour nobody questions, and there is no doubt that landscape work can be likewise improved by the same means. But, here's the rub—How much supplementary hand work shall be allowed? and where is the line to be drawn?

That we should return to the old times of silver printing, when a positive was made just as it would come without other precautions than putting it in a press and exposing for a sufficient time to the light, is out of the question, although this purity of photography is not without its advocates. If it be desirable that any statements

* Our "Peripatetic" friend has, no doubt, "in his mind's eye" the fact that The British Journal of Photography was the outcome of a private adventure somewhat similar in character to the one to which he refers, and possibly behind his expressions of regret at the prospect of the reports of the proceedings of the Bristol and West of England Amateur Photographic Association being in future confined to its own members may lurk a half-formed fear lest the prosperity of the old Journal, in whose columns his *nom de plume* has long been familiarly known, should be jeopardised thereby. We are not selfish enough to deny the right of any one to commence such a journal; but, even if we were, Mr. "Peripatetic" may calm his fears. The Bristol proceedings will continue to be reported as usual in our columns, the new journal being merely a supplementary arrangement for the convenience of members, and as it will be printed at the office of this Journal neither public nor private interests will be at all interfered with, as our friend fears.—Eds.

respecting this matter should be made by an exhibitor, well and good. It is also desirable that pictures sent for exhibition, if described at all, should not be described in misleading terms—assuming to be what they really are not according to the interpretation accepted by both photographers and the public, trusting that the difficulty of discovery will palm off the imposition. Instantaneous pictures, for instance, are throughout the world understood to mean pictures taken *at once* with extreme rapidity, and *not* a picture made from *several* negatives and the free use of brush or pencil. This exemplifies exactly what I mean, and such pictures are, unless exhibited for what they are, not calculated to increase the estimation the public have for either photographers or photography. At anyrate, the matter of retouching in all its phases should be better understood than it seems to be at the present time by all who interest themselves in photographic work in its integrity.

EDWARD DUNMORE.

THE REACTIONS OF CHROMIC ACID AND CHROMATES UPON SUBSTANCES OF ORGANIC ORIGIN, CONSIDERED WITH REFERENCE TO THEIR USES IN PHOTOGRAPHY.*

THE BEHAVIOUR OF BICHROMATED GELATINE WHEN EXPOSED TO LIGHT.

THE behaviour of a mixture of bichromate of potassium and gelatine when exposed to light varies according to whether the exposure takes place in a dry condition or in aqueous solution. The aqueous solution of the glue and bichromate of potassium only begins to turn brown after an exposure that has lasted for days, and the mixture becomes browner and browner without developing any gas. The action proceeds very slowly. Light also acts slowly upon the bichromated gelatine which has stiffened; still the gelatinous mixture is already much more sensitive than the solution. Indeed, Woodbury at first used to expose such still moist bichromated films when preparing printing plates,[1] but their slight degree of sensitiveness induced him later to allow the films to dry first and then to expose.[2]

When it has set in, however, the action of the light is not externally visible for a long time. If a plate be coated with bichromated gelatine and, after being allowed to stiffen, be exposed to the direct rays of the sun, the lighted parts will have become insoluble in warm water. After a longer exposure the light turns the mixture brown and the insolubility will have become still greater. Roderigues[3] works with the bichromated gelatine, as long as it remains fluid, by daylight, and only takes the sensitised photolithographic paper into the dark room when it has stiffened. Vidal,[4] Liesegang,[5] Gentile,[6] Braun,[7] Lambert[8] bichromate their carbon tissue (slightly damped) without injury by daylight, and only carefully shut the chemically-actinic light out when the tissue is dry and its sensibility thereby materially increased.

Air-dried bichromated gelatines become brown with very unequal rapidity. When exposed for a few minutes to clear daylight they become brown, and by a longer exposure they are changed to a brownish-black. If exposed bichromated gelatine be digested in water of from 15° to 20° C. a good deal of undecomposed potassic bichromate will be sucked out. If the time of exposure be short the gelatine will become almost colourless by long steeping in water and will slowly swell up; if the exposure be long the gelatine will no longer swell in cold water, and will remain of a slightly-brownish colour. Hot water only dissolves the undecomposed gelatine, but it also swells up and partially softens the lighted parts. After a very long exposure the bichromated gelatine will have become indifferent to either hot or cold water.

With regard to the duration of the exposure required for the production of a photographic picture I do not feel called upon to say much, as the proportions vary so greatly according to the plan and object of the various methods employed. Generally, however, the light acts more rapidly the more bichromate the gelatine contains. A chrome-gelatine film which contains ten parts of potassic bichromate to 100 parts of gelatine must be exposed nearly twice as long, in order to produce by the photometer scale the same degree of density of image as chrome gelatine which contains thirty parts of bichromate. Carbon tissues behave in a similar manner. Tissue sensitised upon a two-per-cent. potassic bichromate solution must be exposed nearly twice as long as one prepared with a four-per-cent. solution. According to Monckhoven[9] a tissue sensitised upon a half-per-cent. bichromate

[9] *Photographisches Archiv*, vol. xvii., page 20.

solution requires three times as long an exposure as one sensitised upon a three-per-cent. solution. According to Vidal[1] tissue sensitised upon a five-per-cent. bichromate bath must be exposed three times as long as one sensitised upon a six-per-cent. bath. According to Liesegang[2] tissue sensitised upon a five-per-cent. bath requires an exposure of two photometric degrees, while one sensitised on a two-per-cent. bath requires three photometric degrees.

Fontaine[3] was the first to remark the great sensibility to light of the mixture of potassic bichromate with organic substances as contrasted with that of chloride of silver paper. This superior sensibility was, however, formerly greatly exaggerated. Thus, I consider Geymet's[4] directions, that dry bichromated gelatine should only be exposed to the light of a candle and not to gaslight, err in the direction of superfluous caution; still carbon tissue sensitised with potassic bichromate is at least as sensitive as chloride of silver paper. Generally speaking the latter requires three times as long an exposure as the former. The observation that carbon tissue only requires a third of the exposure of silver paper has been utilised by Boivin[5] as a means of determining the length of exposure required for a carbon print in cases where no photometer is at hand. On this point there is no considerable difference of opinion amongst the authorities on the subject. Liesegang[6] says carbon tissue is twice as sensitive as silvered albumenised paper; that is, an albumenised picture must be printed until the twelfth degree of the photometer is visible—a carbon picture only to the sixth degree. It is also often three times[7] as sensitive. According to Jeanrenaud[8], Edwards,[9] and Robinson,[10] bichromated gelatine is four times as sensitive as chloride of silver paper; according to others it is six times as sensitive,[11] and according to Davanne[12] it is from five to six times as sensitive, while Swan[13] and Vogel[14] say it is only three times as sensitive; but, according to Baden Pritchard[15], if a silver print requires to be printed until the twelfth degree of the photometer be reached the carbon print will only require to reach the sixth degree. On these proportions the quality of the tissue has of course a very great influence. Indeed the sensitiveness varies by about one-half according to the variety of the paper. Braun's tissues are, for example, rather less sensitive than the Autotype Company's.[16] The proportion of the colouring matter contained in the gelatine has also a considerable influence upon the sensitiveness of the carbon tissue. Tissues which contain little pigment require about twice as long an exposure as those rich in pigment.[17] The medium is gelatine containing ten per cent of its weight of indian-ink or other colouring matter.

Of course, the duration of the exposure in the sun differs from that in the shadow. My attention was called to this point by observing that on a cloudless day in June lichtdruck plates only required a quarter of the exposure in the sun that they did in the shade. When in November I tried to use the figures giving the time of exposure as fixed in June, I found that with a quarter of the exposure required in the shade all the details were not brought out in those printed in the sun, and that at that season the exposure in the latter required to be increased to about a half of that in the former. Photographers generally say that one should print from three to four times as long in the sun as in the shade. Husnik[18] exposes his lichtdruck plates a quarter-of-an-hour in the sun and three-quarters in the shade. Geymet[19] exposes his chrome plates, for the "dusting-on" process, two minutes in the sun and from five to six in the shade, and his photolithographic paper a quarter-of-a-minute in the sun and from ten to fifteen minutes in the shade[20]. Geymet and Alker[21] expose chromated gelatine for photogalvanography from half-an-hour to an hour in the sun, and from two to four hours in the shade; while they expose chromated gum, for enamel photographs, from twenty to thirty seconds in the sun, and by diffused daylight (with a bright sky at midday) from three to four minutes[22]. Lallemand[23] exposes carbon pictures one minute in the

sun and five minutes in the shade. Despaquis[1] exposes rubber dusting-on plates thirty to forty seconds in the sun and three to fifteen minutes in the shade. Waterhouse[2] exposes chromated photolithographic paper from half-a-minute to a minute in the sun and ten minutes in the shade. Woodbury[3] exposes gelatine plates, for photogalvanography, from half-an-hour to an hour in the sun and from two to four hours in the shade. Rodrigues[4] exposes three times as long in the shade as in the sun, where he exposes chromated gelatine from five to twelve minutes.

As to the variations of the duration of exposure caused by the time of day, the season of the year, and the special requirements of the negative, Laurent[5] expresses himself authoritatively.

In order to have a reliable starting-point for the comparison of the chemical intensity of the light at the various seasons of the year in the sun and in the shade I have made use of the data collated for Vienna and all places of the same latitude, and calculated with such unsurpassable care and exactitude by Holetschek[6]. From his tables we find that at midday in June only a quarter of the exposure necessary in the shade is required in the sun; while at eight o'clock in the morning or four in the afternoon it is necessary to expose half as long in the sun as in the shade. In January the time of exposure in the sun is somewhat more than half of that required in the shade; while at ten in the morning and two in the afternoon the exposure in the sun requires to be nearly as long as in the shade, so weak does the chemical action of the direct sunlight become during that month.

From Holetschek's tables of the intensity of light we gather also the following interesting facts:—In the months of November, December, January, and February we must expose from one and a-half to twice as long in the shade as in the sun; in March and April thrice; in June, July, and August about four times; and in September and October from twice to thrice. These figures will explain my former remarks regarding the length of exposure in June and October. In this case it is both interesting and gratifying to find the astronomer and natural philosopher, quite irrespective of photographic experience, determining the proper time of exposure to be exactly the same as that which is found to be the best in practice; and, on the other hand, this result is a good confirmation of the exactitude of the empirical experiments of the photographer. By means of the numbers given in these tables one can easily reconcile the apparent differences in the opinions cited above with reference to the proper length of the exposure.

In passing I would mention that electric[7] light has only a quarter of the actinic power of sunlight; and that light produced by from forty to fifty large Bunsen's elements is four or five times less than that of the unclouded sun.[8] Electric light is rather extensively used at Lisbon, by Rodrigues,[9] for lighting chromated gelatines for photolithography and heliography, by Winter, of Vienna, for enlarging, and by Vanderweyde[10] for taking portraits. For all three purposes Gramme's or Siemens's electro-magnetic machines are especially adapted.

Magnesium light is much weaker. According to Bunsen's calculations the photochemical intensity of light obtained by the burning of one decigramme of magnesium per minute is about thirty-six times weaker than that of sunlight. It may, however, be increased by about one-third[11] by burning zinc wire along with the magnesium. Magnesium light is used, with an exposure of two minutes,[12] in making enlarged photographs.

These deductions as to the variations of the time of exposure required in sunlight and in diffused light have nothing to do with the phenomenon that carbon tissue requires to be *proportionately* longer exposed in the sun than in the shade; that is to say, a negative must be printed until the fifth degree of the photometer shows in the sun, when in the shade the fourth degree suffices. This fact is authenticated by Liesegang,[13] Honikel,[14] and Stefanowski,[15] while Monckhoven[16] supports quite the opposite view. I believe this phenomenon to be analogous to the purer and harder printing of silver paper under a thin negative in the sun, when by diffused light less contrast is obtained. It appears as if with films difficult to penetrate the same quantity of light, if I may so express myself, produces a greater effect when its action is slow than by a short and "concentrated" action. Perhaps also the so-called "after action" of the exposure comes into play. J. M. EDER, M.D.

NOTES FROM THE NORTH.

"TRY the spirits" is often good advice in more senses than one. An example of the necessity for looking after the purity of alcohol recently came under my observation, which emulsion workers will do well to "make a note of." The operator in whose hands the incident occurred has had considerable experience with almost all the varieties of emulsions that have been introduced, but for real work prefers to stick to nearly the original formula, eschewing all acids and chlorides; and by simply adjusting the emulsion some twenty-four hours after it has been prepared, so as to have the faintest possible trace of bromide in excess, gets plates of absolute certainty, and sufficiently sensitive for most practical purposes. With the intention of preparing a supply of plates sufficient to last over the winter months, and having faith in the almost indefinite keeping qualities of the emulsion, he resolved to make a more than usually large batch; but, to make sure that all the material was in perfect order, he proceeded to prepare a small experimental quantity of two ounces. This, on being tested by practical work, proved to be of excellent quality, and in perfect confidence that the stock would "conform to sample," the emulsification of several pints was proceeded with.

The supply of alcohol being short, a fresh Winchester quart was opened, but, having been drawn from the same source as that which had been employed in the experimental quantity, no difference in result was apprehended on that score. On heating the silver and a portion of the alcohol together in a small flask a more than usual darkening of the solution was noticed; but, as the operation was conducted in the feeble, non-actinic light of the dark room, it did not attract the attention which the result showed it deserved. The emulsion having been made it was allowed to stand for twenty-four hours, and then a few drops were poured into a two-ounce measure and caused to flow around the sides till it had set. About a drachm of distilled water was then added, the film scraped into this with an ivory spatula, and the whole stirred together sufficiently long to ensure complete solution of any soluble salts. The proportion of silver and bromide had been such as should have left a slight excess of the former; but on testing the solution with potassium bromide no evidence of such excess appeared, and, on adding a solution of silver to another portion of the liquid, there was ample evidence of a large excess of bromide. At this stage a plate was coated with the emulsion, but, instead of the usual ruby colour by transmitted light, it proved to be a pretty deep primrose; and although subsequently exposed to bright diffused light for a whole day the colour by reflected light was not perceptibly altered. Additional supplies of silver were added from time to time, with the usual testing after each addition; but it was not till an excess of three grains per ounce had been used that the bromide was decomposed, and the emulsion tests indicated neutrality. Bromised collodion was then added, so as to give an excess of about one-twentieth of a grain per ounce, and a plate coated with the corrected emulsion. The ruby colour was now very decided, although of a purpler shade than usual, and the film darkened rapidly when exposed to diffused light. So far all was apparently well, but a hitch soon followed in the impossibility of getting an image either on the moist or dried and preserved film free from fog. Plate after plate was exposed for various lengths of time and developed with increasing doses of bromide, and the emulsion was found to be extremely sensitive; but in every case the result was a feeble image that fogged all over whenever the slightest attempt to obtain density was made. Acids, chlorides, and additional bromide were tried in succession, with this result—that they each and all simply decreased the sensitiveness without removing the fogging tendency.

The loss of the emulsion and consequent disappointment in not getting the desired work accomplished was bad enough; but the feeling that such a mistake might at any time occur unless the cause could be traced was worse, and so a search for that cause was at once commenced, and fortunately it was not difficult to find. The recollection of the peculiar darkening of the alcoholic solution of silver suggested an examination of the alcohol, and on bringing the flask in which it had been heated to the light a large portion of the interior surface was found to be coated with a brilliant deposit of metallic silver—a deposit which, under the circumstances, could not have been produced by the reducing action of pure alcohol. The alcohol, on examination, smelt strongly of aldehyde, and the usual tests gave unmistakable evidence of the presence of a considerable quantity of that body. How it came there I cannot venture to guess, but it was sent to the place from whence it came, and exchanged for a sample that behaves in every way satisfactorily.

The obvious lesson that this "note" is intended to teach emulsion workers is that they should "try the spirits;" and I may add that, for all practical purposes, the boiling in a test tube of a few crystals of silver nitrate in a drachm of the sample to be examined will be sufficient. If the solution simply slightly darkens in colour without producing a deposit it may be considered perfectly safe; but in the event of a precipitate appearing—and especially if any portion of the inside of the tube be coated with a mirror-like film of silver—it should be unhesitatingly rejected.

Of the many devices that have been adopted for the purpose of securing the attention of sitters—especially the juvenile portion of the photographer's *clientèle*—there are none more likely to be so successful, or that are nearly so amusing, as one I saw in operation a few days ago in a studio within a few miles of Edinburgh. The artist in question is so situated locally that he can hardly expect much patronage during the winter months, and, like a wise man, under the circumstances he has "two strings to his bow," the second being that of a professional public entertainer. His *rôle* is that of a ventriloquist, and a very clever illusionist he is. His "properties," of which a large trunkful stand in a corner of the studio, consist of numerous figures, representatives of various ages and both sexes, and some simple heads, most of which are capable of certain motions being produced by the pulling of a string or pressing a spring. The one I saw in use was a head representing that of an old man. It was simply stuck on a pole or standard, and an animated and highly-amusing conversation kept up between it and the photographer, the result being so to rivet the attention of the little sitter that, although it was a dull, rainy day, a really excellent negative was obtained.

Of course every photographer is not a ventriloquist, but I have no doubt a good many possess the power without being aware of it; and I am under the impression that anyone with a flexible voice and half-an-hour's practice would be able to both astonish and amuse his little visitors. Ventriloquism, as I have seen it practised, seems to be simply a matter of *suggestion*. The human ear is not able to distinguish the exact point from which a sound proceeds, unless the mind is by some of the other senses directed to it. In the case of a speaker the eye of the listener does this; but if the speaker can change his voice, reduce the motion of his lips to a minimum, and at the same time direct the attention of the listener to the moving lips of such a figure as ventriloquists are in the habit of employing, the suggestion is at once taken up, and through the influence of the eye the listener is effectually deceived.

Assuming this explanation to be correct, it will be evident that there are few who could not by a little practice attain to a certain degree of proficiency in the art; and, judging from the effect produced in the case alluded to, I think all who experience trouble in photographing children should give it a fair trial. John Nicol, Ph.D.

PHYSICS IN PHOTOGRAPHY.*

These last experiments were remarkable in another point of view, as they opened out the question as to whether the salts of silver might not prove sensitive to rays to which they had been supposed hitherto to be insensitive. Silver iodide, for instance, when exposed to the spectrum in a solution of potassium sulphite, proved sensitive as far as *a* of the spectrum instead of stopping short at the point indicated in *fig* 2 (page 450); and silver bromide in the molecular grouping which absorbed the red proved sensitive to a wave length of somewhere near 11,000, whereas in its normal state 9,600 was its limit.

Similarly silver chloride proved sensitive to an extent which presumably may be increased till it is equal to that of the bromide. In both these instances we have a proof that the compound was sensitive to these abnormal rays, and that the image formed by those rays was destroyed as soon as formed by their oxidising action, giving an undevelopable form of salt. It may be remarked that, by exposing films in reducing solutions—such as ferrous sulphate and pyrogallic acid rendered very slightly alkaline—an image can be developed as fast as it is formed.

The natural outcome of the experiments on the oxidation of the photographic image just narrated is that it should lead to the solution of the problem of photography in natural colours, such as that of Becquerel, Niepce de St. Victor, and others. In the fourth edition of Hunt's *Handbook of Photography* we read, at page 161, "Niepce de St. Victor has made many experiments to produce the colours upon salts of silver and copper spread upon paper, but without success; the metallic plate appears absolutely necessary, and the purer the silver the more perfect and intense is the impression." The following is recommended as the most effectual mode of manipulating:—"The plate is highly polished with tripoli powder and ammonia; being perfectly cleaned, it is connected with the battery and plunged into the bath prepared in any of the ways stated. [The baths were made from ferric chloride, cupric chloride, hydrochloric acid, &c.] It is allowed to remain in the bath for some minutes, taken from it, washed in a large quantity of water, and dried over a spirit lamp. The surface thus produced is of a dull, neutral tint, often almost black; the sensibility of the plate appears to be increased *by the action of heat*, and, when brought by the spirit lamp to the cerise red, it is in its most sensitive state. The sensibility, however, of the plates is low—*two or three hours* being required to produce a decided effect in the camera obscura. . . . These, when I first saw them, were perfectly coloured in correspondence with the drawings of which they were copies; but the colours soon faded, and it does not appear as yet that any successful mode of fixing the colours has been discovered." The coloured spectra which Becquerel photographed were produced in a somewhat similar way, the variation from which need scarcely be repeated.

In Hunt's work we also find that natural colouration of photographs was found to be possible by one or two other processes, but that the above gave the most satisfactory results. Mr. Simpson also noticed, when using an emulsion of silver chloride, and after exposing the film to white light so as to tint the surface with a lavender colour, that he was able to reproduce on the film the tint of different-coloured glasses to which such a surface might be exposed.

It will be noticed that the coloured spectra were produced on a dark compound of silver, which gradually reproduced the colour falling on it. We have first a case of total or nearly total absorption of all the rays, and a subsequent production of compounds of varying tints. In order to produce any variations of colour it is only necessary that we should have at the most three molecular groupings—one of which should absorb the blue and green, another the green and red, and the last the red and blue. Whether the number of groupings may be reduced to two is a question for future consideration. In Lockyer's note read before the Royal Society on June 11, 1874, *On the Evidence of Variation in Molecular Structure*, we find statements which might have been conceived to be almost too bold at the time when they were made, but which subsequent investigations seem to prove to be exact. In this note he refers to definite molecular groupings of compounds and the absorption caused by them, and indicates that we may have a group which will absorb at the blue end and another which will absorb at the red end of the visible spectrum. It has already been shown that the silver bromide can be reduced to two groupings—one absorbing the blue and the other the red, and it is somewhat remarkable that, by applying pressure to the latter molecular grouping, it is gradually resolved into the former grouping, and passes through all tints of the spectrum between the blue and the red. It must be remembered that these colours are not the colours of thin plates, but are totally independent of the thickness of the film so long as light can penetrate through it. It is not too much to assume that, if silver bromide can be made to group itself into these two states, that the sub-bromide when oxidised should also assume a similar molecular condition. With this compound in a state which practically absorbs all rays, it is easy to imagine that particular sets of vibrations may cause it to resolve itself into groupings which answer to them. We have, in fact, the inverse of the reduction of the silver bromide by different portions of the spectrum. It is found that one molecular grouping can be reduced by a whole series of vibrations; thus the blue-absorbing molecular group is altered by all the radiations from the ultra-violet to the yellow, and the red-absorbing molecular group by the radiations from the ultra-red to the green. If there were a green absorbing molecular group, of which there is a strong suspicion of the existence, it would probably be altered by radiations from the blue to the orange. If, then, one silver compound can exist in two or three states of molecular grouping, it is quite within the range of reason that the oxidised compound should exist in the same three groupings. The black compound to which we have already referred, in fact, does arrange itself thus, probably by a rearrangement of molecules, as formed when it absorbs oxygen. If a plate be prepared in a similar manner to that described above, and if it be exposed in an oxidising medium, these groupings are attained rapidly, a few minutes sufficing where previously hours were required. The images thus formed, however, appear not to be unchangeable, as exposure to white light, or to any colour except that in which the rearrangement takes place, causes the colour to fade. The feat of producing *permanent* photographs in natural colours is as yet unsolved, but it may not be so far distant as might be imagined. In order to obtain them it is necessary that a method should be found by which the molecular groupings of metallic silver can be formed in either of the two (or three) states already described. As is well known, the absorption by metallic silver in a thin film takes place entirely in the red end of the spectrum; but it is a fact well known to photographers at large that in certain processes it is perfectly feasible to obtain silver in which the transmitted light is of a pink red colour, whilst tints varying from indigo, passing through olive-green to rich brown, are familiar. In order to obtain permanent photographs in natural colours, the object to be sought is a method by which the sensitive silver compound may be reduced by the red rays to a molecular grouping, which on development (probably by the alkaline method) shall be grouped into the red-transmitting molecular grouping, and so on. When this is discovered, the leap between monochromatic pictures and chromatic will have been taken, and the once apparent improbability have become more than a possibility.

We have finally to return to the subject of photography with the light of those rays which are usually inactive upon sensitive salts, and at which we have already glanced.

To Dr. H. Vogel, of Berlin, is undoubtedly due the new interest which has been taken in this branch of photography. Towards the end of the year 1873 he announced that he had discovered a method of making the non-actinic rays in certain circumstances actinic. We quote his own words*:—"I have found that bodies which absorb the yellow ray of the spectrum make bromide of silver sensitive to the yellow ray. In like manner I find bodies which absorb the red ray of the spectrum make bromide of silver sensitive to the red rays. For example, by the addition of *corallin*—which absorbs the yellow ray—to a bromide of silver film it becomes as sensitive to the yellow ray as to the blue ray." In articles which he published at various times he enlarged on

* Concluded from page 450.

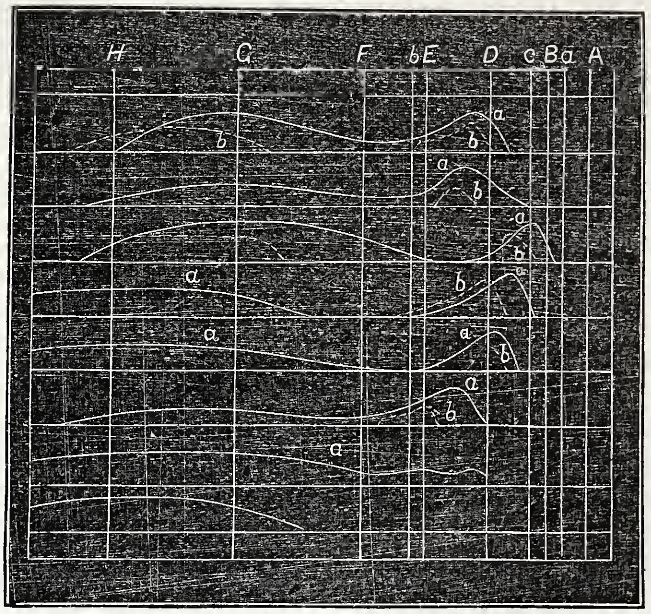
* *Photographic News*, December 5, 1873.

this idea, some of his most striking experiments being conducted with aniline dyes of various kinds. He and Waterhouse have shown that a silver bromide film becomes sensitive to the part of the spectrum which certain of those dyes absorb, whether the absorption be due to a compound formed between the dye and silver or to aqueous or alcoholic solutions. This at once opened out a large field for inquiry, and made research in this direction doubly interesting, owing to the fact that apparently certain physical laws would have to be modified if Vogel's theory were correct. He divided the action of the substances so added into two. The dye he called an "optical sensitiser" for that particular part of the spectrum which it absorbed, whilst bodies which absorbed the halogen (thrown off by the reduction of the molecule) he called a "chemical sensitiser," and a combination of both properties in a dye made the film sensitive to the absorbed rays. The theory of the optical sensitiser seemed to clash with the received notion of molecular motion; but before analysing the results the accompanying figure should be studied, which is taken from Vogel's work on photography (*fig.* 5).

which the further reduced silver shall occupy, and thus the image is built up. When there is an excess of soluble bromide in the film the developing action will be retarded. This series of experiments seems, then, to indicate that there is no need for optical sensitisers to alter the oscillation of the molecules or molecular groups, but that, in some instances, the same theory may be applied to the action of dyes as may be applied to the deposition of metallic silver on a glass plate which has not been freed from "dirt"—a disagreeable phase which is well known to photographers at large. The explanation of the diagram is, therefore, not hard to understand when viewed in this light. The theory of rendering the silver salt sensitive to the red has already been explained, and the same explanation is naturally applicable to those dyes which, when brought in contact with silver, form a definite compound with it.

There are many interesting physical researches which spring out of these various experiments, amongst which may be mentioned a method of determining the size of atoms and their arrangement in the molecule; and last, and not least, the production of permanent photographs

FIG. 5.



Effect of the solar spectrum on silver bromide stained with—

I. Naphthaline red.

II. Fuchsin.

III. Aldehyde green.

IV. Cyanine blue.

V. Methyl violet.

VI. Eosine.

VII. Carmine.

VIII. Effect on unstained silver bromide.

The curves marked *a* show longer exposure than those marked *b*.

Let us take one or two examples from the above figures and see whether they agree with Vogel's assumption. We will take VIII. as a standard of comparison, being the effect on unstained bromide, and this will be fair (though it does not take the form given, shown in *fig.* 2, page 450), as it is presumed that this sample of bromide was worked with throughout. Comparing say IV. with VIII. we see that in the blue the sensitiveness, as shown by the ordinate of the curved line, is very similar, but that the action is got in the yellow. In examining cyanine blue, the dye used, we find that the absorption takes place just at that part of the spectrum. Similarly examining V. and VI. we arrive at the same results, and in fact the absorption of the rays invariably corresponds with the photographic action.

It will be seen, then, that without doubt the principle Vogel contends for might explain the phenomena. He, however, found that if the silver bromide film had been prepared with an excess of bromide the actions indicated did not take place. This seemed to indicate a weak spot in the theory, and it pointed at first sight to the idea that it was necessary to form a coloured compound of the dye with silver in order to render it sensitive. In the majority of cases this still seems to be, if not a necessity, yet a cause of increase of sensitiveness to the region of the spectrum absorbed. Vogel, however, shows that if the silver bromide film, prepared with an excess of bromide, be washed, and be then treated with a dye and a chemical sensitiser, such as tannin, the same action takes place. The theory of a silver compound in this case must evidently be abandoned, and would point to the correctness of Vogel's theory did not other experiments in a certain degree offer an explanation more accordant with our preconceived ideas. Let the dye be mixed with *plain* collodion and a film of it be exposed to the spectrum; it will soon be visibly evident that there is a marked effect produced by the rays absorbed. Thus cyanine blue will be found bleached in the region near D and below it. If over the dyed film of collodion thus exposed a film of silver bromide in collodion be poured in the dark, and the alkaline developer be applied gradually, a silver image of the altered portion of the dyed collodion film will make its appearance, although the film of silver bromide has received no impression by light. The explanation of this remarkable phenomenon is to be found in the theory of alkaline development already given in these articles. The reduced dye acts as a nucleus on which the metallic silver will first adhere, and this first reduction of metallic silver determines the position

painted in natural colours by light itself. The attempts made of late to form photographs in proper colours by taking distinct negatives through blue, through green, and through red media, and then printing positives from such, and finally obtaining red, green, and blue prints, and superimposing them, is not a step in a scientific direction, since it is utterly impossible to secure monochromatic colours which are pure enough to give the truth of nature. Such efforts, though they may be commercially valuable, yet are not to be followed with too much zeal by scientific photographers.

We may now axiomise the results we have indicated:—

1. That the undeveloped photographic image on a silver compound is formed by the reduction of that compound.
2. That the compound may exist in two (or three) molecular groupings.
3. That the compound can only be sensitive to the rays which it absorbs.
4. That the reduced silver compound may be rendered incapable of development by combining with oxygen.
5. That light of every refrangibility may cause an acceleration of oxidation provided the compound acted on absorbs such light.
6. That the oxidation of the compound reduced by any particular ray may be as rapid as the reduction, and thus to give a false idea of their limit of sensitiveness to the spectrum.
7. That the oxidation of the reduced silver compound may account for the phenomenon of photographs in natural colours hitherto produced.
8. That in all probability the action of dyes on silver bromide is a secondary one.

W. DE WIVELESLIE ABNEY, *Capt. R.E.*

OPINIONS OF THE LONDON PRESS ON THE PHOTOGRAPHIC EXHIBITION.

THE PHOTOGRAPHIC EXHIBITION.—The annual exhibition of the Photographic Society of Great Britain is now open for a short time at the Gallery of the Society of Painters in Water Colours, Pall-mall. We miss from the walls some of the most valuable contributors of former years, particularly of the class of amateurs whose legitimate success was due to their aiming at purely scientific and artistic results, without resorting to any artifice to secure a trading profit. We think the Society would act wisely by not only rendering (as already done) ineligible for a medal photographs "improved" by hand, but by limiting the works admissible in the exhibition to pure photographs from unsophisticated negatives. At all events, any "retouching" of portraits, any additions of skies to landscapes, any "combination" contrivances—in short, any falsification of the direct products of the camera from nature, taken at a single sitting, should be distinctly avowed in the catalogue. This would prevent the Exhibition from degenerating into a show-room and advertising medium for the benefit, principally, of those who are least scrupulous in the means adopted to catch the eye and flatter ignorant or perverted taste. Take, for example, the portraits. We may safely say that nearly the whole have been touched up by hand; in most cases the flesh has been stippled all over, though the touches may be almost too minute for the eye to follow. It is this "retouching" which gives the waxen hue or the woolly or puffy surface to the flesh, the insipid expression, the characterless want of detail, the glaring eyes, that render so much photographic portraiture comparatively worthless. A remarkable illustration of the truth of our remark is afforded in the present display. We allude to two photographs by Mr. G. Nesbitt, from a negative portrait of a man in slouched hat and swathed cloak, called *The Brigand.* The first (142) is "untouched," as stated in the catalogue; the other (202) has undergone the usual manipulation. In the former the eye may, it is true, lack due brilliancy. The lips may be too white, owing to the diffusion of the light on smooth surfaces in photography; the skin may appear unnaturally coarse; and freckles and the colour of the hair may be much deepened in tone, because, while photography is almost insensible to the softening, pearly tints, it greatly exaggerates in intensity the yellows and reds. Nevertheless, an artist would not hesitate for a moment in preferring the former. The difference is that between a painting by Rembrandt in his more vigorous manner and a tame, overwrought miniature. Several other portraits by Messrs. Lombardi, Slingsby, Boucher, and Lock and Whitfield possess much merit, making due deduction for the retouching; and the costume portraits of Mr. Shuter may afford suggestions to artists. Mr. Faulkner's faint portraits of children on opal glass strengthened in sepia are more frankly wrought up by hand, and are charming vignette sketches, so to speak. This operator is peculiarly happy in seizing—of course by the instantaneous process—the characteristic attitudes and gestures of his little models. It is much easier to work by the instantaneous process on a small scale, and a tiny photograph may be enlarged to nearly any dimensions, as shown in some remarkable examples exhibited by the Autotype Company. The value of the process in the rendering of animals is illustrated in contributions by Mr. H. Dixon; and in sea-studies with yachts in full sail, by Mr. P. Jennings—the latter of which have been awarded a medal. In the department of *genre* a medal has also been given to Mr. G. Nesbitt for an artistically-arranged group of a little girl fondling a dog with a "broken leg" enveloped in bandages. Another medal has been carried off by Mr. A. W. Wilson for one of an expressive series of figures illustrating Shakspeare's *Seven Ages of Man.* In landscape the exhibition is, as usual, very rich. Some views in Warwickshire, by Mr. Bedford, leave, it need hardly be said, nothing to desire. They are "not for competition," Mr. Bedford having been a member of the jury. To Mr. Vernon Heath a medal has been awarded for a series of landscapes; and there are many other admirable works in this section by Captain Abney, Messrs. H. Cooper, Pringle, &c. One of the surprises of the Exhibition is the excellence of the work turned out by the School of Military Engineering, Chatham, considering that the students can have little experience of the requirements of picturesque landscape photography. A view *Near Bettws-y-Coed* by the school has been justly awarded a medal, although there are few planes of distance to test the operator's delicacy of chemical manipulation and focal adjustment. Mr. England sends numerous illustrations of the buildings and courts of the Paris Universal Exhibition; and Mr. G. Berwick points to the applications of photography to scientific purposes in his "microphotographs." Mr. Warnerke has lent a highly-interesting series of Russian and Swedish subjects, some of them taken in the Russian state establishments. The Woodbury Company (to whom a medal has been given) exhibit samples of its highly-ingenious process of reproduction in a series of "book illustrations," which present great fidelity to the originals from which they were taken. By the side of the printed impressions are the metal blocks from which they were taken; and a fresh wonder is awakened at seeing hard metal dug into as though it were by the burin, knowing all the while that these furrows are due to pressure of a mere photographic film. The sole drawback of the process—and it is only a commercial one that is perhaps compensated for by other advantages—is that the printing is less direct than in the rapidly-improving processes of the "Eliotype," the French "photogravure," and the "autotype." A transparency of an interior taken by lamp or gaslight (of course, by means of a long exposure), exhibited by Mr. Bennett, is suggestive of the possibility of new applications of photography being found on the introduction of electrical lighting. A rule of the Society which forbids the introduction of photographs coloured by hand has not prevented some specimens of the so-called "Poikilographic process" of colouring, introduced by Lombardi and Co., from finding their way to the stairs leading to the gallery. These are simply photographic transparencies on thin prepared paper or canvas, printed in colours on the reverse, so as to show through. Artistically considered the process is almost valueless, though less objectionable than painting on the obverse, for the reason that the photograph is less obscured and falsified. It is also an advance on the "photochromie" of M. Vidal—that is to say, the application of variously-coloured films of gelatine—for the display of which a special pavilion has been provided in the Champ de Mars. But it is obviously not the slightest approach to photographing in colours: the photographers are as far off as ever from making Apollo a colourist as well as a draughtsman; and, if they were to succeed, the result would be no more a work of art than the present photograph is so, and the sun-god would be no more an artist than he now is. In the section of apparatus a medal has been awarded to Cadett's patent pneumatic shutter, devised for rapidly closing the mouth of the camera. It is more portable than the electrical apparatus for the same purpose. We may announce, in conclusion, that a competition is invited, by the dry-plate process now so much in use, for a prize of £50, offered by Mr. Joseph Paget.—*Illustrated London News.*

ON PROCESSES OF MAP PRODUCTION BY PHOTOGRAPHY.*

Photocollotype.

The great defect of all the processes of photolithography described in the last section is that they can only be applied with advantage to the reproduction of drawings or subjects in which the gradation of shade is shown by lines or dots separated by white spaces of varying sizes and at different intervals apart, as in line or stipple engravings and lithographs in line or chalk. Even such drawings, to be successfully reproduced, must be in a good, bold, open style, and have all the lines or points composing them of an equal and perfect blackness. In the many attempts that have been made to reproduce photographs from nature by photolithography or photo-engraving, or to copy paintings and brush-shaded drawings in which gradation of shade is continuous, success, only partial at best, has been secured by breaking up and destroying the continuity of gradation. By the processes of photocollotype—so called from the printing surface being of gelatine—these defects are entirely obviated, and absolutely permanent photographic prints may be produced in the printing press almost equal to silver prints in perfect delineation of detail and delicate gradation of shade, but vastly superior to them in permanence and cheapness of production.

Poitevin was the first to recognise, so early as 1855, the fact that the half-tones were better preserved on stones that had been treated with a chromated colloid mixture, if, after exposure to light under a negative, instead of being inked all over and then washed with water to remove the superfluous ink, they were first moistened and then inked in with a lithographic roller charged with printing ink.† He seems, however, to have always regarded the stone as the principal printing surface and treated it by the ordinary methods of lithography. Only a few impressions could be obtained from stones thus treated.

In 1866 MM. Tessié du Mothay and Marechal, of Metz, discovered that the stone or metal plate hitherto used as a printing surface might be replaced by a mixture of isinglass, gelatine, and gum, treated with an acid chromate, and evenly spread upon a well-polished metal surface; because if, after exposure to light under a photographic negative, such a gelatinous surface were moistened greasy ink applied upon it with a roller would adhere well to the parts of it that had been acted upon by light, and would be taken up by those parts in proportionate quantities, according to the intensity of the gradations of light and shade produced on them by the action of light, and their consequent impermeability to water. Photographic prints in fatty ink, reproducing the most delicate gradations of shade without any apparent grain or break of continuity, could thus be produced.‡

It will be seen that this process was based on exactly the same principle as Poitevin's photolithography, but differed from it in the distinct recognition of the colloid film as the printing surface. MM. Tessié du Mothay and Marechal were also the first to recognise the necessity of adding a certain proportion of acid or of oxidising or reducing agents to the chromate salt used for sensitising the gelatine, with the object of rendering the colloid surface more apt to receive the greasy ink and also of hardening the film so as to enable it to withstand the wear and tear of printing. This they did by exposing the sensitive plates to a high temperature before using, but the effect was produced in great measure by the decomposition of the chromate salts by the acids or other substances added to the colloid mixture.

MM. Tessié du Mothay and Marechal printed off their "phototype" plates in a lithographic press in much the same way as ordinary lithographs, but with certain modifications due to the peculiar nature of the printing surface. The principal of these was the use of two inks—one stiff for giving force to the shadows; the other thin for bringing out the more delicate half-tones.

The "phototype" process as at first proposed laboured under the defect of not being able to yield a large number of prints from a single plate, but, in 1869, it was improved upon in this repect by Albert, of

* Continued from page 489.

† *Traité de l'impression photographique sans sels d'argent*, p. 78.

‡ *Photo. News*, Vol. xi., p. 260.

Munich, who substituted a thick glass plate for the metal plate used by Tessié du Mothay and Marechal as a support for the colloid film. His films consisted of albumen, gelatine, and bichromate of potash alone, and he gave them the required solidity and adherence to the glass by first coating the plate with a sensitive colloid mixture containing a large proportion of albumen, and then giving the under side of this first coating a preliminary exposure to light through the glass. The second coating containing more gelatine was then applied, and, after it had dried and the photographic image had been impressed upon it, the plate was again exposed from the back, in order to thoroughly solidify and combine the under part of the compound film. The gelatine films so prepared were capable of yielding some hundreds, or even, it is said, thousands, of perfect copies. This process is still largely used by its inventor, and is known by the name of "Albertype."*

According to some authorities, MM. Ohm, Grossmann, and Gemoser, of Berlin, took out a patent, in 1867, for a method of photocollographic printing, comprising, in addition to the use of glass as the support of the gelatine film, of the double coating of the plate and of the hardening of the film by exposure of the back surface, the introduction into the sensitive gelatine mixture of certain resinous compounds dissolved in spirit, by which the gelatine film is rendered quite insoluble and admirably adapted to form a fine printing surface. It is said, on the other hand, that the credit of all these improvements is due to Albert; but, in any case, it is certain that until after the publication of Albert's process, early in 1869, Ohm and Grossmann's was almost unknown, and had not come into general use. In October, 1869, the Autotype Company in London acquired the patent, and have since worked the process with the greatest success.

About a year after the publication of Albert's method Mr. Ernest Edwards, of London, introduced, under the name of "heliotype," a very important modification of the photocollotype process. He first waxed a glass plate and then coated it with a substantial layer of gelatine and bichromate of potash, containing a small quantity of chrome alum, with the object of hardening the gelatine and rendering it insoluble without destroying its impermeability to water. When dry the gelatine film was removed from the waxed glass plate, and the side which had been next to the glass was exposed under a reversed negative in the usual way, and then, as in Albert's process, the back surface of the film was hardened by exposure to light. After this the film was attached under water to a metal plate, preferably pewter, coated with india-rubber, and squeegeed into perfect contact with it. The bichromate salt was then removed by washing, and the plate was ready to be printed in an ordinary Albion printing press.

In this process the peculiarities were the use of chrome alum for hardening the gelatine; the separation of the colloid film from its original support, by which perfect contact with the negative was secured, as well as less risk of breakage of the latter; the subsequent transference of the film to a metal plate, by which the liability to breakage of glass plates in the progress of printing was obviated; and, lastly, the substitution of vertical instead of a scraping pressure in printing, by which the gelatine films were not exposed to injury by wear and scraping of the surface.

This process is still, I believe, largely practised, and full details of it, with various improvements suggested by Capt. Abney, R.E., will be found in the latter's excellent little work, *Instruction in Photography*.

About the same time Herr Obernetter, of Munich, proposed another process of the same kind offering some peculiarities and said to produce very satisfactory results.

A sheet of glass is coated with a mixture of gelatine, albumen, sugar, and bichromate of potash, dried, and exposed to light under a negative. The plate is then dusted over with finely-powdered zinc, which attaches itself only to the parts protected from the light, and in proportion to the amount of protection they have received. The plate is then heated to about 369° F., or exposed to light till the whole surface of the film has been rendered insoluble. Before printing the plates are treated with dilute muriatic or sulphuric acid. By this operation the parts of the gelatine film covered with zinc are rendered, by the formation of hydrogen, susceptible of attracting water to a greater or less degree, while the other portions, upon which no zinc has settled, are capable of receiving a fatty ink. The printing is then proceeded with in the usual manner.†

J. WATERHOUSE, *Capt.*

(To be continued.)

FOREIGN NOTES AND NEWS.

ON THE MEANS OF DETECTING THE ADULTERATION OF WAX.—WHITE CARBON TISSUE.—DR. RICHARD'S RAPID NEGATIVE PROCESS.

The *Photographisches Wochenblatt*, from which the following is taken, in what appears to be the first of a series of articles on the adulteration of various substances used in photography, treats of the impurities mixed with wax. In adulterated wax have been found starch, flour, gypsum, pipeclay, sulphur, resin, stearine, and talc; but the most difficult of all to detect is the stearic acid, because it resembles the cerolic acid which is present in beeswax.

"Of all the methods of detecting stearic acid the most reliable is found in the different proportions in which the two acids dissolve in cold alcohol. For this purpose boil the wax to be tested for about five minutes in twenty parts of alcohol of eighty to eighty-five per cent.; then let the solution stand several minutes, after which add cold water. If the wax be pure the clear solution above the sediment at the bottom will scarcely become turbid at all; while if it contain stearic acid it will become very turbid, and white flakes will be precipitated. Resin may be detected in the same way. Starch, flour, gypsum, &c., may be found by dissolving the wax in ether or oil of turpentine, when they will fall undissolved to the bottom. Sulphur is found by boiling in a dilute solution of potassic lye with the addition of a few drops of muriatic acid, when the well-known smell of sulphuretted hydrogen will announce the presence of sulphur. A few drops of plumbic acetate will produce in the solution a brownish-black precipitate of sulphate of lead.

"An admixture of talc can only be detected with certainty by its melting point.

Pure talc melts at	from 37 to 40° C.
19 parts talc to 1 part wax melts at	47
7 " " 1 " " "	49·5
5 " " 1 " " "	52·5
3 " " 1 " " "	55·5
1 part " 1 " " "	59
1 " " 3 parts " "	60·5
1 " " 5 " " "	61·5
1 " " 7 " " "	62·5
1 " " 11 " " "	63
1 " " 19 " " "	64
Pure wax	64

This method gives, however, only the approximate value of the admixture, because when the proportion of wax is great no great variation indicates the melting point.

"More exact are the results given by the solution of the glycerine formed by the talc, because wax contains no glycerine. so that its presence in wax is a sure indication of the presence of talc. This method has, however, the disadvantage of being too difficult for inexperienced persons, and can only be properly adopted by a professional chemist. When there is a very considerable proportion of talc in the wax the latter will be soft and smeary, and the talc may be recognised by its smell, by the greasy-looking break, and, above all, by the disagreeable smoke produced when the talc containing wax is heated over live coals. When less than a fifth of the mixture is talc this method of detection is no longer to be relied upon.

"Japanese vegetable wax can almost only be recognised by its melting-point, and even this wax—which on account of its low price is used as an addition to beeswax for many purposes—often comes into the market in an adultered condition, and, according to Dr. Wimmel, the chemist, contains an addition of from fifteen to twenty per cent. of water. There is also wax which contains even thirty per cent. of water. This addition causes the wax to lose its clear, shiny, beeswax appearance, and to become matt white, coarse, and easily broken By melting the wax the water can be run off; but in what way the adulterators succeed in getting the wax to retain it is not known, as it does not form a chemical compound with it."

Herr Schierer, the editor of the Vienna *Photographische Notizen*, writes unfavourably of the result of experiments with white carbon tissue.

Dr. Richard offers for sale a rapid negative process which, he says, is based on pure chemicals, new collodion, fresh developer, and weekly examination and determination of the exact chemical strength of the negative bath. The principal novelty in his process, as far as it is known, seems to be the use of two baths to sensitise the plate. In his own words:—

"Given a glass-house measuring at least 8 metres in length, 3·5 metres in breadth, and 3·5 metres in height, quicker results will principally depend on the determination of the chemicals; therefore I use two negative baths. A and B. This idea of working with two negative baths ought to be very welcome to the photographer when working in winter or on cloudy days in spring or autumn. By doubling the negative bath, which may be regarded as the basis of the process, greatly increased density is produced.

"It is to be understood that the contents of these two baths, A and B, are not alike. When both baths are used the negative picture developes rich in detail, fire, and depth, and ladies' velvet dresses come out of the richest texture. For summer, unfortunately, both the baths A and B cannot be used, because when the temperature of the laboratory exceeds 16° R. the temperature of the second or additional silver bath cannot be used on account of fogging. Our two negative baths demand that their contents should be proportioned with the utmost accuracy, so that they may correspond. Either bath may be used alone.

"The difference which using one of the baths A or B should make to the length of the exposure is for a *carte de visite* one-third of a second, and for a cabinet one second. When both baths are used, and the same exposure is given, the detail should be richer and the image stronger.

"The contents of the negative bath should be exactly determined every week, and a bath must only be in use one day in each week (to take from fifteen to twenty persons); it should then rest until it is again determined as A or B.

"In using the rapid process I require six negative baths. With the developer it is the same. In winter I use one or other of two developers, according to the subject to be developed."

We shall leave Dr. Richard's method for his rapid negative process to speak for itself.

Our Editorial Table.

THE MANUAL OF PHOTOGRAPHIC COLOURING, FORMING A HANDY-BOOK ON THE ART OF PAINTING ON THE PHOTOGRAPHIC IMAGE.
By JOSEPH WAKE.
London: HENRY GREENWOOD, 2, York-street, Covent Garden, W.C.

IT is in the recollection of our readers that an admirable and valuable series of practical articles on the art of painting photographs was recently published in THE BRITISH JOURNAL OF PHOTOGRAPHY. These papers were received with so much favour as to justify the author, Mr. Joseph Wake—well known as the head artist to the Autotype Company—in collating them in the form of the neat manual which is now before us. The matter has been subjected to careful revision previous to its being made to assume its present "handy" form; and we feel certain that never before was a *brochure* presented to the photographic public in which was compressed such an amount of valuable practical matter relating to the "art of painting on the photographic image"—whether in oil, water, or crayon colours—as that comprised in the sixty-two pages of Mr. Wake's *Manual*, which, like most handbooks connected with the fine arts, is issued at the exceedingly low price of one shilling.

Respecting the merits of the work we have only to say that the various directions are given in so lucid a manner as to render it valuable, both for those who desire to engage in the practice of the art of colouring as a profession and those whose requirements partake more of an amateur character. For these reasons it deserves to, and will, be extensively circulated among those who follow our "gentle art," whether as professional or amateur photographers.

Correspondence.

MR. COOPER'S EMULSION PROCESS.

To the EDITORS.

GENTLEMEN,—I have lately received so many letters asking when I intend to publish the details of an emulsion process I have worked out recently, and which gives me almost entire satisfaction, I trust you will allow me to say, through the medium of the Journal, that I hope to write a short paper on the subject in time for the meeting of the Photographic Society of Great Britain in December.

I must also crave the indulgence of several correspondents to whom I have been unable to reply privately; and I may hint to some of these that my time is too fully occupied for me to write long letters to unknown inquirers.—I am, yours, &c., HENRY COOPER.

Holmehurst, Torquay, October 28, 1878.

A NEW STUDIO.

To the EDITORS.

GENTLEMEN,—I observe in your issue of this date that Mr. Samuel Fry has, with much ingenuity, *reproduced* the "new (?) studio" described by me in THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for 1876, page 97.

In the concluding paragraph of my article I invited photographers to inspect my studio, and many came.—I am, yours, &c., J. WERGE.

11*a*, *Berners-street, London, W.*,
October 25, 1878.

STOPPING-OUT BACKGROUNDS.—OXYGEN RETORTS.

To the EDITORS.

GENTLEMEN,—In your article in last week's issue, under the first portion of the above heading, you refer to the difficulty of obtaining straight lines in painting out backgrounds. I am happy to say I surmounted the difficulty some time since; and here is my plan, by which the most inexperienced may obtain straight lines of indefinite length:—

Procure a straight-edge of any material (I prefer vulcanite, as being light and pliable), also an ordinary drawing-pen. With these you may rule a line as fine or as coarse as you please; it is then an easy matter to paint up to the line without going over it. The points of the pen must not be too sharp, or they will cut through the film; rubbing them with a piece of rough drawing-paper will effectually remove any existing scratching propensity. I always use indian-ink with a little ox-gall as the stopping-out medium.

With reference to the melancholy death of Mr. E. J. Wrench: I imagine the retort must have been made of cast-iron. If any of your readers are possessed of such an abomination as a cast-iron retort I would strongly advise them to break it up at once, and procure one of wrought-iron instead, and for this reason—that should an explosion occur with a retort of cast-iron (cast-iron having no fibre) it will fly into pieces, any one of which may be a messenger of death. In the case of wrought-iron a "rip" would be the result, the concussion being then the only element of danger.—I am, yours, &c. H. WILKINSON.

Ashton-under-Lyne, October 28, 1878.

[Some observations on the latter subject will be found in *Notes on Passing Events* in another column.—EDS.]

THE LONDON PHOTOGRAPHIC EXHIBITION.

To the EDITORS.

GENTLEMEN,—Before saying a word on the subject I desire it to be understood that I write purely for information, and that an understanding may be laid down.

I have always understood that in the class designated "landscapes," untouched, *singly-printed* work was implied, that no composition pictures were admissible, and that such pictures must be *entirely* the work of the exhibitor.

Now, anyone who has seen the exhibits at Pall Mall must be aware that in many cases the beautiful cloud negatives of Mr. Perry have been extensively used. Of course nothing could be further from "the work of the exhibitor" than this.

I shall be glad to know if in future "cloud negatives not by the same artist as the subject" may be used in exhibition work legitimately and as an understood thing.—I am, yours, &c., H. A. H. DANIEL.

Bristol, October 28, 1878.

THE MEDAL AWARDS AT THE PARIS EXHIBITION.

To the EDITORS.

GENTLEMEN,—It is well said "fools rush in where angels fear to tread;" and on this principle, it may be, am I now about to address you.

The squabble between Mr. A. L. Henderson and Mr. J. R. Sawyer respecting enamels is a small one, and may well be allowed to pass. But far otherwise is it with the very plainly-expressed innuendo in Mr. Henderson's letter, in which charges of the most serious nature are hinted against the honour of certain jurors. This is a matter which concerns every one of the photographic public, and ought to be probed to the very bottom. I am the more concerned in this because Mr. Henderson is not the only one who appears to be aware of the circumstance to which reference has been made.

Let me, as a member of the British public, take this opportunity of requesting that the English juror, Mr. England, will lose no time in stating publicly whether, in response to any request expressed on the part of either himself or his brother jurors, it is in accordance with his knowledge that pictures were delivered to any of the jurors; whether the receipt or non-receipt of such asked-for pictures influenced the decision of the jurors in regard to the awarding of gold or silver medals; and whether he is aware of the "irregularity" hinted at by Mr. Henderson in the delivery of pictures forwarded for that purpose, by which an intended award of the highest kind was commuted into one of lower grade.

These are matters which concern every photographer, and if they are shirked the public will draw their own conclusions. The character of jurors, like that of Cæsar's wife, must be above suspicion; and French jurors will thank me for affording them an opportunity for clearing themselves from a grave imputation.—I am, yours, &c.,

A BRITISH PHOTOGRAPHER.

[Although in our append to Mr. Henderson's letter, last week, we stated our opinion that there was some grave mistake in his allegations, still, as it seems possible that there may, after all, be some foundation for what has been alleged, we print this letter in order that those concerned may have an opportunity of rebutting such innuendoes if they feel so inclined.—EDS.]

MR. HENDERSON AND HIS ENAMELS.

To the EDITORS.

GENTLEMEN,—I scarcely feel constrained to reply to Mr. A. L. Henderson's letter in THE BRITISH JOURNAL OF PHOTOGRAPHY, inasmuch as, so far as I am concerned, it touches me but slightly. True, Mr. Henderson is unable to see that there was any lack of courtesy, because he asked me to inform the person who reproduced my remarks that he had been awarded a bronze medal, and that his were all untouched photographs; and then he asks, naïvely enough, "What is this but publication?" I had nothing whatever to do with the reproduction of my remarks, and do not know to this day who reproduced them. Why did not Mr. Henderson write to the journal in question himself, instead of trying to force a quarrel on me? If he thought he had a grievance that was the proper course. If he decided to write to me at all upon the subject, I say it was great want of courtesy not to state that he intended to publish the letter; but, having published his letter, why had he not the fairness to publish my reply? His question of "What is this but publication?" is as ridiculous as his slanderous innuendos against men like Davanne, Luckhardt, Frank de Villecholles, Chardon, and England.

Who, indeed, would be a juror if this sort of calumny were usual? Let anyone read the names of the jurors—men known to all Europe as men of science, as honourable men, as distinguished in their respective branches—and then say if it is not scandalous that a disappointed competitor could so far lower himself as to make such charges of corruption as Mr. Henderson has thought fit to make.

As to Mr. Henderson's impugning my judgment: that is a small matter, and not worthy of consideration. I simply said that, in my opinion, this country was far behind in enamels, and the jury seem to have been of my opinion. I had not the slightest feeling in the matter. I wrote what I considered to be the truth after a careful inspection of the enamels shown in the two sections; and Mr. Henderson is quite within his right when he differs publicly and privately from my criticism.

On my part I take the liberty to differ with Mr. Henderson when he says "what photographers require is a process that demands little or no artistic work." In my opinion, if the customers of photographers require enamels at all they would like to have them as good as they can be produced; and it is probable that the artistic treatment of the French enamels gives them that superb effect which we look for in vain amongst those exhibited in the English section.—I am, yours, &c.,

Autotype Works, Ealing Dene, W., J. R. Sawyer.
October 30, 1878.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

R. T. H.—Apply to the print a one-grain alcoholic solution of Castile soap.

A. D. wishes to know where he can send ivory-coloured miniatures for exhibition.

An Apprentice.—Apply a strong solution of cyanide of potassium nearly saturated with iodine.

Anxious.—We shall try the formula you give, and if we obtain the gritty film spoken of shall investigate the cause.

J. R.—Thanks. The process alluded to is probably one of those of which we have frequently given details in this Journal.

J. Smith.—The writer of the letter signed "Fair Play" is well known to us, but his name is not among those of whom you send a list.

"Rubber Solution."—1. Dissolve white rubber in benzole.—2. Decomposition has set in; it will therefore be necessary to make a fresh bath.

Z. A. R. wishes to know the best method of making a ten-grain aqueous solution of chloride of palladium. He finds it to be exceedingly insoluble.

Cymbro.—Unless informed to which of M. Lambert's processes you allude we could not answer your query. Repeat the question again, and state to which process you refer.

Geo. F. D.—Remove the lens from the cell, place it in water made slightly warm, and then transfer it to water of such a temperature as to soften the balsam by which it is cemented.

F. Harrington.—The varnish you are using as a substratum will not injure the silver bath. There are other media—such as india-rubber solution or albumen—which we would prefer to it.

J. L. Leak.—Send the roller of the press to an engineer, and instruct him to repolish it. He will have to take a shaving off the surface in order to eliminate the fissures, but this will not render it less efficient.

R. Miller.—Do not attempt to doctor the toning-bath, for the brown discolouration proves in an unmistakable manner that decomposition has set in. Pour the whole contents of the bath among your wastes, and make a new one.

Semper Idem.—To produce the stereographs employ the albumen process and tone by means of gold. This will prove durable, and yield the qualities you so much desire. If you are ignorant of the process recommended, write again.

A. O. T. T.—Nothing of which we are aware answers so well as a strong solution of cyanide of potassium *nearly* saturated with iodine and thickened with mucilage of gum arabic. Let this be applied by means of a finely-pointed camel's-hair brush.

Obernetter's Paper.—In reply to a querist who, a few weeks ago, wished to know if Mr. J. Solomon were still agent for Obernetter's collodio-chloride paper, we are informed by that well-known dealer that he ceased several years ago to have anything to do with it.

L. E. T.—For such a purpose as that of making varnish, methylated spirits of wine will answer quite as well as the pure ethylic alcohol. If the odour be too strong and unpleasant add a few drops of oil of lavender, by which it will be completely disguised, without any ill effect being produced.

George Scott.—Imperfect stopping of the bottle will explain the thickening of the collodion; it is evident that either you or your assistant must have omitted to insert the stopper after using the emulsion. The remedy will be found in the addition of a little ether. Do not add any alcohol.

One Who is Sadly Troubled.—In addition to the various methods we have recently published for effecting the removal of alkaline-developer stains from the fingers, try the effect of rubbing them with a mixture of hydrochloric acid and water, making use of a lump of pumice stone, but no soap.

B. H. B.—White hard spirit varnish will answer quite well, but it must be diluted with alcohol in the proportion of one-third of the latter. The varnish may be procured from any dealer in varnishes. We are uncertain of the prices, but it is very cheap—so cheap that it would never pay you to prepare it for yourself.

George Hercus.—So far as we are aware the publication, *Studies from Nature*, was discontinued before the completion of the first volume. Our opinion of its merits will be found recorded in our volume for 1875, to which we refer you. Respecting a suitable title for a new work of a similar kind we must decline to offer any opinion or suggestion.

Pyro.—The half-plate lens is quite suitable for enlarging from *carte* size; but it will be necessary that the back lens be placed next to the negative that is to be enlarged, otherwise the definition will be imperfect. The lens marked No. 3 on your list is much more suitable for producing a perfect enlargement than any of the others mentioned, including your favourite half-plate lens.

J. Green.—We cannot offer even a hint as to what method should be adopted in the photographing of sound, unless it be in the direction of attaching to the resonant string a mirror capable of reflecting in a zigzag manner upon a rapidly-moving sensitive surface those reflections it will give from a luminous point. While we are aware of the various fantastic figures assumed by dry sand when it is strewn upon a flat, elastic surface and placed in contact with a vibrating string, we fail to see in what manner this fact would prove of practical utility in your case.

Bengal.—While we cannot speak from an extended experience respecting the comparative value of prisms and mirrors for reversing the images in the camera, still, having had a certain degree of experience with the use of both in this connection, we have arrived at certain conclusions respecting them. It will be enough for your present purpose to be assured that, as respects sharpness, reversed negatives of the first order may be obtained by photographing through the glass plate upon which the collodion film is supported. If flat glass of the best quality be made use of—and for such an important purpose as yours no other should be employed—no defects will be produced by causing the rays from the lens to pass through the glass previous to their impact upon the sensitive film. When an ordinary dark slide is employed there are difficulties of a mechanical character to be encountered in order to ensure correct focussing; but these difficulties are of such a nature as to be very easily surmounted.

South London Photographic Society.—The next meeting of this Society will be held on Thursday next, the 7th inst., in the rooms of the Society of Arts, Adelphi, when Mr. F. A. Bridge will bring before the members a peculiar incident in connection with paper enlargements.

The Photographic Exhibition.—On the evening of Wednesday next the Exhibition will be open from six till ten for the benefit of a worthy object, namely, to aid the funds of the Photographers' Benevolent Association. The admission will be sixpence. We trust that all who can will attend on this occasion.

Paris International Exhibition Awards.—In the list of awards which appeared in our last number there occur several errors, mainly in the addresses of the foreign exhibitors. A proof was forwarded to Mr. Harrison (our Paris correspondent) for correction, but it was not received back at our printing works until after we had gone to press. Our foreign readers will please accept this general notice in lieu of our giving a detailed list of *errata*, which will not now be required.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.

No. 966. Vol. XXV.—NOVEMBER 8, 1878.

TAKING PORTRAITS BY THE ELECTRIC LIGHT.

Now that the fogs and gloom of November have set in, what theme can be more attractive than that of taking portraits and conducting other business connected with photography by means of a powerful artificial light? And what light can equal in popularity, cheapness, and efficiency the electric light? Before proceeding to deal with the possibilities of the electric light in the production of portraits, it is necessary that we go back a little way and inquire what has been already done in this direction.

We commence by saying that we have in our possession portraits taken by the *magnesium* light in 1865 which are in every respect equal to any obtained in daylight in 1878. What, it may be asked, has the magnesium light of a bygone period to do with an inquiry into the capabilities of the electric light of the present time? Much, as we shall speedily show.

Given an intense light in which the element of quantity or diffusiveness does not exist: a subject for inquiry arises in considering the best means for converting intensity into quantity. But, lest any ambiguity attach to our use of these terms, we shall give a popular explanation. By intensity we mean such light as that emitted by the sun when seen surrounded by a blue sky; by quantity we also understand the same luminous waves when intercepted by a widespread mass of vapour or clouds, by which the solar light, instead of reaching us from one point as before, is now radiated from every point of a cloudy mass that includes an angle of many degrees. The powerful beams of the sun no longer reach us in their fierce intensity, but, notwithstanding, we are illuminated none the less. To bring about a similar condition in the strong light of a gas or oil lamp flame it has to be surrounded by a ground glass or opal translucent shade, by which the intensity is softened.

When the magnesium light was first introduced its powerful actinic rays were found to possess certain qualities by means of which photographs of the objects upon which they fell could readily be taken; but at that time photographers seemed to have no other thought than to establish the scientific possibility of obtaining portraits at night by a very brief exposure. While writing this article we have on the table beside us a portrait of Sir David Brewster, taken by Mr. John Moffat and his assistants, at a meeting of the long-defunct Photographic Society of Scotland, nearly twenty years ago. At that time properly-constructed lamps for burning magnesium had not been introduced, and the results obtained were deficient in those graces of fine shading that were afterwards obtained. But we have also beside us, while we write, portraits of Mr. Mellor and Mr. Mather, both of whom were intimately connected with the introduction of magnesium as prepared by Sonstadt's process. These were taken about the year 1865. We are not quite certain whether or not Mr. Alfred Brothers, of Manchester, was the artist on the occasion. We do know, however, that about that time the gentleman just named evinced a keen practical interest in the application to photographic portraiture of the magnesium light. We further know that by means of a lamp which Mr. Brothers sent for editorial notice about that time we were enabled to obtain several charming negatives by magnesium light; and we have ocular demonstration in the pictures before us that the quality of the portraits obtained in 1865 quite equals that of those obtained at the present time. The "Brothers" lamp consists—or rather *consisted*, inasmuch as it is not now made—of a tin reflector of a parabolic form, and of large dimensions, having fittings upon which to place three tapers formed by magnesium wire or riband, and which, being arranged at a short distance from each other, caused the light to come, not from one point as before, but to fall upon the sitter from a large area of illumination. In our own practice with this lamp we preferred covering it with a large plate of ground glass, so as to prevent the direct light of the incandescent magnesium from falling upon, and distressing, the eyes of the sitter.

We have introduced the subject of magnesium light because the precise conditions by which its photographic use is governed prevail also in the employment of the electric light, or even the direct light of the sun. All these systems of lighting are placed on terms of equality as respects their application to the illumination of a sitter for a portrait.

There is now every reason for believing that the electric light will become general amongst us. Let us see in what manner this will affect photographers. With such a source of illumination at command one may imagine himself living in uninterrupted sunshine, all that is required being the means of controlling such a powerful volume of light as to render it subservient to his ends. "A well-lighted picture," said Mr. Jabez Hughes thirteen years ago, "is one where the light falls chiefly in one direction so as to form well-defined but soft shadows. Then a secondary light must be admitted,—not so strong as the principal, otherwise it would produce flatness; but it must be just strong enough to light the main shadows, so that they shall not appear hard and abrupt, but delicate and soft." In this passage is summed up the whole principle of lighting. Let us apply it to lighting a sitter by the electric light.

By the known methods of distributing the electric light a diaphanous screen—whether formed of paper, textile fabric, or ground glass—may be illuminated from behind, and a light so powerful may be radiated from every portion of its surface as to answer all the purposes of photography. By actual measurement we have found that such a screen four feet wide by five feet high serves to illuminate the sitter under precisely the same conditions as those which are found in a studio where the finest work is produced. Let it be remembered that it is the angular, not the actual, dimensions of the radiant—whether that radiant be sky or an artificial cloud—which determines the illumination of the sitter, and that the character of the illumination is determined by the point from whence the dominant light shall fall. For example: if a luminous sheet or artificial cloud light the sitter, certain effects of *chiaroscuro* may be introduced by imparting to one point of this cloud a greater degree of luminousness than to the rest of the surface. The greater portion serves the general purposes of illumination, while the special point gives force and piquancy to the lighting. Effects of this kind may be obtained with the greatest ease by the carbon points of the electric light. Daylight may be imitated in the most perfect manner, and the effects obtained in daylight may, consequently, be thus secured.

It is an old optical axiom—not true, however, in every case—that what has been done by dioptrics may also be done by catoptrics.

To apply this to the case before us: the "artificial cloud" by which the sitter is to be illuminated may itself be illuminated either in front or from the back. The case is similar to the projection of a magic-lantern picture through a transparent or upon an opaque screen.

If a powerfully-illuminated screen of a few feet in dimensions be placed in front of and at a short distance from the sitter, the effect upon such sitter will be the same whether the screen be illuminated from behind or from the front. The great points to be attended to are—first, the preventing any of the direct rays from the radiant falling upon the sitter; and, secondly, controlling the light in such a manner as to utilise as much of it as possible. If an artificial cloud—whether it be formed of ground glass, thin paper, or textile fabric—is to be illuminated from the side opposite to that on which the sitter is placed, the light to be employed in such illumination—or each of the lights, if there be several—must, to prove effective, be encased in a parabolic reflector of such an open form as to ensure the whole of the rays being projected upon the screen, and nowhere else. Nicety in constructing the reflector is not of consequence here, as it would be in the case of a lighthouse; for the present purpose all that is required is that the light be by some means directed on to the screen. Indeed, if the reflector were sufficiently large and brought tolerably close up to the screen, one such reflector would answer exceedingly well even for several flames; and if Mr. Brothers' magnesium lamp, to which reference has been made, were twice the dimensions of the one in our possession and covered in front with a white or pale-blue diaphanous material that would radiate light without absorbing much of it, a more convenient and handy apparatus for illuminating a sitter need not be desired. In this case, of course, a separate screen would not be necessary. In constructing a lantern according to this system we found it necessary to place a broad band of tin round its front margin, so as by its projection to prevent the loss of light which might otherwise take place by radiation to the sides of the sitter, where it is not required.

As regards the nature of the "burner" of the electric light: that subject cannot be entered into at present, but it will afford a theme for an article on a future occasion. Every day is now seeing some fresh advance recorded, and since we commenced to write this article we have been given to understand that, doubtless in consequence of competition and the improved methods resulting therefrom, the entire cost of a set of apparatus requisite for the production of the electric light is stated to be about one-half of what was quoted only three weeks ago. More of this anon.

THE PHOTOGRAPHIC EXHIBITION.

[Fifth Notice.]

Mr. Alfred Harman exhibits two fine, bold enlargements illustrative of a process of enlarging regarding which no details have yet been published.—Several views in the grounds of Grove Spa (250), and others exhibited by Mr. H. G. Inskipp, attest the quality of his dry plates.—A portrait (312), exhibited by Messrs. Wratten and Wainwright, bears testimony to the rapidity of the gelatine plates of this firm; the exposure is stated in the catalogue to have been a fourth of that required for a wet plate.

Messrs. Alder and Clarke have contributed several portraits taken by artificial light with an exposure of twenty seconds. The instrument, or apparatus, in which the light is contained is designated a "luxograph." Four specimens which we have received from Messrs. Alder and Clarke enable us to form an idea at leisure respecting the efficiency of the luxograph, concerning which instrument we shall have a descriptive article in the course of a week or two, when the specification shall have been published. Every effort made to facilitate the production of portraits by artificial light must be gladly welcomed.

Microscopic photography is represented by Dr. George Berwick, who exhibits a frame of neatly-executed specimens of this fascinating branch of our art.

A variety of views taken in and around Hampstead are shown by Mr. E. Bayston.—Among several clever compositions, by Mr. William Cobb, the excellent one, *School Board Dodgers* (258), is worthy of very high commendation. It is an enlargement by the artist himself.—A frame of cabinet portraits (85), by Messrs. Donovan and Co., are fair specimens of average work.—The frame numbered 299 contains two dozen groups and single figures of children, by Mr. W. Allen Richardson. These are of excellent quality both in grouping and manipulation.—Messrs. Law and Sons also exhibit a frame of children's portraits.

Mr. Seymour Conway's collection consists of a frame containing six well-executed landscapes (62). Mr. Conway must have overlooked the fact that two different views which are mounted in juxtaposition have the same clouds. *Verb sap.*—The three pictures exhibited by Mr. Marcus Guttenburg have been produced by a patent process the nature of which has not yet been divulged. The pictures (portraits 144-5-6 respectively) are certainly effective. They possess a grain all over the whites which, combined with certain hatchings, serves as an artistic finish to the vignettes, which may have been executed by lithography. This is merely a surmise; when the specification of the patent is published we shall be enabled to describe Mr. Guttenburg's method.

The contents of two frames of photographs of statuary, by Mr. R. Hedges, appear good, but they are placed too high to be easily seen. —Mr. Hubbard's large photograph (101) from an oil painting is exceedingly fine; so is the copy of a drawing (6) by Mr. Hollyer.—Of similar quality is the collection of cabinet portraits (282) by Mr. S. Symonds, as well as five carefully-executed landscapes exhibited by Mr. R. Keene.—A frame numbered 262 contains a collection of photographs, by Mr. Pointer, of trained cats and dogs.—In No. 256 will be found a large and varied selection of photographs, exhibited by Messrs. Reeves and Hoare, illustrating the effects obtained by Seavey's most artistic backgrounds.—The four landscapes exhibited by Captain Rawes are of a very warm tone.—Mr. Thomas Parkinson has sent several landscapes of fair merit, of which it is perhaps difficult to point to any one picture as being better than another.—A good example of the artistic work of Mr. J. H. Ritchie is numbered 46, representing a window surrounded by foliage.

Excellent alike in conception, arrangement, and execution is a frame of *Costume Portraits* (263), by Mr. W. Shuter.—The *Blind Village Postman* (147), by Mr. H. N. White, is an effective picture, and of two landscapes by Captain Verney preference will, we imagine, be given to his *Fountains Abbey* (103) rather than to *Ripon Cathedral*, in which the clouds are somewhat strongly marked.

Mr. R. Slingsby confines his exhibits to two pictures. *Satisfaction* (208) represents a lady of middle age who, having just completed her toilet, is seen contemplating the effect in a pier-glass (not visible in the picture). The result of the examination is depicted in her countenance, which is befittingly expressed by the title of the photograph. Mr. Slingsby's other picture, *Portrait of a Lady* (209), is a charming picture of a pretty girl. Both are depicted in Mr. Slingsby's well-known effective style.

The frame of interior and exterior views of Hughenden (274), by Mr. T. C. Starling, will be carefully examined on account of its associations with one who wields a great power for good or evil.—A view of *Magdalen Tower, Oxford* (308), by Mr. W. Wheeler, is probably the largest direct photograph in the Exhibition. It is well executed.—Mr. Augustus W. Wilson's *Seven Ages of Man* (293) is an effective series of pictures of large dimensions. To one of this series a medal has been awarded.

On Wednesday morning an interesting feature was imparted to the Exhibition by the display of a screen of views taken in Cyprus by Mr. John Thomson, F.R.G.S. Such charming transcripts of our new possession in the East are in every way worthy of the camera of Mr. Thomson, who in this artistic raid has ably brought to bear his experience acquired in China and in other of his oriental travels several years since.

We shall conclude our notices of the Exhibition next week.

THE SURFACES OF FILM SUPPORTS.

We left the subject last week at a point where the consideration of the porosity or otherwise of the surface was under discussion, our argument tending to show that, while molecular irregularity of surface might exist, the assumption of a state of porosity was not likely to be a correct one.

A question at this stage will naturally arise—What is the cause of the adhesion of the film to the surface? Putting aside the case of a "porous" film where the original cause of adhesion may not unreasonably be assumed to exist—a consideration of which would not be useful in forming an opinion—we may at once look at the film, which, by the action of the acids in the developer and intensifier, has been converted into the "tough" state. Why does it not always become loosened by the action of the water? Granted the same mechanical condition of a number of films, what is the cause of some loosening and others remaining adherent? Such circumstances do exist, and the most likely hypothesis is that the state of the glass surface or the presence of an intermediate agent is the cause.

In the case of albumenised plates, or plates covered with caoutchouc solution, it is very easy to imagine that the well-known natural tenacity of albumen and caoutchouc, &c., enables them to cling to the glass (but into the cause of this we need not stay to inquire); the new surfaces thus produced have a porosity or inequality quite sufficient to give a grasp to the collodion, just as two pieces of smooth writing-paper wetted and placed together will adhere, while two pieces of clean glass with a film of water between them will slide over one another with perfect ease.

With the pure surface of glass, however, a different set of phenomena arise. A tough film will adhere, if no break in its surface be made nor any undue strain; but if a drop of water once gain admission underneath it is capable of separating the whole film from the glass, showing that the adhesion is practically atmospheric, and that when another substance is introduced in any place between the film and its support adhesion ceases.

It should follow, then, that the purer the surface of the glass the easier the film should be made to leave it, and such we have found to be the case. We took a number of pieces of "patent plate," and subjected them to the action of a rather strong solution of nitric acid (one to four of water) for several days, and then most carefully washed all traces of the acid away, wiped with a pure linen cloth, and polished with a similar dry piece. In using these for iron development, followed by pyro., we found the greatest difficulty in keeping the film in its place, even though the surface was roughened all round the edges of the glass; the slightest extra strain upon the film by the washing water seemed to loosen the film, which, in some instances, absolutely broke away if an accidental rent were made near its edge. We could not imagine a stronger argument against the porosity theory, as the glass would have been in perfect condition to allow the collodion to penetrate the pores and adhere by their means.

We found that the surface of the glass treated by solution of wax well rubbed off increased the adhesion materially; so much so that we were on the point of trying an exhaustive series of experiments with it, when we found out a fatal defect. A gentleman informed us that he had in his possession a number of negatives whose films were completely loosened from the glass though standing untouched in his negative rack, and he was able to trace these particular negatives as having had surfaces treated with wax. The use of wax to enable a film to be easily transferred would seem to indicate that adhesion could not be expected to continue—most probably from its atmospheric origin, and the varnish not being able to penetrate through the wax freely enough to bind it in the usual manner to the glass.

A little time ago some foreign writer recommended the employment of tallow for the purpose of causing the film to adhere, and was rather laughed at for his pains. In order to discover if its action were analogous to that of wax we smeared several glasses with it, and wiped it off very carefully in some cases, and in others only to such an extent as to leave a visible film. We were astonished to find that it proved in no way injurious to the general cleanliness of the plate; indeed, rather the reverse. The negative was free from all stains and uneven reduction, but we found a scarcely-perceptible reduction of silver between the film and the glass. We purposely under-exposed and over-developed; but the negatives were otherwise in no way inferior to those taken on the purest of glass, and the adhesion was about natural—certainly not inferior to an average glass. As our aim, however, was practical we did not continue its further use.

The cleanliness of working during the tallow experiments led us to think that if a uniform film of any material which would not spoil the bath were spread over the plates they would be free from that occasional unevenness and spottiness to which we have alluded. The albumen coating so often brought before photographers, but which is by us never universally employed, is a case in point. Albumenised glass *does* work cleaner, evidently through the surface being completely uniform, and so preventing anomalous deposits. But the objections to its use are so numerous that we endeavoured to hit upon another medium, which, with the limited experience we have had, has been completely successful. We coated plates with a thin solution of shellac, made by letting down ordinary varnish by spirits of wine in the proportion of one of varnish to five of spirit. It was difficult to get an even-looking film of the shellac; but we tried even an excessively chilled-looking plate with perfect success. The development was regular, the plate clean, and the film wonderfully adherent.

We do not say this will be a universal panacea for dirty plates, but it is very well worth a careful trial, and led up to it, as we were, by simple theoretical induction it would be interesting should it turn out to be a cure for imperfect glass.

RECENT PATENTS.

No. XX.—NEWTON'S METHOD OF PREPARING AND COLOURING PHOTOGRAPHS.

THE above is merely our own curtailment of the somewhat lengthy title adopted by Mr. Harry Robert Newton in his specification, and which title in full is as follows:—"Preparing materials for and for imparting to photographs and other illustrations of all kinds the tones and tints of natural colours for rendering their representations more real and lifelike, and for improvements in mounting them and coupling them together, and in enclosing them in or between glass, metal, leather, wood, vulcanite, and other frames or cases or ornaments, parts of all of which are applicable to other useful purposes."

THIS invention (which we here reproduce *verbatim et literatim* from the specification) consists in preparing albumenised, gelatinised, plain paper, or other photographs, or other illustrations, similarly coated or not on one or both sides, or with fibrine or analogous or other substances, and all macerated materials—for example, from the thinnest tissue paper to the thickest cardboard—and all fibrous or woven substances or fabrics—for example, from the thinnest silk gauze to the thickest linen or calico—all either plain, coloured, or parti-coloured, or similarly coated, by removing all size, dressing, foreign, or other matter contained therein, by immersion in warm or cold solutions of chloride of lime, soda, benzole, volatile oils or essences, sulphuric, acetic, or other acids, as may be required from the particular manufacture of the various substances to be operated on, or from the quality of specially-prepared materials or fabrics, or other substances, and when cleansed in soft or other waters, immersing them by preference in a bath of warm Canada balsam in its natural state, or in other gums or resins dissolved in benzole, fixed, drying, volatile, or other oils, and when saturation is complete drawing them out between glass or other rollers or plates, removing thereby nearly all the excess of liquid with which the material or substance is saturated, and from which, when set, the remaining encrustation can be removed by benzole or by fixed, drying, volatile, or other oils, so that according to the transparency or semi-transparency required the natural or other surfaces may be left exposed, and when, according to the condition obtained, water, gum, transparent, body, powder, oil, varnish, printing, and other colours or pigments, or chalks, stains, or dyes, can be laid on to the front, back, or on to similarly-prepared or oiled, plain, or coloured, or parti-coloured, macerated, or woven materials, in single thickness or layers, or other substances, on or in front of or between which they are to be mounted, such substances mainly being plain and tinted and coloured glass, opal, enamel, japan, vulcanite, china, earthenware, or gelatine, painted, varnished, and oiled papers, and cardboards, and woven substances, or painted wood or ivory, the two latter of which, to prevent warping, are put together to any size in thin cross-pieces with bevelled lapping edges, and in as many thicknesses as the size requires.

My invention also consists in stretching such photographs or other illustrations on or between perforated metal or other frames, and mounting them on or in front of or between them, and fixing them on to similar or other naturally or artificially-coloured or tinted photographs or other illustrations, materials, or substances, as before described, and also for taking and printing photographs on paper, as before described, mounted on similar perforated metal, vulcanite, or other frames, and for using such perforated or other frames for forming thin folding albums fixed on continuous lengths of woven substances, ribbon, leather, parchment, paper, or other flexible materials, and for applying the method of mounting the photographs or other illustrations to metal and other lockets, or ornaments, or cases, designed to show, by double continuous rollers or revolving centres, one, two, or more photographs or other illustrations, and for the ready changing them with or without opening the metal or other ornamental enclosures or cases within which they are contained, the varying parts of all of which are applicable to other useful purposes; thus, for instance, the prepared papers and woven substances, and the method of mounting, provide a new medium or ground capable of being toned as required for the better luminous production and preservation of pictures generally in oil, water, or other colours, and for drawing, tracing, and transparent uses.

In order that my said invention may be better understood and carried into effect I proceed to describe the same more in detail.

The making all photographs and other illustrations transparent or semi-transparent by saturation as described is for the purpose of mounting them on various materials, plain or coloured, and on white and coloured linens and lawns, and raw and coloured silks and gauzes, and which have also been made transparent or semi-transparent and prepared for mounting on a clear white ground, having first delicately covered with proper shades and tones in oil, water, body, or other colours, or stains, or dyes, the high and white lights, and any other small or other objects or parts to be coloured at discretion in photographs, &c., &c., the usually better, but not invariable, course being to colour out only very small parts or features, leaving the broader surfaces and features undisturbed, and this is done by putting either of the various ordinary kinds of colours, or materials, or liquids on the back or front of the photograph or illustrations where required, or else on the front of the prepared base; and by preference I use body colour with isinglass or size, the effect of which is that the light transmitted upwards from the lowest ground has a blending effect and a translucency for all colours it can penetrate above it, and which is of the first importance for flesh colours, to avoid what is called "chalkiness" in appearance; and to obtain this by saturation as aforesaid, Canada balsam is employed by preference, though nearly all other gums and resins give a somewhat similar result, but lack a certain class of necessary purity and toughness, changing thereby the quality of the reflecting power. Oil is also used, and when in combination with Canada balsam and other gums or resins only sparingly, for a toughening action that is to destroy brittleness.

To prepare the various grounds or bases a pure white gelatine, glazed paper (or any smooth-painted, or glazed, or enamelled material) is stretched on a frame, sizing it strongly on the back to prevent saturation. On this is mounted with Canada balsam any flesh-tinted or other silk gauze of whatever degree of tone necessary, and thin or thick, and in one or more layers as required. Over that again is mounted in a similar way linen or lawn of whatever coarseness or fineness required, and in one or more layers, and this forms the flesh base in portraiture and the ground base in general subjects.

To form the upper coloured base a tracing on stiffish gelatine is made of the principal lines of the subject, and the lines marked on the gelatine are then cut through as in stencil plates. As many coloured squares of paper (thick or thin) or squares of silk, according to judgment, are then taken as the intended colouring of the photograph or illustration necessitates, and, when required for flesh subjects, one additional layer of white linen. The gelatine stencil plate is then put over all these squares of paper and pressed down firmly, and while so held the different thicknesses of the coloured or other paper or materials are cut through, the cut in the lines of the stencil plate guiding the cutting point, so that all thicknesses are correspondingly cut at one operation. One of each of these is then mounted on the flesh or ground base, covering it over entirely, and then (the small parts being coloured out, and which is best done when mounted on metal frames or mounts) the photographs or illustrations are mounted in the same manner on the prepared bases or grounds; ordinary bookbinders' cloth is then mounted on the back, the edges turned over on to the front, and hermetically sealed down, as it were, by varnishing over afterwards.

There are different and various ways of approaching somewhat towards the same result, among them the lower prepared base could be printed in colours in the ordinary way; but the risk of inaccuracy in shrinking, printing, and otherwise, in high-class works and delicate subjects would probably interfere with its general application, besides which there is always a loss of translucency in dealing with opaque colours.

In colouring by hand the photograph, &c., &c., on the prepared base the foregoing difficulties do not exist, though there is greater care required in getting evenness of tone, tint, and colouring.

The foregoing system, though referred to especially for portraiture, as flesh colours and tones are the most difficult to obtain and the most important to achieve, is applicable to any class of subject in any photograph or illustration. All the different substances mentioned, as well as others, form in a greater or less degree materials to operate on to produce the foregoing results, especially ivory, but the grain and the non-absorbent properties, and perhaps the opacity of that material, seem to prevent it returning that depth of reflection which can other ways be obtained, and which is essentially necessary, so as to take off the ordinary hardness of features and outlines that are in a greater or lesser degree characteristic of photographs and other illustrations.

Somewhat similar effects to those hereinbefore described can be obtained by the insertion between the photograph or illustration so prepared and the coloured and toned base underneath of a metal, card, or other frame, so that the representation is lifted up from the surface of the base, and a blending and softening effect is obtained irrespective of the materials of which the base is composed, but more powerful and violent colours have to be used, and more care taken in treatment, though the base can be coarsely and roughly formed, as the absence of impact with the lower layer ceases to require delicacy of adjustment, and, where it is possible to obtain excessively thin patent plate glass, it is best to mount the photograph, &c., &c., between two pieces, and then mount the coloured base on the lower glass, finishing with a cloth back and turning over the edges as previously described.

The different and various materials employed can be either highly polished or else have a ground surface, according to whether the effect is desired to be bright and sparkling or subdued, and the greater the care and the greater the evenness of the materials used the more perfect will be the effect in general, and in treating photographs or illustrations so prepared as transparencies by placing daylight or artificial light behind them.

In preparing paper for photographs (the printing and taking of which is chemically performed in the ordinary way) I find that better results than ordinary are obtained by mounting the paper first on vulcanite or similar classes of frames before coating it or sensitising it, the more so as very much thinner paper can be employed than is ordinarily used; the impact with the negative seems more complete and even, and the positive therefore relatively better printed, besides which the sensitised surface is kept more flat, while drying no creasing takes place, and the whole of the operations of manipulation can also be more easily carried out, and, what is perhaps more important, without the photograph or illustration being touched by the hand.

For the better preserving and exhibiting photographs, &c., &c., so treated (and whether in the first instance mounted on perforated metal frames or not) all mounting frames have perforated edges, so as to be able to sew them round those sides on ribbon (or other endless material) back and front, leaving the bottom ends open until the illustration has been inserted; the whole can then fold up (being fastened continuously) very closely, and in a similar way to an ordinary album, and with a separate or fixed case attached thereto. In the same way photographs, &c., &c., mounted without frames on continuous lengths of materials are wound round double rollers, large or small, and inserted in wooden cases or frames for standing on tables or otherwise, so that with handles to the ends or centres of rollers they can be turned round forwards or backwards without opening the case, and which arrangement in miniature is carried out for lockets or other ornaments, so as to have a number of portraits or illustrations within one enclosure, and changeable with or without opening the frame, case, locket, bracelet, or other article.

Having now particularly described and ascertained the nature of my said invention, and how the same can be carried into operation, I would have it understood that what I desire to secure under the hereinbefore letters patent are the several modes and methods and appliances herein mentioned for dealing each in their degree with the treatment of photographs and all other illustrations, and that I claim the uses of all or any of them in that or other ways, and the application of silks and gauzes, linens and lawns, plain or coloured, prepared transparent or otherwise, using them according to size or otherwise in a greater or lesser degree of coarseness or fineness, and that I do not bind or limit myself by the recited particulars and explanations against the free use of the liquefying or other agents or of colours of whatsoever sort besides coloured materials, as in all works of art the effect of blending or contrast in colour is obtained by placing colours of different qualities in juxtaposition by different means, methods, and applications, according to ever-varying circumstances, combinations, and natural conditions.

The foregoing comprehensive specification of patent will prove suggestive to those who aim at securing coloured effects in photographs.

Our friend, Mr. Herbert B. Berkeley, favours us this week with some "notes" on which we here make some observations. First, with regard to citrate of silver, or, rather, citric *acid* in emulsion: Mr. Berkeley's remarks with regard to the formation of silver citrate by the addition of citric acid to concentrated solution of the nitrate are quite in accordance with our own experience; and in this respect the citrate behaves in a similar manner to the sulphate and other salts which are soluble to a comparatively slight degree in water. It is obvious that if to a strong solution of silver nitrate (which is very freely soluble) we add a snbstance capable of forming a secondary salt possessing a lower degree of solubility no precipitate will be formed until the point of saturation is reached, after which the decomposition of the nitrate results in the deposition of the new substance in extemely minute crystals having the appearance of a fine powder. This explains why citrate, sulphate, and, to a less extent, acetate of silver are precipitated from strong solutions of the nitrate and not from weaker ones by the addition of the respective acids in the uncombined state, and also why, in the case of alcoholic solution of the nitrate, the precipitate is invariable. The newly-formed salt, having no solubility in the latter menstruum, is precipitated, no matter how small the quantity. Mr. Berkeley suggests that the action of the citric acid in restraining or removing fog in emulsion is due to the liberation of nitric acid which takes place, rather than to any specific action of its own. If such were the case, however, how are we to get over the fact that the addition of nitric acid itself under similar circumstances fails to produce a like result? And, again: how is it that the addition of citrate of soda, which entails no liberation of nitric acid, produces an almost identical result as regards the prevention of fog? Theoretically speaking, too, the citrate of silver formed by the addition of citric acid or a citrate to an emulsion containing free silver nitrate would be removed by a prolonged washing owing to its solubility in water; but, practically, we have not met with the "riddled" appearance of the film which Mr. Berkeley describes. It seems to us that the citrate would be formed in a state of division so fine as to preclude all possibility of any such "speckled" result if it were subsequently dissolved out of the film. If it were coarse enough for its particles to leave visible evidence of their removal surely the same particles would be visible *before* removal; but, in our experience, emulsions containing citrate of silver are as fine and homogeneous in texture as any others. With regard to our alleged misconception of the properties claimed for cupric bromide, we may say that our recollection of Mr. Warnerke's classical researches in that direction did not supply us with the "inspiration." We must lay the blame, if blame there be, to the credit of a foreign writer who claimed, on the alleged authority of Mr. Warnerke, the feature we mentioned in connection with bromide of copper. Since Mr. Warnerke obtained the silver medal for his process it has been the privilege of his continental admirers to claim anything and everything as belonging to his method of working or to his teaching, and we, perhaps, erred in not duly inquiring into the assertion we quoted. Our experience with bromide of copper, however, shows how far we support the claim.

ON DRYING GELATINE PLATES.

Although still under the impression that, for ordinary landscape purposes, plates possessing a moderate degree of sensitiveness—such as is easily obtained by numerous modifications of the collodio-bromide process—are more reliable, more certain in their results, and in many other respects better than those of the extremely rapid type that are now being prepared with gelatine emulsions, it must be admitted that there are circumstances in which the greatest possible degree of sensitiveness is desirable, and one cannot read the photographic journals or mix much amongst photographers without being convinced that gelatino-bromide is gradually, but certainly, forcing itself into favour. Of course gelatino-bromide may be made to work as slowly as the slowest collodion emulsion, and there are many advantages which gelatine possesses over pyroxyline as a vehicle for the silver bromide; but, notwithstanding, it has several disadvantages which, especially to the inexperienced, tend to make its working difficult. The most important of these are, doubtless, the difficulties connected with the drying of the plates after they have been coated, and the attendant evils of dust and decomposition incident to gelatine films kept long moist.

A considerable experience with gelatine plates warrants the belief that frilling and red fog both arise from some change occurring in the film in cases where it has been kept long moist; or, at least, when the drying has been rapidly performed those banes to gelatine work have not shown themselves. But, unfortunately, to dry such a plate rapidly is no easy matter, and requires conditions very different from such as are suitable for drying collodion films. The conditions are well understood, namely, frequent or, rather, constant change of dry air at a moderate temperature and freedom from dust. But, although many arrangements have been devised, I had until a few days ago seen nothing that seemed to me capable of doing the work efficiently and certainly.

The apparatus which I am now about to describe has been constructed by Mr. Dickson, an Edinburgh amateur and a mechanical genius of much ability; and I am so satisfied with its suitableness for the object in view that I believe it only requires to be known to be generally adopted by all who have the necessary convenience. It consists of a chamber in which the plates lie, an arrangement for the supply of heated and filtered air, and a mechanical appliance by which such air is constantly and rapidly drawn through the chamber. The chamber is a box not unlike an ordinary plate-box laid on its side, and measures $15 \times 8\frac{1}{4} \times 11\frac{1}{2}$. In what would be the bottom of the plate-box, but which is one end of the chamber, there is a three-inch hole, which, when the apparatus is in use, receives the kneed end of a zinc tube coming down through the roof of the dark room. To the other end of this tube, outside the building, is fixed what is known as "Dobson's induced current ventilator"—a simple piece of apparatus similar to that described in this Journal by Mr. Laing as "Boyle's patent ventilator," which will be found in the last volume of the Journal, at page 219. About three inches of the box, corresponding to the lid of the plate-box, is movable, and fixed in its position by hooks, or by a hook and hinges in the ordinary way. On opening this it is found filled with a series of three sets of overlapping laths, intended for the double purpose of excluding light and diffusing the current of air, which enters by a three-inch tube in the lid—that is, the end of the chamber. The two sides of the chamber are fitted with horizontal grooves sufficient to hold three dozen 9×7, or, by a slight alteration, twelve dozen quarter plates; and, as it is easy to make the box level, the plates are slipped in one by one as they are coated. The opening in the lid—that is, end—of the chamber is fitted with a three-inch tube about two feet in length, and pressed nearly flat for a few inches in the middle. Under this flattened portion is placed a small lamp or Bunsen burner, the size of the flame of which can be adjusted so as to raise the ingoing air to any required temperature. The end of this tube is partially closed by a filtering medium of muslin and cotton-wool, for the purpose of keeping back the particles of dust with which the air is at all times charged, and which, without some such arrangement, would render the plates useless.

From this brief description the action of the apparatus will be obvious. The ventilator, acting on the same principle as the once-popular perfume spray producer, causes a constant upward current in the tube connected with one end of the chamber. The air thus withdrawn is replaced by the heated and filtered air from the tube at the opposite end; and, as warm air holds more moisture than air that is cold, the plates are uniformly and rapidly dried.

It will, of course, be evident that the ventilator, which is the mainspring of this arrangement, will only act in presence of a current of air—when, in fact, there is some wind blowing; but I feel certain that nothing short of an actual examination of the apparatus in action would convince any one of how little wind is required to produce a sufficiently-rapid current for the purpose. On the occasion of my visit to Mr. Dickson there was not sufficient wind to stir the few remaining leaves on the trees, or to indicate the direction from which it was coming, and yet on placing an anemometer at the end of the inlet tube it at once indicated a velocity of fifty feet in twenty seconds, and a number of trials gave an average of about two miles per hour.

A thermometer placed in the drying-box showed how perfectly under control the temperature of the ingoing air was; and by a variation in the size of the flame or in its distance from the tube the temperature might be steadily maintained at from 60° to 90°—a range quite wide enough for anything connected with gelatine plates. I do not, of course, mean to say that Mr. Dickson's drying apparatus is incapable of improvement—few first attempts are; but I am satisfied that, even as it is, it will be a boon to all gelatine workers who may give it a trial, as it will do away with what I believe to be the main cause of most of the complaints so frequently made against that interesting and valuable process.

Although in the case in question the ventilator has been let in through the roof of the dark room, this is merely an arrangement for the sake of convenience and not of necessity, as it may equally well be let in through a window or hole in the wall by kneed joints, and when not in use for drying purposes will form one of the most effectual means of changing the air of the laboratory and getting rid of the vapours of ether, &c., generally so injurious to the health of those who have to breathe them for any considerable length of time. JOHN NICOL, Ph.D.

ON RECOVERING WASTE SILVER IN PRINTING.

[A communication to the Liverpool Amateur Photographic Association.]

It has often been a matter of surprise to me that so few make any attempt to recover the waste silver which usually goes down the sink during the operation of toning silver prints.

I am sure it will repay recovering, even to the amateur who works on a small scale, unless, indeed, it is on a *very* small scale. As to professional photographers: I fancy most save their residues in some form or other, though on lately conversing with one in a large way of business I was surprised to find he made no attempt to save any portion of the large amount of silver that was constantly being thrown away; for he considered that the amount, if recovered, would not repay him for the time, trouble, and expense of such recovery.

In order to test this point I have recovered the silver from the printing of a known quantity of prints, and I will now lay the results before you. The operations were performed in a very rough and ready manner, and therefore the result will probably not show as favourably as if more care had been taken and a larger quantity of residues had been experimented upon.

I operated on forty-eight (8×5) prints, or a quarter of a quire of a commercially-sensitised paper. By adding a little common salt to the first two waters in which the prints had been washed before toning I obtained fourteen grains of chloride of silver ($Ag\,Cl$). By adding a little solution of sulphide of potassium, or liver of sulphur, to the fixing bath I obtained seventy-six grains of sulphide of silver ($Ag_2\,S$).

Now, in 14 grains of $Ag\,Cl$. there are 10 grains of pure silver,
And in 76 „ $Ag_2\,S$ „ 66 „ „

Total.........76 grains of pure silver.

This is equivalent to 119 grains of nitrate of silver ($Ag\,NO_3$); and, taking nitrate of silver at three shillings per ounce, its value is tenpence, or twenty per cent. of what the sensitised paper cost me.

But, properly, the percentage should be taken on the amount of silver in the paper originally, and should not include the cost of the albumenised paper. I have no ready means of ascertaining this, but I imagine it would be about forty to fifty per cent., and probably more when larger quantities are operated upon.

W. HORSEMAN KIRKBY.

NOTES ON VARIOUS MATTERS.

I SEND a few notes, the result of several observations lately made. All the plates I took with me on a photographic tour last August, though apparently perfect on preparation, were entirely spoilt by a peculiar kind of spot, which generally gave density to the parts of the sky they affected and clearness to the shadows. On further keeping, the plates, on development, show clear spots only. This is my present experience. The plates prepared from washed emulsion had been washed previously to drying, without a preservative. In despair of any chance of success I wrote for some Liverpool emulsion. With this I prepared a few plates, but was only able to expose one during the next day—the result was spotless. This was a comfort, though I felt that "borrowed plumes" had something to do with success. Next day I exposed the remainder of the plates, fully expecting equal results; but fate had ordained otherwise, and I came to the conclusion, which experience justified, that I could not expect to secure passable results if the plates were prepared more than a few hours before exposure.

I was also sometimes troubled with numerous little purple-black spots in the lights, sky, &c. These appeared after fixing and drying, as far as I could discover. Then there were also black "stars and stripes." Sometimes this effect appeared to start from a nucleus, straight lines being drawn from this at various angles; sometimes the marking proceeded "herring-bone" fashion; and sometimes straight, fine, hair-like lines crossed each other at right angles, giving the idea that something more than chance operated in their formation. The hydrosulphite developer was used, and this leads up to another "note."

I do not find, as M. Sammann stated, that sodic hyposulphite ($SSO\,Na\,o_2$) is formed on keeping the bisulphite and sulphite solutions I use in long contact with zinc—even for days. No precipitate of sulphur is given with hydrochloric acid; sulphurous acid is alone evolved, proving the solution to contain a sulphite. In addition, the action of such a solution is more energetic than that of a solution which has been in contact for half-an-hour only, and generally produces fog. With this knowledge, when I wish part of a bottleful to keep well during a day or two I put a fragment of zinc into the bottle used for storing the hydrosulphite. This, I believe, resists the oxidising action which would otherwise set in.

I have been struck by another fact in connection with this developer. I have been using lately a pyro. solution containing a small proportion of tannin. On addition of the hydrosulphite solution to the alcoholic pyro. a drab-brown precipitation takes place, which continues during the development of a plate. The developer, on keeping, does not darken, as is usual; neither does it do so on addition of ammonia in small quantity. The precipitate appears to be insoluble, or nearly so, in water and in alcohol. I have not determined the action of the tannin, but believe that the usual discolouration ensued when the solutions were freshly made. The effect may be due to the formation of sodic sulphate, which, probably, is a powerful restrainer.

I have several times found ammonic sulphate to restrain powerfully; it acts vigorously in this way in keeping a collodio-*chloride* plate clean under the hydrosulphite development. I think I have already published the fact that washed silver paper which has not been exposed to light will give a clean image with the hydrosulphite developer. The albumen, probably, prevents too energetic action.

Now for the next "note." Mr. W. B. Bolton stated, not long ago, that he had obtained plates which transmitted a bluish light when dry and a yellowish light when wet. At that time my experience was the opposite to that just stated. I have lately prepared a plate or two from Liverpool emulsion (after the addition of a rather large dose of ether, and I note this) which act in a similar manner to Mr. Bolton's. It is a result purely due to the state of aggregation of the particles. Apparently, pyroxyline during drying may act either in bringing the particles closer together or in separating them. Very coarse films, however, may transmit a red or orange light. I find that a collodion which had been treated to a large dose of potassic carbonate and then to a similar haphazard addition of sulphuric acid, though giving a coarse, white film, still transmits mainly the yellow rays of a lamp. I see it stated in Watt's *Dictionary* that argentous citrate gives on heating the solution, which is of a red colour, first a green and then a blue colour, then depositing metallic silver. May not these colours be caused by metallic silver in different states of division?

This brings me to the next "note." I have been trying a few experiments with silver citrate. I find that if a nearly-saturated solution of silver nitrate be formed, and then crystals of citric acid in combining proportion (210 : 510) being added, a crystallisation takes place in the tabular form of silver nitrate. The effect is the same on heating moderately. If a small quantity of alcohol be added no change seems to be effected; but, on addition of a larger quantity, the transparent crystals become milky white. These are fairly soluble in water, but hardly at all so in alcohol. These experiments show what happens when citric acid is added to collodion emulsion containing free silver nitrate; the citric acid decomposes the nitrate, and nitric acid is set free. This latter in the nascent state is, probably, the cause of the removal of the fogging tendencies, and not the citric acid *per se*. On washing the emulsion the whole of the silver citrate is dissolved out—more quickly with warm water. If a plate containing silver citrate be washed, dried, and all the operations gone through, the film will be found riddled with pinholes and transparent specks. These are due to the silver citrate, after the film has set, being removed by the water. It is absolutely necessary to wash the emulsion before coating plates with it. It is possible that silver citrate may have advantages of its own as replacing silver nitrate for the formation of emulsions. By the addition of a soluble bromide to the silver citrate silver bromide is formed, the citrate of the base remaining in solution.

The mentioning of "bases" reminds me that the Editors appear to be somewhat in error as to the alleged capabilities of copper bromide. If they refer to Mr. Warnerke's experiments they will find that copper heads the list for "*intensity*," while in sensitiveness it is far behind—barium, zinc, calcium, and manganese being most favourable to sensitiveness. Calcium, lithium, and strontium were found not to fog; all the others did. Copper preserved "perfect transparency in the darkest parts." I thought my memory had not failed me *there*, so I turned to page 148 of the Journal for 1876.

While on this subject I would say I have remarked it as curious that so few appear to recognise the fact that, with zinc bromide *collodion* emulsion, *the silver nitrate being in excess*, plates may be obtained which, for all ordinary landscape purposes, do not require "backing" or a stained substratum. I have prepared a good, rich emulsion when using zinc and ammonium bromides in combining proportion. I never make any addition whatever to my plates, and they do not "halate" (if I may use the term) so much as many plates which have been "backed."

I omitted to say in an earlier portion of this communication that I trace the cause of the "stars and stripes" to the filtering material, which was wool—not the *American* article, but sheep's wool. The emulsion after standing some days, with shaking, fails to give these bad imitations of the national emblem! I would suggest well-cleaned glass wool, kept in a bottle, as a possibly-useful material for filtering.

Herbert B. Berkeley.

PRACTICAL INSTRUCTIONS IN MODERN PHOTO-MECHANICAL PRINTING METHODS.

Part I.—PHOTOLITHOGRAPHY.

V. Management of the Inking Rollers, and Further Treatment of the Fatty Image.—Before proceeding to subject our lithographic stone to any further treatment, it is necessary to provide at least one good inking roller, which, if new, will require a course of preparation before being fit for use.

If the student should not intend to begin his actual printing operations for a few weeks he had better purchase a new roller, and get it into working order himself; but if, on the other hand, he should wish to begin work at once, it will be better for him to buy a second-hand roller, or one which has undergone the course of preparation necessary to fit it for immediate use.

The lithographic roller, as generally employed, consists of a cylindrical core of wood about three or three and a-half inches in diameter, and ten or twelve inches in length. Each extremity of this cylinder is provided with a handle about four inches long and an inch in diameter. This wooden cylinder is covered with one or more layers of flannel, and over this is placed the covering of calf-skin which forms the working surface of the roller. This calf-skin covering is sewed together so as to form a tube a little longer than the body of the roller, and those parts of the leather tube which project beyond the cylindrical part of the roller are drawn together by means of cords interlaced in the ends of the leather covering. In the case of the ordinary lithographic roller, intended for line or crayon work, the flesh side of the skin is placed outside; but in the case of rollers intended for colour work, or for certain other special uses, the flesh side of the skin is turned inwards. The projecting handles of the roller are usually provided with loose leather covers, intended to protect the hands from continual friction against the wood.

In selecting a new roller care should be taken that the skin is uniform in thickness and even in texture. It often happens that some parts of a roller are soft and spongy, while other parts are compact and close in the grain; but this state of things is very inconvenient when fine work is to be inked with the roller, as the soft parts tend to deposit more ink than those which are harder and more compact.

The roller having been selected, the next step is to prepare it, or so to saturate it with lithographic varnish or printing ink as to prevent its absorbing any undue amount of moisture during the process of printing. Before commencing the operation of saturating the leather of the roller with fatty matter it is well to see that the roller is quite dry, and if it have remained in a warm room for a few days it will be in a better condition to receive the fatty matter than if the preparation were commenced immediately on receiving it from the warehouse. Lithographic varnish, which is used to saturate the skin of the roller, consists merely of a very carefully-prepared boiled linseed oil; and the consistency of this varnish varies according to the purpose for which it is intended. The most generally-useful varnish is known as "middle varnish," this having about the viscosity of ordinary golden syrup, while a thinner kind is sold as "thin varnish;" and a still less viscous preparation is procurable under the name of "tint varnish," or "S. H. varnish." Thicker varnishes, sold as "strong" or "extra strong," are often required. The new roller, having been well worked in middle varnish, is left at rest till the next day, in order to allow the fatty matter to penetrate into the pores of the leather. On the next day the surface of the roller is well scraped with an ordinary table knife, which ought not to be extremely sharp; and during this operation great care should be taken not to cut or otherwise damage the surface of the roller. The roller is then well worked backwards and forwards on a slab charged with a fresh supply of varnish, and after a day or so has elapsed the operation of scraping must be resumed. These operations should be repeated every few days until the leather becomes thoroughly saturated with the varnish; and the time requisite for this will depend not only on the character of the leather, but also on the extent to which the operations of rolling and scraping have been practised. When the leather covering of the roller becomes soft and rather elastic to the touch the preparation may be continued with a mixture of equal parts of lithographic printing ink and of varnish. After a preparation extending over a week or ten days the roller will be fitted for rough work consisting of clear, bold lines; but, as an insufficiently-prepared roller requires to be charged with a considerable amount of ink in order to protect it from the effects of moisture, such a roller cannot advantageously be used for the inking of delicate subjects which contain approximations to half-tone, as an unduly-charged roller would certainly clog up and destroy the more finely-shaded parts of such subjects by gradually overloading them with ink. After a roller has been in use for some time—especially if it have not had sufficient preparation—it is frequently necessary to allow it an interval of rest, in order that traces of moisture which have been absorbed during the operation of printing may be permitted to evaporate. It will naturally be understood that the occasional using of a roller, together with the cleaning and scraping required to keep it in working order, amount to the same thing as continuing its preparation.

If the student should determine to purchase a second-hand roller he should take care that the skin is not worn thin in parts, and that it is free from indurated ink. It sometimes happens that an old roller is so thoroughly sodden in varnish or ink that all the grain of the leather is gone, and the surface of the roller feels dead and totally inelastic. Such a roller should be rejected. The second-hand roller must be scraped, and then carefully wiped with a cloth moistened with oil of turpentine, after which it may be charged with a mixture of ink and varnish. Any parts of the surface which are slightly indurated must be softened by rubbing with a wire brush or with powdered salt.

Having now provided an inking roller* which is in good working order, and is uniformly charged with a thin film of ink, we now proceed to soften the gum covering of our lithographic stone by gently sponging it with water. When the whole of the gum is dissolved the surface of the stone is freed from the excess of water by means of the sponge; and care should be taken, while the stone is uniformly damp, that there are no drops or ridges of water projecting beyond its surface. The inking roller is now worked backwards and forwards over the surface of the stone, a considerable pressure and a slow rate of motion being employed. Under these circumstances every part of the device should become fully charged with ink, even to repletion; and no tinting of the whites of the stone ought to occur if all the operations have been properly conducted. Every

* Many attempts have been made to introduce india-rubber rollers for lithographic printing, but with varied success. Quite recently Messrs. Blades, East, and Blades have introduced an india-rubber roller which bids fair to do much towards the disestablishment of the usual leather roller. The new roller, manufactured under a patent of Mr. Lanham's, consists of a rigid stock clothed with a moderately-thick layer of red india-rubber, which is vulcanised after having been put on the stock; and this india-rubber covering is finally worked to a true surface on the lathe. This kind of roller has the advantage of being always ready for use, and it can be rapidly cleaned by gentle friction with a cloth moistened with oil of turpentine, after which it may be immediately used for another coloured ink. For occasional use there can be no doubt as to the superiority of a properly-made india-rubber roller over a leather one. More will be said regarding the various kinds of india-rubber rollers when the subject of collotypic printing is brought under consideration. Those who wish to experiment on this subject may, in the meantime, cover an ordinary lithographic or typographic roller with a sheet of red vulcanised india-rubber, the edges of the india-rubber being cemented together so as to form a tube. An india-rubber roller requires far more frequent feeding with ink than an ordinary roller; as in the case of the former the ink lies only on the surface, while a leather roller is saturated with ink to a considerable depth below the surface.

part of the image having been thus thoroughly charged with ink a rapid motion is imparted to the roller, and the pressure on it is at the same time reduced. This quick rolling is continued until all excess of ink is removed and the image is seen to be clear and sharp. In the case of a bad transfer, or of one carelessly put down on the stone, it will often happen that some portions refuse to take the ink in a satisfactory manner, the lines appearing grey and spongy. When this is the case it is generally best to make a fresh transfer and to be more careful with the manipulations; but the defective parts may often be improved by covering them with mucilage and then rubbing them with a little palm oil spread on a piece of rag, after which treatment the inking is repeated.

The stone is next flooded with water, and any ink-marks on the edges are removed by friction with a piece of pumice or of snake stone, after which the lithographic stone must be reared up to dry. When dry it is to be dusted over with finely-powdered resin, and the excess of this substance is removed by means of a broad camel's-hair brush. The stone is now ready for the acidulation or etching, and a convenient mixture for this purpose is made by dissolving ten ounces of gum in fifty ounces of water, and then adding one ounce of strong nitric acid (s.g. 1·42). The stone being placed horizontally, the etching mixture is freely applied by means of a soft brush, and this having been done the stone is ready for the press. If, however, the printing operation is not going to be performed at once, it is as well to cover the face of the stone with a layer of gum in order to prevent damage if any fatty matter should come in contact with it.

The amount of acid in the etching fluid may vary greatly according to circumstances; but a careful observation of the effects of over-acidulation or under-acidulation will enable the student to regulate the strength of the acid which he makes use of. When the etching fluid is too strong the finest lines of the subject or the most delicate gradations are removed, despite the resinous coating, which is intended to act as a bulwark against the destructive action of the acid. If, on the other hand, there be not sufficient nitric acid in the etching fluid the stone will generally be troublesome in printing, the lines tending to spread out and become thicker, and the whites of the stone tending to take the ink and to become tinted. A bold subject, containing no fine lines, should be very strongly acidulated, as there is but little fear of injuring it, and the strong acidulation renders the printing easy and rapid.

The operator must not lose sight of the fact that during warm weather the etching fluid rapidly decomposes and becomes very much more acid than when freshly made; and, as a high temperature also conduces to render the action of the acid more energetic, the effects of over-acidulation are more likely to be met with in the summer than in cold weather. It is also important to bear in mind that ordinary mucilage of gum arabic becomes acid by long keeping, and the careless use of very sour mucilage may lead to inconvenience and to the injury of delicate subjects. Fine subjects may often be advantageously etched by means of sour gum, applied after the first inking in, and dusting with resin.

Before adjourning the case for a fortnight, when the actual printing operations will be considered, we must provide for the safety of the stone and the roller. The stone is supposed to be gummed, and is so far safe, only it ought not to be exposed to any very direct heat from a stove or the gum may scale off, carrying with it small portions of the lithographic stone. The roller having been scraped, and wiped with a cloth moistened with oil of turpentine, is next covered over with an exceedingly thin film of tallow, by rubbing with a cloth saturated with this substance. Before recharging the roller with ink the tallow must be carefully removed by scraping and friction with a rag moistened with turpentine.

T. Bolas, F.C.S.

NOTES ON PASSING EVENTS.*

By a Peripatetic Photographer.

What *can* be done in order to make the wheels of the medal-award system run smoothly? It is very painful to read about jurors displaying favouritism or partiality in making their awards; but seeing that opinions, whether rightly or wrongly, are entertained by many that there is something rotten in the system by which awards are now made, it may be well to inquire in what manner such grievances may have their *raison d'être* removed. Partiality implies a strong feeling of friendliness existing between the exhibitor and the juror; and owing to such feeling the juror, it is presumed, cannot very well afford to pass over his friend, who might thus be converted into an open or covert foe. Not only so: he may not even dare to make an award to some really deserving exhibitor because it might give offence to his own friend interested in having the former kept in the background. The remedy for such a state of matters is very simple indeed; but it demands more courage for its adoption than is usually found to prevail among the managers of medal-awarding bodies. It consists simply in securing the services of qualified jurors who, coming from a distance, have no knowledge of, and sufficient force of character not to care for, private and personal interests. For example: suppose that, for once, this system were applied to the awards connected with the Photographic Society of Great Britain. Several eminent men of the very highest character for competence and skill could be brought together to act as a jury who would scorn to be influenced by partisanship; at anyrate, the public would accept their *dicta* as having been given untrammelled by any private considerations. The expense would be nothing compared with the advantages; indeed, it may be questioned if such jurors would not willingly defray their own expenses in recognition of the implied honour. Till some such course as this is adopted I fear that a large proportion of those well able to produce prints for exhibition will decline doing so. "Desperate diseases require desperate remedies." The adoption of the course indicated might be taken as a confession on the part of the managers of such a society as that named that they recognised the justice of the aspersion thus cast upon their personal honour; but it would give great satisfaction to many photographers, and immensely increase the number of contributors to these annual exhibitions. Referring for a moment to the non-award of a medal by the jurors in Class XII. at the Paris Exhibition, for the reason hinted at by Mr. A. L. Henderson: the affair seems one that should be brought into the full light of day. The charge is an ugly one, and the public expect that some notice of it shall be taken by those interested. It is said that correspondence exists which, to some extent, bears out the charges that have been made.

* Concluded from page 518.

Of all the examples of impracticable ingenuity which have appeared during the past month that displayed in the production of "plastic" pictures stands unrivalled in absurdity. Instead of making use of a round aperture in the diaphragm of the lens, as determined by theory and common sense, and in practice found to be best, Herr Paul Gliese imagines that he obtains better results by making use of apertures of various fantastic forms than by adhering to that furnished by the optician. This far exceeds a small but similar absurdity that wellnigh became epidemic a good many years ago, and which took the form of making the aperture in the diaphragm of such shapes as keyholes, bottles, vertical and horizontal slits, crosses, and soforth. This nonsense soon passed away, and English photographers, like men of sense, relegated such things to the limbo of forgotten whims; but *now* an aggravated type of the same disease is breaking out on the continent. I would suggest as something different from any of these diaphragms one formed of nickel silver electro-plated and perforated with holes similar to the rose of a garden watering-pot. This would possess at least the attribute of novelty, and most certainly answer the purpose quite as well as any of the methods suggested.

Observing from the annual report of the Manchester Photographic Society that Mr. D. Young exhibited a "Keevil's lantern, *perfected*," I am tempted to inquire in what respect it has been rendered "perfect," or, to use a better term, "improved." When Mr. Keevil achromatised the rectangular prism by which the side light of one of the elementary portions of the lantern is converted into direct or front light he, in my estimation, gave the finishing touch to what must be admitted is an ingenious and very effective instrument. Now that the magic-lantern season is approaching—nay, has already arrived—one is naturally desirous of being made acquainted with every improvement to which this amusing and instructive piece of optical apparatus is subjected.

NOTES FROM AMERICA.

Attaching Photographs to Glass —Posing Chairs.—Rustic Studio Appliances.—Rock Scenes.—Imitating Snow.

On the authority of the *Scientific American* we give the method of attaching photographs to glass and making them transparent adopted by Mr. W. Watson, of Harriston, Canada:—

Allow the photograph to remain in water till thoroughly soaked, then place between blotting-paper. It should remain until it is just damp enough to be pliable. Then coat the face of the picture with good paste made from flour or starch, and lay face on the glass. Commence in the centre of the picture and rub outward toward the edges to dispel all air or paste. Be very careful not to get paste on the back of the print.

Keep it damp with a sponge until the rubbing is finished, being careful not to break the surface of the paper. When perfectly dry lay on a heavy coat of castor oil, and it will soon afterwards become transparent. If you get too much oil rub off the surplus with a cloth. Allow it to stand for a day or two, when it may be coloured.

Apropos of posing and posing chairs, upon which topics Mr. John L. Gihon has been treating in the *Photographic Rays of Light*, that writer observes:—

These posing chairs are generally very ingenious contrivances, but photographs into which they are introduced seem to carry with them the very odour of the operating-room. They are too unmistakably conventional in character. A great deal of care is bestowed on the principle of raising and lowering the back. As much attention should be extended to the seat of the chair. There are human beings whose nether extremities are decidedly long, as well as there are those who are endowed with "elegies" tending in the other direction. The one height of stool is neither comfortable or becoming to all classes.

I have seen a pianist's chair that would be most useful in a studio. The seat and back are joined together, and are elevated or depressed simultaneously by turning them around upon a central screw. No arrangement can be more simple or satisfactory. It used to be a prevalent idea that actors and actresses clothed in shiny muslins or cambrics, whilst on the stage and at a distance from the audience, would look equally as well dressed as if clad in silks and satins. In my boyish days I remember on several occasions hearing the talk of those who were about to sit for daguerreotypes. They always claimed that gaudy designs, and not a superior quality of fabric, were all that was necessary to adorn one's person. The principle in both cases was that a sham could be made to answer the purposes of a genuine article. So in the furnishing of operating rooms I have frequently seen accumulations of shams that were expected to successfully take the place of good, solid cabinet-ware. A book-case, writing-desk, sideboard, table, and no end of other accessories are formed by the movement of the various parts. The arrangement reminds one of a box of building blocks. The sham in this case, too, is apparent, and cultivated tastes will not, in any of these instances, admit of the imposition.

All rules, however, admit of exceptions, and so does this one. Outside or landscape effects can be successfully imitated. The forms of the object that surround the figure are broken in character, and, as particular sharpness is not desirable, it is difficult when looking at the photograph to decide of what material they are composed.

Rustic Accessories.—An entry in my diary declares that I had spent the greater part of the week in the construction of rustic accessories. Of all the work in connection with our business this can be counted upon as being the dirtiest. You use a great deal of glue; that sticks to your hands and clothing. You are continually handling powders of various colours; they adhere to the glue. In fact, your person receives a fair share of all that is consumed in the manufacture.

Studio Grass.—When first we commenced to make rustic pictures it was some time before a good imitation of grass suggested itself. Ultimately some happy wight of a photographer must have wiped his feet upon one of those large Indian mats that have long shreds of grass woven into them. Their suitability for our purposes occurred to him at once. His discovery became known, and his ingenuity was rewarded by every one in the craft copying his idea, or rather adapting it to his own use. Nothing can be better.

Rocks and Stumps.—The making of rocks and stumps of trees is a more serious matter. The real articles are, of course, inadmissible on account of their weight. In one of my galleries I had reserved a sky-light room which I used for no other purpose than the production of these landscape effects. In it I accumulated an immense amount of stuff that a tidy housewife would doubtless have entitled "trash." I had rocks (?) six feet in height. Upon one occasion I built up quite an extensive grotto. It took up the entire width of an ordinary background. When finished and tried I became disgusted with it; but, contemplating its shape and pondering over the matter a few moments, I made up my mind that it could be utilised. I sawed it in half, and with a few alterations that readily suggested themselves I found that I had a splendid rock, and the trunk of a tree almost large enough to represent one of the Californians. These articles must be made strong enough to be tumbled about, to stand rough usage, to be sat or stood upon, and yet light enough to be easily handled. The most generally useful form that I know of is a rock to one end of which is attached the stump of a tree. The top of the rock should be large enough for a grown person to sit upon comfortably, and the stump should rise above it high enough to allow the arm to rest easily upon it. To construct such a contrivance, procure an empty, well-made packing-box, two and a-half feet in length, eighteen inches in width, and twenty inches in height; knock off the lid and turn it bottom upward. Remember that all superfluous weight is to be avoided. Within about six inches of one end, and at an angle, bore a large hole and drive into it a stout stick that will have an altitude of twelve inches. Make a disk of wood about six inches in diameter, bore out its centre, and let it drop to the base of the stick. Nail a round cap upon its top, four inches in diameter. To this top cap and to the lower disc nail strips of lath around their entire circumference. You now have before you an oblong box surmounted by a sort of leaning tower. They are indispensable foundations for that which is to be, but, I own, not very attractive ones. The next effort must be to break up the straight lines of the model. Procure a number of sheets of the stoutest and toughest wrapping-paper you can obtain; also a quantity of any sort of cheap packing, corn-husk strippings, old newspapers, shavings, or, in fact, whatever worthless stuff may be at hand. With this rubbish make piles, ridges, or whatever shaped inequalities of surface suggest themselves to you. Secure them in position by tacking over them the heavy paper. Pay attention to the forms of natural objects, and don't make your rock look like a meal bag. Wrap some of this loose material around your stump that is to be, and to its base attach a couple of snake-like appendages that will answer for roots. Don't try to make this part of your work smooth in appearance. The rougher it is the better, so long as the forms you create are possibilities. Since everything is so easily altered whilst in this condition, be sure that you are thoroughly satisfied with its shape before you advance further. When ready, soak some stout muslin, or, better still, light canvas ducking, in a kettle of strong glue water. Take it out, all dripping, and spread it loosely over your model; then with pieces of wood, shaped like chisels with blunt edges, fashion your covering to the inequalities you have already planned. Maintain sharp and angular edges as much as possible. The tree stump must have its imitation of bark made up of wrinkles or ridges. The top of the rock—that part which is intended for the seat—can have the ducking drawn over it smoothly. In doing all this forget personality and all care of your clothes. Before you commence you must make up your mind to get dirty. Put your whole attention to the work. As the glued canvas becomes about half dry it is in the best condition for modeling into shape. If you have spent much time over this stage of the work, and portions of it have already become stiff and hard, you had better let it rest over until the next day. Then tack down all loose edges, and make whatever corrections in shape you think would be beneficial. You can next procure some paints, in powder, of sombre colours, such as raw umber, Vandyke brown, light red, dark green, black and white. Paint your "bit" over with more glue sizing, and upon the wet space sift the colours with as near an approach to their proper natural position as you can reach. It is not necessary or proper to use these colours singly. Combine them together. When you wish to lighten them in tone, add white; to darken, add black. When you get to the stump incorporate a considerable amount of green to your compound. A sprinkling of finely-broken-up *mica* upon the rockwork will do much to heighten the effect. As a finality, I would suggest that the top or flat surface of the rock should be painted in oil colours, also the top of the stump. No matter how well the glue takes hold of the powders there is still a possibility of a portion of them adhering to the dresses or clothing of the sitters. When in use such a piece as I have been endeavouring to describe can be much enhanced in value, or rather denuded of much of its bare appearance, by throwing upon or around it strips or remnants of one of the mats I have spoken of, and that had most likely been condemned to be thrown away. Those stray bits are often more useful than the perfect mats. I have often been accused of wanton destructiveness when I have been seen slicing one into all sorts of shapes. My description of the making of this particular rock is certainly sufficiently clear to act as a guide for the manufacture of others. I neglected to state that in the make-up of the picture still greater improvements in effect can be obtained by the introduction of light vines made up of artificial leaves. The great trouble is that in all photographs of this class the photographer has a tendency to overdo the matter. A little stuff well placed is far better than a great deal when put where it should not be.

Rustic Bridge.—There is scarcely a limit to the number of effects that can be readily produced with but slight changes of accessories. A rustic bridge over a brook makes a charming scene for children from five to ten years of age. One or two sheets of zinc laid upon the floor will give an excellent imitation of water. The banks of the stream can be represented by some of our mats, and a few pieces of real stone will serve to hold it in place and to break up the foreground. A plank with some pine bark nailed to its front edge makes an excellent bridge when its ends are rested upon chairs that are concealed from view. Let a child sit upon this, holding a short rod in his hands, with a string dangling from it and a cork resting upon the zinc, and you have a very pretty *genre* picture of a fishing-scene. It is often possible to introduce real bushes into these composition effects, but unless your gallery is a large one I should not advise you to go too extensively into these specialities.

Snow Scenes.—Many of you have seen the really fine "made-up" photographs published by Mr. William Notman, of Montreal. They are almost all of winter hunting scenes. Many novel practices were resorted to, and much ingenuity displayed in their production. Briefly, when salt is carelessly thrown over the clothing and accessories you have a very good imitation of snow. Falling flakes of snow can best be imitated with the aid of one of the little bottles such as perfumers, druggists, and barbers use for scattering essences. You fill it with a solution of Chinese white instead of perfume, and, squeezing a spray of it into the air, hold the varnished side of your negative half vertically under the falling drops. The effect is naturalistic in the extreme. I was told by one of the *employés* of the establishment that the camp-fire effects were produced by placing a magnesium lantern in the centre of the group.

FOREIGN NOTES AND NEWS.

ERRATUM IN LAST WEEK'S *NOTES.*—DR. BOETTGER'S JUBILEE.—GLYCERINE CEMENT.

OWING to a clerical error made by the present writer in the first paragraph of *Foreign Notes and News*, in last week's number, "*talc*" is mentioned amongst the adulterants of wax along with rosin, stearine, &c. The list ought to read starch, flour, gypsum, pipeclay, sulphur, rosin, stearine, and *tallow*. In the table which follows, the ridiculous statement is made that the melting-point of pure talc is 37° to 40° C. That should, of course, also be read "pure tallow melts at from 37° to 40° C.", and wherever else in that unfortunate paragraph the word "talc" stands "*tallow*" ought to take its place. The error in question was not observed in time for correction, as the Journal had already gone to press.

The well-known chemist, Dr. Rudolph von Boettger, of Frankfurt-am-Main, who has rendered so many services to chemistry, photography, and the allied sciences, has just celebrated the fiftieth anniversary of his appointment as professor of chemistry and natural philosophy to the *Physikalischen Verein zu Frankfurt.* The celebration took the form of an academical banquet, at the close of which the learned doctor was decorated with the insignia of the order of the Red Eagle on behalf of the Emperor of Germany, and presented with a valuable silver tea service by his friends and pupils. Representative deputations from many universities, academies, learned societies, and corporate bodies took part in the festivities.

The *Rep. de Pharmacie* gives a formula for a glycerine cement suitable for cementing all sorts of metals, even in the form of pumps and steam boilers, as it can withstand the action of a temperature of 275° C. It may also be used as type for galvanoplastic purposes, as it reproduces with delicacy and fidelity the surface of the copy, and is easily made a good conductor. Before the application of the cement the parts that are intended to be dense should be carefully cleaned and coated with dilute glycerine. The cement, as it comes into the market, is made by mixing ordinary glycerine with the greatest care with washed and sharply-dried litharge, in such proportions as to form (according to the purposes for which it is required) either a stiff paste or a thickish liquid, which quickly hardens into a homogeneous mass.

ALL IN A CARTE.

SCENE—*The Waiting Room of a Publishing Photographer's. Popular Celebrities discovered in Readiness for their Sittings. Enter* Mrs. Peacock, *who is received by* Polite Employé *at the door.*

POLITE EMPLOYÉ: We are rather busy this morning, madam; but, doubtless, you come by appointment?

Mrs. Peacock: Certainly *(giving pasteboard).* Here is my card.

Polite Employé (looking at his list): Oh, yes, of course, the lovely Mrs. Peacock! I trust, madam, that you have brought a ball dress with you? Mr. Kammerer particularly wishes to take at least one of the portraits in *décolleté* costume.

Mrs. Peacock: My maid has, I believe, the larger part of my wardrobe in boxes in the hall.

Polite Employé: A thousand thanks, madam! Mr. Kammerer will have the honour to attend upon you immediately.

Aristocratic Bride (in white satin and orange blossoms): I trust that Mr. Kammerer will see me as soon as possible. I have been waiting here for some time.

Polite Employé: Certainly, my lady, certainly. But you see there will be a greater demand for Mrs. Peacock's *carte* than for yours for the moment. Mr. Kammerer thinks it better to keep your ladyship's picture back until after your ladyship's marriage. It will be published simultaneously with the account of your ladyship's nuptials and wedding presents in the morning papers.

Aristocratic Bride (with an unpleasant look at Mrs. Peacock*):* I can't help feeling that Mr. Kammerer is neglecting me for others.

Polite Employé: On the contrary, my lady, Mr. Kammerer is most anxious to take a really popular portrait of your ladyship. He has ordered a special background, representing the castle in which your ladyship purposes spending your honeymoon.

Mrs. Peacock (with a scornful glance at Aristocratic Bride*):* I must have a castle in the background, too! If Mr. Kammerer does not provide one, I shall go off at once to Messrs. Strutt and Stareleigh. They have been boring me for weeks to give them a sitting.

Polite Employé: Certainly, madam. You shall have any background you please; although Mr. Kammerer thought that perhaps the seashore would be appropriate to one of your *cartes*—with, perhaps, a bathing-machine in the middle distance.

Clerical Dignitary: I hope Mr. Kammerer will not keep me waiting *much* longer. I have a missionary meeting to attend, and—

Polite Employé: Certainly, my lord. I think you wish to be taken in your vestments. (Clerical dignitary *looks displeased.)* I beg pardon. I was mixing up your lordship with the Ritualists. I should have said lawn-sleeves.

Miss Sallie Plantagenet, née Sarah Snooks (entering briskly): Now, then, young man, look sharp! I have got a rehearsal on at the Revelry Theatre at eleven, and I shall only just have fifteen minutes to slip on my togs, give the guv'nor a sitting, pop into my brougham, and get to the stage door in time to save a fine.

Aristocratic Bride, *Mrs. Peacock*, *Clerical Dignitary* } together: { Surely, Mr. Kammerer will not presume to give this young person a sitting before any of us.

Miss Sallie Plantagenet: Come, I say, who are you calling "a young person?" As young as you please—but person, indeed! I am sure my *cartes* sell just as well as Mrs. Peacock's, or any of the swell beauty-women; and as to the Bishop's, why he's just nowhere. But there, don't let's quarrel. I daresay this young man will settle it for us somehow. Won't you, my dear?

Polite Employé: Certainly, madam, I hope your ladyship will excuse the delay. *(To* Mrs. Peacock *and* Aristocratic Bride): Oh, pray don't think of going, ladies. Mr. Kammerer will be so distressed, and the public will be so disappointed! Oh, do think of Mr. Kammerer and the public!

Miss Sallie Plantagenet (good naturedly): Don't get the poor young man into trouble. And why should you and me quarrel (*to* Bishop), when we shall be all next door neighbours in the shop windows for the next two years? (*To* Aristocratic Bride): Look here, you are ready, and she (*pointing to* Mrs. Peacock) is readier than me, as *I* have to make up my face and get into my never-mention-'ems, so you two shall be taken first; and, by the time you are done, the Reverend gent and me will be ready. There, that's real jam! Don't you see—while Kammerer is knocking off your two be-oo-tiful nobs, the Bishop can be putting on his lawn sleeves, and I can be getting into my tights.

(Scene closes in upon the arrangement.)

—Punch.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
November 12 ..	Photographic Soc. of Gt. Britain	5a, Pall Mall East.
,, 13 ..	Glasgow	172, Buchanan-street.
,, 13 ..	Cheltenham Amateur..........	Savings' Bank.
,, 14 ..	Manchester	Memorial Hall, Albert-square.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE monthly meeting of this Association was held on Thursday evening, the 31st ult., at the Free Public Library, William Brown-street,—Mr. H. A. Wharmby, President, in the chair.

The minutes of the previous meeting were read and passed, and Mr. W. D. Meade was elected a member of the Association.

Mr. J. A. Forrest exhibited some fine photographs of lake scenery, and Mr. Potter and Mr. Clarke showed a number of capital pictures taken during the summer.

The Secretary called attention to two prints from the same negative by Mr. W. E. Potter. One print was from a negative before it had been improved; the other from the negative after it had been varnished on the wrong side with matt varnish and then painted with a wash of yellow water-colour over the heavy shadows, foreground, &c. By these simple means a result had been obtained which made a decidedly more artistic and beautiful picture.

Mr. W. H. Kirkby read a short paper *On Recovering Waste Silver in Printing* [see page 532], and the Rev. H. J. Palmer one on *A New Cure for Blurring.* [See page 517 in last number.] Several negatives illustrating the latter paper were handed round, but it was thought that the cure was not an absolute one.

The Secretary exhibited some prints and a negative to show the qualities of the "Waverley" plates.

The Rev. H. J. Palmer showed some prints from Swan's plates, which indicated the advance that had been made in dry plates in being able readily to secure pictures including children and animals. Mr. Palmer also showed some capital transparencies from Swan's plates developed with the ferrous oxalate developer, and recommended it highly. He had used the developer over and over again for at least fifty negatives during the past six weeks, only once restoring its vigour by boiling down. It worked then as good as ever, being kept in order by adding pieces of iron wire to the solution.

It was announced that the Association would take part in the intended associated *soirée*, to be held before the close of the year in St. George's Hall.

Mr. L. W. Weber exhibited the Chadwick oxygen generator, and illuminated by it the sciopticon. The Rev. H. J. Palmer also showed by its aid a large number of transparencies which he had mentioned in his late paper on *Switzerland from a Photographic Point of View.*

After hearty votes of thanks to the Rev. Mr. Palmer and Mr. Weber, the meeting was adjourned to the 28th ult.

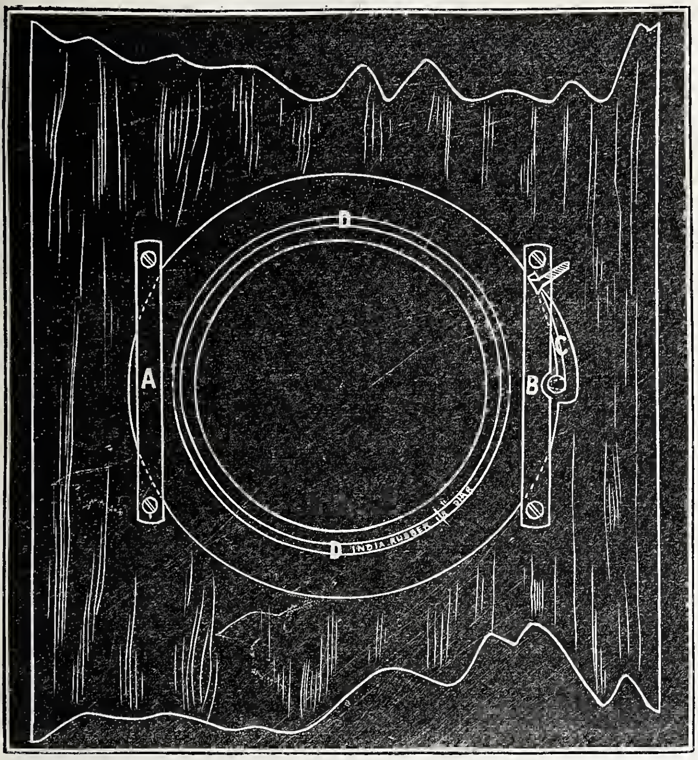
Correspondence.

IMPROVED CAMERA FRONT.

To the Editors.

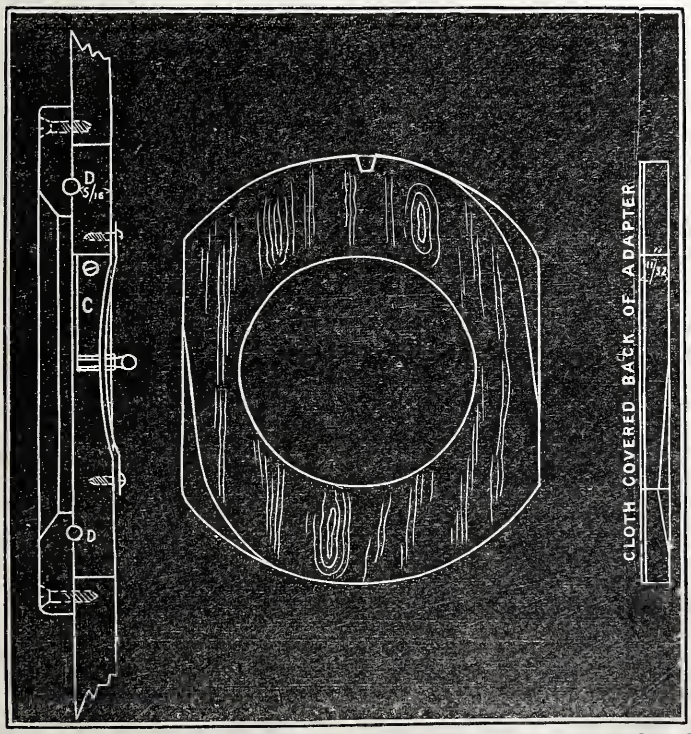
Gentlemen,—I herewith enclose a plan of an arrangement for camera front and adapters. Having made one and used it, and being perfectly satisfied with it, if you think it would be interesting to the readers of the Journal you are quite welcome to publish it.

ELEVATION OF CAMERA FRONT.



The brass plates A and B are slightly curved inwards to act as springs to keep the adapter against the india-rubber ring D. The adapter is secured when in position by a spring catch C, on which is a projecting button by which the spring may be released.

VERTICAL SECTION. ELEVATIONS OF ADAPTER.



The adapters are made of mahogany, backed with cloth and slightly chamfered at opposite corners (as shown in the plan), so as to pass under the side springs A and B.—I am, yours, &c., Sam. Bamforth.

Hollingworth, Hadfield, Manchester, November 5, 1878.

THE BRISTOL SOCIETY'S REPORT.

To the Editors.

Gentlemen,—I write from Paris (where I have had The British Journal of Photography forwarded) to set at rest the mind of your disinterested and affable correspondent, the "Peripatetic Photographer," who, I am glad to see, regrets the expected loss from your columns of our Society's proceedings and discussions.

But we are not going in the slightest degree to lessen the contributions to your Journal of our reports of proceedings; they will continue as before, our own Association journal being a separate and additional (not substituting) matter.

With kind regards to your jolly old "Peripatetic," who is so fatherly,—I am, yours, &c., H. A. H. Daniel,

Paris, November 6, 1878. *Hon. Sec. B. and W. of E. A. P. A.*

"A NEW STUDIO."

To the Editors.

Gentlemen,—My old friend Werge has discovered a "mare's nest.' If he will consider the above heading as equivalent to "a newly-built studio" he will see all I mean. I know well the principle is "as old as the hills." Besides seeing Mr. Werge's studio I have inspected two others before building mine.—I am, yours, &c., Samuel Fry.

Surbiton, November 5 (Guy Fawkes' Day), 1878.

Miscellanea.

Photography in Court.—At the Bloomsbury County Court, on Friday last, the 1st inst., the case of Watkins *v.* Hooper was heard before the presiding judge to recover the sum of £1, being the alleged balance due by the defendant to the plaintiff. The plaintiff (who conducted his own case) stated that he was a photographer residing in Bristol, and during the defendant's residence at Newport he (the plaintiff) was instructed to enlarge a certain family portrait, and to colour it in oil. After executing the order he sent it to the defendant, accompanied by an invoice for the arranged price, £6. No complaint was made; but in August last year he received from the defendant, who now resides in Great Portland-street, London, a cheque for £5, which was acknowledged. He (the plaintiff), however, on reference to his book, found that the defendant still owed him a balance of £1, for which he applied, and, not receiving any satisfactory reply, the present proceedings were brought.—The defendant said no charge was agreed upon, but he sent to the plaintiff the cheque in full satisfaction of his claim, and he could prove by the evidence of skilled witnesses that such sum was a sufficient payment.—At this stage of the case his honour said he need not do so, as the plaintiff, by accepting the cheque and cashing it without returning it, in point of law received it in full satisfaction. Judgment was entered for the defendant, with costs.

A Photographic Recollection.—The imagination of some people is simply wonderful. Those who are familiar with the comedy of *Masks and Faces* will find this fact strikingly illustrated. We have in mind something similar. To copy, finish in ink, and frame a picture of an elderly lady was our order. We had executed the first and second stage of the work; but, before framing it, the parties came to see if it was all satisfactory. It was not. The son of his mother said "the hair came down too low on her forehead, and the chin was not double enough, and it seemed to him that the laughing line at the left corner of the mouth was a little too deep." The daughter, who seemed to remember her mother very well, said "that, somehow or other, it kinder did and didn't look like her." The faults her brother mentioned she couldn't agree with. "Mother never had no double chin, nor no laughing lines around her mouth; and as to her hair, which was nothing but a wig, she always wore it very low to cover up a scar." She thought, "if anything, it was too much like the copy, and didn't have mother's expression at the time she died!" We assured the gentle critics that, by calling a few days later, we would try their suggested alterations, and hoped to answer their very reasonable requirements. The time passed so rapidly that, amid other engagements, we forgot the promised changes until the morning it was to be called for, so, slipping the picture under a mat and into the selected frame, awaited the second examination and verdict. We were just in the "nick of time," for our customers stood before us at the counter. Holding up the maternal features in a good light, we watched the play of expression which came and went and came again, till both they that were divided at the first conference were now of one mind, to the effect, that the alterations made had rendered the picture so "natural like that it seemed as though mother would speak!"—*Anthony's Bulletin.*

EXCHANGE COLUMN.

No charge is made for inserting these announcements; but in no case do we insert any article merely *offered for sale*, that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a *nom de plume* be thought desirable), otherwise the notice will not appear.

Wanted to exchange, a splendid first-class electric machine, ebonite disc on mahogany stand, for a tourists' pocket set of apparatus.—Address, D. B., 248, High-street West, Sunderland.

A good half-plate copying camera, with slide, screen, and a full-plate glass bath, with dipper and box, offered in exchange for a good three and a-half inch condenser, suited for enlarging.—Address, J. R., 11, Briggs-street, Arlington-street, Salford.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

Notice.—Each correspondent is required to enclose his name and address although not necessarily for publication. Communications may, when thought desirable, appear under a *nom de plume* as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

PHOTO-MECHANICAL CORRESPONDENCE.

Lex.—The patent is no longer in force.

S. Smith.—Your stone was probably too hot, and the gelatinous coating was certainly thicker than necessary.

Zinc Biter.—Typographic etching on lithographic stone was practised by Senefelder and the earlier lithographers. Many attempts have been made to revive it, but metal plates appear to be better adapted for this kind of work.

David.—You must not expect to get over all the difficulties of lithography without careful study. The works of Senefelder and of Hullmandel can be consulted at the Patent Office library, or you may be able to get second-hand copies. Lithography has only been brought to its present state of perfection after many failures and patient investigation.

GENERAL CORRESPONDENCE.

Errata.—In our article on *The Surfaces of Film Supports* in last number, page 517, second column, line nine, for "and" *read* "as."

M. J. R.—Chloride of strontium is soluble in water, alcohol, and probably many other liquids.

F. R. S.—1. The book is scarcely worthy of the reputation of its author.—2. Try Messrs. Beneman and Wilson, Philadelphia.

W. Weston.—Both dealers named are highly trustworthy, and either will serve you to the best of his ability. We speak from personal knowledge.

G. T. C. B.—Let the camera be stationary, and mount the mirror equatorially. This will provide an enlarging camera possessing a maximum degree of comfort and excellence—so far, at anyrate, as concerns the nature of its construction or design.

F. M. S.—The two ladies cannot possibly be the same, notwithstanding the similarity of the name. The one enclosed by you seems young and fair, whereas the other is —— well, we are not judges of feminine charms, and may be trenching upon dangerous ground.

Fred. (Jun.)—1. You are quite mistaken in your estimate of the photographic ability of the official alluded to, for he is a skilful manipulator.—2. About one drop of castor oil to the ounce of collodion will be found a very good proportion for use in the preparation of enamelling collodion.

T. O'Hara.—Water alone is incapable of dissolving so much bichloride of mercury as will be requisite in bleaching the picture. It will be better for you to make a saturated solution of the salt in hydrochloric acid, and then add water sufficient to reduce it to a working degree of strength.

Wm. Robinson (Liverpool) writes as follows:—"I beg to request the favour of your attention to the enclosed advertisement, issued by a local firm recently established here, in connection with a 'bazaar' or 'sale of work,' for some religious object, which has lately been held in this town." [The advertisement contains the following statement:—"A diploma of merit has just been awarded to Don Levie and Cheetham by the committee of the present Paris Exhibition for high-class portraiture. They are the only Liverpool photographers so honoured."—Eds.] Mr. Robinson continues:—"Is the 'diploma of merit' referred to something outside (inferior or superior to) the awards at the Paris Exhibition, as given in the Journal? Have their names been accidentally omitted by the 'P. D.'? Or is it a mere assertion made to impress the public with the superior excellence of this particular firm's work as compared with that of other local photographers? I am led to ask these questions in consequence of not being able to find any mention of the said award in the pages of the Journal."——Upon receiving this note we immediately consulted the official list of awards, of which we possess a copy, and not only do we not discover the name of the firm in question in connection with any *awards*, but we do not find the name either of the firm, or of any of the individuals composing it, among the exhibitors in *any* of the sections. It is, therefore, evident that a serious inaccuracy exists somewhere.

G. (Liverpool).—We have submitted your print and letter to an experienced carbon printer, and he says that the fault lies in the negative, which has not been sufficiently intensified. By practising with a somewhat strong negative you will be certain to succeed. The indications in the print enclosed warrant this assertion.

Major Foster.—In reply to your query: it has, we believe, been ascertained that a negative nitrate of silver bath may be kept a long time in a paraffine-coated wooden bath-holder without its qualities becoming impaired. We cannot say how long this continues, but it is worthy of a careful trial to ascertain the precise value of the statement.

George Spence Dobson makes a suggestion relative to the construction of lenses possessing a greater degree of rapidity than usual. Divested of extraneous matter it consists in making the lenses of a larger diameter than is commonly the case, while grinding the surfaces to the same curves as are adopted in the smaller lenses. The lenses, he observes, would of necessity be thicker, but this would not prove of any disadvantage if the glass were pure.—To the foregoing we reply that the principle suggested is that which has always been adopted in the construction of portrait lenses possessing an abnormal degree of rapidity, some slight modification of the curves being necessary to meet the altered circumstances. We infer from the remarks of our correspondent that he is a practical optician; if so, we should be glad if he constructed such a lens and let us know to what extent he finds it necessary to depart from the curves requisite for the smaller lens.

M. Shelley (Bowdon) desires to submit the following queries to our readers. He says:—"I wish to know what form and aspect of studio it would be best to construct on a piece of land having a north frontage to street of eighteen feet, and a depth of four feet? There are one-storied buildings on either side, and in the rear a two storied building—all adjoining the land. The street is about forty feet wide, and on the opposite side of the street there are two-storied shops. The following considerations have to be borne in mind:—1. The direct rays of the sun to be prevented entering the studio through the top light without the aid of curtains.—2. The studio to be large enough to take full-length pictures, from *carte* up to whole-plate sizes daily, and often up to 12 × 10 inches, or, at least, 10 × 8 inches.—3. What is the best kind of glass for the studio? and what the size of panes?—4. Dimensions of lights to be stated in feet.—5. A due regard to appearance desired. As some of your numerous readers may have had special experience under similar circumstances to the above, and as the information sought for may be of equal utility to others as to myself, I shall be greatly obliged by your insertion of this brief note. Any original or practical information will be highly valued."

The Photographic Exhibition.—The Exhibition at 5a, Pall Mall East, will remain open the whole of next week, the last day being Saturday, November 16th, and *not* Tuesday, November 12th, as previously announced. The Exhibition has been enriched by a collection of views in Cyprus, recently taken by Mr. John Thomson, F.R.G.S.

South London Photographic Society.—On Thursday next, the 14th inst., at seven o'clock, this Society will hold its annual Technical Exhibition meeting at the House of the Society of Arts, Adelphi; admission free. Also, on Saturday, the 16th inst., the annual dinner of the members and friends will take place at the Café Royal, Regent-street. Further particulars of both these meetings can be obtained of the Hon. Sec., 57, Queen's-road, Peckham.

Photographic Society of Great Britain.—The first meeting of this Society for the winter session will be held on Tuesday next, the 12th inst., at the Exhibition Gallery, 5a, Pall Mall East, when the presentation of the medals awarded will take place. A paper, by Mr. Leon Warnerke, will be read, entitled *Photographic Notes from Travel in Russia, with the Exhibition of various Works, Apparatus, and Materials.* Also, will afterwards be read *Photographic Experiences in Cyprus*, by John Thomson, F.R.G.S.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician.

CONTENTS.

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 967. Vol. XXV.—NOVEMBER 15, 1878.

OUR FORTHCOMING ALMANAC.

The Editor of The British Journal Photographic Almanac desires it to be known that he is now actively engaged in the compilation of this favourite annual and handy-book of reference in every branch of photography. In order that it may be at least equal, if it do not surpass, its predecessors, he takes this opportunity of requesting the numerous readers of The British Journal of Photography kindly to favour him with such hints, "dodges," items of experience, notes on difficulties encountered and overcome, as well as their ideas on subjects possessing general interest to those who study photographic literature, as will enable him, with their assistance, to render the Almanac for 1879 successful in every respect. It will enhance the kindness rendered by such responses if the Editor be favoured with contributions at the *earliest possible moment.*

The Publisher desires to repeat the fact that as an advertising medium the Almanac is without a rival; and, being retained as a standard work of reference in photographic matters, advertisers will find their announcements more permanent than in the case of serial publications, while it is also true that the Almanac finds its way into many studios and on to the library tables of amateurs where the usual weekly journals may fail to gain regular recognition. For these reasons it is recommended to the notice of advertisers as the most valuable existing medium for popularising their various business announcements. Terms and other information may be obtained at the Publishing Office, 2, York-street, Covent Garden, W.C., or from the advertising columns of this Journal. Immediate applicaton is absolutely necessary in order to secure priority of position.

A NEW POINT OF DEPARTURE IN THE PREPARATION OF EMULSIONS.

The difficulties which have been experienced in securing certain qualities in washed emulsions have, we fear, led to the almost total neglect of other properties equally important but in another direction. In plain words, in our endeavours to secure density and facility of development we have come, unconsciously perhaps, to disregard the more easily-obtained physical characteristics which go to form a perfect film.

We are led to make this remark from an examination not only of commercial films and emulsions, but also of different samples of pyroxyline specially prepared—or, at least, specially sold—for emulsion purposes. The defects to which we allude in the case of commercially-prepared films and emulsions are not, perhaps, very marked, because the reputation of the maker depends upon his supplying a good article; and hence he is obliged, for his own sake, to pay attention, not only to one particular property, but to the general quality of his preparations. In the case of pyroxyline, however, it is extremely easy to lay the blame of any deficiency in quality on the clumsiness or ignorance of the user; and that faults *are* found with commercial pyroxylines supplied for the special purpose we speak of none of our emulsion workers nor, we dare to say, the dealers in pyroxyline will be inclined to deny.

Formerly the great complaint was, in this connection, want of density. Now, however, this quality is readily obtainable, but, as we have hinted, at the expense of physical properties equally important. The fault is not, perhaps, very noticeable where small plates are concerned, but when large ones are in question it becomes painfully evident. We need only go a week or two back to quote from our own columns the experience of a gentleman who had to wash off a number of 9 × 7 films on account of a defect arising from "something wrong with the pyroxyline;" and we have very little doubt that many similar complaints remain unpublished.

What may have been the particular fault in the case to which we allude we do not know; but the form in which we have met with it is a deficiency in fluent properties in the emulsion and a want of homogeneity in the film obtained therefrom. Speaking of the latter, the evil may take a variety of forms—mottling and wavy markings, reticulation, granularity, liability to spots, and even drying marks may be classed under the same head. None of these, however, singly form the subject of our complaint, but rather an intimate mixture of nearly all of them. Briefly stated, it may be described as a crapy sort of reticulation over the whole film, with a strong tendency, especially in large plates, to mottling at the thicker end of the plate. The emulsion flows with difficulty, as if the solvents were overloaded with solid matter, and sets with the peculiar "lumpy" appearance which is usually the sign of weak solvents. The reticulation, it may be noted, does not take the form of transparent lines, as in the case of a rotten collodion, but the opposite; the fine lines forming the network are denser than the remaining portions of the film.

The emulsion is, in fact, too thick; but that the lack of fluency does not come from excess of solid matter is easily proved by the fact that dilution with fresh solvents only mitigates, without removing, the evil. Further: we have experienced the difficulty in its most glaring form when employing solvents of a far higher grade than there is any necessity to use when things are going smoothly; we may, therefore, set on one side any suspicion as to the presence of water being the inducing cause, and, in fact, we fall back upon the inevitable conclusion that there is "something wrong with the pyroxyline."

The latter substance has formed the subject of careful research at the hands of many experimentalists during the last five-and-twenty years, and from one point of view may be said to be pretty thoroughly understood; but we are far from believing that the rules laid down for its preparation for use in the wet process are to be relied upon for dry-plate work; while for emulsion work there can be little doubt that we are as yet scarcely past the threshold as regards our knowledge of the special requirements. The fault lies in this: in endeavouring to obviate the difficulties or deficiencies in the preparation for a special purpose we resort to the means we should adopt under entirely different circumstances, losing sight of a new set of conditions which belong to the particular purpose we have in view. Thus, wanting density, we resort to high temperature or to an increase in the proportion of sulphuric to nitric acid in the preparation of the pyroxyline, either of which conditions undoubtedly favours density *per se*, and also, as any one who has made comparative experiments in the manufacture of pyroxyline for emulsions will acknowledge, introduces complications of a physical nature. In the course of a somewhat extensive series of experiments in the manufacture of the soluble basis of collodion from various materials—cotton, hemp, linen, woody fibre, paper, &c.—we found that temperature and the proportion of the acids were by no means to be relied upon to produce a uniform effect as regards density, while the vagaries in the matter of physical properties were something surprising; and we must confess our inability to prepare a really uniform and *thoroughly satisfactory* product from any written formula. In view of this somewhat discouraging state of affairs we set ourselves to work in another direction to overcome the physical defects of the emulsion film; and while we attained a large amount of success in that direction we also developed some new facts which caused us considerable surprise, and which we are sanguine in believing will throw a new light upon the requirements in the preparation of emulsions.

The first and most obvious way of treating an emulsion which flows too thickly is to dilute it by the addition of fresh ether and alcohol; but this plan, though it may secure a more even film, produces so thin a layer of the sensitive material that a vigorous image becomes almost an impossibility. We have then to turn in another direction, and, looking at the pyroxyline as the ingredient which is inimical to the quality of the film, to consider how far its proportion may be reduced without bringing about a similar result as regards thinness and poverty in sensitive material. By merely decreasing the actual quantity of pyroxyline contained in each ounce of emulsion we may easily produce a thin and even film; but then the result is little different from that obtained by simple dilution of the emulsion already formed. What we have to do is to counteract the increased transparency by augmenting the quantity of silver bromide held in suspension, so that the thinner film may possess the same degree of opacity, and may contain an equal quantity of silver, as the thicker film obtained under other conditions.

Now, it has generally been accepted as a fact that a certain quantity of pyroxyline to the ounce of solvents is necessary to the formation of an emulsion of fine grain. We know that plain solutions of silver nitrate and a soluble bromide, if mixed, produce a precipitate of bromide of silver too coarse to be utilised in the formation of a photographic film of any practical value; but by dissolving one or other of the salts in a viscous solution, such as collodion or gelatine, we have the bromide precipitated in a state of extremely fine division; and it is reasonable to suppose that in proportion to the density or viscidity of the vehicle so will the fineness of the precipitate vary. To a certain extent this may be true; but our preconceived notions on the subject received a rude shock when we found that a collodion bromised with the usual quantity of salt and sensitised with its due equivalent of silver, but containing only *two* instead of five or six grains of pyroxyline to the ounce, produced an emulsion as fine and clear as if the full quantity of cotton had been used.

Encouraged by the success of this result we next attempted the increase of the proportion of silver bromide to pyroxyline, and without going into minute details we may say that we have succeeded in producing a satisfactory emulsion with such widely different proportions as a grain and a-half of cotton and fifteen grains of soluble bromide to the ounce of solvents. This, however, is perhaps overstraining the powers of suspension, but to produce a really workable film two grains and fourteen grains, respectively, work admirably, producing a film equally free from any granularity on the one side or structural defects on the other; in the latter respect, indeed, the result is equal to a gelatine film without its density.

So much for the purely physical view of the matter. Turning to the chemical or photographic phase the difference is still more surprising. An emulsion composed, as above stated, of two grains of pyroxyline and fourteen grains of double bromide of cadmium and ammonium to each ounce of solvents and sensitised with twenty grains of silver produced a film at least *four times as sensitive* as a washed emulsion prepared with a similar excess of bromide, but with six grains of cotton to the ounce. This result, too, was obtained only three hours after sensitising—a period which, under ordinary circumstances, would be wholly inadequate to the proper combination of the salts.

The first plate developed from the new emulsion, and which had received the same length of exposure under a negative as a plate prepared for comparison from another sample, gave a result which, at first sight, appeared to be hopeless fog. But a careful examination of the film led to the suspicion that the fault was *over-exposure*, not *fog*; and after three or four trials we found that *one-fourth* of the exposure gave a *better* exposed result than the comparison plate. Exposure under a negative by gaslight is not, we are bound to confess, a sure criterion of the relative sensitiveness in the camera; but if there be any difference we are inclined to think that it will be even more in favour of the new emulsion than we have stated. We have the following grounds for saying this:—The negative employed—one which we are in the habit of using for test purposes—includes a white building in strong sunshine. The deposit in this portion of the picture is, as may be well imagined, of great density; but in a good light a great deal of fine detail may be *seen*, though we have never before, even upon paper, succeeded in making it *print*. The new emulsion, however, with the shortest exposure we have mentioned, succeeded in bringing it out without, at the same time, overdoing the other portion of the picture; and this, we think, is fair evidence of sensitiveness to feebly-illuminated details, if any analogy exist between superposition printing and camera exposures.

A strong tendency to abnormal reduction or *fog* is evident if the strength of the alkali be too great. A moderately-strong ammonia developer may be allowed to remain on the plate for a considerable time without producing any reduction if the light be really non-actinic; but by slightly increasing the quantity of alkali the *unexposed* film may be reduced completely through its whole thickness.

If any of our readers doubt the correctness of the theory that has been propounded as to the restraining action exercised by the collodion film, we do not think a stronger argument could be brought in its favour than the behaviour of one of these films—rich in bromide, but poor in pyroxyline; and we have a strong impression that something may be done towards increasing the rapidity of collodion emulsions by working in the direction we indicate, while the gain in the physical qualities of the film (supposing that due intelligence be exhibited in the preparation of the emulsion) will be sufficient to recommend the change, if no other advantage accrue.

THE PHOTOGRAPHIC EXHIBITION.

[Concluding Notice.]

During the whole series of exhibitions of the Photographic Society of Great Britain the Autotype Company have never exhibited grander works than those to be found in the present one, nor pictures possessing a higher degree of refinement. The eight pictures contributed by this Company bear evidence of the important status at which the art of enlarging has arrived. The place of honour at the north end of the gallery is allocated to a magnificent enlargement (110)—from a negative by Messrs. Downey—of one of the popular "beauties" of the day, whose face is familiar to those who examine the pictorial displays in the usual dealers' establishments. The picture of *The Culvers, Carshalton* (157), one of the largest in the room, is also one of the most perfect. A small sheet of water in the foreground was so still during the photographic operations as to give the most charming reflections of the house, which is lighted under those conditions said by Rejlander to be indispensable for securing the finest effects, namely, a sky obscured by light clouds during the greater portion of the exposure, with a slight dash of sunshine towards the close to impart character and force to the high lights. The *Great Hall, Mentmore* (251), from a negative by Lemere and Co., is another work of great merit, although it is apparent that the negative possessed a greater degree of intensity than would have been necessary in order to produce the finest and softest result.

We cannot conceive of a more effective portrait than the profile enlargement of Professor Max Muller (281), by Messrs. Lock and Whitfield. This firm also exhibits other portraits equally perfect as regards the technics of photography; for example, *The Bishop of Lichfield* (305), *Portrait of a Child* (315), and others.

The Woodbury Company exhibit very largely, and if their works were removed from the gallery the Exhibition would suffer a sad deprivation. Some of their enlarged architectural views are singularly delicate, and display most eloquently what *can* be done in the way of enlargements. Who, after seeing the picture of the *Church of St. Rouen* (121), with its soft and beautiful carvings and tracery, would ever even attempt to produce such a work direct by means of a large camera? Possessing similar characteristics is the front view of *Rouen Cathedral* (317), which is replete with fine gradation. In no respect inferior to these works are the charmingly-executed portrait enlargements of this firm. The *Portrait of a Lady* (267), one of the largest pictures in the gallery, is nearly life-size, and admirable from its many excellent qualities. The large portraits of *H. J. Byron* (78), and *Henry Irving* (130), are also exceedingly fine. That of the latter gentleman is enlarged from an original to be seen in the highly-useful "educational" frame exhibited by the Woodbury Company—a frame which contains the engraved metal plates from which the choice specimens of photographic printing in juxtaposition were produced. Their frame of works, adapted for book illustration (321), show the capabilities of the Woodbury process for this branch of work. The purity of the tones is charming, and the quality, as a whole, has been such as to secure for this collection the medal of the Society.

Another exhibitor whose works impart a peculiar charm and value to the Exhibition is Mr. Payne Jennings, who, as heretofore, confines himself to landscape, as in contradistinction to portrait, photography. This skilful artist has of recent years adopted a rich bistre tone in his landscapes—an example which, we find, is being followed by several amateurs. The large frame, or joined series of frames, numbered 231, contains twelve of the choicest examples of this artist, and these immediately arrest the eye of the visitor upon entering the gallery. These charming works represent, respectively, scenes in the English lake district and in Ireland. Several pictures by the same artist are "mounted" singly in carved gilt frames—a peculiarity in this style consisting in there being no margin, indeed none of the mount, shown. Mr. Jennings also exhibits two frames of photographs mounted as, and intended for, book illustrations. For his frame of *Instantaneous Effects* (199), representing a number of yachts and other vessels in motion, he has most worthily been awarded a medal.

Of the exhibits of Mr. Leon Warnerke too much cannot be said as regards their educational interest to photographers; for, culled from the works of eminent photographers in Russia, they enable us to see many peculiarities in style and treatment that might, with advantage, be imported into our home practice. The grouping of some, the peculiar effects of sunlight of others, of the numerous groups and *genre* photographers here brought together by this skilful collector, must exercise an influence for good upon every photographer who carefully studies this remarkable collection. In this series we have admirable specimens of photographic engraving, lichtdruck, surface-block printing, photolithography, "hyalotype," and of ordinary photographic printing, representing character studies of figures, groups, landscapes, and architecture. The artists by whom these have been executed are Scamoni, Carrick, Kareline, Srezniewsky, Lewitzky, Denier, Jæger, Felish, Sapteff, Classen, and Reinhardt. We may add that Mr. Warnerke is entitled to the thanks of the Society for having contributed so valuable a collection of pictures to this year's annual display.

The Exhibition is announced to close tomorrow (Saturday) evening.

A PLEA FOR EXACTITUDE.

In the course of conversation with photographers having a large staff of operators, printers, &c., they have not infrequently complained to us of the irregular results that were sometimes observed in a day's work, both in the operating-room and the printing department; while, among those amateurs whose time for photographing is limited to an occasional afternoon, the most common complaint is the uncertainty of processes in their hands. But this need not, and should not, be. In an important branch of science, looking at photography from its physical aspect, for the results to be uncertain and the exact conditions governing them unknown or neglected is most unworkmanlike, and can have no other tendency than to degrade the importance of photography in the eyes of scientific workers generally.

The vast progress made in chemical science, for instance, during the last few years would never have been achieved had no more attention been paid to rigid exactitude than is commonly given in the practice of photography; neither would the marvellous commercial production of complicated chemical substances have arrived at its present stage of magnitude and excellence if the strictest watch had not been kept at every stage of the process to ensure scrupulous attention to the carrying out of all the necessary conditions. But in even the largest photographic establishments how rare is it not to find such cases! How many operators and printers use their thermometers, their hydrometers, or the simplest form of *burette?* Rule of thumb prevails almost universally, with the result of many thousands of pounds' worth of material being wasted beyond redemption. True it is everyone knows that in cold weather his chemicals require strengthening, and that in hot weather stains are apt to occur, and some little alteration is made by guesswork to bring things right.

What is required, however, is a set of tables for strengths of various solutions required for different temperatures, a few days' rigid examination of results under such varying conditions as are likely to occur, and such a tabulated statement of them as would enable each to alter for himself the chemicals he is using, or know from their strength and temperature the effects he is to expect, thus establishing the routine of operating on a thoroughly sound basis.

We may give an example of what we think ought to be possible in the hands of an ordinary and careful manipulator. Every morning he would take the temperature of his dipping-bath, and, as the strengthening or weakening of that solution would take up time, he would best bring it to a uniform temperature, which could be very easily done; but if time or circumstances prevented that being accomplished, he would refer to his table and find for a given temperature what was the equivalent strength, and could then vary his developer according to the table—a definite alteration in strength of which would be given for (say) each two degrees of temperature. Working with a collodion of uniform quality he would then know at once what would be his results. Then, again, every few days, more or less, according to the greater or less work the bath has had, he might test its strength, and bring it up to the exact strength he considers best. He would also be able by previous experiment to have a rule for determining the effect of an excess of ether and alcohol in the bath (on this subject we shall dwell in a future article). And so, in the printing department, when the greatest irregularity usually is found, his table would show him what difference in strength would be equivalent to a fall or rise of a degree or two in temperature, and every time he prepared for floating the paper he would bring up the temperature or add strong solution of silver in cold, or *vice versâ* in hot, weather. The effect of an alteration of a few degrees in the temperature of the printing bath is most marked. So, again, in making his gold toning bath: if he make it of an acid sample on one occasion and nearly neutral on another, he must expect to find want of uniformity of result; but if he make his gold as nearly neutral as he can before adding his alkali he will know exactly how it will tone.

These remarks are merely meant to give what we might term the skeleton of "practical" modes of introducing exactitude in all departments, and the preparation of such tables as we suggest would only require very careful attention and comparison of results. One set of tables would in practice suffice for all photographers; and, when they were really fairly applied in daily routine, their broad bearings would be thus learned by heart to an extent far more exact than the practical knowledge of even the most experienced operator—so much so that it would only be when results of especial exactitude were required that anything like "calculation"—the bugbear of the rule-of-thumb manipulator—would be needed.

We should like to see our ideas practically worked out, for we are assured they would add not a little to comfort in working and to the economy of materials.

RECENT PATENTS.

No. XXI.—CADETT'S PNEUMATIC SHUTTER.

We have already [see page 240, *ante*] given a description of the method of using this ingenious lens cap, for which, as our readers are aware, a medal has been awarded at the Photographic Exhibition now open. The specification of the patent having been published, we are now enabled to follow up that description with another in which the mechanical details of the invention form the leading feature. The patentee, Mr. James William Thomas Cadett, says:—

My invention has for its object the application of pneumatics for photographic purposes, so that the lens, by means of a shutter or other covering, is uncapped or exposed at will, according as required.

In carrying out my invention I adopt substantially the following arrangements:—

To a portion of the apparatus holding the lens I fit or secure a case or box which contains a bellows or wind-box acted on by spring or otherwise, said bellows being in communication with a pipe or opening into the pneumatic tubing.

On a spindle acting on or by the said bellows is fitted or secured a shutter or cap, which projects beyond the said case or box.

The action is as follows:—By pressing an air or gas chamber in communication with the tubing the bellows or case fitted or secured to the apparatus is actuated, and the shutter or cap is moved, so as to uncap or expose the lens as required.

The bellows, disc, or chamber can be fitted to the photographic apparatus without a case, and springs may, as is evident, be sometimes dispensed with, though a spring or springs are preferred to be used.

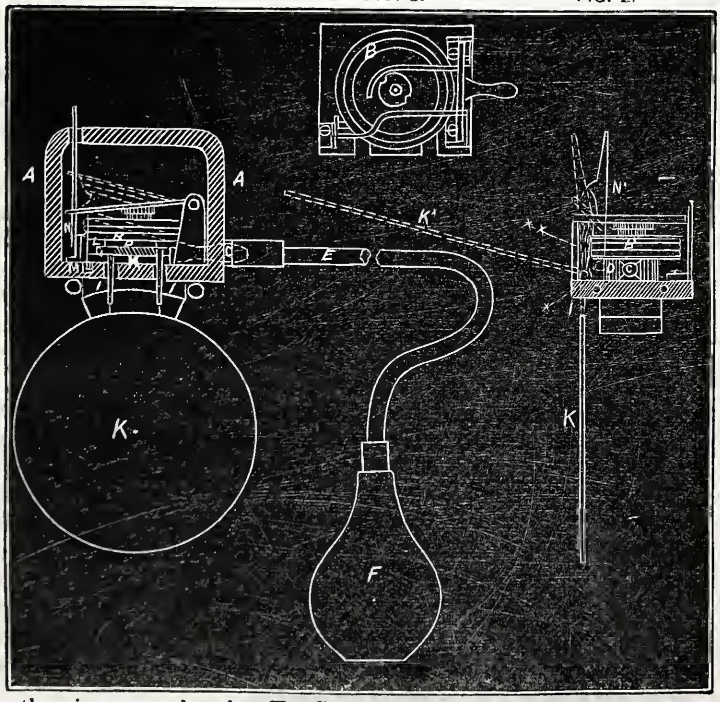
A locking arrangement is generally used, which holds the shutter or cap so as to keep the lens uncovered while setting the proper focus.

Having thus far described the nature of the said invention, and incidentally intimated in what manner the same is to be performed or carried out in practice, I will now proceed (aided by the accompanying drawings) to further and particularly describe and ascertain in what manner the same is to be performed or carried out in practice; that is to say:—

Description of the Drawings.—*Fig.* 1, front view of my improved pneumatic arrangements for photographic purposes (with case in section); *fig.* 2, side view without case; *fig.* 3, top plan without case.

A is the case or box fitted or secured to the portion of apparatus holding the lens; B, bellows or wind-box; C, pipe secured to portion D, said pipe being in communication with the bellows or wind-box; E, length of tubing fitted on to said pipe C, terminating

FIG. 1. FIG. 3. FIG. 2.



in the air or gas chamber F; G, spindle fitted in bearings, as shown, said spindle being provided with a spring H; I, arms secured to spindle G, said arms being fitted with the cap or shutter K; L, connection formed between the arm M fitted to spindle G and the portion pressing on the bellows or case B, whereby the shutter or cap, when the bellows is inflated, turns the spindle G, and with it the shutter or cap K, to the position shown by dotted lines in *fig.* 2.

By releasing the pressure on the air or gas chamber F, the bellows, chamber, or disc assumes its normal condition, as shown in the drawings.

N is the locking arrangement for holding the shutter or cap.

The arrangements shown by the drawings represent those for adoption outside the camera. When fitted inside the arrangements are substantially the same, with the exception of means suitable for attaching the instrument, which are modified according to the kind of camera used.

At *, *fig.* 2, the position of the arm M and connection L is shown by dotted lines as holding the shutter or cap K closed, and the locking arrangement is then at N×.

In the same *fig.*, at ××, the dotted lines show M and L as when holding open the shutter K× for focussing, the locking arrangement being then as at N.

Having now particularly described and ascertained the nature and object of the said invention, and in what manner the same is to be performed or carried out in practice, I hereby declare that I claim the invention of new or improved pneumatic arrangements (substantially as hereinbefore set forth and described) for facilitating the uncapping or exposing and capping or shutting the lenses used in apparatus for depicting persons or objects by photographic means, it being understood that I do not bind myself to the particular form of arrangements shown by the accompanying drawings and herein described by reference thereto, as same may be varied without departing from the principle of my said invention.

We take our leave of this invention by remarking that it is one of the most ingenious of the many ingenious mechanical inventions made in connection with photography, and we know that our opinion is shared by all who have seen it in action.

NOTES ON STAINING GELATINE FILMS.

[A communication to the Bristol and West of England Amateur Photographic Association.]

Blurring being a defect common to most emulsion plates—particularly when prepared with a bromide alone—has given rise to numerous expedients for its cure, that most employed being a backing of a non-actinic colour which is usually applied in the form of a mixture of gum with some brown or red pigment, a small quantity of glycerine being added to allow of its more easy removal during development.

Commercial gelatine plates are not usually supplied with a backing, and for most purposes it is unnecessary; but, when long exposures to objects presenting great contrasts have to be given, these plates, particularly if thinly coated, are very liable to halation, and some satisfactory method of obviating it is very desirable.

A coat of paint on the back of the plate is both troublesome to apply and remove, and I am not at all certain that it is thoroughly efficacious. The more simple plan is to introduce the colouring matter into the emulsion. This idea is not new, as I believe Colonel Stuart Wortley's uranium plates were similarly dyed. The objections that may be alleged against this proceeding are impaired sensitiveness and the difficulty of removing the colouring matter from the negative. That the first exists in some degree there is but little doubt; but with the exalted sensitiveness we can obtain with gelatine emulsion a slight loss of rapidity is but of little importance, especially as the subjects most liable to blurring do not usually require a very rapid plate. Indeed I may add that my experiments in this direction were made with a view to reducing sensitiveness, as I have found that very rapid plates are unsuited to the generality of landscape work.

I first tried the aniline dye, aurine, employing a solution of eight grains in an ounce of alcohol. Of this half-a-drachm was added to each ounce of emulsion. When dry the resulting films were of a rose-pink colour, though why a golden-coloured dye in combination with yellow bromide of silver and gelatine should possess this appearance I am at a loss to explain. This colour completely disappears during development, the negative presenting no appearance of having been dyed.

Although aurine appeared to be in every way satisfactory, with the exception of the slight effect on the sensitiveness of the plates, still, as a vegetable dye might prove equally useful, and perhaps be more convenient, I concluded to try turmeric. A strong decoction in alcohol was made, and half-a-drachm added to each ounce of emulsion.

The addition did not cause any curious change of colour as in the case of aurine, the original yellow colour of the emulsion merely becoming deeper. The sensitiveness of the plates did not appear to be as much affected as when the aniline dye was used; but the great objection to the use of turmeric is that the colour does not disappear from the negative during development, but necessitates a soaking in alcohol to remove it.

I regret that I am unable to exhibit any negatives in illustration this evening, not having brought any over from Ireland.

J. D. Lysaght,
Lieut. Royal Madras Fusiliers.

COMMON GAS AS APPLIED TO PHOTOGRAPHIC PORTRAITURE.

I have been greatly interested in the article on *Taking Portraits by the Electric Light,* which appeared in last number. Indeed, in my opinion, it is impossible to overrate the importance of being able to take photographs from living subjects without the agency of daylight or sunlight. "Art" may be "long;" but most assuredly a November day is very short and its light most feeble and exceedingly unstable. *Now,* we may be basking in sunshine; but in a moment we may be enveloped in a brown, murky fog. How to render ourselves independent of such a state of matters is a question of vital importance to numerous photographers beside those who reside in the great metropolis, where fogs, during certain seasons, most undoubtedly do hold high revelry and become changed into the blackest of atmospheric surroundings.

In the place where I have recently been residing the opportunities for forming an intimate acquaintance with the capabilities of common house gas have been most abundant, and I desire to direct attention to this kind of illumination as one which, in my opinion, is quite possible to develope into what may be advantageously adapted for photographing the "human face divine."

Carburetted hydrogen, although possessing a fair degree of illuminating power, is sadly deficient in those rays which permit photographs to be taken. To prove that even the brightest gaslight is of a decidedly yellow colour all that is necessary is to ignite a few inches of magnesium wire or ribbon, the pure light from which will, by contrast, show the other to be of the colour to which I have alluded.

My efforts in the direction of rendering house gas suitable for employment in the production of photographs were first of all begun by rendering the flame white. To this end, after devising various forms of "blowers" for the purpose of securing a large volume of heated air to impinge against the flame and thus whiten it, I found eventually that, as a preliminary, it would be necessary to carbonise the gas to a much greater extent than is at present the case. It may not be known to many readers that if the gas in common use be passed over the surface of certain hydrocarbons just before it emerges from the orifice of the burner its illuminating power is greatly increased. Patents innumerable have been obtained in connection with this simple fact, and very many appliances for securing its full benefit have been proposed, and in several instances introduced; but the gas companies and those interested have hitherto successfully discouraged their general adoption.

The means by which success might be achieved may be ascertained from a recital of the expedients to which I have resorted. A circular tin box was procured, four inches in diameter and two inches in depth. In this were fixed two pipes, one of them—the supply pipe—entering the bottom, and the other emerging from the top. The inside was stuffed very loosely with torn scraps of felt; and by means of an orifice in the tap, closed by a screw—such as can be obtained from any dealer in lamp furnishings—a quantity of coal naphtha was poured in, sufficient to thoroughly impregnate the felt scraps, and to allow the little vessel to remain half full besides. As the gas was admitted near one margin of this carburetter, and passed out at the other, it had to find its way through the naphthalised stuffing, by which means it became highly charged, or enriched, by the hydrocarbon, and yielded a flame far surpassing in intensity that which it afforded in its unaltered state. Upon applying a gentle heat to the carburetter the gas was enriched to such a degree as to smoke in an offensive manner when burning.

My next step was to have constructed a suitable burner for the ignition of the carbonised gas, and I eventually adopted one of the Argand form. But even with this class of burner I could not get the smoke of the flame consumed—nor indeed did I desire to do so—by means of atmospheric air alone. I preferred, instead, to convey into the interior of the burner a very gentle stream of oxygen, which immediately gave an intensity to the flame greater than I had hoped to secure. Not only was the flame rendered very intense, but it was whitened to such a degree as to render it apparent that it would prove most useful for photographic purposes.

Its value having been ascertained from a few practical trials, it was considered that six such lights would prove sufficient to illuminate the human figure for the purpose of producing a well-exposed negative in a reasonable time. These burners were mounted, slightly detached one from the other, upon a light framework of wood, each light having been placed in a reflector not greatly unlike those used in coach lamps. The whole of the burners were supplied with oxygen from one pipe, and the oxygen was turned on only when the picture was about to be taken.

The photographs obtained by means of the apparatus here described have proved, in a satisfactory manner, that good portraits may be taken by means of common gas, provided the latter be considerably enriched by being brought into contact with a suitable hydrocarbon before ignition, and oxygen be introduced to the flame to render it pure in colour.

I would have given a detailed description of my burner, but I am engaged in making a modification in its form by which I hope to obtain such an increase of light as to enable me to work with an exposure of twenty seconds, which at present I cannot do. Instead of naphtha as the fluid in the carburetter I have tried others with advantage. Benzole gave good results, but at present I am most favourably disposed towards oil of turpentine.

It is, perhaps, rather premature for me to have made public my experiments; but I have elected to do so in order that others may also be induced to make experiments in this most fertile, but as yet uncultivated, field of research. Alfred Irvine.

A CURIOUS INCIDENT IN CONNECTION WITH PAPER ENLARGEMENTS.

[A communication to the South London Photographic Society.]

A few days since, at a committee meeting of the South London Photographic Society, I happened to mention a curious circumstance which had occurred to me, and it was then suggested that, as none of the gentlemen present could account for it, I should bring the matter before our meeting tonight. This, with your permission, I shall now be happy to do.

A short time ago I was engaged making a developed paper enlargement by artificial light, and had sensitised the iodised paper and exposed it whilst wet in the usual way, when, much to my surprise, directly the developer came in contact with the paper the sheet assumed a brown colour, which so rapidly darkened that in less than a minute the entire surface was a beautiful purple-black.

Now, the paper used was part of a batch iodised some time before, and the developer a portion of ordinary stock solution. The sensitiser, however, I found had been made from a fresh parcel of silver, and, curiously enough, the glacial acetic acid was the first taken from a Winchester only recently supplied by a well-known firm.

The fault then clearly rested either with the silver or the acid. Another sample of silver and the same acid produced similar results; but the same sample of silver, and acid obtained from another source, cleared up the difficulty, and everything worked as usual.

I will just show you the sort of pictures I generally obtain when working in a similar way, and also two specimens of the blackened paper, to endeavour to find out the cause of which I have brought the matter before you.

We have usually considered glacial acetic acid as an article rarely contaminated with anything injurious to photography, although occasionally the most peculiar results have been attributed to it—none, possibly, much more curious than that to which I have just alluded. F. A. Bridge.

JANSSEN'S NEW METHOD OF SOLAR PHOTOGRAPHY.

In two papers published respectively in the *Comptes Rendus* for December, 1877, and in the *Annuaire* of the *Bureau des Longitudes* for the current year, M. Janssen has described a new method of photographing the solar disc, which he has successfully carried out at the Meudon Observatory, during the past twelve months; and he has also drawn attention to some striking features in the constitution of the photosphere, disclosed for the first time in the beautiful pictures which are among the first results of his process. These may be regarded as only the forerunners of further important discoveries. Through the courteous liberality of M. Janssen, I have lately had the advantage of studying the process in the Meudon Observatory, and a description of its distinctive features, and a brief notice of such of the results as

M. Janssen has already published, will certainly be acceptable to many who are interested in the recent developments of solar physics, and have not ready access to the original papers.*

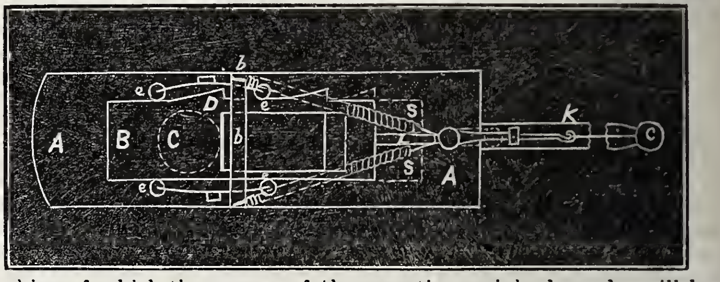
M. Janssen's pictures of the solar disc are distinguished from all those previously obtained with the photoheliograph, not only by their great size (30·5 centimetres diameter), but more especially by the remarkable sharpness and definition with which they display the details of photospheric structure, which are such that, for the purpose of their more effective study, it is found advantageous to enlarge the original pictures to three and even nine times their original linear dimensions. The greatly-extended means of research which M. Janssen's invention places in the hands of the solar physicist will be obvious when we consider the difficulties which attend any prolonged ocular inspection of the solar disc, hitherto the only practicable method of examining its detailed structure. "In spite of the interposition of coloured glasses, helioscopes, &c., the eye must seize on the details in a dazzling field, and perform its functions under conditions which are quite unfamiliar. The true variations of luminous intensity in different parts of the image can no longer be appreciated, and the impressions produced do not correspond to reality. Thus may be explained the diversity of the opinions which have been put forward respecting the forms and dimensions of the granulations, and of the constituent parts of the solar surface"—diversities well illustrated by the old controversy of the "willow-leaf" and "rice-grain" bodies in the photosphere. In M. Janssen's pictures the forms, sizes, and arrangement of the bodies described under these appellations are exhibited in the most satisfactory manner, and as, in a favourable state of the atmosphere, the pictures may be repeated at as short intervals as the operator pleases, the movements and changes of form exhibited by these bodies may be studied with the utmost ease in a register which preserves the most fugitive phases of their appearance, and is available for leisurely re-examination at any future time.

Before noticing the novel facts which M. Janssen has thus brought to light I will briefly describe the principles of the process itself. The main difficulty to be surmounted in order to obtain a sharply-defined photographic picture of the details of the solar disc is presented by the phenomenon known as photographic irradiation, in virtue of which a brilliantly-illuminated surface occupies, on the negative picture, a proportionately exaggerated space, its borders being extended over the darker objects around. This phenomenon, M. Jannsen remarks, "is very striking in all the photographs of total eclipses which have been obtained since 1860, which exhibit the images of the protuberances encroaching on the lunar disc, to the extent in some cases of ten and twenty seconds of arc, and even more." The granulations (to employ M. Janssen's terminology) visible on the solar disc have a mean diameter of not more than one second of arc, and in ordinary photoheliograms their very existence is therefore completely masked by irradiation.

The simple and beautiful contrivance by which M. Janssen has succeeded in getting rid of irradiation is to restrict the photographic action to one small sheaf of rays of the spectrum, viz., those which extend from the line G a short distance towards H. In a series of experimental photographs of the spectrum, which M. Janssen took in my presence (with calc-spar prisms and a rock-crystal lens), and in which the time of exposure was varied successively from two-thirds of a second to three minutes, those obtained with the shortest exposure represented only that part of the spectrum immediately contiguous to G and extending a short distance towards H, and in this the spectral lines were exhibited with extreme sharpness. With a more prolonged exposure the range of the image was greatly extended in both directions, accompanied by intensified action in the G-H region, which impaired the local definition.† Taking advantage of this fact, in the new process, the collodionised plate is exposed to the sun's action only so long as to allow of the action of the most actively photographic rays, and this is the cardinal condition of success. In practice the duration of the exposure is restricted to between $\frac{1}{2000}$ and $\frac{1}{3000}$ of a second in summer, being varied according to the season and to the time of day. The means by which this delicate adjustment is effected and verified will be described presently.

A second condition is so to adjust the distance of the sensitised surface from the lens of the instrument that it shall exactly coincide with the focus of the G rays. The necessity of this precaution will be readily understood when it is borne in mind that no lens is perfectly achromatic, and that, in virtue of the first condition, the rays in the vicinity of G alone produce the image. The remaining conditions are the adoption of as large a plate as can be readily manipulated, and some improvements in the process of preparing and developing the plates, whereby a very perfect surface is ensured for the reception of the image, and a graduated development after exposure.‡

The photoheliograph employed was constructed specially for the Meudon Observatory by M. Prazmouski, of Paris. It has an object-glass of five inches diameter, and a reversing ocular, giving an erect image on the sensitised plate. The finding telescope casts an image on a disc of ground-glass; by observing which, the operator can judge the exact instant for releasing the sliding screen, which causes the instantaneous exposure of the sensitised plate. At present the position of the telescope is adjusted by means of winches worked by hand. The construction of the sliding screen, on the accurate adjustment and



working of which the success of the operation mainly depends, will be understood on reference to the accompanying rough diagram (which, however, is not drawn to scale, and in which, to avoid confusion, some of the minor details are omitted). A A is an oblong brass plate which serves as a frame for the mechanism, and is introduced through a slit in the side of the telescope, exactly at the spot where the real image is formed by the object-glass. At the spot where the image falls the plate is pierced with a circular aperture somewhat larger than the image, shown by the dotted circle C. But this is completely covered by the sliding screen B, excepting such portion as is momentarily uncovered by the transverse slit D, in its passage across the image. The width of the slit D can be varied by means of a micrometer screw, which is omitted in the diagram. The sliding screen works between four small grooved wheels *e e*, fixed to curved springs, which press them against the edges of the screen-plate; and one of these edges is shaped in the manner shown in the diagram, so that the pressure is increased from the instant at which the slit D reaches the margin of the circular aperture C, neutralising the acceleration of the movement by the continued action of the springs, and rendering it uniform during the passage of the slit across the image*. Thus the image is allowed to fall on the sensitised plate—not as a whole, but in successive slices; and the width of the slit is so adjusted to the rate of motion that each slice is exposed during from $\frac{1}{2000}$ to $\frac{1}{3000}$ of a second only. The motion of the screen is effected by three spiral springs, two of which, S S, are shown in the diagram (the central spring being omitted). The fixed ends are attached to a bar *b b* screwed to the slide A A, the free ends to a stud on the bar *l* which projects from the proximal end of B, which is bent twice at right angles and terminates in the hook *k*. In setting the screen, before operating, a loop of twine is passed over the hook, which is then drawn towards the clip *c*, extending the springs S S, and bringing the screen into the position shown by a dotted line on the diagram. The twine is made fast in the clip *c* and all is in readiness for the operation. At the critical moment the retaining string is cut and the slit D is rapidly drawn by the tension of the springs across the field, till checked by a stop not shown in the diagram. The movement of the screen is generally horizontal, but a gravity compensation is attached which can be employed when the movement is vertical.

The rate of the movement and the uniformity of the motion are determined by attaching, by means of wax, to any part of the sliding screen a glass slip coated with lamp-black. A tuning fork, with an attached bristle, being made to vibrate transversely to the movement of the screen, the latter is released as in the actual operation of photographing; and the length of the wave marked by the bristle on the carbonised surface, multiplied by the width of the slit D and divided by the number of vibrations of the fork per second, gives the duration of the exposure, while the uniformity of the movement is tested by the equality of the wave-lengths, which correspond to the passage of the slit D across the circular aperture C. By this means the uniformity of exposure can be regulated to $\frac{1}{10000}$ of a second.

In order to obtain the exact position of the sun's axis on the plate the instant of the exposure is noted by the chronometer, and the exact level of the slide containing the sensitised plate is observed with an accurate clinometer before removing it from the camera.

As M. Janssen has pointed out, the chemical preparation and development of the plate require very great care in order to obtain the requisite sharpness of detail. The gun-cotton for the collodion is prepared at a high temperature (70° C.), and numerous precautions are taken to ensure that the collodion film shall be perfectly even and free from the smallest speck of foreign matter. The image is developed gradually, beginning with a solution of ferrous sulphate, and, after thorough washing, completing with a solution of pyrogallic acid, after which the image is strengthened with a mixture of pyrogallic and silver nitrate solutions.

* The present notice contains a more detailed description of the process than M. Janssen's original papers, and is published with his full approval and authority. With characteristic liberality M. Janssen writes:—"Quant au procédé lui-même, il est evident que toute personne un peu au courant de la photographie astronomique pourra l'appliquer et obtenir bientôt des photographies semblables à celles que nous obtenons. Je serai aussi très probablement devancé sur plusieurs points de la constitution du soleil que ces procédés peuvent révéler. L'inconvenient n'est què pour moi, et je crois qu'il vaut mieux dès aujourd'hui livrer la méthode au public scientifique. Les progrès de la science y gagneront certainement."

† Owing, probably, to spherical aberration.

‡ In this part of the process M. Janssen acknowledges the assistance of M. Arents, to whom the writer is also indebted for much information.

* This, M. Janssen suggests, may be otherwise effected by an arrangement which will arrest the action of the springs at the instant when the slit reaches the margin of C.

In a favourable state of the atmosphere the pictures thus obtained leave nothing to be desired in point of sharpness and definition of detail. But, as a matter of course, all states of the atmosphere do not permit of equal success, the process being subject to the same atmospheric contingencies as in all astronomical work with the telescope. The best results were obtained in the late autumn and during this last spring.

The character of the photospheric surface, as displayed in the new photographs, will be best described in a translation of M. Janssen's own words :—

"The photographs show that the solar surface is covered everywhere with a fine granulation. The forms, dimensions, and arrangement of the granular elements are very varied. Their size varies from some tenths of a second to three or four seconds. The shapes are circular or elliptical, and more or less elongated; but often these regular forms are more or less distorted. The granulation is exhibited everywhere; and, at first sight, it does not appear to present a different constitution towards the polar regions. But this is a point to be further investigated. The illuminating power of the granular elements, taken separately, varies much; they appear to be situated at different depths in the photospheric layer. The most luminous of them—those which more especially contribute to the luminosity of the photosphere—occupy but a small fraction of the surface of the sun.

"But the most remarkable result yet obtained, and which is exclusively due to the employment of the photographic method, is the discovery of the photospheric network *(réseau photosphérique)*. An attentive examination of the photographs shows that the photosphere has not an uniform structure throughout, but is divided into a series of figures, more or less distant from one another, and exhibiting a special constitution. These figures generally have rounded contours, but also often rectilinear and sometimes polygonal. Their dimensions are very variable, and they sometimes attain to a minute or more in diameter. While, in the intervals between these figures, the grains are distinct and definitely bounded, although of very variable size, in their interior the granules are half obliterated, drawn out and confused; most frequently, indeed, they have disappeared, giving place to trains of matter which replace the granulations. Everything indicates that, in these spaces, the photospheric substance is subject to violent movements which have confounded the granular elements. * * This fact enlightens us as to the forms taken by solar activity, and shows that this activity is always very great in the photosphere, even though there be no spot visible on the surface. I will further draw attention to this very important fact, of which very distinct evidence is furnished by certain photographs, viz., that numerous very dark points appear in the regularly granulated tracts, indicating that the photospheric layer can have but a very small thickness."

In another paper M. Janssen deduces some further conclusions of interest. He observes :—

"If the solar layer which forms the photosphere were in a state of repose and perfect equilibrium, it would result from the fact of its fluidity that it would form a continuous envelope around the solar nucleus; the granular elements would be confounded together, and the lustre of the sun would be uniform in all its parts. But the ascending gaseous currents do not admit of this state of perfect equilibrium. They break up and divide the fluid layer, escaping at a great number of points. Hence results the formation of the granular elements, which are but so many fractions of the photospheric envelope, and which tend to take a spherical form, in virtue of the gravity of their constituent parts. * * But even this state of equilibrium of the individual parts is but rarely realised; in numerous points the currents drag along with them the granular elements, and these latter lose their spherical form, and eventually become no longer recognisable where the movements are most violent. * * Moreover, in the regions of relative calm, the movements of the photospheric medium do not allow the granular elements to arrange themselves in an even layer, whence results the greater or less immersion of the grains beneath the surface, and, consequently, owing to the great absorptive action of the medium, the great differences of their lustre shown in the photographic pictures. * * We may further conclude, from the fact of the relative rarity of the most luminous grains in the photographs, that the illuminating power of the Sun is due principally to that of a small number of points on his surface. In other words, if the solar surface were completely covered with granular elements of equal brilliancy with these its illuminating power, according to a first approximate estimate, would be from ten to twenty times greater than it is."

It will be interesting to ascertain, at the next epoch of sun-spot maximum, whether the brilliant granules occupy a relatively larger proportion of the solar disc than at the present time. The direct evidence which such an observation will afford on the important question of the periodic variation of solar radiative intensity—a question on which much diversity of opinion still exists—will be of the highest value.—*Nature*. THE REACTIONS OF CHROMIC ACID AND CHROMATES UPON SUBSTANCES OF ORGANIC ORIGIN, CONSIDERED WITH REFERENCE TO THEIR USES IN PHOTOGRAPHY.*

Influence of the Aqueous Contents of the Chromated Gelatine upon its Sensitiveness to Light.

The aqueous contents of chromated gelatine has a great influence upon its sensitiveness. It is, therefore, maintained that the sensitiveness of the aqueous, and of the already-stiffened but still moist, chrome-gelatine is extremely small by the side of the same mixture when dry. Gelatine films dried in air are, however, by no means free from water, of which, indeed, they contain on an average about seventeen per cent. By storing them in places the air of which contains varying quantities of moisture the aqueous contents of the gelatine also vary without changing its appearance, and even without swelling it up. Such gelatine films are usually spoken of as "dry," and it is of the influence of the varying proportions of moisture in them upon the properties of the chrome-gelatine that I shall speak here.

I find the idea that carefully-dried chrome-gelatine is considerably more sensitive than less dried is generally accepted. It is also the case that tissue is less sensitive ten or twelve hours after being sensitised than twenty-four hours after[1]. Sensitised tissue is most sensitive on the third or fourth day after sensitising; the cause of this phenomenon is complex, and no longer depends simply on the degree of dryness, but partly on the commencement of insolubility, as I shall show[2].

I determined the influence of moisture on the behaviour of chrome-gelatine in the following way :—Some carbon tissue was sensitised upon a three-per-cent. solution of bichromate of potassium and dried by twelve hours' exposure to air, but in the dark. It was then divided into three parts, one of which was placed in a desiccator over calcic chloride; the second was placed in another desiccator, the bottom of which was covered with water; and the third was simply kept in air. In these conditions they remained thirty-six hours, and were then—that is, two whole days after being sensitised—exposed with a continuous wide photometer of tissue paper. The result was extraordinary. The tissue which had been kept under the bell glass, over water, always showed one distinct photometer degree more than that of the air-dried; while that kept in the desiccator, though distinctly less sensitive, was yet scarcely a whole degree behind the air-dried. The tissue kept over water was, therefore, the most sensitive; that kept over calcic chloride in an atmosphere free from moisture showed itself the least sensitive; while the air-dried stood between the two others. The repetition from day to day of the same preparation, exposure, and development gave no variation from these results. On the fifth day, however, the air-dried paper had printed to the eighth degree of the photometer, while that kept over calcic chloride had only reached the sixth degree, and that over water the ninth degree. Their solubility was on that fifth day equally various. The tissue dried over calcic chloride and that dried in air developed perfectly in water of 30° C.; while that which had been kept damp could only be developed by water of from 50° to 60° C., at which temperature they were all three placed upon a flat sheet of glass, when the two former were found to have already lost two photometer degrees of density—that is, they were reduced to the sixth and fourth degrees. The tissue that had been in the desiccator, over the calcide chloride, remained the most soluble, and the spontaneous insolubility which had set in in the tissue stored over water had not attacked the driest at all.

In order to learn the influence exerted by this beginning of insolubility upon the sensitiveness of the chrome-gelatine, and to eliminate the influence of the moisture, which for the moment hindered it from setting in, I made the following experiments on the sixth day with the same tissue :—I placed tissue No. 1, which had lain five days over calcic chloride, in the bell glass, the bottom of which was covered with water. No. 2, a piece of the same, I exposed to air; and I left No. 3 over the calcic chloride. No. 4 was a piece of air-dried paper, which I placed over water. No. 5 was the same over calcic chloride; and No. 6 I left in the air. No. 7, tissue from the atmosphere saturated with moisture, I left there. No. 8, a piece of the same, was exposed to air; and No. 9, still a piece of the same, was placed over calcic chloride.

When these pieces of tissue were next day exposed simultaneously under the same photometer and then developed I found that No. 7 had printed to the thirteenth degree, No. 8 to the twelfth, No. 9 to the tenth, No. 5 to the seventh, Nos. 2 and 3 to the fourth, No. 1 to the fifth, and No. 8* between the fifth and sixth degrees. With regard to their solubility, Nos. 7, 8, and 9 were most insoluble; then came No. 4; and the others were about all equally soluble. On the seventh day the experiments were discontinued because the dampest tissues had so far lost their solubility that they could no more be clearly developed.

From these figures it will be distinctly seen that chrome-gelatine is most sensitive when it has lain some time in an atmosphere saturated with moisture, and least sensitive when kept in absolutely dry air, in which it also becomes so brittle and hard that it can neither be rolled up nor laid out flat without breaking. I ought, however, to say that the gelatine films dried for a week over calcic chloride had not even then given up all their water, but that they still retained some four or five per cent., which was only given off by heating to 120° C. With such perfectly-dry chrome-gelatines no experiments could be made, as at 120° C. they became thoroughly decomposed and insoluble. The temperature of the dry thermometer in the dark room in which the tissue was kept was during the experiment on an average 17° C.; that

[1] *Photo. Mittheilungen*, vol. xiv., p. 98. Sawyer.

[2] It is recommended that in order to work with all security, chrome-gelatine films (carbon tissue, &c.) should be used twenty-four hours after sensitising, but it may be kept perfectly fit for use until the third or fourth day.

* Note by Translator.—In the German version there are two Nos. 8, the second of which, probably, should be No. 6.

* Continued from page 520.

of the wet thermometer was 13° C., which indicated that the air of the room contained sixty-one per cent. of water, and that the atmospheric pressure was equal to 8·8 millimetres. The pressure of the bell enclosing the air saturated with moisture was 14·4 mm. The temperature of the well-closed room was liable to slight variations of + 0·5° C.

I have spoken of this experiment at some length, because my deductions are directly opposed to the prevailing idea that "the drier the chrome-gelatine the more sensitive it is." I found that *air-damped*[1] chrome-gelatine is more sensitive than either air-dried or over-calcic-chloride-dried, though this phenomenon was first manifested when very carefully observed.

Chrome-gelatine, more or less swollen up with water, is much less sensitive than "dry" films in the ordinary sense of the word; therefore the gelatine should not contain too much water, but merely what it would naturally absorb of the aqueous vapour present in air of an ordinary temperature.

From the foregoing the following simple but practically important rule may be deduced:—Sensitised chrome-gelatine should be kept in as dry a place as possible, so that it may remain long unchanged, but before exposing it should be placed for some time in a damp atmosphere (over a vessel containing water, or in a cellar, &c.), which will render it more sensitive. At the same time, in the case of carbon tissue, it acquires a greater pliability, owing to the moisture absorbed, which renders it very agreeable to handle without going so far as to make one fear that it would adhere to the negative. It is, of course, understood that one must avoid making the gelatine sticky by using water vapour of too high a temperature. Jeanrenaud's[2] observation that perfectly-dry tissue gives flat pictures and that the prints are improved if a piece of damp paper be laid upon the back of it, and Liesegang's[3] and Gentile's[4] perfectly-correct observation that carbon tissue is more sensitive in damp weather than in dry, are explained by the above. According to Waldack,[5] also, tissue is more sensitive in damp than in very dry weather. He attributes this partly to the slow drying, but he also mentions that it depends less upon that than upon the degree of moisture in the air. He says that very dry, brittle tissues are less sensitive than those which are damp and pliable. Lichtdruck plates are also, according to Waldack, much less sensitive immediately after they are taken out of the drying-box than when they have had time to absorb a little moisture from the air. This agrees exactly with what I have shown above. Lambert[6] also states that damp chromated tissue is more sensitive than dry (of course that means air-dried) tissue.

J. M. Eder, M.D.

(To be continued.)

ON PROCESSES OF MAP PRODUCTION BY PHOTOGRAPHY.*

The great difference between the photocollotype processes and lithography is that, whereas the lithographic stone receives a like quantity of ink in all parts of the image, and is incapable of producing a true and continuous gradation of shade, the moist gelatine film possesses the valuable property, not possessed by the stone, of receiving a greater or less amount of ink in different parts of the image, in exact proportion to the intensity of the action of the light upon them, and is thus capable of reproducing the most delicate gradations of shade as perfectly as they are shown in an ordinary silver print.

It will thus be readily understood that, instead of the advantages of photographic reproduction by cheap and speedy mechanical processes being confined to the reproduction of certain special subjects, they can be extended to all classes of subjects, such as photographs from nature, brush-shaded and coloured maps, MS. records, drawings, and paintings of all kinds. Even for line subjects the process surpasses most of the known processes of photo-engraving, photozincography, or photolithography in the delicacy, sharpness, and clearness with which the finest lines can be reproduced, as well as in perfect accuracy of scale, owing to there being no intermediate process of transfer, with its attendant washings and pressings, and the plate being printed by vertical pressure.

The process has the further advantage that the prints do not require mounting, and this makes it very suitable for book illustration, for which, indeed, it is now being very largely used. It is especially valuable for illustrations of a scientific character in cases where otherwise only the highest class of lithography or engraving would be applicable, and at an enormously-increased expense.

For the most successful application of the photocollotype processes to the reproduction of maps the result depends, as in photozincography, very much on the quality of the negative, and that, again, on the original.

[1] I use this expression to indicate shortly gelatine which had lain for some time in an atmosphere saturated with aqueous vapour, in contradistinction, on the one hand, to gelatine swollen up with water in the fluid state, and on the other hand to gelatine dried by the air in its normal condition (air-dried). Of course before the gelatine is laid in the damp air it must be air-dried, otherwise a certain excess of water would never disappear.

[2] *Photo. Mitthsilungen*, vol. v., p. 262.

* Continued from page 524.

Any negative that will give a good photographic print will answer; but the successful reproduction of shaded maps or drawings demands considerable care in the execution of the original drawing as well as in taking the negative.

One of the great drawbacks to the extended use of the photocollotype process for the reproduction of maps is the difficulty of making corrections on the plates. When the printing surface is a metal plate or lithographic stone, upon which a map has been either engraved, zincographed, or lithographed, additions and erasures may easily be made without any risk of the loss of the printing surface, or even of much damage to it. With the tender gelatine films the case is different; and, although writing or simple lines may be inserted without much difficulty, it would be almost impossible to successfully alter gradation of shade or to insert shaded details. On the other hand, the taking out of details must be done by some chemical means, which must always be attended with the imminent risk of raising the gelatine film from its support and the consequent utter destruction of the printing plate.

As maps, almost more than any other printed subject, require that it shall always be possible to make corrections on the printing plates, it is obvious that the use of any process which will not permit of this being done must be confined more to the reproduction of maps already printed or of an ephemeral character than to the preparation of new or standard ones. And thus, though photocollotype is admirably adapted for reproducing copies of old or other special maps, which are or can be finished once and for all, it is not suited for maps on which corrections are likely to be required.

With the plates prepared as described we have found that details may be inserted by two or three methods. The first is by writing in the required additions on the dry gelatine surface, using an ink composed of bichromate of potash, either alone or coloured with Indian ink. After the insertion of the additions the plate is exposed to the light for a few minutes to reduce the bichromate, and may then be washed and printed as usual; or an ink composed of solution of chrome alum may be used, and will not require exposure to light. In some cases the part to be corrected may be washed over with a solution of bichromate of potash and allowed to dry, and then the required details may be printed in from another negative.

The taking out of details is more difficult, and requires care. It may be accomplished by washing the part with a strongish solution of caustic potash or cyanide of potassium. Should a plate print dirty it may be cleaned up and greatly improved by being washed with a weak solution of cyanide of potassium, or, better, with a solution of citric acid, which not only clears up plates that print dirty but at the same time facilitates the inking in. A weak solution of ammonia is also said to be useful in this respect.

In all cases where the photographic image is impressed directly on the printing surface a reversed negative must be used, as before explained, and these are sometimes rather troublesome to produce. I have lately tried whether the use of this reversed negative could not be dispensed with in the photocollotype process, by taking the negative in the usual way direct on to the thick ground glass plate, and then, while still wet and without varnishing, coating this negative with a thin layer of any of the foregoing mixtures of gelatine, either with or without bichromate. When the sensitive gelatine coating is dry it is exposed to light through the negative on the under side and allowed to print well through the film. This plan was found to have many conveniences to recommend it, and to answer very well for subjects in line, but not for half-tones. For map work it has the undoubted advantages of perfect accuracy of scale and the greatest possible sharpness of the image.

The foregoing descriptions will give an idea of those interesting processes which are now being very largely used for producing photographic prints of all kinds, though I believe the successful working of them still presents some difficulties, even in better climates than India. Against their employment for map work on the large scale there will, however, always remain the impossibility of joining up several sections of a large map on the printing surface, the difficulty of producing the finest tints of a shaded map with a perfectly-clean white ground, and, above all, the difficulty of making additions and corrections on the plates.

Woodburytype.

We have already seen that the great drawback to the production of photographs in printing ink with continuous gradation of shade, by either photography or photo-engraving, is the necessity for breaking up the continuity of gradation by a more or less marked "grain," and that this difficulty has been overcome by the photocollotype processes.

By a very ingenious process, invented in 1864, Mr. Walter Woodbury succeeded in solving the problem in another way, and, by a mode of operation analogous to "nature-printing," has been able to produce absolutely permanent prints with such perfect photographic gradation, combined with the most exquisite transparent delicacy and richness of tone, that none but the initiated would know that they were not the ordinary silver prints.

A tissue is first made by coating a tough film of collodion with a moderately thick, even layer of gelatine and bichromate of potash, slightly coloured in order to see the progress of the development.

When dry the tissue is laid collodion side next to the negative film, and exposed to light proceeding from one direction only, in order to prevent diffused rays acting through the thick gelatine coating, and so blurring the image. This tissue of gelatine and collodion is then temporarily attached to a glass plate and treated with hot water—very much in the same way as in the pigment printing process already described. The whole of the gelatine upon which the light has not acted, and which, therefore, remains soluble, is dissolved away, leaving an image in relief, the highest parts of which represent the deepest shadows of the picture, while the parts intervening, down to the lowest, represent the intermediate gradations between the deepest shadows and the highest lights.

When dry the gelatine composing this image will be quite hard and capable of resisting the heavy pressure required to indent it into soft metal, without itself being injured.

The tissue bearing the image having been stripped from the temporary support, is laid face downwards on a sheet or block of lead or type-metal, about one-third of an inch thick, between two finely-surfaced steel plates, and submitted to the pressure of a very powerful hydraulic press. The prominent parts of the relief are thus forced into the soft metal, and produce a mould, the deeper parts of which represent the shades and the shallower the lights of the picture. As the relief obtained from gelatine and bichromate of potash alone will impart to this mould a smooth surface without grain, such plates could not be printed with printers' ink, like a copperplate engraving. Mr. Woodbury, therefore, uses a semi-transparent ink consisting of gelatine coloured with any suitable pigment.

The leaden plate or mould is laid in a suitable press of peculiar construction,* and slightly greased. A small quantity of the coloured gelatine having been poured in a liquid state into the middle of the mould, a piece of suitable paper is laid above it and pressed strongly down, so as to force the ink thoroughly into the depressions all over the plate, and squeeze out all the ink between the surface of the metal and the paper in the parts forming the highest lights of the picture. The gelatinous ink is allowed a short time to "set" and attach itself to the paper; the paper is then removed and brings with it a perfect impression of the picture in coloured gelatine, of different thicknesses corresponding in intensity and gradation of shade to the depth in different parts of the plate. The print has now only to be "fixed" in a solution of alum, and, when dry, is perfectly permanent and ready to be trimmed and mounted.

The rate of impression is about the same as of ordinary copperplate printing, and may be carried on quite independently of the light. If very large numbers are required of a single subject it is easy to produce as many printing-plates as may be required from the original gelatine relief, which may afterwards be put away and kept indefinitely. The cost of printing is exceedingly small, and prints are produced in large numbers at a marvellously cheap rate. As the process requires special mechanical appliances and apparatus, it has generally been worked on the large scale by public companies.

The Woodburytype is unfortunately not well adapted for the reproduction of maps, because it has been found very difficult to produce impressions of large dimensions, and, owing to the peculiar method of printing, it is almost impossible to obtain the clear black lines and pure white ground so indispensable in a good map. The prints also have to be mounted, which is an objection. However, in special cases where the work is within the capabilities of the process it will be found valuable, because it possesses the great advantage over the collotype processes for the reproduction of half-tone subjects—that the printing of an almost indefinite number of copies can be carried on with as perfect certainty as in ordinary lithography or engraving—while in beauty, transparency, and delicacy of gradation the Woodburytype prints are undoubtedly superior to collotypes.

J. Waterhouse, *Capt.*

(To be continued.)

Meetings of Societies.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

The first meeting of this Society for the winter session was held on Tuesday evening last, the 12th inst.,—Mr. James Glaisher, F.R.S., President, occupying the chair.

The following gentlemen were elected members:—Charles Bennett, Arthur Clark, T. G. Hemery, J. G. Ritchie, S. Victor White, J. E. Bliss, T. J. Dixon, W. Perry, J. G. Small, S. Wolstenholme, James Cadett, F. Downer, A. Lombardi, and W. Vanner.

The President then proceeded to distribute the medals awarded to the School of Military Engineering, Messrs. Vernon Heath, A. Wilson, George Nesbitt, Payne Jennings, J. Cadett, and the Woodbury Company. Of the gentlemen named above only two were present to receive their medals in person. After strongly commending the pictures of Mr. Charles Bennett, which had been taken by artificial light, he (the President) explained that the pictures placed in competition for the other subjects for which medals had been offered did not come up to the standard determined upon by the jurors, who, consequently, had declined to award medals in those classes; and, stating how much they were indebted to Mr. Warnerke for the display of his Russian collection, he closed by saying that emulsion processes promised a great future.

The Secretary then read a paper, *Notes on a Visit to Russia*, by Mr. Leon Warnerke. This will appear in our next number.

Mr. John Thomson, F.R.G.S., gave an account of his recent visit to Cyprus, and described graphically the circumstances under which he obtained the photographs exhibited on one of the screens.

Votes of thanks followed these two communications, upon which no discussion took place.

The meeting then assumed the form of a *conversazione*, and was soon afterwards adjourned.

* For a drawing of this press, see Abney's *Treatise on Photography*, p. 175.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

The monthly meeting of this Society was held on Thursday, the 7th inst.,—the Rev. F. F. Statham, M.A., in the chair.

Messrs. H. G. Cocking and Christopher Bennell Cutchie were elected members.

The officers and members of committee for next year having been nominated,

Mr. F. A. Bridge brought before the meeting some troubles he had recently experienced. In the course of his business he had occasion to develope paper enlargements produced by the oxyhydrogen light and magic lantern. Having obtained a new sample of glacial acetic acid from a well-known firm of manufacturing chemists, every picture obtained by its agency was totally destroyed through fogging—to such an extent as to blacken the entire surface of the paper. He had noticed that the picture flashed out upon the application of the gallic acid developer, but the darkening followed immediately after the appearance of the image. He exhibited specimens of this peculiar kind of defect, and concluded by asking the opinion of the members as to the cause.*

Mr. E. W. Foxlee thought that if aldehyde were present as an impurity it would cause such a fogging as that described.

Mr. T. Bolas said that either formic acid or aldehyde would account for it.

Mr. W. Brooks suggested iron as a likely agent by which the blackening might be caused.

In reply to a question as to the possibility of making use of the acid,

Mr. Bolas said that a little nitrate of silver might be dissolved in the acid, and after exposure to light for some time a precipitate would doubtless be formed, after which it would be fit for use.

Mr. T. J. Pearsall thought that it would be doing the manufacturers a kindness to return it and explain the reason for so doing. It would enable them to trace the history of that individual sample, and thus to arrive at the cause of the defect.

Mr. F. York had at one time a sample of acetic acid which produced an effect quite contrary to that just spoken of, for one drop of it produced the same result as twenty drops of the ordinary acid. He had concluded that it was extensively contaminated with sulphuric acid.

Mr. Brooks remarked that he once had a similar experience. There was much impurity to be found in the chemicals of modern times.

The thanks of the meeting were awarded to Mr. Bridge for introducing the subject, which was then dropped.

Some discussion on the blistering of paper prints followed, prefaced by Mr. E. Dunmore giving a synopsis of his remarks on that subject at the previous meeting of the Society.

In reply to a question,

Mr. W. M. Ayres said that paper prepared with albumen which had been salted with seven and a-half grains of chloride of barium and the same quantity of chloride of ammonium to the ounce, and excited upon an eighty-grain bath, was well adapted for winter work, and gave an image which lost nothing in the subsequent operations.

Mr. Brooks considered that blisters in albumenised paper arose from the paper being too weakly salted, and used in conjunction with too strong a bath.

Mr. Payne Jennings was scarcely ever troubled with blisters except with an occasional appearance of very small ones like pimples, and even these he never saw when he resided in Dublin, which convinced him that the water made use of had a great deal to do with their formation. He used a printing bath of the strength of from fifty to sixty grains to the ounce, and after the paper had been sensitised each sheet was drawn over a glass rod to remove the superfluous solution.

Mr. Ayres said he imagined that the surface of the paper was apt to become injured by drawing it over the glass rod, but did not experience this in his own practice.

After some other observations and the transaction of private business the meeting was adjourned.

* Since the report was written we have received from Mr. Bridge a written statement of his remarks on the occasion referred to. This will be found at page 543.—Eds.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

On Wednesday evening, the 6th inst., the Exhibition at Pall Mall was open, by kind permission of the Photographic Society of Great Britain, in aid of the Photographers' Benevolent Association, attended with satisfactory results. During the evening the gallery was visited by the President (J. Glaisher, Esq.), and other eminent gentlemen connected with the profession.

On the same evening the Board of Management considered an application for relief, and granted the assistance required by the applicant.

BRISTOL AND WEST OF ENGLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

The ordinary monthly meeting of this Association was held at the Museum, Queen's-road, on Wednesday, the 6th instant,—Mr. T. Davey in the chair.

In the unavoidable absence of the Hon. Secretary the reading of the minutes was postponed till the next meeting.

Lieut. Lysaght read a paper entitled *Notes on Staining Gelatine Films.* [See page 542.] After the reading of his paper Lieut. Lysaght exhibited a gelatine film stained with aurine, and called attention to the peculiar rose tint imparted to the film by the dye, the colour given to the film being quite different to the golden colour of the dye.

Mr. E. Brightman suggested that the molecular condition of the dye in the film was such as to impart a colour to it differing in shade from a simple solution of the dye, giving, as an instance of change of colour produced by altered molecular conditions, the well-known experiment of passing a glass rod over a sheet of paper prepared with iodide of mercury, when, by the simple pressure of the rod, a molecular change is produced, resulting in the production of an altered colour on those portions of the paper where the rod had passed.

The Chairman suggested the use of an emulsion giving a thick and dense film as a preventive of blurring.

Lieut. Lysaght mentioned the use of denser films; but, although there was less tendency to blurring when a dense film was used, he preferred a thin film as less likely to blister, instancing Swan's plates as liable to blister on account of the thickness of film.

The Chairman and Mr. Brightman had both worked with Swan's plates without noticing any tendency to blister whatever, five separate batches of these plates being developed without a single blister.

After a vote of thanks to Lieut. Lysaght for his paper, the meeting was adjourned.

EDINBURGH PHOTOGRAPHIC SOCIETY.

The nineteenth annual general meeting of this Society was held at 5, St. Andrew's-square, on the evening of Wednesday, the 6th inst.,—Mr. John Lessels in the chair.

The following new members were elected:—Mr. George Turnbull, Mr. Marshall Wane, and Mr. James Meek.

Mr. Pillans, the Honorary Secretary, then read the following

ANNUAL REPORT.

The Council, in presenting the nineteenth annual report, have pleasure in congratulating the members on the large accession to the membership and the increased popularity of the Society.

During the past year the Society has lost sixteen members by death, resignation, and removal, and sixty-six names have been added to the roll of membership. The Society now numbers a total of three hundred and forty-three.

Sixteen meetings have been held during the past session, nine of which were ordinary, three outdoor, two popular, one special, and the annual excursion.

The meetings have been well attended, and an increasing interest has been displayed by the members generally in the subjects brought under consideration.

The "popular" meetings have been largely taken advantage of by the members and their friends, and continue to be one of the interesting features of the Society's operations.

The Council regret that the outdoor meetings have not been so well attended as they deserved to be, and they hope that in future this interesting and instructive branch of the Society's work may be more largely taken advantage of. During the past session visits have been paid to North Queensferry, North Berwick, and Bridge of Earn.

A special meeting was held on the 16th November, 1877, for a practical demonstration of the working of Keevil's patent lantern, sent by Mr. F. York, of London, to whom the Society has been largely indebted for the loan of transparencies.

The annual excursion was pre-eminently successful. A company numbering over one hundred spent a most enjoyable day at Winton Castle, the beautiful grounds surrounding that fine old historical mansion having been thrown open by the special favour of Lady Ruthven.

The papers read before the Society have been chiefly noticeable for their practical character. The following is a list of the subjects:—

The Comparative Merits of the Different Dry-Plate Processes, Exemplified from the Studies of Several Amateur Members of the Society. By Mr. Norman Macbeth, A.R.S.A.

The Progressive Results of the Past Session. By John Nicol, Ph.D.

On Some Properties of Glass. By Mr. Wm. Gilmour.

Transparencies. By Mr. W. T. Bashford.

Remarks on Landscape Work, and its Relation to Art. By Mr. Payne Jennings.

The Collodio-Bromide Emulsion Process, with Practical Experiments. By Mr. Alexander Mathison.

A Résumé of the Gelatine Process. By the Rev. H. J. Palmer, M.A.

A Month Amongst American Photographers. By John Nicol, Ph.D.

The thanks of the Society are due to the following gentlemen:—To Messrs. Macbeth, Mathison, Murray, and Jennings, for exhibiting selections from their works; to the Rev. H. J. Palmer, M.A., of Birkenhead, for samples of his gelatine plates and transferred films, and also for his portable dark slides; to Mr. W. H. Davies, for exhibiting a *photogravure* plate, and likewise delivering the lecture at the second popular meeting; to Mr. W. T. Bashford, for transparencies; to Mr. M'Kean, for exhibiting his portable camera and tent; and to Mr. G. W. Wilson, of Aberdeen, for his presentation of an Archer's fluid lens.

As a special feature in the transactions of the past year your Council would refer to the handsome presentation print of a picture by Sir Noel Paton, who kindly permitted it to be reproduced in carbon by Messrs. Doig, McKechnie, and Davies, exclusively for the members of the Society.

In conclusion: it will be seen from the Treasurer's report that the financial position of the Society contrasts favourably with any past period of its history.

Mr. Alexander Mathison, Treasurer, then read his report, previously drawing attention to the fact that the funds of the Society were locked up in the City of Glasgow Bank, but that, in consequence of an arrangement come to by the other banks for the relief of depositors, one-half was rendered available, and the Royal Bank of Scotland had given credit to that amount. The following is a summary of the Treasurer's report, which had been certified as correct by the Auditor, Mr. Alexander Niven, C.A.:—

Dr. BALANCE SHEET. Cr.

Receipts.	£	s.	d.
To Balance in hands of Treasurer and Arrears Collected from last year	57	0	1
,, Subscriptions from Members on the List at the commencement of the year—308 at 5s.	77	10	0
,, Subscriptions from New Members—70 at 5s.	17	10	0
,, Subscription from One Life Member	3	3	0
,, Balance of Proceeds of Sale of Photographs	4	6	7
,, Interest on Bank Account..	1	13	4
	£161	3	0

Expenditure.				£	s.	d.
By Rent of Room				3	7	0
,, Presentation Prints				37	10	0
,, Expenses incurred at two Popular Meetings—						
Lecture Fee	£2	12	6			
Rent of Hall	6	0	0			
Oxygen and Loan of Bags	1	0	0			
Fitting up Screen	1	1	0			
Miscellaneous ..	1	0	2			
				11	13	8
,, Printing Billets				9	3	6
,, Postage of ditto, Stationery, Carriages, &c.				10	0	6
,, Fees for Secretary's Clerk, &c.				6	5	0
,, Arrears of Subscriptions written off				5	5	0
,, An Advertisement				0	6	0
,, Subscriptions in Arrears, 1876-7-8.				6	0	0
,, Balance due by Treasurer—Amount in Deposit Receipt with City of Glasgow Bank, including int...	£61	7	5			
On Account Current ditto	55	5	11			
	116	13	4			
Deduct one-half thereof, for which credit has, meantime, been obtained with the Royal Bank of Scotland	58	6	8			
	58	6	8			
Balance on Account Current with the Royal Bank of Scotland, per Pass Book	10	11	2			
In hands of the Treasurer	2	14	6			
				71	12	4
				£161	3	0

The above financial report having been adopted, the meeting proceeded to the election of office-bearers for the ensuing year, when the following gentlemen were unanimously chosen:—

President: John Lessels.—*Vice-Presidents:* Dr. J. A. Sidey and Lieut.-Col. Herne.—*Hon. Secretary:* Malcolm G. Dobbie, 320, Leith Walk, Edinburgh.—*Treasurer:* Alexander Mathison.—*Corresponding Secretary:* William T. Bashford, Portobello.—*Lecturer:* W. H. Davies.—*Auditor:* A. T. Niven, C.A.—*Councillors* (to supply the places of those retiring): William Forgan, Robert Murray, C.E., Duncan Anderson, Hugh H. Pillans, and James Dickson.

The only alteration of note was that of lecturer. It was agreed that this officer should henceforward have a seat at the Council board, and that no fee be attached to the office.

The usual vote of thanks having been passed, the meeting terminated.

Correspondence.

The Inaugural Meeting of the Session of the Photographic Society of France.

The opening meeting of the new session of the Photographic Society of France took place on Friday, the 8th instant, the chair being occupied by M. Peligot, member of the Institute of France. In consequence of the wet and unfavourable weather the *séance* was not so numerously attended as is usual on the Society reassembling after a vacation.

The proceedings commenced with the election of MM. Mieusement and Arembourg as new members. Captain Jolly, commandant of the new fort of Palaiseau, was presented for election by MM. Alfred Chardon and Davanne.

M. Pector, in the absence of M. Perrot de Chaumeux, the Secretary, read the extracts from the foreign journals, quoting largely from The British Journal of Photography and from the *Philadelphia Photographer*, in which Professor Stebbing gave Mr. A. L. Henderson's formula for the wet collodion process.

M. Davanne said he had received from the Mayor of Chalons a request for sympathy and aid from the Society towards erecting an international statue to Niepce. To carry out the object of the application, he proposed that an international commission should be named, consisting of the Duke de Chaulnes, Dr. Hornig, Balaguy, Berthaud, Civiale, Levy, Pector, Bardy, Harrison, and Robert de Sevres.

The proposition was warmly received and carried unanimously.

M. Adolphe Martin made a communication on the awards of the jury in class XII of the Paris Exhibition, and complimented the Photographic Society of France on the success of its members generally, and especially M. Peligot, who had been promoted to be commander of the Legion of Honour, and MM. Gauthier-Villars, Davanne, Dujardin, and Rousselon, who had each received the cross of chevalier, as well as M. Poitevin, who received an exceptional prize—probably some £500. The Societies of Paris and Vienna, and the state establishments of St. Petersburg and Lisbon, had each been accorded high honours, and he thought the awards had given general satisfaction. True, several exhibitors complained, but that always occurred in a great competition, when individuals form a different opinion of the value of their labours to that of an international jury composed of competent and honourable men whose decisions in a matter of judgment should be final.

Prof. Stebbing exhibited an untouched, rather feeble negative—a portrait of himself—made during his last visit to England, by means of the electric light, by Mr. Vanderweyde, with an exposure of thirty seconds. The light was not offensive to the eyes. The arrangements were of a very primitive nature, the carbon pencils being moved by the hands of the photographer during the operation, which was hastily done and without extra care, as may be seen from the fact of the head-rest appearing in sight.

M. Poitevin having found amongst his collection of enamels a bust portrait of the late M. Balard, formerly President of the Society, begged their acceptance of the same, which M. Davanne proposed should be framed and added to the archives of the Society.

M. Pistoja, on the military staff of Italy, sent for the inspection of the Society several photo-engravings made by a process which he could not divulge. They consisted of ordnance maps, pen-and-ink drawings, and engravings of great beauty and fineness of execution, rivalling anything yet exhibited before the Society.

MM. Insley and Pacheco, of Rio Janeiro, sent also a collection of the Californian promenade-sized *cartes*, showing good photography. The form and proportions of the pictures, for the first time exhibited at Paris, did not meet with approval.

M. Carlos Relvas made a present to the Society of a handsomely-bound portfolio containing a collection of his works, for which he had been rewarded with a gold medal by the jury of Class XII., and which consisted of specimens of silver, carbon, printing-ink, collotype, and photo-engraving proofs, all executed by himself, and which made the Portuguese exhibition so resplendent and interesting.

M. Henri Pellet forwarded the results of his improvements in the ferro-prussiate process, with specimens of four different papers called "cyanofer paper," the last of which was of a resinous character, and so highly glazed as to be sufficiently transparent to serve for tracing-paper as well as for the reception of the prussiate image.

M. Adolphe Martin recollected that Lacroix exposed in the Exhibition of the Champ de Mars, in 1867, laminated paper, and which was not only uniformly transparent, but tough at the same time.

To this M. Davanne added that the No. 4 paper of M. Pellet might be considered as an able application of that principle.

M. Ferrier, on behalf of M. Vivien, exhibited the *iconometre* of M. le Commandant Faure-Biguet, which, in outward appearance, resembles the small focussing-glass of Dallmeyer, and consists of a small brass tube with telescopic slide, containing a parallelogram-shaped diaphragm, the eyepiece sliding in and out, and showing the focal length of the lens required to produce the image shown within the diaphragm. It appeared a very elegant little instrument, and might form a companion during a photographic tour, and render assistance in the choice of points of view suitable for the size and form of the photographic lens.

M. Garcin forwarded a sealed box of plates prepared by the gelatino-bromide emulsion process, which, on the motion of M. Davanne, was referred to the commission on emulsions for trial.

Prof. Stebbing presented a number of proofs obtained with the salts of platinum by the new process of Mr. Willis, Jun., and gave an experimental demonstration of the process. He said that about three years ago Mr. Willis sold his patent in France to MM. Poulenc and Wittmann, but the French photographers refused to buy licenses to work the process, inasmuch as hyposulphite was used in the manipulations. To remedy this state of things Mr. Willis made experiments which resulted in an improved process in which no hyposulphite of soda was required. He also found that oxalate of iron would be very useful for developing dry plates, but it required a restrainer. Mr. Willis begged Professor Stebbing not to publish the fact, preferring to continue his experiments. Shortly afterwards Mr. M. Carey Lea published his process, containing what was wanted, namely, a restrainer—gallic acid; and although Mr. Willis and himself had some months before experimented in connection with the discovery, it was undoubtedly the property of Mr. Lea, he having made the first publication of the complete process.

The thanks of the Society were voted to Professor Stebbing for the communication he had made, for his demonstration, and for the copies of prints developed before the members and thereupon presented to them.

Asnières (Seine), Paris, November 11, 1878. W. Harrison.

THE BOISSONNAS' PROCESS.

To the Editors.

Gentlemen,—If you think the publication of the extra-rapid process of M. Boissonnas, about which so much has been said recently, will interest your readers I beg to send you the formula employed by him, by which photographers will be enabled to judge for themselves of the rapidity of the process.

The most important part consists in the addition of acetate of copper in the developer, which is composed as follows:—

Distilled water	1,000 parts.
Protosulphate of iron	60 ,,
Acetate of copper in solution of ten per cent.	20 ,,
Glacial acetic acid	50 ,,
Alcohol	50 ,,
Pure honey	12 ,,

The silver bath must be quite neutral. The collodion is as follows:—

Sulphuric ether	500 parts.
Alcohol	500 ,,
Pyroxyline	7 ,,
Iodide of ammonium	3 ,,
,, ,, cadmium	3 ,,
,, ,, zinc	1 part.
Bromide of ammonium	6 parts.

—I am, yours, &c., G. Morgan.

12, *Rue la Bruyére, Paris, November* 5, 1878.

Photographic Recollections.—"Whatsoever man has done, man can do." We don't know who may be the author of this old saying, but remember it as among the mottoes. It seems reasonable and consistent at first thought, but we have a case in mind where the problem wouldn't solve. It was a four-four negative, and the subject was a lady from the provinces, who was in such a hurry she could not give but one sitting, though we tried to secure a second; but, as she had to catch the train, we had only time to receive the pay and take express directions for sending. Owing to a rare combination of unexplainable causes, we had background effects which were more prominent than picturesque, and which we could hardly get rid of by ordinary masking manipulations. Our silver bath had all upon a sudden become bedevilled. We looked into our dirt barrel to see if our new sweed had not dumped its contents into the said bath, but that was intact. We examined our developer to see if it had not been recruited from the slop jar containing our waste, but we could not have the heart to lay the trouble there; it looked too blameless. The picture was to be a *plain* albumen print, which we were to frame and forward for value received. How to make a plain print from this negative was *positively* a sticker. It was so ornamental, so full of accessories, that we felt the value of it as a *specimen* was out of all proportion to the contract price, and yet we sent it with all extras thrown in. Much to our surprise we failed to receive some suitable expression of the lady's opinion of our artistic efforts. We had reason to fear she might write upon the subject, possibly by return mail; but she didn't. Some weeks after, however, we were waited upon by a family who hailed from the provincial town where our work of art had been sent. They brought a letter of introduction from our lady subject, saying that these persons were her friends and neighbours, and were so much pleased with her pictures that they wanted some *just exactly the same;* and in order that we might see the point, they brought the sensational picture with them. They then showed us an editorial paragraph from the village chronicle, in which its wonderfully unique effects were set forth, closing with the remark that *no other artist in the country* *could produce anything approaching it;* and, what was noted as equally astonishing, it cost no more *than ordinary* productions of its class! Though the paragraph was brief and very complimentary, it started a profuse perspiration as we perused it; for with all our ambition to keep up our reputation as a skilful artist, we were "cornered" to know how to reproduce the chemical chaos represented in this art specimen, "just exactly like which" five more were wanted from new subjects, who had come a long distance for the purpose. It may be thought reasonable that we should close this article by giving a formula for such reproductions under such circumstances; but formulæ, you know, are so liable to mislead.—*Anthony's Bulletin.*

EXCHANGE COLUMN.

Wanted, a quarter-plate lens in exchange for a 14 × 12 glass bath.—Address, John Beringer, Helston.

A very clean copy of Senefelder's *Instructions in Lithography*, with numerous illustrations, will be given in exchange for anything useful in photography.—Address, J. Webber, Wells, Somerset.

I want a rolling-press 20 × 16, and offer in exchange a press by Bury 18 × 12, a Newton lantern, and a quantity of slides or the choice of several lenses to balance.—Address, W. Ayres, Boundary Villas, Royal Crescent, Notting-hill, W.

A Dubroni apparatus (No. 2), in perfect working order, with portrait and landscape lenses—size of plate $2\frac{3}{5} \times 2\frac{3}{10}$ inches—in exchange for a tourist camera, by any good maker, for dry plates of about the same size.—Address, H. A. T., Port Ballintrae, Bushmills, Co. Antrim, Ireland.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

A. C.—The effect is obtained by working on the negative with a finely-pointed pencil.

Rev. S. T. P.—Both lenses are good, but No. 2 will be slightly quicker than No. 1, if both be used without any diaphragm.

T. T. T.—"Biborate of soda" is merely common borax. It does not reflect credit upon your local dispensing chemist that he is unacquainted with this simple fact.

M. D.—Not having tried the lens we are unable to speak from experience; but depth of focus and width of aperture are two properties which cannot exist together, good definition being presupposed.

Geo. F. Reade.—Not only is there no copyright in the pamphlet, but we have reason to believe that if you were to reprint all or any of it and distribute it widely you would receive the thanks of the publishers.

X. Y. Z.—1. Gelatine is soluble in hot, but not in cold, water; hence you are wrong and your "better half" is right.—2. Chloride of ammonium will answer better than any other salt. Let the proportion be twenty grains to the ounce of water.

Tyro.—For positives on glass let the collodion be tolerably thin and not too heavily iodised. Also, let there be two drops of nitric acid added to each ounce of the developer in addition to the acetic acid in the formula. Fix with cyanide of potassium.

P. O. Strahan.—As there are some individuals who have no ear for music, and are unable to appreciate "sweet sounds," so there are others who are incapable of appreciating colours, and of such may be your client. Do not give way to her foolish whims, which to us seem quite unreasonable.

R. E.—Monckhoven's treatise on *Photographic Optics* is published by Hardwicke and Bogue, Piccadilly. The second part of that volume is devoted to the production of enlargements—or, speaking more correctly, to the apparatus for enlarging—having special reference to the construction of the solar camera.

Instantaneous (Haverstock Hill).—1. The lens is much too slow to permit pictures to be obtained in the manner intended, even when making use of the most sensitive plates.—2. The lens C is also quite unsuitable, but either of the others will answer. We have made use of all the three with excellent results. D is slightly quicker-acting than the others.

J. E. G. Ford.—Unless the nitrate of silver be washed out of the prints the toning-bath will most certainly be destroyed. Mr. A. J. Wilson, writing on this subject in his manual of *Silver Printing*, says:—"It is hardly necessary that the prints should be absolutely freed from silver before putting them in the toning-bath, but it will prevent some waste of gold if they are nearly so."

A. A. C. Swinton.—1. No manual of the collodio-chloride process has been published.—2. No.—3. We are not aware of any remedy for the blistering of Swan's plates, unless a preventive at one time suggested to us by Mr. J. Werge meets the want, and which consists in making use of warm solutions. —4. We have never experienced the mealiness alluded to in such samples of ready-sensitised paper as we have used.

J. R. S.—Unless you have a very bright light you must either give a much longer exposure than you have been giving, or otherwise make use of a portrait lens, by which you will be able to secure well-exposed positives in a few seconds. With the lens you are at present using you may have to increase the exposure to nearly a minute, but without possessing more complete *data* than you have furnished, from which to judge, we cannot speak with definiteness. The time required for the collodion setting depends entirely upon the relative proportions of ether and alcohol; but a pretty accurate idea may be arrived at by applying the finger to the film after it has been formed.

George Scott wishes to know if any reader has had experience in the coating of silver prints on albumenised paper with collodion with the intention of preserving them from fading. Several years ago this subject received much attention, and many strong statements were made respecting the value of such a mode of preserving prints; but, so far as we can recollect, the facts eventually turned out to be contrary to the assertions, and the process was discarded.

R. R. Abel.—We do not comprehend precisely what you mean by the "*principle* of vitrified photographs." From your letter we gather that you have not bestowed much study upon either the principles or practice of this branch of photographic art. Suppose that a collodion transparency were heated to redness in a furnace the picture would be found to have been burnt-in, the "blacks" being of a bright yellow colour. But, if previous to burning-in, the picture had been toned with platinum, iridium, gold, manganese, or other substances, the tone of the picture, instead of being of a canary colour, would be brown, black, violet, or other tint, depending upon the nature of the toning agent employed. Make a few practical trials and then write again.

Major Ross.—After reading carefully the account of your method of practising the glycerine process, we believe that we are enabled to indicate with accuracy the cause of your failure. The silver bath which you have been recently using—unlike that employed five years ago, when, you say, success crowned your every effort—contains a large proportion of nitric acid. For the special purpose for which the bath was prepared the presence of nitric acid was beneficial; but for the glycerine process it is hurtful, because glycerine is decomposed by nitric acid. The first thing to do, therefore, is to get rid of this acid, which may easily be effected by adding oxide or carbonate of silver to the bath until the whole of the nitric acid has been utilised, and then acidifying by means of glacial acetic acid. Should it be thought desirable to make a new sensitising bath let it be composed of—

Nitrate of silver	1 ounce.
Distilled water	12 ounces.
Acetate of soda	3 grains.
Glacial acetic acid	6 minims.

The preservative should consist of equal parts of glycerine, honey, distilled water, and the above bath solution, with a moderately-large proportion of kaolin—say about one-sixth of the quantity of the glycerine. Shake well, and place it in strong light for two or three days. It will become at first dark, but afterwards clear and bright. Decant, and use the clear portion.

The Royal Academy.—At a general meeting of Academicians, held on Wednesday evening last, Mr. Frederick Leighton, R.A., was elected President.

Indecent Photographs.—At the Middlesex Sessions, before Mr. Serjeant Cox, on Tuesday last, the 12th instant, Joseph Cave, 35, described as a photographer, pleaded guilty to selling and publishing several lewd and obscene prints and photographs. Mr. Besley, who appeared for the prosecutors, the Society for the Suppression of Vice, stated that the defendant kept a shop in Euston-road, and was reported as dealing in these pictures, in consequence of which an agent was employed to buy, and detection followed. The seizure was small, as it is the practice now not to keep a stock, but to get from travellers daily what customers previously order. Detective Kerley, who made the seizure, stated that the photographs were produced in England. Mr. Montagu Williams, for the prisoner, said he had made very few sales, and had not been long acquainted with the trade. Mr. Serjeant Cox sentenced the prisoner to nine months' imprisonment, with hard abour, and the photographs were ordered to be destroyed.

LONDON GAZETTE, *Tuesday, November* 12, 1878.

Petition for Liquidation by Arrangement.

Alfred Wilkinson, Sunderland, optician, photographer, and stationer.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician.

For the Week ending November 13, 1878.

These Observations are Taken at 8.30 a.m.

THE BRITISH

JOURNAL OF PHOTOGRAPHY.

No. 968. Vol. XXV.—NOVEMBER 22, 1878.

ON THE EFFECTS PRODUCED BY REDUCING THE QUANTITY OF PYROXYLINE IN EMULSIONS.

Continued experiments with the modified emulsion we briefly described last week lead to a strong confirmation of the remarks we then made in its favour. Not only are the physical qualities of the film much improved, but a great increase of sensitiveness is obtained without, as is usual under such conditions, a corresponding loss in density. We are inclined to believe, however, that the degree of density obtained is less in proportion to the quantity of bromide contained in the film than when an emulsion containing a larger quantity of pyroxyline is used. It is necessarily difficult to arrive at an accurate judgment of the comparative quantities of bromide forming the respective films, which bear much the same relationship to one another as ordinary carbon tissue and special transparency tissue—the one being a thin film rich in bromide; the other having greater body but less bromide.

As we have said, there is no loss in actual density in the new emulsion; but, if two images of similar intensity be each treated with chloride of copper until thoroughly bleached, there will be found a surprising difference in their appearance by transmitted light, the new emulsion showing far greater density, and the difference is again increased when the chlorised images are reduced by means of alkaline pyro. Thus it would seem that, atom for atom, the bromide contained in the thinner film produces less density under the first development than that formed in the presence of a larger quantity of pyroxyline; but the fact that the atoms are packed closer together makes up for any deficiency which might otherwise arise.

Another remarkable feature in the thinner films is their increased permeability. We mentioned last week the tendency which they exhibit to abnormal or total reduction under the action of a slightly stronger developing solution than is ordinarily employed. Our experimental readers will know that an ordinary collodion film, whether prepared with the bath or from an emulsion, and entirely freed from nitrate of silver, may be kept in contact with a tolerably strong solution of alkaline pyro. for a very long time without suffering any appreciable reduction, provided always that it be carefully preserved from the slightest actinic influence. Pure silver bromide precipitated from aqueous solutions is, however, instantly reduced by the weakest developer, even though the precipitation may have been performed in the presence of excess of soluble bromide; indeed, the presence of a very large dose of the latter in the reducing solution scarcely causes any retarding action. Clearly, the difference is due to the presence of the pyroxyline; but whether the action of the latter is mechanical or chemical is not so easy to decide. If it be chemical it must arise, one would think, from some combination formed with the other constituents of the emulsion during sensitising; but that it is not wholly due to this is proved by the fact that silver bromide formed separately and afterwards incorporated with collodion is capable of producing a developable image. On the other hand, if we suppose that the retarding action of the pyroxyline is wholly due to mechanical causes—that is, to the fact of the particles of bromide being locked up in and protected by the collodion—how are we to account for the discriminating action of the developer in reducing only the exposed portions, the whole of the film being uniformly permeable? As neither of these views seems to be tenable, we must fall back upon the supposition that the action of light overcomes in some way the protective power of the collodion.

Whatever may be the truth, it has come to be accepted that coarse films—that is, films in which the particles of bromide are formed in a state of greater coarseness—are more sensitive and give less density than when opposite conditions prevail, and this result is attributed to the fact of the individual particles being less exposed to the retarding influence of the pyroxyline than when a more intimate mixture, arising from a finer division of the atoms, exists. Looking at the matter in this light it would be reasonable to expect that, if the influence of the pyroxyline be reduced by diminishing its quantity as compared with the bromide, a like result would ensue; and certainly our experiments would seem to bear out the expectation, the grain of the film being at the same time finer and its texture more homogeneous than if some other means had been resorted to to produce the change in character.

The colour of the emulsion, as well as of the film, produced with a minimum quantity of cotton is identical with that obtained under ordinary circumstances, but the shade may vary slightly from difference of thickness. Thus we have invariably met with orange or ruby tints, and never, so far, with the grey or violet shades, which are usually supposed to mark coarseness of deposit. By reflected light the appearance of the new film, however, is totally different. Whereas with a full quantity of pyroxyline the film presents a smooth, brilliant, and slightly-reflecting surface, under the opposite conditions it offers a fine matt or dead appearance—not, however, amounting to what has been described as "dusty."

If we extend the examination to the developed image the difference is, if possible, still greater. Let us hold an ordinary negative (in its dry, unvarnished state) in such a position that the light falls upon it at an acute angle, and we find that the surface presents to the eye an even, polished appearance. The image, however, is distinguishable, owing to the difference in the colour of the light reflected from the different portions, this being of a "coppery" or orange shade where the deposit exists, and white in the transparent shadows. We now submit to the same treatment a negative produced by means of the "reduced" emulsion. While the shadows present the same appearance, the lights show a dead, velvety surface, wholly devoid of reflecting power, and giving the impression of having been "dusted on" with lampblack. So striking is this that a positive exposed in this manner to the even light of a clear sky gives the effect of a brilliant picture on polished silver.

As regards the tenacity of the film and its capacity for resisting damage during development and washing, there does not seem to be any deficiency—in some respects the opposite. It never shows the slightest tendency to slip even under trying circumstances, and if, under the action of a violent stream of water, it should be damaged, the injury is totally different from that produced under like conditions upon a strong film. Instead of tearing away in large pieces the damage is merely local, the film having so little tenacity or continuity that the injury does not spread beyond the area immediately affected, and then the image seems to wash away in the state of powder rather than in a continuous "skin." When dry, the deposit is easily rubbed off as powder, very slight pressure with the finger sufficing to lay the glass quite bare and clean, whereas with a film of ordinary strength the same treatment would only communicate a higher polish to the surface without producing a scratch. The difference is not such as to render the film practically more tender than an ordinary one, for it is really better fitted to meet the dangers arising from the various washings; and, we imagine, few of our readers (except they be collodio-albumen workers) are in the habit of submitting their negatives to friction before varnishing.

Another important point to be considered in connection with the subject is the capability of the thin emulsion to resist washing or precipitation. We have not yet tried the first; but have gone through the operation of *precipitating* several samples with complete success, and, we must confess, with some surprise at the non-realisation of our expectations, for we had quite anticipated that we should break down at this test. If the emulsion be first mixed with a small quantity (half its own bulk) of water and thoroughly stirred or shaken, and fresh water then added till three or four times its volume has been used, the solid portions settle down at once in fine powder without any appearance of "strings" or "clots," and with no tendency to remain in suspension or float upon the surface, as is often the case. In this state it is easily and rapidly washed and dried, and, when redissolved, forms an emulsion scarcely differing from the unwashed one. In one instance in which the precipitation was done hurriedly a slight granularity was noticeable in the resulting final emulsion, but this was entirely removed by filtration. It is remarkable, as bearing upon what we have said above regarding coarseness, that the granular particles, upon development, became black specks, even in the non-exposed portions, thus showing their stronger tendency to reduction.

Since writing our previous article we have been reminded that Mr. B. J. Sayce, so long back as 1864, recommended the reduction of the proportion of the pyroxyline to two grains to the ounce. This was, no doubt, done in order to improve the fluent properties of the emulsion; but, in the then knowledge of emulsion requirements, it was not found to answer, as we find in subsequent formulæ Mr. Sayce went back to the old proportions. Now, however, we have confidence in again bringing to the surface Mr. Sayce's long-forgotten modification, and, in the present condition of our knowledge, we believe that it will be found a very decided improvement, though it may not, perhaps, under all circumstances be advisable to carry the principle to the length we have indicated.

THE ELECTRIC LIGHT AND PHOTOGRAPHY.

Since writing the article on the above subject, which appeared in our issue for November 8th, we have become still more convinced that the electric light is destined to play no unimportant part in the future of photography, and that at no distant period; for we have recently heard of more than one large London establishment that is about to adopt it—not as a substitute for ordinary daylight, although that has already been done at one studio—but as a power to be used when that light is too feeble to produce a good negative; and we think they will do wisely, too. Here is a case in point:—We called on a photographic friend a few days back, and found him bitterly bewailing his fate. He had, it is true, by the aid of quick-acting lenses and extra-sensitive chemicals, managed to secure a dozen or so negatives of more or less merit; but he had also been compelled to turn away nearly three times that number of intending sitters for want of sufficient light to secure such negatives as even with the assistance of skilful retouching would pass muster and be a credit to his establishment.

It is always a serious matter for the photographer who may be, and generally is, subject to heavy expenses to have to refuse sittings, as although many sitters might, no doubt, return, all cannot be expected to do so, as they may be only visitors to the metropolis, or, perhaps, may be leaving England, or subject to the thousand-and-one things that occur in daily life to prevent a large proportion of them ever again visiting the studio. Further: the disappointment of the would-be sitter is not less than that of the photographer, as the former may have frequently put themselves to great inconvenience in dressing expressly for the occasion, or have travelled long distances on purpose to be photographed by their favourite artist; and their disappointment is very great when they are informed that the light is not sufficiently good for the desired purpose. Now, if the electric light were at command—and we know that good portraits can be produced by its aid—all would be satisfied; the photographer would secure his guineas and the sitters their portraits.

It may be argued that the outlay for the necessary apparatus would prove a very serious matter, and so, no doubt, it would be, especially in the case of a small business; but we feel convinced that those who may spend a couple of hundred pounds or so in a Gramme or Siemans' electro-dynamic machine and a gas engine will find it in the end a good commercial speculation, as they will then be able to secure negatives of all sitters visiting the studio regardless of the weather. We also feel assured that many would be induced to go on dull days by preference, owing to the novelty of being taken by the light which is just now creating such excitement in all circles as well as on the Stock Exchange; and by this means a large accession of business might fairly be expected by those who adopt the electric light for photographic portraiture.

At the last meeting of the Photographic Society of Great Britain the result of a new application of the electric light to photography was shown in the shape of a carbon enlargement made by enlarging from the small negative direct on to the tissue, the time of exposure being, we are told, fifteen minutes. And we may here remark that some of the best enlargements we have seen have been produced by enlarging direct from the original negative by the aid of the solar camera. This means of enlarging is very generally employed on the continent and also in America; and from suitable negatives there is little doubt that it is the best and most economical way of working, especially when only one or two enlargements from the same negative may be required, as it saves the trouble and expense of making transparencies and enlarged negatives, which entails also a certain amount of loss of sharpness and detail existing in the original negative. But, unfortunately, the solar camera is practically useless for the greater part of the year in this country, owing to our variable climate, and the uncertainty as to when "old Sol" will next show his face after every preparation has been thus made for his reception. This is amply proved by the weekly returns of registered sunshine, which show that our great luminary *now* shines something less than twenty hours per week. It is well known that the sun's actinic power is at present at its minimum; so that if any means can be devised for producing the same effects by artificial light as are obtained by the use of the solar camera it will be a boon to photographers.

Now the electric light seems to fulfil these conditions, as the result shown at the meeting to which we have referred fully proves. If it can be worked on a commercial scale—and we can see no reason why it should not—it will have many advantages over the present system of producing carbon enlargements, as no transparency or enlarged negative will be required, thus effecting a great saving of time and, consequently, expense; for the time required to produce the enlargement direct will be less than is necessary for the production of a print from the enlarged negative when it is made.

As regards the question of cost of this method of working: there will be a great advantage in favour of the electric light; that is, if the published estimates of the necessary expenditure be correct, which, for a light of suitable power for this purpose, is from fivepence to eightpence per hour. But when we consider that the rays of the electric light, unlike those of the lime light, are equally luminous in every direction, it will be seen that if it be placed in a square lantern, condensers may be fitted on each of its sides, and that if this lantern be placed in the centre of a room four negatives can be exposed simultaneously on tissue placed in each corner of the room with one expenditure as regards light, thus reducing its cost to a mere bagatelle.

We had no opportunity of examining the negative from which the enlargement shown the other evening was made, nor are we aware whether the tissue used was extra-sensitive or that it was kept for any length of time after exposure and before development, so as to take advantage of the so-called "continuating" action of light. We think, however, that sufficient was shown to warrant us in directing the attention of our professional readers to this means of supplementing the present limited supply of sunshine, and carrying on their ordinary operations with profit to themselves during the winter months.

A PHASE OF ENLARGING.

Taking a hundred average enlargements, an experienced photographer would be able at a glance to see that they were not pictures and to point out the mode of working that had been adopted in ninety-nine of them, and of those ninety-nine we are afraid there would be but a small proportion which could be classed as excellent. But yet there would appear to be no reason why, if properly treated, an enlarged photograph should be in any way different from a plain one, except in so far as the *texture* of the film is concerned; and there are many modes of enlarging in which this quality may be quite put on one side, owing to the ease with which it is perfectly avoided.

Any photographer who has taken the pains to perfect himself in copying pictures knows the ease with which a negative can be obtained—say of whole-plate size—from a *carte de visite* which is perfect in every respect, save only that the grain of the paper also is enlarged so as to give a disagreeable granularity or unevenness of texture in the resulting print. There is no way of avoiding this fault, though it may, to a considerable extent, be palliated by various means.

The process of enlarging direct on to silvered paper and bringing out the image by development is capable of almost perfect results; but the scope of this mode is very limited, as it is practically out of the field for small work, and, being most under control for plain paper only, there is sometimes a difficulty in obtaining sufficient depth and richness in the shadows, while the producing of large numbers of a given negative would occupy such time as to make the price prohibitive in comparison with other and more rapid means.

The process of enlarging through the medium of a transparency, and obtaining from it a negative of the required size, is, without doubt, the theoretically perfect one, and it is now practised, we believe, by most photographers who make a *specialté* of that branch. It is, however, in the hands of most workers, liable to two capital defects, viz., a tendency to a line of halation round the boundaries between dark and light spaces, and, most common fault of all, a peculiar flatness and want of vigour in combination with due variety of shadows and tones.

This latter fault, which only we wish to consider at present, though not always seen in everyone's work, is practically the grand stumbling-block, and we are inclined to believe that a true conception of its causes has not hitherto been formed, or, at anyrate, its governing principles formulated. Actuated by a determination to arrive, if possible, at a true solution of the problem we have lately produced many enlarged negatives, and made a special study of such transparencies as we had the opportunity of examining, as well as their resulting negatives.

We believe we have thoroughly established an explanation of the cause of this deficiency of modelling, vigour, and transparency of the deep tones. At first sight there seemed to be no kind of classification which could be adopted that would be capable of including all the transparencies we examined, for to these we naturally looked for the true solution. We had silver transparencies, beautifully rich, of all shades of colour, toned and untoned, and of all intensities—from those where the shadows seemed formed of velvet to the lightest and most gauzy-looking films—and each of these had produced an almost perfect negative difficult to be detected as not direct from life. (We confined our examination to portraits, as we considered the greatest nicety was there needed to produce a perfect result.) Then we turned to negatives obtained from carbon tissue, and among these was a still greater proportion of perfect results, the transparencies being obtained likewise from tissue of all colours, varying from the richness and depth given by the "transparency tissue" to the faint image from a thin portrait tissue. From each variety had been obtained excellent results.

Clearly, then, it was not to the transparency that we had to look to discover the secret of success, and, as the result showed to be correct, we surmised it all depended upon the strength of the light sent through the transparency whether the negative obtained was good or bad, the strength of the transparency determining the intensity of the light. It has been constantly argued that when examined in an average light, if complete gradation existed there to start with, an extra intensity of light would merely require a diminished exposure to obtain identical results; but this argument is fallacious, as we will show. Taking a transparency of average density, let us assume a weak light sent through it enables a perfect negative to be taken; then, if we send a light (say) ten times as strong through it, the scale of proportion existing between the high lights and the deep shadows is entirely different. For in the first case there was an entire gamut of tints, and in the second only a portion of it, for there would be able to exist a further series of deep tints below the deepest of the shadows; in other words, with the stronger light the relative intensity of the lights and the shadows in the transparency become considerably reduced, and the scale of tints in consequence incomplete.

The argument from these principles is obvious, and needs not to be dwelt upon at length. All that is necessary is either to make a transparency of rigorously-exact uniformity to suit the special light employed, or, if that be impossible, to have the light so under control that screens of various degrees of translucency could be placed before it so as to diminish and modify its power to any extent. With the light we have thus thrown upon the subject we believe we have indicated a decided advance in the power of producing good enlargements or reproductions of negatives.

RECENT PATENTS.

No. XXI.—ALDER AND CLARKE'S LUXOGRAPH.

The patentees must not be held responsible for the above heading, which we have adopted from the trade title of the instrument by which were taken several excellent portraits that formed part of the pictorial display at the Photographic Exhibition just closed, and of which pictures we have been permitted a more detailed examination at leisure. The title of the invention patented is "Improvements in Means and Appliances for Producing Powerful Artificial Lights for Photographic and other Purposes;" but the instrument or apparatus described is, we understand, that which is now commercially known as the "luxograph"—a designation to the correctness of which hypercritical etymologists might demur. The patentees say:—

Our invention has for its object the production of photographs without the aid of daylight, and at times and in places where it would ordinarily be impossible to produce them.

We use any of the well-known actinic artificial lights, such as the electric, magnesium, or pyrotechnic compounds, by preference the pyrotechnic, on account of its not requiring expensive apparatus and machinery. It is well known, however, that unaided artificial light is useless for the production of satisfactory pictures, as rays of light coming from a point are quite unsuitable for the purpose. Our invention enables the operator to produce pictures equal to those taken by ordinary daylight. For this purpose we employ a reflector of suitable size, by preference one about four or five feet in diameter, in conjunction with the said light, and with the reflecting surfaces placed at suitable angles; we prefer to render the rays of light parallel or convergent to a focus. In conjunction with the reflector or otherwise we employ one or more semi-transparent screens placed between the source of light and the object to be photographed, by which means the rays of light are dispersed or diffused equally, and a soft and suitable light obtained for photographic purposes.

The improvements are to be performed by making the reflectors of silvered glass or other reflecting surfaces built up of small pieces, or otherwise formed, and fixed in a curved or other convenient shaped metal or otherwise constructed frame. In front of the reflector and in its centre of focus is placed the light, and in front of the light is placed one or more screens of opal or ground glass, or of *papier* *mineral*, tinted or otherwise, or other semi-transparent media of sufficient size to prevent the passage of any rays of light save through its medium, and thus all rays are dispersed.

In practice we often find it desirable to subdue the principal light by placing a violet or blue-tinted glass in front of it.

When either a pyrotechnic composition or magnesium is employed to produce the light a lantern of glass must be used with a chimney to carry off the fumes arising from the burning of the light, and the light supplied with air by suitable inlet.

Having thus declared the nature of our said invention, and the manner in which it is performed, we claim—1. One or more screens in conjunction with artificial light for diffusing the rays of said light. 2. One or more suitable reflectors for multiplying rays of artificial light and reflecting them at proper angles, in combination with one or more semi-transparent media for diffusing said rays, all for the purpose of illuminating objects for photographic pnrposes, all substantially as described and set forth.

Without making any observation upon the points of the specification, we may state that the portraits which have been taken by means of the luxograph are undoubtedly successful. We have seen the apparatus in operation, and have been present when a portrait was taken by its agency. The light, while undoubtedly powerful, was so soft and delicate as to be quite inadequate to disturbing the equanimity of the sitter. It caused the little room in which the experiment was conducted to be illuminated with a mass of pale violet actinic light, by contrast with which the gaslight in the room became of a sickly-yellow colour. The negative we saw taken was very successful, the exposure being reasonably short. This negative and a print from it are now in our editorial office, where they may be seen.

During the past week we have made an experiment bearing upon Mr. H. B. Berkeley's recent remarks with regard to the behaviour of citrate of silver or citric acid in washed films and emulsions. The first and most important part of the experiment consisted in the preparation of an emulsion of citrate of silver alone. For this purpose seven grains of citric acid were dissolved in three drachms of alcohol; four grains of pyroxyline and half-an-ounce of ether were then added, forming a collodion (to use a Hibernicism) "bromised" with citric acid. This was sensitised by the very gradual addition of seventeen grains of nitrate of silver, first dissolved in a few drops of water and afterwards mixed with one drachm of hot alcohol. The silver was added a few drops at a time with vigorous agitation after each addition, in order to avoid, as far as possible, the crystallisation of the salt in the collodion; and the result was a fine, smooth emulsion which, in the yellow light of the operating room, was only distinguishable from an ordinary one in that the colour by transmitted light was no deeper than a medium orange. Poured upon glass it formed a film of a bluish-white, opalescent appearance and extremely translucent; but when partially dry the opalescence entirely disappeared, and when quite dry the surface was covered with a crop of very fine, frost-like crystals. The slightest contact with water, either while in the opalescent or subsequent stages, immediately discharged every appearance of either opalescence or crystallisation, which did not return upon re-drying. This was scarcely the result we had expected, and so far agrees with Mr. Berkeley's view as to render it extremely improbable that any trace of citrate of silver remains in a film or an emulsion after washing. It entirely negatives his supposition, however, that the removal of the citrate by washing would cause the film to be riddled with pinholes. If present in sufficient quantity along with silver bromide to crystallise out in the manner we have described, upon drying and subsequent washing efflorescent crystalline markings would, no doubt, result; but in washing previous to drying, the citrate, being evenly diffused throughout the film, would be removed in such extremely minute particles as to leave not the slightest visible trace behind. It remains to be said that, upon the addition of twelve grains of double bromide of cadmium and ammonium, a fine, rich emulsion of the ordinary description was formed, which only differed in general characteristics from one prepared from a similar formula (*minus* the citric acid) in giving a thinner and more powdery film, and in working with great freedom from fog—both owing, no doubt, in this case, as Mr. Berkeley suggests, to the large quantity of nitric acid liberated.

A FEW MORE REMARKS ON THE SUBJECT OF NITRO-GLUCOSE.

Rip van Winkle is up again in the shape of nitro-glucose, which after sleeping quietly—not for twenty years certainly, but sufficiently long to have been almost forgotten—now makes its appearance once more amongst us claiming recognition. Not that I object to the re-appearance—far from it. I agree with all M. de Pitteurs states in its favour, and believe that the chief, if not only, reason why it has failed in finding its way into use is the difficulty experienced in its preparation. This difficulty is not an absolutely necessary one, but I have not made any of the substance for the last four years, simply on account of the impossibility of obtaining acids of the requisite strength in Liverpool. To this may be added that the same necessity does not now exist for its use as prevailed when washed emulsion was as new here as it is now in Belgium. Other and readier means of obtaining density are now common; hence the trouble of preparing or obtaining nitro-glucose may be dispensed with.

I think, however, that M. de Pitteurs errs slightly in taking it for granted that density is dependent upon the formation of nitro-glucose simultaneously with the pyroxyline. As a rule *old* pyroxyline gives a denser image than it did when freshly prepared, and it is an undoubted fact that such is the case with a collodion which has been allowed to "age." Now, if we suppose that a sample of freshly-prepared cotton contains a minimum quantity (or none at all) of nitro-glucose, it is difficult to imagine by what reaction that substance can be developed as the pyroxyline acquires age, and the same remark applies equally to the case of collodion; therefore, in the presence of an actual gain in density under those circumstances, it must be evident that some other agency is at work.

Again: M. de Pitteurs supposes that the extra power of giving density, which high-temperature cotton is usually held to possess, is attributable to the presence of a larger proportion of nitro-glucose than exists in samples prepared at a lower temperature; but in making this special claim in favour of nitro-glucose in connection with *high*-temperature cotton he is quite at variance with the conditions necessary in the preparation of the substance, which are concentration of the acids and *low* temperature. If either of these conditions be neglected the result is that the sugar is carbonised, and though it may be urged that a portion of it may be at the same time converted into nitro-glucose, I have several times tried to detect the latter substance in the bulky black residue of an unsuccessful operation without the slightest success.

Furthermore: though sugar may exist in small quantities in raw cotton, the latter may be submitted to such treatment as to completely remove all traces of sugar or other matters without destroying the density of the resulting pyroxyline. Cellulose, too, may be converted by the action of sulphuric acid—first into dextrine, and then into glucose, but the change is only produced under circumstances widely different from those which accompany the formation of pyroxyline; and then we have to consider that nitro-glucose, so called, is formed from *saccharose*, not glucose—two substances similar in character, but differing widely in many of their reactions. For these various reasons I think that the existence of nitro-glucose in pyroxyline is, to say the least, extremely doubtful.

That the change which takes place in collodion in the process of "ageing" is one of decomposition there cannot be a doubt, and it is possible that a substance resembling but not identical with nitro-glucose may be formed in the process, but what the full extent of the reaction may be cannot be said. It is certain, however, that in the case of some descriptions of pyroxyline—especially if kept in a stoppered bottle or otherwise cut off from free access to the atmosphere—that nitrous acid fumes are formed. With nitro-glucose this change is far more rapid as well as more marked, and I have known a bottle containing a sample of that substance to be filled with brown vapour after remaining only two or three weeks without the stopper removed. It is worthy of notice that nitr*ite* of silver has long been known to conduce to density, and various nitrites have been recommended as additions to the bath or to the emulsion in order to produce a similar effect. Is it not possible that the beneficial effect of nitro-glucose may be solely due to the formation of nitr*ite* when brought into contact with nitr*ate* of silver? and that the difference brought about by the "ageing" of collodion is due to the same cause, the change being produced more gradually?

This brings me to another point. Since reading M. de Pitteurs' paper and the editorial comments thereon, I have obtained from a friend the remains of a quantity of nitro-glucose in solution prepared by myself and given to him more than four years ago. This I have tried in various ways in emulsion, both in the presence of free silver and the reverse, and the result has been somewhat remarkable. Instead of giving increased density the tendency is in the opposite direction, accompanied by the production of greater sensitiveness. Such, at least, would seem to be the case, as, with a given exposure, a larger amount of detail and an altogether flatter picture results from the nitro-glucose emulsion, together with a peculiar appearance as of incipient reduction over the whole surface of the film.

I could not at first understand these results, but after considering the facts it now seems to me, though I may be wrong, that I can explain the matter in accordance with the theory of decomposition before suggested. The nitro-glucose solution employed is labelled "thirty-five grains to the drachm," the solvent being a mixture of equal parts of ether and alcohol, which dissolves a far larger quantity than either ether or alcohol separately. When it came into my possession it was perfectly clear and showed no sediment, and possessed a powerful odour of *sweet nitre* (which is an impure solution of nitrous ether), the smell of sulphuric ether having either disappeared or become lost in the more powerful one. It is not difficult to believe that the nitrous acid given off in the decomposition of the nitro-glucose would gradually act upon the alcohol in the solution, forming nitrous ether (and possibly other compounds); but to test the accuracy of the supposition I made the experiment of adding sweet nitre to an emulsion before sensitising, and obtained a result so nearly identical with that secured with the nitro-glucose as to leave very little doubt in my mind.

The same solution of nitro-glucose when only a few months' old would have given a considerable increase of density, and I can only suppose that during the four years it has been kept the liberated nitrous acid has been re-absorbed by the alcohol, and thus entered into a combination from which it is not displaceable by silver nitrate to form silver *nitrite*, and thus the gain in density is lost.

I may mention that a portion of the solution precipitated in cold water formed a white pasty mass which, after several hours, refused to harden; the water in which it was contained was raised to the boiling point, when the nitro-glucose rapidly dissolved, forming a perfectly clear solution. The flask was then plunged into cold water, and, when cool, the nitro-glucose was found to have divided into two portions—one of which formed a transparent skin upon the surface (resembling in appearance a tough collodion film), the other remained in suspension, rendering the water perfectly milky and opaque. The transparent skin, when kneaded between the fingers, was reduced to a gritty mass without any of the peculiar silky cohesiveness of freshly-prepared nitro-glucose, and separated into granular particles upon rubbing. To the other portion remaining in suspension a few drops of a sixty-grain solution of silver were added, and the mixture exposed to light for several hours without undergoing the slightest change of colour. Leaving out of the question the doubt which exists as to the constant composition of nitro-glucose when freshly prepared, I think this proves that long keeping changes its character most entirely.

W. B. Bolton.

PRACTICAL INSTRUCTIONS IN MODERN PHOTO-MECHANICAL PRINTING METHODS.

Part I.—PHOTOLITHOGRAPHY.

VI. Printing from the Stone.—The inking-roller, having been freed from tallow as directed, is ready to be charged with the ink which is to be employed in the actual printing of the copies. The colour of this ink will, naturally, be varied according to the nature of the subject; and, as an example of the kind of consideration required in selecting the right tint, it may be mentioned that a deep jet-black will generally be suitable for the reproduction of an engraving, while an ink having a decided tinge of blue will, more correctly, imitate a pen-and-ink subject.

The right consistency of the ink and the amount of pigment required to be present in it, are only to be determined by experience and a careful observation of the effects caused by variations in respect to these qualities. The relative proportion of pigment and fatty matter in the ink is adjusted by mixing the commercial ink with more or less lithographic varnish, and the consistency of the mixture depends on the viscosity of the varnish employed. In order to enable the operator to make these adjustments at his discretion it is usual for lithographic inks to be sent from the manufacturer in a tolerably stiff state and highly charged with pigment. For a first experiment equal parts of the ink and of middle varnish may be tried, and after the working of this mixture has been well studied any required alteration may be made. The ink and varnish should be mixed together on the inking slab by means of a palette knife, and when the materials are well incorporated a tolerably even layer is spread over the slab by dabbing with the knife, after which any superfluity may be stored up at one corner of the slab for future use. The roller is then worked about on the slab until the film of ink is uniform and the grain of the leather is sufficiently charged with the ink.

This having been done, the stone is placed on the bed of the press, a few sheets of paper or of thin cardboard are laid on its surface to form a backing, and the pressure is adjusted. The gum on the surface of the stone is next softened and removed by gentle friction with a damp sponge; and the excess of moisture having been removed the inking roller is applied, a gentle pressure and rather slow motion being first employed. If, under these circumstances, the design should take the ink with extreme readiness, it is probable that the ink is too thin or that the motion of the roller is not sufficiently rapid. If, on the other hand, the design is found to take the ink with difficulty a slower motion of the roller may be required, or a thinner ink may be necessary. When the stone is over-moist, and an undue pressure is exercised on the inking-roller, it often happens that the roller slips over the stone without revolving on its own axis. Under these circumstances there is great danger of entirely removing parts of the design, and some of the above-mentioned conditions must be so altered as to prevent this gliding action of the roller. Not only in inking the stone, but also in working the roller on the inking slab, care must be taken to lift the roller after each movement to and fro, as, if this were not done, mischief might arise from the seam of the roller constantly coming in the same place.

One of the most difficult points in connection with the use of the inking-roller consists in applying an equal pressure during the whole of each stroke, the tendency of most persons being to press more heavily when the roller is near to the body than when it is far off, and also to exert more pressure with the right hand than with the left hand. The consequence of this is that that part of the stone nearest to the operator and towards his right hand receives more ink than its just share. In placing the stone on the press the above circumstance should be borne in mind, and those parts of the subject which have least tendency to take the ink should, when practicable, be placed in the most favourable position for receiving a good supply. After the stone has been inked a few rapid strokes of the roller are generally required, in order to clear the stone and to remove any excess of ink from the broader lines of the subject.

We are now ready for our paper, and when ordinary printing paper is to be employed it must be in a slightly moist condition; and it is best to moisten a quantity the day before it is required for use. The damping of the paper is performed as follows:—The paper having been cut to size, a bundle of ten or a dozen sheets is rapidly drawn through clean water, and is then placed on a smooth board, after which a bundle consisting of about the same number of dry sheets is placed on the wet bundle. Alternate bundles of wet and dry paper are thus piled up until sufficient paper has been treated, after which a board is placed on the top and gentle pressure applied by means of weights, the whole being now allowed to remain at rest until the moisture has equally diffused itself. In the case of enamelled paper it is generally best to moisten each sheet separately by gently sponging the back just before printing on it; but some samples of enamelled and hot-pressed paper will not bear being moistened, and have, consequently, to be printed dry.

A sheet of the damped paper is now laid on the inked stone in such a way as to avoid friction, the most convenient way of doing this being to lay one edge of the paper against a pencil line, which must be made on the stone; and after having clamped this edge by a slight pressure of the fingers, the sheet is steadily lowered into its position. The backing sheets being now placed over all, the tympan is shut down and the carriage passed through the press. Care must be taken not to tear the printed sheet in removing it from the stone, and when the adhesion is considerable the best way is to fold one edge of the paper quite back, and then to draw it off just as one pulls off the skin of a rabbit.

The first proof must be carefully examined in order to ascertain if the pressure has been uniform, a deficient pressure on any part being indicated by a want of ink on the corresponding part of the proof, notwithstanding the fact of the stone being well inked. Next examine the proof in order to ascertain if any of the fine lines of the original are wanting, any deficiencies in the coarser lines having already been made good as previously directed. In case any retouching should be required proceed as follows, but if it be considered necessary to remove the stone from the press it is as well to mark its position on the carriage, so as not to lose any part of the labour of backing-up and adjusting:—Gum the face of the stone with thin mucilage, and then wipe this off, so as to leave the surface of the stone covered with a thin and an almost imperceptible film of gum. When this is quite dry proceed to make good the defective lines by tracing them through the gum by means of a needle point mounted in a suitable handle. This operation will be found extremely easy if the layer of gum be thin enough; but when the layer of gum is so thick as to resemble a coating of varnish it will be found difficult to trace through it. The lines traced with the needle should be cleanly cut into the stone, and when they are satisfactorily traced a little dust is thrown out on each side of the trench cut by the needle point. By providing oneself with a collection of needles having points worked up to various degrees of obtuseness lines of any required width may be easily traced; and the operator will find it easy to produce lines so fine as to rival those made by any other engraving process. Any false lines may be easily rendered of non-effect by covering them over with thin gum water, and when the part is dry it may be worked on again. When all necessary lines have been traced the retouched parts are moistened with oil of turpentine to which a little printing ink has been added, and, after the excess of this has been wiped off by means of a soft and dry rag, the stone must be well rolled with the ordinary inking-roller until an even and not too thick film of ink is deposited over the whole face of the stone. The stone is then moistened so as to soften the layer of gum which lies underneath the ink, and a gentle sponging will now remove the excess of ink and leave the design clear and ready for printing.

The above method of engraving on the stone is extremely well adapted for use when it is required to add fine work to the subject in the shape of titles, signatures, or skies, as it is impossible to produce very fine lines by the use of the ordinary lithographic ink applied by means of a steel pen. In the case of skies a machine may be employed to rule a ground, and parts of this may be stopped out by the application of gum water before the inking has been performed.

When a sufficient number of impressions has been taken from the stone it is best to grind the impression off at once, as the longer the face of the stone remains charged with fatty ink on the one hand, or with gum on the other, so much deeper will these materials sink into its substance, and the labour of grinding will be proportionately increased. When, however, more copies are likely to be required the stone must be preserved, and, in order to prevent the ink of the design becoming extremely dry and hard, it is proper to roll the stone with a non-drying ink before storing it away. An ink of this kind is sold under the name of "preserving ink," or a mixture of one part of tallow and two parts of the ordinary printing ink may be employed. It is scarcely necessary to say that the stone should also be gummed before it is put on one side.

It very frequently happens that several copies of the same design are required on a stone, or that it is necessary to transfer a design or a portion of a design to a fresh stone. In either of these cases the subject on the original stone may be reproduced by means of a transfer or transfers printed therefrom. The best kind of transfer-paper to employ is a sized or coated india paper, which is to be obtained at the lithographic material warehouses. This paper should be very slightly damped by being placed between two layers of moist blotting-paper, after which the impressions from the original stone should be printed on its coated side, care being taken to obtain the best impressions which can be secured; and these printed transfers are to be put down on a fresh stone just as in the case of the original photographic transfer. When it is intended to make use of the transfers as soon as they have been printed, the ordinary ink may be employed; but when they are to be kept for some days it is well to employ a special transfer ink, which may be obtained from the dealers. If, however, it is intended to keep a transfer indefinitely the following mixture will be found to answer the purpose:—

Yellow wax	4 parts.
Shellac	2 „
Resin	2 „

Melt these together and add—

Tallow	2 parts.
Olive oil	2 „
Venice turpentine	1 part.

A transfer made with this mixture should be printed on the coated india paper, and every care must be taken to ensure a good impression, the printing compound being thinned with a little oil of turpentine, if necessary. The stone on which a transfer of this kind is put down should be heated more strongly than in the case of ordinary work, and the transfer must not be moistened. Under these circumstances only one pressure should be applied in effecting the transference, as the dry transfer does not adhere to the stone. It occasionally happens that the dry transfer will slide over the stone and destroy the design; but this can be avoided by the following expedient:—

Take two smoothly-faced sheets of paper which are rather larger than the backing-paper employed, and well rub the smooth faces of these sheets with French chalk in powder. Now lay the French-chalked surfaces together face to face, and then insert the pair of chalked sheets in the middle of the bundle of backing-paper. Under these circumstances any tendency towards slipping which may result from insufficient tension of the tympan, or any other cause, will take place between the French-chalked sheets of paper rather than between the stone and the transfer. When this device is resorted to it is often safe to apply several pressures to a dry transfer. The French-chalked sheets form a kind of safety-valve for slipping, and they are useful in many lithographic operations.

In the next chapter directions will be given for obtaining a transfer in grain or stipple, an ordinary negative from natural objects being employed; and after this the most usual sources of failure will be considered.

T. Bolas, F.C.S.

THE TECHNICAL MEETING OF THE SOUTH LONDON PHOTOGRAPHIC SOCIETY.

In another page, among the reports of the meetings of societies, we publish an outline of what took place at the annual Technical Meeting, or Exhibition, of the South London Photographic Society. What follows here is merely a more detailed account of some of those articles exhibited. We commence with—

Special Cotton for Making Pyroxyline.

This, as we have said in our report, was exhibited by Mr. Payne Jennings on behalf of Mr. Leon Warnerke. Mr. Jennings's address was as follows:—

Mr. L. Warnerke, during his late tour in Russia, came across a specially-prepared cotton admirably adapted for making pyroxyline. I give at his request his own words on the subject:—"It is a matter of the highest importance in the manufacture of pyroxyline to use cotton easily permeated by acids; ordinary cotton in acids or any aqueous solution is permeated only with difficulty, and for this reason can be only put in in very small lumps at a time, and must be worked vigourously with the spatula. In the meantime, the conditions of the acids as regards concentration and temperature are changed, and the result is lacking in uniformity. To obviate this difficulty I have been in the habit of submitting ordinary cotton to the process of boiling in alkalies, by which means the silicious covering of the fibres of the cotton (or, as some persons prefer to affirm, the covering of vegetable wax) is dissolved by the alkalies, and the fibre is instantly permeated by water or acids. But the process of boiling in alkali, and subsequent washing and drying, is tedious and disintegrates the fibres; for this reason I was very glad to discover in Russia a product answering all the enumerated conditions ready-made, and by a process far superior to alkali treatment. This new product is called, rather inappropriately, "hygroscopical cotton," and is produced by the action of steam under heavy pressure and high temperature on the ordinary cotton. It is manufactured for dressing wounds, instead of *charpie*, which could not be produced in quantities sufficient for the requirements of the late war in the East."

To show you the difference between the ordinary (best medicated cotton) and the new Russian I dip these two pieces in the water, and you observe that while one goes instantly to the bottom the ordinary cotton floats on the surface indefinitely. The same result is observable when this cotton is dipped in mixed acid.

An Apparatus for Verifying the Coincidence of Focus in the Dark Slide and Ground Glass.—This is an apparatus I am requested also by Mr. Warnerke to show to this meeting—his absence in Russia preventing his doing it personally—for verifying the ordinary dark slide. It is customary to use a wooden lath, in the middle of which is placed a screw; the lath is put on the frame of the slide or ground glass, and the screw is worked till it reaches the ground glass, or a glass inserted in the dark slide. It is obvious that in the case where the slide rests upon the same support as the ground glass this process may answer; but in practice the position of the dark slide is generally regulated by the groove, into which the ground glass does not enter at all. This new apparatus gives the position of the sensitive surface referred not to two different surfaces of the ground glass and dark slide frames, but to one, viz., the camera front, and for this reason is superior; besides this, it indicates the difference (if any) in the most palpable manner. Mr. Warnerke required such an instrument as this for the verification of his roller slide, the extreme nicety of its action rendering it invaluable for that purpose.

On the instrument just referred to we may state that, in this country, where we possess camera-makers of so much experience and accuracy in construction, elaborate instrumental appliances for measuring the distance between the front of the camera and the surfaces of the ground glass, forming the focussing-screen, and the sensitive plate are not required. If any photographer be in doubt whether those two planes are coincident he has merely to lay a rigid lath or straight-edge across the focussing-screen, insert a long wedge-shaped slip of cardboard between the straight-edge and the ground glass, note how far it can be inserted, and do the same with the dark slide. The coincidence of the two surfaces may in this manner be ascertained with a considerable degree of accuracy.

HEMERY'S PATENT PRINTING AND TINTING FRAMES.

Having, subsequent to the Technical Exhibition, been afforded by Messrs. Marion and Co. an opportunity of examining Mr. Hemery's ingenious and useful printing-frames, we are in a position to give complete details of these exhibits; but the time occupied in the preparation of diagrams to illustrate their construction and mode of action is such as to compel us, very reluctantly, to defer the more complete description till next week, when it shall appear. In the meantime we give the following extract from Mr. Hemery's address before the meeting at the recent South London Technical Exhibition, premising that Mr. Hemery commenced his remarks by describing the action of the various parts of his printing-frames, which observations will be given, with the necessary diagrams, in our next number, confining ourselves this week to giving his general remarks on the subject.

Mr. Hemery observed that the frames introduced by M. Lambert were found, generally speaking, clumsy, awkward, and useless. For his own part, not wishing to exclude silver printing entirely from his practice, he wished for the means of adding the ornamental border, so attractive and effective, in the Lambertypes to his silver prints, which was not possible, or at anyrate practical, with the Lambert frames. The result was the new frames now before the meeting, and which, simple as they appeared in their perfected or matured state, had cost considerable time, and, more resembling the troubled surface of water on a windy day, was the medium from which the ornamental border was to be printed, and from which no amount of pressure would obtain a passable print. Under such circumstances, he (Mr. Hemery) bethought himself of collodion skins on which to print the ornamental borders, similar to the one he then held, which he handed to the President for examination. Such a substance was admirably adapted for printers' ink, and being, as it were, waterproof, not open to the objections he considered fatal to gelatine. Another great advantage was that the collodion skins could be fixed in optical contact with the glass on which they were mounted, becoming, in fact, a collodion negative. That was not the case with gelatine, as by no means was it possible to attach them permanently to the glass.

But perhaps the most important of all the advantages was the readiness with which autography could become a part of the portrait; for the collodion skin could be written upon with pen and ink as easily and with as much freedom as writing paper. Hence a new power was given to the photographer; for one has only to open albums to find constantly the autographs of people written on the card mounts with ordinary ink—a proceeding which, however interesting, is most inharmonious, the crude blackness of the ink killing out all the colour from the photograph itself.

Here, then, was a purpose indeed to which the new invention might be applied with the greatest effect. On that topic much might be said, for certainly a new field might open to the photographer which up to the present, in consequence of the many difficulties presented, had altogether been unexplored, or, if attempted, abandoned, from the very nature of the constant and vexatious failures attending the effort. How greatly enhanced (Mr. Hemery continued) would portraits become by bearing the signature of the person pourtrayed! In the family circle a certain degree of affection is entertained even by the remotest members of relationship, and the sentiment of reverential love always inspired by coming across accidentally an old letter bearing the signature of a deceased father or mother, sister, child, or brother. Apart, however, from the natural promptings of family affection, there is a still broader field afforded by those who make their mark in the contemporaneous history of the world; and the curiosity to see the lineaments would be equalled by a desire to possess the handwriting of "fortune's favourites," if the means were equally available of gratifying the wish. For instance: if Her Most Gracious Majesty permits her loyal subjects to possess her portrait, it is not too much to think that she would also graciously permit them to have what they would perhaps prize as much—her autograph. Who would not value such an autograph as "Albert Edward, P.?" or such as could be afforded by our British statesmen, from their own hands and pen? The arny, the navy, the clergy, the leaders of science and art, the eminent of every profession, would each furnish names that the public would be proud and eager to possess without any degrading or fulsome homage.

That being so, it seems strange that no effort has hitherto been made to bring out such a portrait as the "photo-autographic;" but, however it may have been, whether from difficulties imaginary or real, it is now, at anyrate, easy of accomplishment, and, by the new "lock-automatic," as certain in result as an ordinary print would be.

The collodion skins are supplied to the photographer mounted on good stout paper, so that they may be handled freely and fearlessly, and offer as suitable a surface for writing upon as a sheet of writing paper.

The designs are various, and a tablet is left in which the signature is made. The collodion being transferred to the glass carrier, it is obvious that no further trouble is occasioned than the tinting of the portrait occupies, and the signature being white on a delicate tint of the same colour as the portrait itself, the picture and autograph are in *complete harmony*, and very ornamental, real, and characteristic.

The value of such a portrait can hardly be realised. As a matter of family sentiment it cannot be over-estimated; but with those whose fame is cosmopolitan, and who are the common property of the world, its importance, whether living or posthumous, is beyond doubt so illimitable that a source of profit may be "tapped" to which many may, perhaps, be strangers, by the most insignificant negative in his possession. At anyrate it only remains with photographers to introduce the photo-autographic portrait to the public, and they will soon reap the harvest always accorded to novelty and enterprise.

As we have stated, the mechanical details of Hemery's frame or pair of frames—for it is a binity in unity—will appear in our next.

MORLEY'S PORTABLE CAMERA-STAND.

This is a useful and simple form of camera-stand which may already be known to some of our readers, but of which, in the interests of many others, we shall give a full description, with a diagram, next week. Owing to a "conveyance accident" it did not reach the meeting in time to be exhibited, but we are happily in a position to give a detailed account of the apparatus; for we know that every improvement or modification of existing apparatus is watched with interest by our numerous readers.

EXPERIENCE WITH BEECHEY EMULSION PLATES.

Two years ago last summer I procured some of this emulsion from a commercial source, and having prepared some plates I exposed one or two with Kennett gelatine and Liverpool plates. I found them slower than I had expected, and obtained pictures which, compared with the others, were hard. I could not continue my experiments at that time; camera and plate-boxes were packed away with the Beechey, the Kennett, and the Liverpool plates, together with some of the latter that had been prepared the previous summer. Since then, until last summer, I worked with another size of camera and plates.

Last summer, however, they were brought out again. The Kennett and Liverpool plates abundantly vindicated their keeping properties, as I knew already they would do; but I was very curious to learn how it would be with the Beechey plates. My exposure of the first plates proved much too short, and several plates were more or less spoiled by dust; yet there were not wanting signs that with proper exposure very clear and vigorous negatives might have been obtained. With my moist plates—to which I gave a longer exposure—I exposed, also for a shorter time, one of the same kind that had been recently prepared. My subject was the Grand Hotel at Eastbourne. The last-mentioned plate gave me a negative equal in every way to my wishes; and the former, were it not for dust spots and rather too short exposure, would have given me a negative equal to it. I had not opportunity for more crucial experiments with the remaining plates of that batch; but, speaking for myself, I feel little doubt of the keeping properties of such plates when certain precautions are taken in their preparation. The slowness of the plates when first prepared, the hardness of the pictures, and the long exposures required for the plates which had been kept, seem to point to rather a large excess of bromide in the original emulsion. The question is as to how they would keep if that were reduced to a minimum.

Last spring I worked with plates of the same kind prepared—some from emulsion which I had bought and corrected, some from emulsion which I had made towards the end of summer, and I worked with others which had been prepared for me. I found the whole of these plates capable of furnishing excellent negatives with very moderate exposures. I discovered, however, one cardinal point in connection with them, which I have since heard mentioned as a defect by others. Examining the films by transmitted light some appeared perfectly homogeneous, and I think that from such there should be no difficulty in obtaining perfectly clean negatives. In other films there is a mottled appearance, either partially or entirely covering the plates.

When I first prepared the Abney beer-and-albumen plates with the silver bath I met with an appearance in many of the films very similar to the above, and drew certain conclusions as to the prints in which the preparation had been defective. With many of the last-mentioned Beechy plates good negatives may also be obtained. In developing, endeavouring (as I was doing with all my plates at that time) to obtain very considerable intensity without after-intensification, I found, when the developer had reached a certain strength (short of that prescribed) and the development had proceeded to a certain point, an abnormal reduction begun in the spots I have mentioned, and spread itself rapidly, so that very soon a reduction would have taken place through the whole film. When I saw this commencing I washed and fixed as quickly as I could, and in many cases my negative was saved. I noticed also that where the abnormal reduction had not commenced the hyposulphite cleared the whole away, so that there was no longer any mottled appearance left in the film. Also, the abnormal reduction more often begins in the sky; so that after fixing I have only a mottled sky and a perfectly clean negative in other respects. This is entirely the case with those of the plates more recently prepared for me which presented the mottled appearance. The sky being most affected in this way may arise, either from my placing the plate so that the part most mottled comes in the sky, or because the light has acted most strongly on the sky.

The questions I ask and the conclusions I draw from this experience for my own guidance in the future—and which I now write down for the benefit of any to whom they may be of interest or of value—are the following:—What is the cause of this mottled appearance? How can it be avoided? And how can the best negatives be obtained from the plates in which it has not been avoided?

The fact that it is only after the developer has been on the plate for some time seems to show that the cause must lie on the very underside of the film, which the developer has to penetrate before the cause can operate. The fact that some films are without the mottled appearance altogether seems to show that the cause has been removed entirely from these. How? I think that in the preparation they must have been plunged into the water before the film was too far set for the water to operate right through; also, a longer washing in the different changes of water may have fallen to their share. At anyrate, the next time I prepare Beechey emulsion plates I intend to plunge them into water the very first moment the film will bear it, and to take care that they have a thorough washing.

Next: for any plates in which the mottled appearance may show itself notwithstanding, I shall no longer seek to obtain great intensity by the alkaline developer alone, but, taking care to wash it off before incipient reduction about the spots can commence, shall build up my picture afterwards, if necessary, by silver intensification, obtaining doubtless, although with more trouble, a better picture than I could in many instances obtain by the alkaline method alone.

There is one fact connected with my own operations which I ought to point out, because many, operating differently from myself, may possibly have a very different experience. My exposures are longer than many give, and I begin with a weak developer, gradually strengthening it; but where a strong developer is prescribed—as for the Beechey plates—I seldom require to bring it up to the strength. I say this is my usual, not my invariable, practice. In cases, for instance, where I do not succeed by this method I go back to the very letter of the formulæ. With regard to the Beechey plates, I think, perhaps, by giving the shorter exposure and applying at once a developer of full strength in the first place, the light, having acted less powerfully on the sensitive particles in the film, the by-products left at the bottom of the film will have less power to cause abnormal reduction; and, in the second place, the developer doing its work more rapidly (though this will be somewhat neutralised by the shorter exposure) will not require to remain on the film so long, and so not have time to penetrate it completely. If this be the case—this being, probably, the more ordinary way of working—the majority of workers may have remained strangers to these objectionable spots.

For myself, I cannot help thinking that if a slight excess of bromide obtain in the finished emulsion, and if the washing be carefully performed and the drying afterwards properly managed, these plates should have good keeping qualities. I say the drying also "properly managed," for one reason among others, because I found on some of the plates which I first prepared, on bringing them out last summer, a fungoid growth exactly like that which I had previously found on some of my gelatine plates in which beer had been mixed with the water used to dissolve the gelatine. The drying should be at a temperature not too high, continuous, and complete within a given limited time.

WM. WASHAM.

NOTES FROM AMERICA.

SPOTTING OUT PRINTS.—THE FRENCH EXHIBITION.

On the subject of "spotting-out" prints Mr. S. M. Robinson writes:—

Since I wrote you *(Phil. Phot.)* about spotting prints for burnishing I have tried some experiments. Take an egg, beat it thoroughly, let settle, then take such colours as you want (india ink being the base); rub them with the albumen on a palette, and let dry. When wanted for use have a little ammonia and alcohol, equal parts; dip your brush in the solution, then rub the colour previously dried on the plate (palette). This will adhere readily to the print. Do this before putting on the soap and alcohol, or lubricator. I find it just the thing. It leaves no dead spots.

Dr. Vogel, the German correspondent of our Philadelphia contemporary, has sent to it a detailed and graphic account of the Paris Exhibition, which we believe will interest many of our readers. It will be seen in what high estimation he holds the English landscapes:—

I have spent a fortnight in Paris, and have gathered with great pains a general idea of the immense mass of photographic material stored in the Exhibition. As to the Exhibition, it surpasses, as usual, all previous ones in magnificence and greatness. The French photographic department is as large as the whole photographic pavilion at the Philadelphia exhibition. The exhibits of other nations would take up an equal space. These are scattered over the whole Exhibition—found once among a pile of furniture, once surrounded by show-cases with soap, brushes, combs, &c. I do not exaggerate when I claim to have seen more than ten miles through the buildings before I had seen all the photographic products. The trouble is that there no such facilities here as there were in Vienna or Philadelphia for the purpose of reaching the different points of the Exhibition. In Vienna was a street-car, in Philadelphia a narrow-guage railroad; here are nothing but rolling-chairs, which one rather leaves to ladies or sick persons. In the Rue des Nations, in the neighbourhood of the fronts representing buildings of different nations, the photographs are generally found. Only the Austrian photographic exhibit is in a separate pavilion. As might be expected the exhibits consist principally of portraits. A glance at the same will tell at once that there has been no great success made. Old-known firms maintain their reputation. There is Sarony, Rocher, and Gutekunst, in America; Reutlinger, Walery, and Lumière, in France; Luckhardt and Adèle, in Austria; Bergamasco, Mietzokowsky, &c., in Russia. All these are well-known names, whilst there are still others from every country who have exhibited some excellent works. One is vainly searching for a new style or a shape. A surprise like that by A. Salomon, who made a *furore* in 1867, is not to be had, and even A. Salomon has not exhibited at all. As real novelties in the portrait line there are only two kinds to be mentioned. First, the Seavey background, which you know so well that I need not stop to explain them. Second, the portraits with electric light, by Vanderweyde, of London. Both were known before, but none of them have ever been exhibited before at a European exhibition. As to the backgrounds, it is strange to observe that only one European (a Parisian stock-dealer) has exhibited backgrounds, which are, however, so beyond all expectations dreadful that one cannot help being astonished at the fact that these things are possible in Paris—the centre of taste. Even a German country photographer would be ashamed to use such backgrounds. It is, therefore, not at all surprising to see but very seldom a painted background on a French photograph. Let us hope that the French—and other nations too—will profit by Seavey's exhibit. Vanderweyde's exhibit proves it to be a possibility to make equally good pictures by electric light and daylight. Since through the Parisian Exhibition vitality has been given to a new, interesting method of using electricity for illumination, it is to be expected that this light, which may be produced with a few horse-powers, will soon attract the attention, especially in the northern parts of Europe—Russia, Sweden, &c.—where there is sometimes only four or five hours' daylight during the winter months. America, which is blessed with an abundance of daylight, will not have any occasion for the use of electric light for portrait work. America has sent some really good work. Sarony, with his inexhaustible ingenuity, always brings something new in positions; Rocher occupies his space with pictures of finest finish; Landy brings his well-known *Seven Ages of Man;* and Gutekunst his panoramic view of the Centennial Grounds of Philadelphia, and some very good cabinet pictures, which seem to have the background retouched in. Sarony exhibits crayons; Gubelman, of New Jersey, brings elegant cabinet pictures, smooth in the centre and grained toward the illuminated edges. He also exhibits nice pictures of children. Gueria, of St. Louis, arranges men as marble statues. It shows too well that many men have a weak chest. These make-up things do not look altogether nice. More lucky is Smith, of Chicago, who has sent a large number of pictures of children, which can compete with the best pictures of the kind. Under the frame is printed—"We came all the way from Chicago." The large views of the Centennial Exhibition exhibited by the Centennial Photographic Company, Edward L. Wilson, proprietor, Philadelphia, are admirable, and far ahead of any pictures made of the Paris Exposition, both in quality and size, and they make one wish that the same company had had the management of the exposition of photography here, and thus continue their fame. I see nothing in the line of exteriors and interiors of buildings to equal them, and certainly no world's fair was ever so well photographed as the one at Philadelphia by the Centennial Photographic Company. As you see, the representation of American photography is very moderate; many well-known names, as Kurtz, were not represented. So it is with Canada. Notman and Sandham occupy the first place with their well-known winter scenes and cabinet pictures, *à la* Salomon. Laughlin, of Ottawa, exhibits views of architecture which have a respectable finish. Henderson, of Montreal, has sent very nice landscapes, among which are some taken by the emulsion process. Gurney, of New York, has exhibited burnt-in enamel photographs much better far than those exhibited in Philadelphia. According to the number of French enamellers it seems as if this kind of business were picking up; I counted not less than fourteen exhibitors, among which the oldest of all burnt-in photographers was M. Lafon de Camarsac, whose process is still a secret. He sends pictures of life size, which did not please me as well as the smaller ones. I consider those of M. Deroche the best. These pictures guided me involuntarily to the French department, which may have the most interest for you, with the exception of the American department. I allow myself, therefore, to continue relating what I have seen from the French. The French department is crowded with portraits, leaving hardly any room for the landscapes. Lumière and Victor, of Lyons, attract principally attention with pictures of the size of a whole sheet, though there is nothing new in regard to position or light. They occupy the corner of the main aisle, which is greatly to their advantage. In nearly all the departments of the Exhibition the top light is shut off by means of white screens, which are double along the sides of the rooms, where they shut off a great deal of daylight, and work very disadvantageously on photographs exhibited in that neighbourhood. Walery's frame, for instance, is at times half in the dark. He exhibits small pictures, which are better than those exhibited in Philadelphia. Reutlinger is represented with small and large pictures, all equally well. A special interest is excited by some large pictures of his, made by the carbon process. Nadar, who did not exhibit at the last two exhibitions, appears again with an excellent tableaux of pictures, remarkable by their good light. Rembrandt celebrates here his triumph. The effects of his pictures are multiplied by the well-chosen positions. However, they smack a little too much of the *demi-monde*. As it is not necessary to mention every one of the French photographers, I confine myself to saying that the average of the work exhibited is very good, though there is nothing new; on the contrary, the general impression is rather fatiguing, as there is too much of the same kind without variety. The "lightning" process, which excites nearly the whole of America, is scarcely represented. The best occasion to study it was with M. Klary, the apostle for this process. He offered me at once to make some experiments, to which I might sit as model. The skylight, covered with ground glass, was open; only one screen shut off a part of the top light; the day was clear. Several experiments were made, and it was found that those with five seconds' exposure for card size and eight seconds' for cabinet size were the best. Both were made with a Dallmeyer three B lens, of twenty-four centimetres focus and three seconds' opening. The plates were sensitised by Klary himself for an unusual length of time, and on developing the picture appeared a little hard and intense. Klary told me that his collodion was rich with bromide salts, which would explain the long sensitising. He added then that his chemicals were not in their highest state of sensitiveness. In connection with the above I would like to say that there is in Paris still another instantaneous photographer, M. Chambay, who stops in the Grand Hotel. His exhibit is composed of a number of pictures of babies, among which are groups of four to six of them. The unexpected sharpness of every one of the babies speaks for itself. There is no other explanation for the probability of making such pictures than the short exposure. M. Chambay keeps his invention secret, and has even declined the highest offers made for the sale of his method. A third one among the lightning men is M. Richard, in Switzerland, who, following the example of Boissonnas, offers his process for sale. I do not doubt that after a short time there will be still some more similar processes in the market. The carbon printing process has found in France quite a number of admirers. Liebert, formerly in America, works exclusively with this process. Reutlinger has exhibited a large carbon print. Rousseau, Provost, Cavett, Frank, Fabre, &c., exhibit carbon pictures; some of them are in life size and very good. Braun, of Dornach, is ahead of all. His branch house in Paris is the former firm of Meyer and Pierson, who made principally painted carbon portraits. Those exhibited by Braun are slightly painted on the back before the second transferring. In some of them only flesh and hair are painted. The effect is generally very good, but sometimes a little cold, which may be attributed to a little grey tone of the carbon paper. I remember that Ott had sent to the Philadelphia exhibition some small pictures of the same kind. They arrived there in the month of June. Braun has been lucky to take the oldest of the crowned heads of Europe—the Emperor William I., and also Pope Pius IX. and Leo XIII. The two latterp arade on the Exhibition in life-size, the Emperor not. Braun's masterpiece is a picture two metres (4′ 7″) high, representing the Medzäro Grave, of Florence. Alongside of them are some other very interesting reproductions, all made in Dornach, now belonging to Germany; and I am curious to know if this work can be put in competition for the award. The result of the work of the judges is not known yet. M. Gombetta, *le vrais representant de la republique* (the real representative of the republic), as the French call him, was the cause of the delay of the distribution of the awards until after the *corps legislatif* has gathered. If the portraits are amply represented, the landscapes, on the contrary, are much neglected in the French department. There is one thing certain: nobody has ever done better landscape work than the English. Among the French exhibitors Lamy is the best; then follows Thiers, of Fontainbleau, with dry-plate emulsion plates. More neglected than the landscape is the architecture. Anybody having seen the excellent architectural work which Baldwin and Ferrier and Soulier exhibited ten years ago will be surprised, when seeing in the work of a photographer, *des ponts et chaussees* (of bridges and turnpikes), the vertical lines merely converge with the edges of the pictures. Lichtdruck seems to have found not many admirers in France. They have not even a term for it, as they call it simply "photolithography," though lichtdruck and photolithography are two different things altogether. When Poitevin, with his gelatine and chromate solution on a stone, exposed under a negative, developed, inked-in, &c., he attributed a great deal of his success to the operation of the stone. Later the stone was replaced by a zinc plate; but he knew not that the gelatine film by itself has all the printing qualities. Tessié du Mothay was the first who proved this with certainty, and was recompensed for it with a gold medal at the exhibition of Paris in 1867. By that time the French knew very well the difference between photolithography and phototype, as Tessié names his process; now they have forgotten all this, after Albert has given vitality to Tessié's method. "*C'est le procede Poitevin*" (that is, the process of Poitevin) was the reply when I spoke of Albertype, not knowing Tessié's, the Frenchman's, merits. I found only five or six exhibitors of lichtdruck—Berthaud, with architecture, among the rest. The Woodbury process is amply represented by Goupil, Vidal, &c. It is owing to Goupil's success that the Woodbury process has found so many admirers in France. He exhibits here equally as well as in America. The Woodbury prints form the frame of his magnificent tableau, and in the centre are photo-engravings as sole novelty. I saw two coloured pictures in which the colours seem to be put on by inking-in of the printing plate. If Goupil has made any progress it is principally due to the chief of his establishment, M. Rousselon, who has at his disposition the immense means of the house, which enable him to make the experiments which a poor devil of an inventor generally cannot make. Goupil's establishment, in Asnières, is magnificent indeed; one hundred and thirty workmen are constantly working in one great room with a skylight on the top. A gallery is established in the same for the purpose of mounting the pictures. For printing they have eleven large copperplate printing presses, and six tables for the Woodbury process. Every workman is able to make two hundred prints daily on either machine—20 × 60 centimetres large for Woodbury prints, 60 × 85 centimetres for photolithographs. The well-known method for the preparation of the Woodbury printing plate by means of his gelatine film requires one million pounds of hydraulic pressure. For plates larger than 20 × 60 centimetres this pressure is insufficient; that is the reason they then use the photolithographic process, where the plates are made by means of galvanoplastic. Goupil's principal occupation is the reproduction of paintings, which are taken in the open air. Only in bad weather a skylight is used, which is glassed all round. Rousselon told me that he does not retouch his negatives, and also showed me some negatives which got, indeed, no retouching whatever; but I saw, also, many negatives which were considerably retouched. This is, however, without any consequence, as it is certain that all his work is very good. Rousselon told me, also, that he overcomes the injurious effects of the different colours by the different proportions of bromine salts and iodine salts in his collodion; also by making several trials with different exposures. I give you this apparently doubtful assertion, as it has been given to me, with all reserve. Next to Goupil is the *Societe Anonyme des Publications, Periodiques, Photographique, et Photochromique*, which attracts most attention. This establishment is managed by Vidal, and manufactures principally coloured pictures. The same firm exhibited also in Philadelphia, where its success was not altogether decided, especially in regard to the portrait work. Their principal occupation is now reproduction of articles of art and industry, and I must say it is a success. Reproduction of gold and silver signs are really so well done that one should think they were made of metal. Other pictures, in four colours, are an equal success. The same establishment also makes Woodbury prints and lichtdrucks. The English method for the manufacture of coloured pictures is more direct and simple. The photographs are simply painted over; then it seems to be a success, according to what I saw exhibited at the South Kensington Museum. Since I stopped so long with the coloured pictures I dare not forget to mention the photographs in natural colours, by Ducos du Hauron. He has a competitor, M. Cros, unknown to me until now, whose process does not differ from that of Ducos du Hauron as far as the optical part is concerned. In contemplating their pictures I must say that I was greatly surprised in comparing them with Albert's and Obernetter's work, who are far ahead of Ducos du Hauron. Landscapes after nature are principally inferior. Better are his reproductions of oil paintings. In my next letter I propose to write about the French heliographs, and also about the photographs of other nations.

OPINIONS OF THE LONDON PRESS ON THE PHOTOGRAPHIC EXHIBITION.

The Photographic Exhibition.--One of the most attractive and interesting exhibitions yet given by the Photographic Society of Great Britain has been daily bringing numbers of persons—directly and indirectly concerned in the advancement of this modern art of heliography, with its many branches—to the gallery in Pall-mall East. With an æsthetic conservatism deserving the greatest respect, the council of this institution has heretofore jealously refused to admit hybrid specimens. This reserve was commendable so long as it was practicable; and even now the exclusion of hand-coloured photography, however skilful and artistic, from an array of examples purporting to be strictly the result of light acting upon certain chemicals, is well warranted. It is, however, becoming more and more difficult to distinguish between the photography which is pure and simple and that which admits combinations. On the staircase of this gallery are hung certain pictures which might very well pass as consummately dexterous copies of original works by the great masters; and on reference to the catalogue these are found to be poikilographic paintings, produced by the Lombardi Art Company. There is no inscrutable secret as to the means adopted in the production of these admirable transcripts, although the process, in certain of its details, is in the exclusive possession of the company above named. Moreover, a trained capacity of dealing with pigments, and of managing the niceties of gradation in light and shade, is so imperatively needed to ensure the artistic success of poikilography that, unless ruled and directed by the highest judgment and taste, the whole virtue of the operation would speedily disappear. Under Signor Lombardi's careful control the finest results are attained; and the inestimable value of the process as a "worthy means of conveying to those who cannot see the original pictures a good idea of their colouring and effect, and thus of spreading a knowledge and appreciation of the higher forms of painting," is verified in so many words by no less an authority than Mr. F. W. Burton, R.H.A., F.S.A., the director of the National Gallery. By way of demonstrating the capability of the poikilograph in its direct application to living portraiture on canvas, a charming picture of Miss Curwen is placed in companionship with *facsimile* representations of the art of Rubens, Holbein, Mieris, and Siebold, from their treasured works at Dresden. Conspicuous among the examples of photography proper on the walls of the present exhibition are portraits by Lombardi and Co., either from their Brighton studios or from their establishment in connection with Messrs. Colnaghi's Art Gallery in Pall-mall. Carbon enlargements and exquisitely-finished portraits on "opal" are shown by the firm, chief of whose subjects are Lady Beaumont, Major-General Guise, Colonel Taylor, M.P., King George of Bonny, Signor Zambra, Lord Folkestone, the Rev. J. Cumming Macdona, and Mr. J. Bond, of the British Museum. The Woodbury Company's photographs, printed on their effective tissue, are prominently meritorious objects of the Exhibition, their portraits, including one of Mr. Henry Irving, being exceedingly lifelike, while their copies of such works of art as Sant's picture of *Adversity* show how the difficulties of rendering a composition of colours into monochrome can be overcome. A series of views in the Paris Exhibition, and especially in the "Avenue of the Nations," is exhibited by Mr. William England; an extraordinary collection of Russian photographs, from the War Department and Imperial State Paper Manufactory of St. Petersburg, is lent by Mr. L. Warnerke; and the names of Vernon Heath, Marion and Co., Lock and Whitfield, Chaffin and Sons, R. Slingsby, Boucher, Payne Jennings, and Ezra Greaves are well accredited by corresponding works in the Exhibition.—*Daily Telegraph.*

Our Editorial Table.

Flowers: their Origin, Shapes, Perfumes, and Colours.
By J. E. Taylor, Ph.D., F.L.S., F.G.S., &c.
London: Hardwicke and Bogue.

When we gave a description, in a former volume of this Journal (page 457, vol. xxiii, and subsequently), of certain examples of *heliochromie* executed by M. Leon Vidal, attention was directed to the remarkable facility offered by the Vidal process of producing photographic prints of flowers, possessing not merely the accuracy of form and of light and shade but also the rich colours of nature. One such example of this application we have in our possession. A difficulty appears to have been experienced, and up to the present time it has not been overcome successfully, of applying Vidal's system to book illustration. Not, of course, that it cannot be done, but the time has not yet arrived when large numbers can be produced at a price to render it possible to illustrate a moderately-priced book in this manner.

The elegant work before us contains thirty-two coloured figures, by Sowerby, and over a hundred and sixty woodcuts, all these being so carefully drawn and shaded as to convey a singularly accurate idea of the flower or part of flower represented. Dr. Taylor possesses the happy faculty of expressing his ideas in terse language which no one can fail to understand. As a champion of the new evolutionary views now so generally accepted by men of science he, in treating of the subject of flowers, contrasts the new with the old philosophy to the undoubted advantage of the former. "We hold," he says, "that, even now, in the minds of the most intelligent and thoughtful, and before long in those of the average educated, the new philosophy of flowers will excite more reverence and admiration of creatorial wisdom than the older teachings could educe, and that also in directions which the old views could not possibly indicate. The teachings of modern botanists and naturalists concerning flowers and insects are of a higher and more spiritual kind than those they have replaced; and the whole subject has been lifted to a higher and broader platform, whence a better and clearer view can be obtained of the subjects discussed and their general and special meanings."

This excellent and useful work, which has reached a second edition, will find admirers among all lovers of flowers who have even the slightest *soupçon* of science in their composition, and to these we cordially commend Dr. Taylor's elegant volume.

The University Magazine.
London: Hurst and Blackett.

The November number of this popular monthly is illustrated by a portrait of Mr. William Morris, M.A., a sketch of whose life and labours forms No. 11 of the new series of *Contemporary Portraits.* A scholar, poet, artist, and manufacturer, William Morris is indeed a man of no ordinary kind; but with him in these characteristics we have nothing to do. His portrait displays a man possessing those physiognomical and phrenological peculiarities which, if these be admitted to be reliable and determined departments in the family of the sciences, are bound to lead to success. There is no indication by whom the negative (cabinet size) was taken, but the Woodburytype Company have printed it in their usual perfect manner. The *Notes and Reminiscences*, by the late W. H. Harrison; Mabel Collins's *In this World* (concluded); and *An Appeal Against the Judgment of Malthus*, by Eric S. Robertson, are among the other articles.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.

,, 28 ..	Oldham (Annual Meeting)	Hare and Hounds, Yorkshire-st.

TECHNICAL EXHIBITION OF THE SOUTH LONDON PHOTOGRAPHIC SOCIETY.

The annual Technical Exhibition of the South London Photographic Society was held in the large room of the Society of Arts on the 14th inst.,—Mr. Le Neve Foster in the chair. Mr. William Brooks acted as assistant chairman, to explain such technicalities as might be necessary.

The Chairman having briefly explained the nature of the exhibition,

Mr. John Werge exhibited several enlargements printed from negatives the backs of which had been covered with plain Rive paper and then worked upon by a stump. He also exhibited three gelatino-bromide negatives, one of which had been developed with alkaline pyro., the second by Mr. M. Carey Lea's ferrous-oxalate developer, and the third by pyro. followed by the oxalate. He also exhibited a pneumatic plate-holder.

Mr. George Smith exhibited, on behalf of the Sciopticon Company, one of their new forms of lantern, in which the relation of the picture to be presented to the condenser may be altered. He also exhibited a registering slide-holder for the lantern, and one of Chadwick's oxygen retorts and reservoirs.

Mr. T. Bolas directed attention to several coloured prints in fatty inks by Mr. Pouncy, of Dorchester. These were suspended on the wall.

A model of a double dark slide was sent by Mr. Penny, of Cheltenham, and explained by Mr. Baynham Jones, of the same town. Later on in the evening Mr. Jones exhibited a curious example of "frilling" which occurred on one of Swan's plates.

Specimens obtained by the patent "luxograph" of Messrs. Alder and Clarke were exhibited by that firm, who invited the members to visit their studio in the neighbourhood at the close of the meeting, and see for themselves the working of this apparatus for taking portraits by artificial light. A description of this instrument appears in another column of the current number of this Journal.

Mr. T. G. Hemery exhibited a printing- and tinting-frame, of which some account will be found in another page.

Mr. Payne Jennings, on behalf of Mr. Warnerke, who was absent on the continent, exhibited a sample of cotton wool possessing a high degree of value in connection with the preparation of pyroxyline, inasmuch as it was so completely freed from greasiness that it became at once amenable to the penetrative action of the acids. This change was produced by the action of steam under high pressure. The difference between it and the common cotton was shown by a tuft of each having been thrown on the surface of water in a glass tumbler, when the altered cotton immediately sank to the bottom, whereas the common sample seemed to repel the water and remained floating. An apparatus for ascertaining the coincidence of the planes of the ground glass and the sensitive plate in a camera was also exhibited.

Mr. Cowan, of Messrs. Hills and Saunders, Porchester-terrace, exhibited a studio camera fitted with his patent electric shutter. He also exhibited a copying camera fitted up with great ingenuity, which elicited a hearty round of applause from those present. Mr. Cowan further exhibited and explained the nature of a slide for cutting glass plates to any required size, concluding by showing a body-rest possessing some valuable features.

Mr. F. York exhibited an ingenious plate-cleaning desk designed by Mr. Oakley; also several specimens of glass varnished by a non-actinic varnish prepared with Australian "black-boy" gum.

Mr. J. L. Lane exhibited and explained the use of a printing- and tinting-frame of peculiar construction which he had devised.

A background of "Empire cloth" was exhibited by Messrs. J. Avery and Co. In reply to a question it was stated that it was supplied in various widths up to six feet, and in many different colours.

Mr. W. M. Ayres exhibited an end-grain block of wood upon which to cut and trim photographs; also a set of measures for cutting a sheet of paper without waste. [An article descriptive of these useful articles will be found in a previous number of the Journal—that for February 15th of the present volume.] Mr. Ayres also exhibited a glass vessel for pouring collodion. It was not unlike a teapot in form.

Messrs. Marion and Co. sent for exhibition Cadett's pneumatic shutter; a dancing figure moved by means similar to the shutter and useful for attracting the attention of children while being photographed; also a quantity of spun glass wool for filtering, and one of their improved rolling-presses.

Mr. William Brooks exhibited prints from reproduced negatives; carbon transferred transparencies; some reduced photographs from rubbings from monumental brasses, taken by Mr. Tom Brines; together with a set of the photographs of the caves at Reigate to which special attention has already been directed in this Journal.

The proceedings concluded by a magic-lantern exhibition of Woodbury transparencies by Mr. George Smith, which terminated a pleasant evening.

Votes of thanks were given to all the gentlemen who, by their exhibits, had conduced to the pleasure and instruction of their fellow-members.

MANCHESTER PHOTOGRAPHIC SOCIETY.

The usual monthly meeting of this Society was held at the Memorial Hall, on Thursday, the 14th inst.

The Council had previously met at six o'clock, when Mr. Alfred Brothers, F.R.A.S., Vice-President, occupied the chair. In consequence of Mr. Thos. Heywood, who had been elected President at the previous meeting, refusing to accept that office, on account of ill health and inability to attend the meetings, it was proposed and seconded that Mr. Charles Adin, the late Secretary, be elected President, which proposal met with unanimous support.

At the subsequent general meeting of the members Mr. Brothers again took the chair, and the minutes of last meeting were read and passed.

The Chairman then communicated to the members the refusal of Mr. Heywood to accept office, and also the appointment of Mr. Adin as President.

The latter announcement was received with great satisfaction by the whole of the members; whereupon Mr. Brothers retired in favour of the new President, who took the chair amidst cheers.

Mr. G. T. Lund, Vice-President, in a short and graceful speech, then introduced a "*secrétaire*," consisting not only of a most convenient writing desk but also forming a handsome piece of furniture, the result of a subscription made by Mr. Adin's warmest friends, and which was then presented to that gentleman in the name of the Society, as an acknowledgment of eleven years' diligent services as Secretary.

The Chairman said that, though somewhat unprepared for the honour they had confided by electing him President, he must tender his most sincere thanks for the very kind manner in which his friends came forward with their testimony of esteem, and, in a very amusing manner, he (the Chairman) recounted some pleasant reminiscences connected with his former office, but reserved for the next meeting his remarks in reference to his election as President.

The following gentlemen were duly elected members:—The Rev. F. E. Waldie, Mr. James Shepherd, C.E., Mr. W. B. Wood, and Mr. J. W. Wade.

Mr. Oakes read a second communication on *Combination Printing for the Stereoscope*, which will appear in our next number, and illustrated the same by a large collection of stereoscopic transparencies (the production of the late Mr. Breese), some apparatus, and several drawings and diagrams, and concluded by promising upon the next occasion, which would conlude his communications on the subject of stereoscopic transparencies, to print one or two before the members.

The Secretary then read a letter received from the Liverpool Amateur Photographic Association, to the effect that a negative of a group, taken on the occasion of the joint excursion of the two societies to Hawarden by Mr. W. E. Potter, had been sent down with permission for any of the members who wished to possess a print. Mr. Gregory then very generously proposed to supply prints gratis to all the members who desired to possess one.

A lantern slide was next shown by aid of the sciopticon. This was also a group taken at Hawarden, on a Kennett plate by Mr. L. W. Weber, of Liverpool, and was much admired.

Mr. Brothers exhibited a very novel clock dial arranged for use in portraiture, constructed for him by Mr. Cussons, of Southport. The points of novelty in the apparatus were that the dial was covered by a black disc through which a small square aperture was cut, and only permitting one figure of the white dial to be seen at a time; and by a ratchet wheel and spring at the back (under the control of the operator) it was so arranged that the disc could revolve, thus exhibiting the figures on the dial in succession. The object of the apparatus was that, whilst fixing the attention of the sitter, it gave relief to the eye by following the aperture through its circular motion.

Mr. John Holden said he thought that the pupil of the eye would be enlarged by following the circular motion of the disc.

Mr. Brothers explained that by reason of its small diameter (about five inches) and the distance of the sitter no enlargement would be perceptible.

Several of the members very much admired the apparatus, and expressed a desire to possess one.

Mr. W. J. Chadwick (the Secretary) exhibited some excellent coloured photographs of the Crystal Palace, by Messrs. Negretti and Zambra—one of the Egyptian court exciting universal admiration. He also exhibited a quantity of specimens of a new process in photography, invented by Mr. W. B. Woodbury, representing water-marks in ordinary writing paper, and also a lamp which he (Mr. Chadwick) had devised for burning house gas in the sciopticon. The lamp was on the argand burner principle, but instead of giving a circular flame it was arranged to give two flat flames, as in the sciopticon lamp. A square chamber (similar to those in oil lamps) was provided, and he explained its superiority when this chamber was filled with benzine or mineral naphtha, but stated that he had not yet been able to obtain so good a light as with the sciopticon oil lamp, though very much superior to the ordinary argand burner.

Mr. M. Noton thought if small pieces of coke were introduced, so as to absorb the carbonising agents, the evaporating surface would be much increased and a better light thereby obtained.

After some discussion between Messrs. Noton, Watts, Oakes, and Chadwick, Mr. Noton offered to try a few experiments with the lamp and report the results at the next meeting.

Mr. J. Leigh exhibited a washing box for paper prints, which consisted of a square box on the syphon principle, with trellis-work trays, for the purpose of keeping the prints separate when washing. The same gentleman also exhibited a very simple, inexpensive, and effective "back-pressure valve," constructed of glass and india-rubber tube, similar to that in Bunsen's pump.

A carbon photograph was then passed round—the presentation picture of the Edinburgh Photographic Society, which had been kindly sent for the Society's portfolio.

Votes of thanks wese passed to Mr. Oakes, the President, and various other gentlemen who had contributed to a most interesting evening, and the proceedings terminated.

Correspondence.

THE MEDAL AWARDS AT THE RECENT EXHIBITION.

To the Editors.

Gentlemen,—In giving the medals on the 12th inst. the President said, with regard to the instantaneous photographs of Mr. Payne Jennings, "I am assured these are each printed from one negative."

The gift of a medal is matter of public interest, and I therefore think it right to call attention to the fact that the photographs in question are not printed from one negative, but have skies printed into the foregrounds from separate negatives. The assurance given to the President was, therefore, incorrect.

Not being myself an exhibitor I am free to bring this subject forward.—I am, yours, &c., H. STUART WORTLEY.

Rosslyn House, Grove End-road, London, N.W., November 19, 1878.

[It would be very desirable if Colonel Stuart Wortley would state the grounds upon which he is unable to accept the *dictum* of the President in this matter.—EDS.]

To the EDITORS.

GENTLEMEN,—As an exhibitor it might seem prejudice on my part to call in question the Society's awards of medals; but I cannot refrain from saying that I have always been led to think that a photograph, to be perfect, should not only consist in a well-chosen subject, detail, softness, freedom from blurring, &c., but that, also, the trees should show freedom from movement in the foliage, which is far from the case with the picture of the School of Military Engineering which has been awarded a medal.

It will certainly prevent many, both amateurs and professionals, from exhibiting if just awards are not made.—I am, yours, &c.,

Hoe-place, Woking, WM. WAINWRIGHT, JUN.
November 15, 1878.

THE TECHNICAL EXHIBITION OF THE SOUTH LONDON PHOTOGRAPHIC SOCIETY.

To the EDITORS.

GENTLEMEN,—I do not think the Technical Exhibition at the Rooms of the Society of Arts could be considered a success; but then I was an exhibitor, and, perhaps, expected more applause than I received or deserved. I did not expect to have to talk about my exhibits, because I only brought them at the last moment. I thought that I might have found just sufficient favour for my wares to have been laid on the table for such as felt inclined to look at after the *business* of the evening was over, and, so far, was not disappointed.

My surprise was great when the President, in his opening address, informed us that he knew nothing of the business of the evening, but infinitely greater when I found that I was among the first called upon to address the audience (a very patient and good-tempered one, by the way). Does not this point to a lamentable want of organisation? Surely those who wish to speak or read papers might be called upon to give timely notice so that a syllabus of the business of the meeting might be in the hands of the President, and thus spare those who did not intend to speak from inflicting an unprepared address upon the audience.

I think, further, that a little of the preparations which were so well arranged for Mr. Bolas's Cantor lectures would not only have spared us the time, but the exhibitor the humiliation, of having to go and fetch jugs of water to illustrate his part of the exhibition.

The idea of a periodical Technical Exhibition is too good a one to be allowed to drop, but I venture to predict that they would be far more successful if better organised.—I am, yours, &c., ONE OF MANY.

New Inn, London, November 15, 1878.

EXCHANGE COLUMN.

I will exchange a quarter-plate Voigtlander lens for a Moulton's photo. washing machine.—Address, W. S. B., 103, Newgate-street, London.

A Dallmeyer's portrait camera, with repeating back and rackwork adjustment, and Burr's No. 3 cabinet lens, will be exchanged for a Ross' No. 7 symmetrical, or a 10 × 8 B doublet.—Address, G. HADLEY, 33, Newland, Lincoln.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

PHOTO-MECHANICAL CORRESPONDENCE.

BETA.—It will be described in due course.

LITHO.—For general instructions in taking a negative consult an elementary treatise on photography.

J. B.—If you find it necessary to continue the rolling until the stone becomes nearly dry you must re-moisten it.

S. CORDING.—The markings which you describe probably arise from the contact of some greasy substance with the stone. Perhaps the gelatine which you employed in making your transfer-paper contained fatty matter.

GENERAL CORRESPONDENCE.

REGISTRATIONS.—In our next.

JUNIUS.—The transfer collodion is much too thin. Add at least four grains more pyroxyline to each ounce.

M. SHELLY directs our attention to a somewhat palpable error in the statement of his case which appears in the "Answers" column of our issue of the 8th inst. He is there made to say that the land for which he desired a particular design "has a north frontage to street of eighteen feet, and a depth of four feet," whereas the depth is actually *forty* feet.

W. B. M.—Warm the alcohol in a test tube by means of a spirit lamp, and having powdered the nitrate of silver add it by small pinches at a time. In this way it will be speedily dissolved.

J. R.—Messrs. Marion and Co. will be able to supply you with what is required. Willis's aniline process is still being worked in London, but we are unable to indicate any place where specimens may be seen.

YOUNG GEORGE.—The best proportions for preparing photoglyphic plates for engraving by Talbot's process consist of a quarter of an ounce of gelatine dissolved in ten ounces of water, to which is added an ounce of a saturated solution of bichromate of potash.

H. M. (Amateur).—We recommend you to omit a small portion of the bromide, and supply its place with iodide, the latter, however, being in greater quantity than the former in the proportion of 166·2 to 119·2, the former representing the iodide and the latter the bromide of potassium. Should you decide upon retaining all the bromide and adding iodide, then increase the quantity of nitrate of silver in the proportion of 170 as against the combining quantity of the iodide.

CAPT. O'BRIEN.—The following is the rule for finding the distance at which the lens must be placed from the picture:—Add one to the times of enlargement, and multiply the sum by the equivalent focus of the lens. The product is the length sought for. The other focus is found by dividing the equivalent focal length of the lens by the times of enlargement or reduction required, and adding it to the equivalent focal length. The sum is the length sought for. The relative place of the object and image will depend upon whether the model is to be enlarged or reduced.

B. D. L.—1. With regard to tone: a rule for general guidance may be deduced from the fact that citric acid in the developer produces cold blue tones, whereas with acetic acid the tones are warm.—2. A fifteen-grain solution of tannin will be quite strong enough; but it will not cause you much trouble to try both a ten-grain and a fifteen-grain solution, and to note the points of difference between the transparencies obtained by the use of each preservative. While you are about it you may as well try also the effect of a five-grain solution. Thus, by means of a few experiments, you will soon be enabled to determine which of the above will prove most suitable for the purpose for which it is desired.

GEORGE REID.—1. We have frequently made use of gelatine as well as of collodion for transferring negatives. The proportions we have found best are one ounce of gelatine to four ounces of water, about half-a-drachm of glycerine being added. Having made the negative warm, place it on a levelling-stand and pour the above solution upon the centre of the plate, making use of a glass rod, or even a slip of cardboard, to spread it uniformly over the whole surface. When quite dry give the plate a coat of spirit varnish, and then pass a knife round the edge so as to cut through the combined layers of collodion, gelatine, and varnish, which, now forming a single pellicle, may be easily removed from the glass.—2. In an under-corrected lens the chemical or actinic focus—that is to say, the focus at which a sharp photograph is obtained—is *nearer* to the lens than the surface of the ground glass upon which the image is seen to be sharply delineated.—3. From your description of the unset lens it is evidently very much *over*-corrected.

WHY, INDEED?—Why does a photographer in the excercise of his business always use a black cloth? Why, of course, to make his camera obscurer.—*Judy*.

AMATUER PHOTOGRAPHIC ASSOCIATION.—The prizes awarded at the last Council meeting, consisting of three silver goblets, two elegant albums, and six oil paintings, may now be seen at 12, York-place, Baker-street, W., where they will remain on view until the end of next week.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.—The annual dinner in connection with this Society was partaken of by several members and friends, on Saturday evening last, in the Café Royal, Regent-street. The Rev. F. F. Statham, M.A., President, occupied the chair, Mr. Peter Mawdsley officiating as vice-chairman. There was a good attendance, and the dinner was followed by the toasts and speeches usual on such occasions.

THE INFLUENCE OF PETROLEUM STOVES UPON CARBON TISSUE.—A short time ago we received a note from Mr. H. A. H. Daniel, in which he described his experience with a petroleum stove. He had prepared two batches of carbon tissue, and made use of a stove of that kind for drying it. Next morning the tissue was beautifully and evenly dry, but upon subsequently attempting to develope the image he found that the tissue was perfectly insoluble. As no light had access, the conclusion was forced upon him that the petroleum stove caused the insolubility. No smell existed, as the oil used was highly refined. Since we received the letter from which we have quoted we have dried a sheet of tissue in a small room in which a paraffine lamp was kept burning all the time, and as we did not find insolubility result from doing so, we should like the aid of our readers in determining the conditions under which insolubility takes place, the tissue being, of course, carefully shielded from the light.

JOURNAL OF PHOTOGRAPHY.

No. 969. Vol. XXV.—NOVEMBER 29, 1878.

ON THE PRODUCTION OF A UNIFORM QUALITY OF PYROXYLINE.

Of late years the difficulties which surround the preparation of pyroxyline for photographic purposes, instead of disappearing with the advance of knowledge, seem only to become greater, as if in the general progress towards perfection pyroxyline were being left behind. In one respect this is not a matter of surprise; for, if we take into consideration the great variety of purposes to which pyroxyline is applied in photography, and the widely-different conditions which have to receive attention in the manufacture of the special products—conditions which on a small or experimental scale are almost impossible of fulfilment—we cease to wonder that this branch of research should have remained comparatively neglected at the hands of those who have done so much to advance photography in other directions.

In saying this we do not wish to imply, even in the most indirect manner, that the manufacturers—that is to say, those from whom we derive our supply of this article commercially—have failed in their duty; on the contrary, we think it may be safely said that they have always evinced their desire to keep pace with the demands made upon them. But in view of the constantly-varying requirements in this direction—especially in connection with dry-plate processes—it is obviously impossible for the same individual to play the part at once of manufacturer and experimentalist. It seems equally impossible in one product to combine all the desirable qualities of half-a-dozen different samples; and hence, though we may experience little difficulty in obtaining a pyroxyline eminently suited to any one process, we find that as we vary our conditions ever so slightly difficulties crop up with which we had previously no acquaintance.

Of course, to those of our readers who are content to pursue the even tenor of their way, without troubling themselves with the little niceties of manipulation or most recent "improvements," these remarks will have little application; their sole object is the production of pictorial results, and the chemistry of photography is to them but one means to the end. There exists, however, another class whose interest in the art-science is more widespread. To these photography is both an art and a science, and their love for its pictorial phase is equalled, if not excelled, by their interest in its chemical aspect; and it is to this class we address ourselves, with a hope of stimulating research in the most (of recent years) neglected branch of photo-chemistry.

Research there has undoubtedly been; but, unfortunately, the subject is so wide in its ramifications, and presents so many different points for consideration, that it is an almost hopeless task for a single individual to undertake unless he be prepared to devote his whole attention to it for a very considerable time. None but those who have actually attempted any systematic course of experiment in this direction can fully realise the importance of the undertaking. Something over twelve months ago we ourselves embarked upon such an attempt, and, after conducting between seventy and eighty experiments under a variety of conditions and with nearly every possible material, we became convinced of the utter hopelessness of attaining the end we had in view except by devoting such an amount of time and attention to the subject as we were unable to afford. The experience then gained, however, enables us to point out some of the difficulties which present themselves to the experimentalist, and now that outdoor work is at a standstill the present seems an appropriate time to suggest that some of our chemical readers should take the matter in hand, each confining himself to one part of the subject only. By adopting such a course the personal labour would be materially reduced, and by a subsequent collation and classification of the results thus secured the general question could not fail to be reduced to a smaller compass.

The three principal conditions which affect the nature and quality of the pyroxyline are temperature, strength of acids, and their relative proportions. To these may be added—not as being of less importance, but as being generally less regarded—the nature of the raw material and the time of immersion; and we are, perhaps, not saying too much in expressing a belief that these two latter in their mutual bearing have quite as much to do with the final result as any of those previously mentioned.

We have spoken of difficulties which arise or are specially prominent when working upon a small scale; the chief of these is in connection with the temperature—the element which, *per se*, is supposed more than any other to fix its stamp upon the character of the product. It is only necessary to remind our readers of the fact that a large mass of matter, be it solid or liquid, retains its heat longer, or parts with it more slowly, than a smaller quantity would do under similar circumstances, in order to point out how in manipulating upon a small scale it is more difficult to secure an equable and fixed temperature of the acids. Thus, supposing, for example, we are working (say) half-a-gallon of mixed acids, and at the commencement of the operation the thermometer registers 165°, it is possible that the temperature during the time of immersion may not fall much below 160°; but, if the bulk of the liquid be only eight or ten ounces, it is no uncommon thing to find, after an immersion of seven or eight minutes, that the temperature has fallen as low as 130° if no precautions have been taken to keep it up. Of this, however, more anon. Here is a very evident source of uncertainty and irregularity. The evil is not confined, however, to the mere fall in temperature acting upon the whole mass of cotton. As the immersion of the cotton occupies some time the first portions put into the acids will be exposed during a part of their time to a much higher temperature than the last portions of all, and thus it may be said that each succeeding tuft plunged into the mixture is acted upon under continually-changing conditions, and where the alteration in temperature is so great as we have mentioned it is not difficult to imagine that a very uncertain product will result.

On the other hand, it is possible that a *rise* of temperature may occur, especially when from weakness of the acids, the presence of moisture in the cotton itself, or other causes there is a tendency on the part of the cotton to undergo decomposition. Under such circumstances it is palpable that the increase of temperature will be more easily imparted to the whole bulk of the mixture where the quantity is small than where the opposite is the case; in short, in working on a small scale, the conditions are strongly against uniformity in the matter of temperature. Again: in mixing small quantities of acids a lower degree of natural heat is evolved than when operating upon a greater bulk, and we have frequently found it impossible to secure a temperature of even 160° without resorting to artificial means.

In order to equalise the temperature various means have been recommended, perhaps the safest of which, when it proves sufficient, is to mix the acids in a vessel of considerable thickness—as a Wedgwood mortar — previousiy heated to the necessary point. Where this fails it is usual to recommend the employment of a sand- or water-bath; but the latter is, in our opinion, to be avoided, on account of the strong affinity of the sulphuric acid for the aqueous vapour which must necessarily arise from it. A general objection presents itself, too, to the adoption of either of these latter plans on the ground of the difficulty of regulating the temperature without very great care; and, when employing an original temperature of 170°, it is extremely inconvenient to find the thermometer suddenly run up three or four degrees before the pyroxyline can be removed. In any single experiment it is quite within the bounds of possibility that a satisfactory result may accrue in spite of all or any of these objections; but what we urge is that, in securing an invariable product, the chances are much in favour of the manufacturer as compared with the experimentalist.

As regards the proportion and strength of the acids: there is, perhaps, not much to be said in this connection, except that the latter may indirectly have an effect upon the result, inasmuch as the large consumer is more likely to know the exact strength of his materials, or to ascertain it by actual trial, than one who uses small quantities at uncertain intervals and probably derives his supplies from varying sources. We know that commercial acids rarely rank up to their alleged specific gravity, and any allowance which may have to be made in the added water will be more difficult to calculate accurately on a small than on a large scale.

We have now to turn to an element which works generally against uniformity, whether on a large or small scale of operations, namely, the want of a standard raw material. Cotton, it may be said, is cotton all the world over; but those who are acquainted with the different descriptions of the article which arrive in this country in the raw state will know that their name is "legion." Much has been said about the importance of a long-staple cotton for collodion purposes; but we question if as much depends upon the length of fibre as upon its freedom from the various greasy and mucilaginous impurities with which it is contaminated before it undergoes the earlier processes of manufacture. It is evident, too, that the cotton wool or medicated cotton generally employed in the manufacture of pyroxyline is not wholly freed from these impurities, the only process it undergoes being, apparently, the removal of seeds and particles of seed husks. The cleansed article introduced at the recent Technical Meeting of the South London Photographic Society seems to offer a way out of this difficulty, as, independent of its being more easily permeated by the mixed acids, the process to which it is submitted to give it this character is identical with the method adopted in cleansing the linen rags employed in paper-making.

Much diversity of opinion exists as to the utility or otherwise of the mode of cleansing the cotton with dilute alkali, some alleging that it has an injurious effect upon the character of the resulting pyroxyline. This charge may very possibly be well founded if the alleged injury consist in a loss of density, as the "impurity" removed may in all probability conduce to the production of that special quality. This points to another and separate line of research, namely, the effect likely to be produced by the presence of the different substances found in combination not only with cotton but with flax, hemp, and other descriptions of fibre, and also whether, starting with strictly pure cellulose, it may not be possible by the addition of various foreign substances to produce the special properties now so much desired with certainty and uniformity.

In speaking of the manufacture of pyroxyline it is impossible to pass over what has already been done in the direction we indicate by the Rev. F. Hardwich, whose researches stand to this day as the basis of all our knowledge of the article. But twenty years have worked a wonderful change in photography, and its requirements of today differ very materially from those of the date at which Mr. Hardwich wrote; and we think the time has arrived when his work might well be supplemented. Failing any single individual with time *and "pluck"* enough to undertake the task single-handed, we should be glad to find it seriously taken up by a number of independent chemists, each, as we have suggested, devoting himself to one portion of the subject.

ENLARGED NEGATIVES *V.* DIRECT ENLARGEMENTS.

In our last number, when directing attention to the applicability of the electric light to photography, especially in reference to enlarging, we mentioned that some of the best of this class of pictures we had seen were made direct from the negative without the intervention of a transparency or enlarged negative. These have been sometimes produced on plain salted or albumenised silver paper and on carbon tissue, and for this kind of enlargement the solar camera has hitherto been employed. Sometimes they have been developed silver prints on plain paper, and sometimes what are now so generally known as collodion transfers. The object of the present article is to consider the best method of producing enlargements in our everyday practice, so as to get the highest quality of result from any given negative that may have to be employed.

Speaking from a strictly theoretical point of view there can be little doubt that when the negative is as perfect as it is possible for it to be the best result should be obtained when it is employed for making the enlargement; for if a transparency has to be made there is certain to be a trifling loss of detail and delicacy whatever method may have been adopted in obtaining it. And even with all possible care and skill slight imperfections that do not exist in the original are almost certain to make their appearance, and as a matter of course are magnified in the enlarged negative, thereby marring its beauty. Although in practice this may not be very apparent, it is nevertheless true.

It is and has been for twenty years well known that for the solar camera thin, delicate negatives are required, and images of a similar character would also be necessary if the electric light were employed in its stead. Fortunately the general run of negatives made at the present time are of a character well suited for this purpose. It should also be borne in mind that a negative may be as perfect as were some of those produced a few years ago when pyrogallic acid was employed as the developer—that is, as far as its direct printing qualities are concerned; but such a negative would be quite useless for enlarging in the solar camera, even if the sun could be depended upon or the electric light were at command, and it would have to be reproduced in a thinner and more delicate manner before it could be employed. It frequently happens in business that the photographer is called upon to supply several enlargements from old, hard, and intense, or, perhaps, foggy, flat, and imperfect negatives; and, as in such cases direct enlargement cannot be employed with any degree of success, recourse must therefore be had to the method, now so generally practised by most of those who work this branch professionally, of making enlarged negatives through the medium of a transparency. By this means the operator has the power of producing an enlargement which is often technically superior to prints made from the original negative. We have frequently seen soft and delicate enlargements produced from hard and crude negatives, and also brilliant and vigorous ones from poor, feeble originals; but a little consideration will show how this may be accomplished.

Given a crude, hard negative, such as would produce prints of the "soot and whitewash" type: the first thing to be done is to make a transparency. For this purpose any of the well-known methods may be employed, such as wet collodion, gelatine, or collodio-bromide emulsion, the albumen or carbon processes. Each of these has its advocates, and as each will give good results it matters not which is employed so long as the end is gained, the point being to secure as thin and delicate a transparency as possible. This can easily be done by giving a full exposure, and so managing the development that all the detail is secured with as little intensity as possible, the result being what for other purposes would be called an over-exposed picture. If for this purpose the carbon process be employed then such a tissue should be selected as contains but little pigment, so that the shadows may be comparatively thin and transparent; in this case, also, full exposure should be given, so as to secure all the detail. From transparencies of the character we have just described enlarged negatives may by judicious treatment be produced far superior to the originals.

Now, supposing that the original negative be the reverse of what we have described—weak and poor, with, perhaps, fogging in the shadows—we must then proceed in a manner the reverse of that already indicated, and aim to produce a vigorous transparency by giving only just sufficient exposure to secure the detail and to get as much intensity as possible in the development. We need not take up space now in describing how this is to be accomplished, as it is well known to all our readers. If the carbon process be adopted, such a tissue should be selected as contains a large amount of colouring matter and gives vigorous prints. That known as the Autotype Company's "special transparency" is well adapted to the purpose, as it gives prints of great depth and vigour. If, however, sufficient intensity be not given by the tissue itself, it may be still further strengthened with a solution of permanganate of potash, by which means almost any amount of vigour may be secured.

While on this subject we may call attention to another method of enlargement which, although practised by many, is not so generally employed as it deserves to be, as the results produced by it are very fine. It was published in THE BRITISH JOURNAL OF PHOTOGRAPHY about five years since; it has also been sold as a secret process, and by the same method M. Lambert produced some of his most successful untouched enlarged *prints* when on his visit to this country. The process possesses all the advantages claimed for the direct method, inasmuch as the actual enlargement is made from the original negative; and it also has all the advantages of the system in which transparencies are utilised. It consists in making an enlarged transparency of the full size required in the enlarging camera on wet collodion. In this operation the exposure and development may be "dodged" according to the requirements of the original negative as alluded to above. The transparency when obtained can be retouched to any extent in the same manner as a negative, using a blacklead pencil for the face; also by covering the back with *papier vegetal*, and working on that with a stump and finely-powdered blacklead. By this means lights can be softened, details put in, and shadows strengthened, which it is impossible to do by working on the negative only. It will be found very easy to work on the positive, as the lights and shades are in their proper relation and not reversed as in the negative. After the transparency has been made and retouched a negative is produced from it. There are many ways of doing this, a good method being to print it on carbon tissue (the "special transparency" answering well), developing it on glass in the same manner as a carbon transparency. Should the negative prove to be too thin it may be intensified with a solution of permanganate of potash; but this after-intensification will rarely be required unless the positive has been too weak to allow the light to penetrate sufficiently deep into the tissue to secure the requisite vigour. A carbon negative can, of course, be worked upon in the same manner as a collodion negative when it is varnished; but it can also be worked upon with a stump and blacklead before varnishing, as the pigmented gelatine readily takes the blacklead, especially if it be gently breathed upon before it is applied. We commend this process to our readers as one that is specially useful when a large number of copies are required from one negative. The time expended in retouching the transparency and negative will be amply repaid in the quality of the prints produced.

RECENT PATENTS.

No. XXII.—HEMERY'S PRINTING- AND TINTING-FRAMES.

WE now redeem the promise, made last week, of giving a detailed account of the printing- and tinting-frames invented by Mr. T. G. Hemery, and which, as we have previously explained, were exhibited and the mode of action shown at the recent Technical Exhibition Meeting of the South London Photographic Society. We commence by giving the specification of the patent, which is as follows:—

My invention relates to photographic printing-frames, and has for its object to ensure accurate registration in producing by subsequent printings ornamental borders, marginal tints, signatures, combination backgrounds, or other effects supplementary to the main subject of the picture produced at the first printing, so that any desired number or combination of such effects may be produced by separate printings in one or more tinting-frames, with perfect accuracy and without the aid of special skill on the part of the operator.

My improvement consists in the employment of register pins or studs in corresponding positions on the first and second printing-frames (termed, respectively, the printing- and tinting-frames) in combination with a metal plate (which I term a register plate) having corresponding holes therein, capable of being fixed on the pins or studs of either frame, and transferred from one to the other as required, as hereafter described. The pins in the printing-frame, in combination with the holes in the plate, serve also to punch holes in the sensitised paper or tissue, whereby its proper position in the tinting-frame is ensured.

I prefer that the pins of the printer should be on the back or lid, and those of the tinter in corresponding positions on the frame itself. The printing-frame is also provided with spring catches to retain the register plate when placed in position by the closing of the lid, as hereafter described.

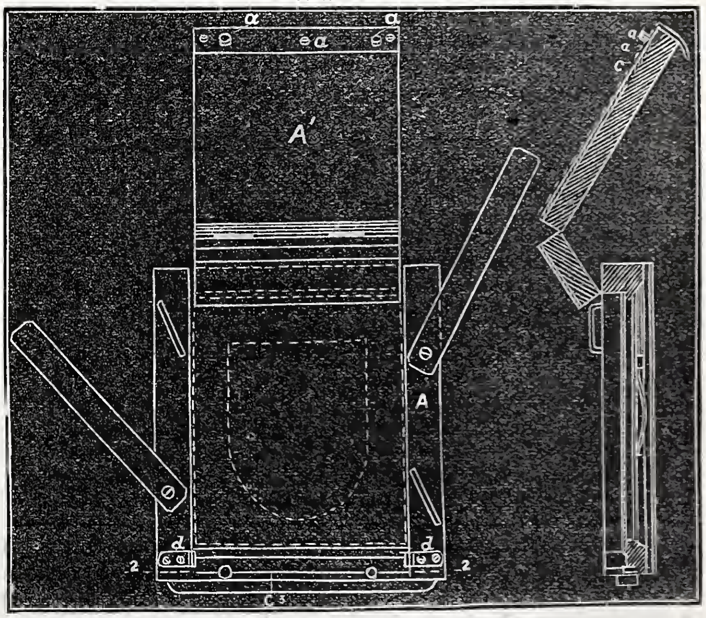
To the register plate is attached the mask for protecting the parts to be sub-printed according to the design. Any number of these register plates may be used, carrying the marks to be employed at the successive stages or printings if necessary.

To enable combination backgrounds and other supplementary effects to be printed in a single tinter, the plate carrying the skin on which such effects are mechanically printed or otherwise produced is removable from the tinting-frame, so that it may be replaced by another carrying a different design.

The pins of the printing-frame, instead of being fixed, might be movable if preferred, and attached to a spring plate which draws them out of the holes in the register plate after being pressed down to punch the register holes in the sensitised paper or tissue.

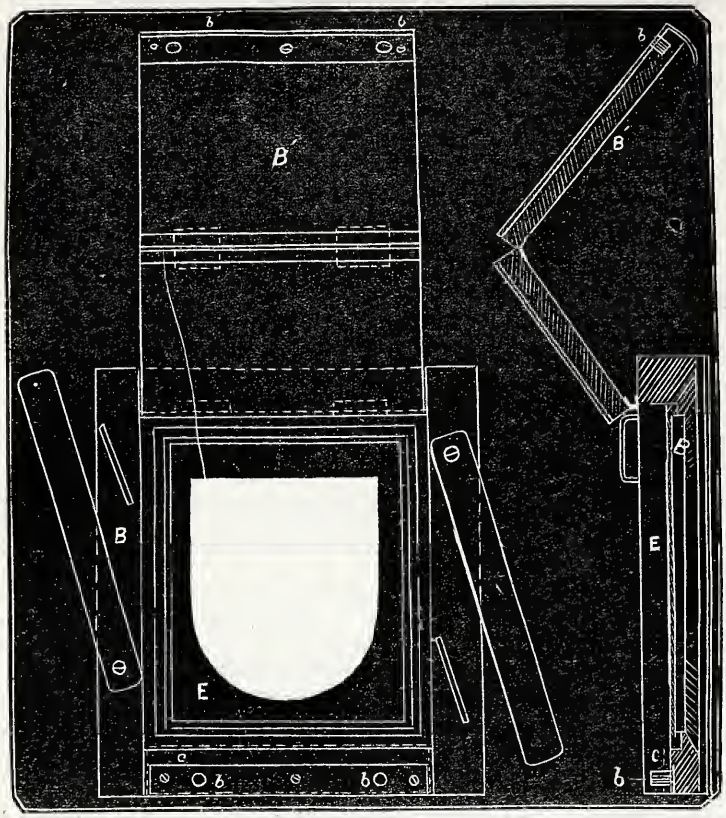
In illustration of the foregoing specification we append diagrams, by which the details will be made clear.

FIG. 1. FIG. 2.



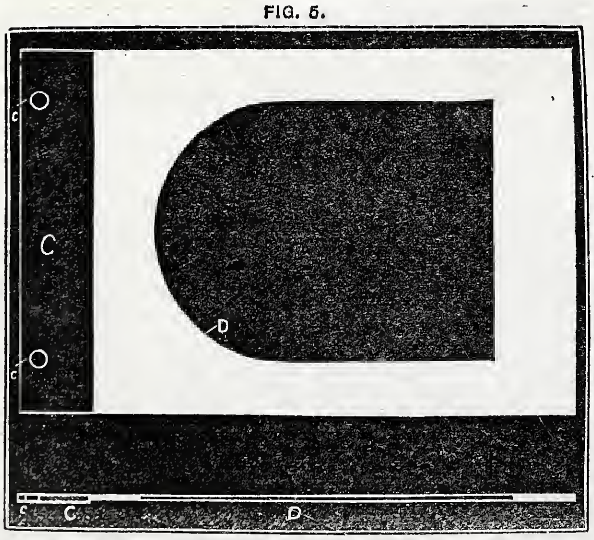
In *fig.* 1 is shown a view of the *printing*-frame when the back is thrown open, *fig.* 2 being a section of the same. *Fig.* 3 represents the tinting-frame, *fig.* 4 being a sectional view. To the hinged back or lid A^1 of the printing-frame are attached, in the position shown, two or more metal register pins or studs *a*. The studs are fixed in a metal plate a^1 screwed to the lid A^1, so as to project from the inner surface of the lid A^1, as shown. The tinting-frame has corresponding register pins or studs *b* preferably fixed to the frame B itself, and not to its lid or cover B^1, the latter having, however, a plate of metal with holes b^1 corresponding to the pins *b* fixed to it in the same position as that occupied by the plate a^1 on the lid of the printing-frame.

FIG. 3. FIG. 4.



The register plate C (*fig.* 5) is of metal and has holes *c* corresponding exactly in size and position, both with pins *a* of the printing-frame and pins *b* of the tinting-frame. The ends of the studs *a* are flat, with sharp square edges, so as in conjunction with holes *c* in plate C to punch out holes in the sensitised paper or tissue. *d*, in *figs.* 1 and 2, are spring catches attached to the sides of the

FIG. 5.



printing-frame A to detach the register plate from the pins *a*, and retain it with the mask attached thereto when placed mechanically in position by the closing of the lid. D is a paper mask attached to a register plate C, the mask shown being intended to protect the border whilst the subject is being printed, it being understood that any form and number of masks, and any number of register plates C may be used, according to the design and effects required. E is the corresponding disc on the glass plate of the tinting-frame to protect the subject, whilst the background, ornamental border, marginal tint, title, or signature is being printed.

The *modus operandi* is as follows :—It being supposed, for the sake of simplicity, that only one register plate C is used, the plate, carrying the disc E and the margin, signature, or other design to be sub-printed, having been placed in the tinter B, the proper position for the mark D to be attached to the register plate C is found by temporarily placing said plate on the pins *b* of the tinter (as shown in dotted lines at C^1, *figs.* 3 and 4), and adjusting the mask D to the disc E, the said mask D being then attached to the register plate, preferably, by india-rubber solution. The register plate, with the mask D now attached, is then removed and placed on the pins *a* of the printing-frame, as shown in dotted lines at C^2, *fig.* 2, and the cover A^1 being then closed down the register plate is caught by the spring catches *d* and retained, as represented in dotted lines C^3, *fig.* 1, in the proper position to ensure accurate register when the lid A^1 is again raised to place in the printing-frame the negative and the sensitised paper or tissue. The latter must be large enough to cover the holes in the register plate, so that on again closing down lid A^1, for the purpose of printing the subject or picture, the pins *a* will punch holes in the paper or tissue, which, when the paper or tissue is transferred to the tinting-frame B, fit on the pins *b*, whereby the correct position of the paper or tissue in the latter frame is assured.

Since the introduction of the combination printing-frames of Mr. B. J. Edwards we have not seen any that permits in such an effective manner the printing of a subject from a number of negatives. The Hemery frames possess, however, certain advantages over those named, one consisting in their greater simplicity and efficiency, there being fewer complications in their construction.

The description of work which can be executed by the agency of the Hemery frames may be acertained from the following details connected with the exhibits at the Technical Meeting to which we have alluded:—

The pictures included a portrait in carbon with the ordinary *entourage* familiar to Lambertypers; also a church with a steeple tapering to a feather point (a very difficult task, and, being successful, a very capital example), in which clouds were printed so perfectly as to render any junction imperceptible, being printed indeed close up to the subject in every part, without that suspicious haze ordinarily seen in pictures all along the line of junction, so suggestive of the use of cotton wool or even of dusters — the method usually adopted when double printing by hand is resorted to. There were also two tinted cabinet vignettes, with ornamental borders, in which *three* printings had been accomplished, the effect being excellent. There was, further, an example of printing Warwick Brookes' "academy" negatives—more accurately done than is possible by the discs provided for the purpose, and which are discarded in Mr. Hemery's frames altogether. There were also included eight *carte*-size portraits with natural backgrounds (Ford Smith's), being the portraits of two children, one position only, but each background being changed, and no two pictures were alike. It was explained that only one adjustment was necessary in the first instance, after which every portrait could receive a second printing by any ordinary assistant without the chance of a mistake on his part; that at will the background could be changed without any alteration of the adjustment, and a great variety of portraits produced, as was evident from the copies shown. The eight *cartes* were perfect examples of the power the frames give the photographer to vary his proofs, as there can be no doubt that this variety would end only with the stock he might happen to possess of background negatives. If an an entire dozen could be printed, each one being different in pictorial effect—as we are assured they can be with no more trouble than if they were simply plain backgrounds (and we see no reason to doubt the assertion from the absolute perfection of the copies exhibited)—we should think the frames would be eagerly sought after and universally adopted by the profession. The frames themselves are certainly ingenious in construction, and it would seem at a glance that perfect accuracy of registration must be ensured.

This combination printing-frame will prove of great use to those photographers who desire to leave the well-worn track of simple printing from single negatives; and, from what has been said, each will easily discover to what extent and in what degree its adoption will prove beneficial in his own practice.

WHAT is the reason that spots and blemishes are more frequent in the sky of a negative than in other parts? This question has been so frequently asked and so frequently answered in a variety of ways that it seems somewhat surprising that it should crop up again (in an indirect manner certainly) with a certain amount of doubt attaching to its cause. Mr. William Washam speaks, in our last number, of a defect which he has recently experienced in connection with certain films he has been using, and which takes the form of a peculiar mottling, most noticeable in the sky portion of the negative. This he attributes to the formation of some "by-product" at the underside of the film, which is only imperfectly removed by the washing which the plate undergoes before drying. This appears a scarcely feasible explanation; for, in the event of an imperfect washing, the evil would surely be spread uniformly over the whole surface and not merely in detached spots. It is extremely unlikely that a film containing (besides the unevaporated solvents) the decomposition salts formed in the operation of sensitising would become impermeable to water; *after once washing* and drying it might do so, but so long as the nitrates remain in the pores of the film the water will always find ready access; but let the pores be freed from crystallisable or soluble matter and closed by drying, *then* impermeability may ensue. From Mr. Washam's description of the facts we see no reason to doubt that the mottling arises from purely physical causes. That it should be visible after fixing only when the development by alkali is pushed to the fullest extent is easily explained. The development commences from the surface, and in a given time acts through a certain thickness of the sensitive matter, and, if not continued sufficiently long to reduce the whole of the bromide in the thicker or mottled parts, the unreduced portion is removed from *the underside* of the film by the fixing solution, and the mottling disappears. If, however, the development be continued long enough to go through the thickened parts the heavier deposit of reduced silver tells its tale. That the defect should make its first appearance in the sky, and should be more generally visible there, is equally easy of explanation. The sky receives relatively a better exposure than the rest of the picture. Over-exposure is, in effect, equivalent to a strong or a prolonged development; hence a development which is insufficient to render the defect visible after fixing in the remainder of the picture may easily produce it in the sky. The reason, however, why the sky is "most affected" is simply because the defect is *more noticeable* in the sky than amongst the broken details of the rest of the picture; and we apprehend that a close examination will lead to its detection in *any part of the picture* presenting a smooth, unbroken deposit of moderate density.

ON COMBINATION PRINTING FOR THE STEREOSCOPE: CONCERNING THE APPARATUS.

[A communication to the Manchester Photographic Society.]

Our Secretary, Mr. W. J. Chadwick, induced me to promise you a second instalment of my paper for the present meeting—a promise, I must confess, I somewhat reluctantly gave, as I would fain have had a little time longer, so that I might have an opportunity of producing some half-dozen transparencies from negatives of my own taking illustrating the peculiarities of Mr. Breese's mode of procedure; but this must be postponed till a future meeting.

I am somewhat at a loss to know where to begin, Mr. Harmer having, in some measure, forestalled me in a great deal of the information I had to give you; but I will supplement as well as I can the very sensible paper he wrote on the subject a few months ago, and I am only too glad I have unearthed a rival in the field, for, between us, I trust the subject will receive the attention it deserves.

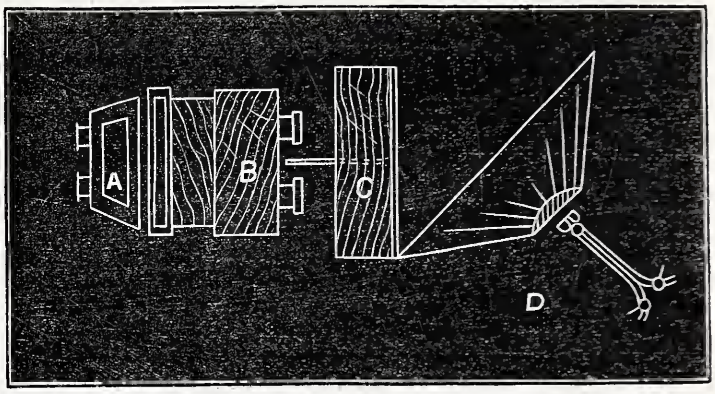
I shall begin by describing what I consider to be the best form of apparatus to meet the wants of those who print transparencies commercially, and, as I am writing with a view of inducing amateurs as well as professionals to take an interest in this matter, I may mention, *en passant*, that the printing of stereoscopic transparencies and lantern slides may very suitably go hand in hand, the same apparatus answering the purpose admirably. Two lantern slides may be printed at each exposure on a small stereoscopic plate with a quarter of an inch to spare, the only difference being that the lenses have to be slightly separated from one another for the latter, and, of course, making such difference in the mode of development as suits that class of picture; for, as you know, lantern slides do not require to be anything like so dense as transparencies for the stereoscope.

Later on I intend to describe for the benefit of those who have more ingenuity than spare cash a form of apparatus that may be made at a very trifling cost; for I am sure there are many who would like to try their hands at this kind of work who are frightened to begin, thinking their means inadequate or that it will take up too much of their time. These difficulties I have set myself the task of clearing away.

Mr. Harmer, in his first communication on the subject, describes the apparatus as follows, and as I do not know that I can improve upon it as a *general* description I will quote it *verbatim*; but, as I know only too well the inconveniences of printing, even with Mr. Breese's own apparatus, and as I have witnessed only too often the sad waste of time in adjusting each subject, I shall venture to enlarge upon the description given by Mr. Harmer, with improvements suggested by my own experience. Mr. Harmer says:—

"The principal pieces of apparatus necessary are a binocular copying camera, and a good tin or other simple form of lenticular stereoscope open at the bottom. The camera should be fitted with twin lenses, and the usual partition to divide the two pictures both in the portion of the camera before the lenses and also that behind. The front carrying lenses must have, besides the rising motion, a means for varying the distance between the lenses, to bring them nearer together or remove them further apart, as circumstances may require. A right- and left-handed screw motion worked by a milled head from the side is most convenient; but rackwork, or any other contrivance which will do that, fully answers the purpose.

"The camera retained for Mr. Breese, by his desire, was supplied by Mr. J. H. Dallmeyer, and fitted with a pair of that gentleman's new stereoscopic lenses, the means for separating them being the right- and left-handed screw movement—suggested, I believe, by Professor Emerson, of Troy University, during the controversy on how far the two lenses of a binocular camera should be asunder. An extra home-made sliding body was fitted to the camera, and a suitable box divided into the two partitions necessary, with an opening in front for the negative and two at the back for the lenses to enter."



A is a stereoscope as used in "combination" effects, such as in moon, gull, and cloud pictures. B is an ordinary stereoscopic sliding-bodied camera, with suitable lenses. C is a box in front of the camera, with central partition holding the negative and its carrier in the front portion. D is a condenser collecting the rays from a limelight jet shown at E, and distributing the same on a semi-transparent screen used in place of the daylight reflector.

By examining the diagram you will see in front of the copying camera the usual box holding the negative to be printed from. This box may or may not be a fixture to a base-board, according to fancy; but, supposing it to be a fixture, which I myself prefer, the slide holding the carrier for the negative should be made so as to be capable of being slightly moved laterally and vertically according to requirement, and it should also have the means of being rigidly fixed when once *in situ*. This you will readily recognise as an important matter in all copying apparatus; but it is particularly important in the apparatus I am describing, and no end of trouble and vexation may be saved by due attention to the matter. The necessary adjustments for each fresh subject take some little time and judgment, but when once a satisfactory result is obtained and all the adjustments made secure, fifty or a hundred, or, in fact, as many pictures as are required may be printed straight away without any further trouble.

All Mr. Breese's negatives were taken on $6\frac{3}{4} \times 3\frac{1}{4}$ plates. This he confessed to have been a great error on his part. No stereoscopic negatives should be taken on less than $7\frac{1}{4} \times 4\frac{1}{2}$ plates, and the copying apparatus should, of course, correspond, though for merely copying purposes the camera itself need not be capable of taking a larger plate than the usual size of a transparency. The little bit of "play," however, one gets on the larger plate is simply invaluable, and the trouble of taking it is precisely the same as taking a $6\frac{3}{4} \times 3\frac{1}{4}$; whereas the slight extra weight in apparatus is of no consequence, as I have before remarked, in these days of cameras of extreme portability, and of dry plates as sensitive and as much to be relied on as wet ones.

While on the subject of negatives and the advantages of dry plates, I should like to suggest that, where possible in outdoor work, it is always worth while to expose two plates—one for the landscape alone, and one for the sky and clouds, taken immediately one after the other.

We will suppose the operator to have focussed his subject, and has in his hand a double dark slide containing two dry plates. He exposes one plate at the first favourable opportunity for the landscape—say four seconds—then quickly whips out his dark slide, reverses it, and exposes for the sky.

A friend of mine once showed me a complicated arrangement he seemed very delighted with, by which there is a sort of flap constructed in the camera, to which flap the operator has to attach a piece of paper cut out approximately to the outline of the landscape. This flap is used to mask the sky while the landscape is being duly exposed.

I confess I have not tried this plan, and I do not think I am ever likely to do so. Surely the plan I suggest is both more practicable and satisfactory in its results. I do not say it has not been done; but it is only lately, when dry plates are comparatively perfect to what they used to be, that the thing is possible. The only way to do this with wet plates is to have a plate double the size of the usual stereoscopic negative, with a shifting arrangement such as is used in the studio portrait cameras. Mr. L. Warnerke's band of sensitive tissue and roller slide would be a convenient form of apparatus for this purpose.

In printing from stereoscopic negatives the picture is not only inverted by the lenses, but the outer edges are transposed and overlap more or less in the middle of the transparency. Now, we have all at times defects in our negatives, especially in outdoor work, done very likely under difficulties, and we know that these defects take place more often than not on the outer edges of the plate. This being the case, in dealing with a small stereoscopic negative having defects on one or both of the outer edges, the said negative is perhaps rendered perfectly useless unless enlarged. This it is never advisable to do, on account of a loss in sharpness; whereas, with the negative taken on the larger scale the defects must be very serious indeed to interfere in the printing of a successful transparency. Besides this, the larger negative will bear reduction, which must contribute to sharpness; and, as I have said elsewhere, sharpness is unquestionably a desirable quality in stereoscopic work, whatever disadvantage it may sometimes possess in an artistic sense in portraiture, for the transparency, be it remembered, has to undergo considerable enlargement when viewed in the stereoscope.

In front of the box holding the negative Mr. Breese used a plaster of Paris slab, tinted of a slightly lavender hue to correct any yellowish tendency the plaster might possess. The advantage in using plaster of Paris over any other kind of reflector is that when soiled it may be easily sand-papered clean in a few moments, but there are of course good substitutes for this kind of reflector. For my own part I would as soon have a piece of looking-glass at an angle of 45° with the light falling upon it filtered through a piece of finely-ground glass or *papier mineral;* but nothing can beat printing against a clear north sky, as there must be a serious loss of light in using a reflector of any kind.

Mr. Breese, however, being very conservative in his ideas, preferred his own plan; for I remember him six years ago printing out in the back garden of his house in Sydenham in this way when he might easily have tilted his base-board and the apparatus attached thereto, so as to get the advantage of the open sky, had he chosen.

I am the more surprised at this as the tone got by printing against a good direct light is unquestionably warmer and better than when printing in any other manner, and the way Mr. Breese himself secured the extremely warm tones for his sunset pictures was by pointing his apparatus direct to the sun instantaneously, and using an old developer rather weak and stopping the development at the right time. This is the difficulty, for if the development be not stopped at the very instant the required tone is reached the colour changes to a cold grey.

There is one slide in particular that I have at this moment in my mind's eye, and that is the one I shall now hand round for you to look at. It is a sunset effect over the sea. I do not know what Mr. Breese called it; but it is the nearest approach to photography in colour that has ever been done—at least as far as my experience goes—and this slide has been entirely the production of photography. Some of his later slides which I have by me were "dodged" to secure this and similar effects. A piece of fine ground glass was used at the back instead of glass obscured with his wax solution, which he employed generally, and the ground glass had burnt sienna rubbed delicately over where a warm tint was wanted, or some cobalt oil colour or indigo when a cold tint was required.

The front glass in the slide I am handing round contains, of course, the sea view and sky and clouds. The back glass is nothing but a gradation beginning from the centre with a beautiful golden tint and fading gradually away into cold gloom. The masked negative from the spot occupied by the sun to the edges of the plate is secured, according to Mr. Harmer, by means of a star-shaped disc set revolving, and then photographed with a stereoscopic camera while in motion. This is no doubt the original way, but Mr. Breese, having no masked negatives by him of the kind he required when printing this very slide for me, had to make one, and the way he did it was by attaching two small india-rubber balls in the centres of each half of a stereoscopic plate, having previously whitened the ball on the side exposed to the camera. This he pointed directly to the sun, exposed instantaneously, and developed with some very weak developer brown with age that we kept by us for this and kindred purposes. The result you see before you.

I should have mentioned that the stereoscopic plate on which the india-rubber balls were fixed was of the finest ground glass; and you will observe that, instead of having to make a photographic negative, Mr. Breese constructed a negative without going through the usual process, the two india-rubber balls, fixed on the ground-glass plate, doing duty for the negative itself. Of course, having once got a good gradation by this means, a negative could easily be printed from it for future use.

The carrier holding the negative in front of the box C may be described as a thin loose board in which an aperture is cut a little smaller than the negative to be copied; and this carrier is kept in the position required by means of a screw and washer, the screw passing through a hole sufficiently large to allow of horizontal, vertical, and oblique movement. The object of this latter movement is to save cutting a valuable negative in the event of the line of the horizon being out of the horizontal, as is sometimes the case when negatives are taken under circumstances that leave little time for paying strict attention to the adjustment of the camera, such as instantaneous photographs of breaking waves, &c.

By referring to the diagram you will observe I have substituted an arrangement by which artificial light takes the place of daylight, so that the work may be carried on during the dark days of winter or by night, independently of the light of the sun—a great convenience to the amateur, who is often engaged during the daytime, and therefore whose only opportunity of pursuing his hobby is after business hours. To the professional it will be found of great convenience (especially in this part of the country, where daylight is not to be depended upon), as stereoscopic and lantern work may be turned to profitable account when other work falls slack, as it invariably does at this time of year.

The condenser must be so placed as to be as much out of sight of the negative as possible, and a piece of finely-ground glass must take the place of the plaster-of-Paris slab on which the disc of light falls. By every other arrangement of the light that I have tried—and I think I have tried all—I find that the sensitive plate prints quicker opposite the flame, in spite of the condenser.

The only other way I can suggest is to project a disc of the brightest possible light one can get—using two lanterns if necessary—on to a perfectly white surface, and print against that. One of these plans, unless we can think of something better, we shall put to the test when I fulfil my promise of printing a combination picture in your presence, and Mr. Chadwick has kindly consented to give me his valuable services and experience on that occasion. So I have very little doubt we shall not fail on the score of finding a good light to print by. S. H. Ashley Oakes.

BEECHEY EMULSION PLATES.

I read Mr. Washam's communication in last week's Journal with interest, as I have had some little experience with Beechey plates, and encountered the difficulties he mentions. Seeing the general interest taken in the process I presume that any experience, however small, tending towards their removal will be acceptable to those of your readers who are working it.

About two years ago I prepared several batches of the plates, but gave up in despair, the negatives being hard and completely ruined by flocculence. The process, however, had a fascination for me, and last spring I returned to the charge, but with as little success as previously. Flocculence of the film (generally miscalled "mottling," I believe) and small black spots were my chief troubles, and from what has from time to time appeared in the Journal I gather I have not been the only victim. Some commercial plates, too, that I tried were anything but free from these defects. The following method has given in my hands complete freedom from these faults, and I imagine that others would find it equally successful:—

The collodion being prepared, in any required quantity, according to the formula, pour *half of it* into a stoppered (or well-corked) bottle capable of holding three times the quantity of the finished emulsion. Now thoroughly dissolve the silver in alcohol in the usual way, and add it to the collodion in *eight* or *ten doses*, shaking violently between each addition; then pour in the remaining half of the collodion, shaking violently as before, and let it rest for twenty-four hours. If the pyroxyline be of good quality a perfectly smooth and creamy emulsion ought to be the result. I have found it unnecessary to use other than methylated solvents.

I was much troubled at one time with black spots—some with tails, some without—which appeared on some of the plates of a batch but not on others. Canon Beechey, in reply to some questions on the process, assured me that they arose from dust; but I imagine they are silver chloride, arising from free silver remaining upon the plates after washing, and which combine with the chloride in the beer. Washing the plate under the tap before placing it in the preservative secures absolute freedom from these unpleasant visitors. Clots in the film are caused by returning the surplus emulsion from the plate into the coating-bottle. The use of a second bottle obviates this difficulty, and is a security against dust.

The defects alluded to I regard as technical; but want of rapidity and hardness are the worst faults to be contended against. They are best overcome by the addition of a few grains more silver than recommended in the formula, with an increase of acid in the chloro-bromide solution if found necessary; but it is well to bear in mind that too great an excess of silver gives thin images, rather inclined to fog and difficult to intensify. Although I have discontinued working with Beechey plates, in favour of those prepared by the old collodio-bromide formula, I regard the former process as capable of giving very good results; and I take this opportunity of acknowledging my indebtedness to Canon Beechey for several valuable suggestions. H. Manfield.

PHOTOGRAPHIC NOTES FROM TRAVELS IN RUSSIA, WITH EXHIBITION OF VARIOUS WORKS, APPARATUS, AND MATERIAL.

[A communication to the Photographic Society of Great Britain.]

Six winter months I spent in Russia, and now I intend to communicate to you a few notes regarding my travels. Before, however, I proceed any further, permit me to assure you that I had nothing to do either with Plevna or with the treaty of San Stephano. My notes are purely photographic, and therefore I hope I shall not encroach either on British interests or on the rules of this Society. It was my good fortune that although I arrived a perfect stranger in St. Petersburg I very soon made very valuable acquaintances among persons connected with science and photography; and, thanks to friendly relations that followed our first acquaintance, I have been able to see a great deal, to learn much, and to bring over with me a rich and numerous collection, a part of which is exhibited in this room.

You will not be surprised to hear that photography in Russia is very well represented. In certain branches it occupies a foremost position; and there is sufficient originality to authorise me in stating that there is in the collection before you a great deal that is quite novel and deserving of more than a passing glance.

Most remarkably cultivated is undoubtedly the portraiture, and in this branch very high excellence is attained. Many causes have contributed to this perfection; but most prominent is the artistical culture of the photographers, many of the best-known names having attained a high degree of proficiency as painters before they embraced the new art. At the time of my arrival at St. Petersburg there was no photographic society and no special publication devoted to photography; but several gentlemen belonging to various scientific bodies occasionally touched upon photographic problems, and made them objects of special investigation. For want of time it will be impossible for me to enter at present into the details of these investigations. I simply enumerate the names of authors and subjects of study, intending in some other place to give a full account:—

W. Lermantoff, professor, attached to the St. Petersburg University, investigated the theory of the formation of the photographic image obtained by development, and explained it by galvanoplastic action. Interesting is the experiment in support of his theory. A small funnel made in parchment is filled with a negative silver bath, and inserted in the ordinary iron developer. Silver wire in the shape of a horseshoe is then inserted in such a manner that one end of it is dipped in silver and the other in iron. After some time crystals of metallic silver are formed on the end dipped in the liquid contained in the funnel.

N. Egoroff, professor, of the same University, studied the action of the electrical photometer, based on the principle discovered by E. Becquerel, that if two silver plates covered with iodide of silver be dipped in a weak solution of sulphuric acid—one kept in the dark and the other exposed to a beam of light—the galvanic current will be formed, the intensity of which is proportionate to the intensity of light.

E. Kotelnikoff explained the theory of the formation of the photographic image (negative) by phosphorescence, asserting that iodide of silver by a short action of light in the camera became phosphorescent with ultra violet light, and this light ultimately produced precipitation of silver in the mixture of silver and iron salts when the developer is applied.

H. Wild introduced in the physical Observatory in St. Petersburg quite an original instrument, named "uranphotometer," to determine daily the intensity of the diffused light of the sky, based on the theory of polarisation.

I have in my possession the publications mentioned, and anybody wishing to make nearer acquaintance with them is quite welcome.

During my stay in Russia I had the pleasure of witnessing the organisation of a new photographic society. Existing laws of the country put many difficulties in the way of the formation of any society; but fortunately in Russia there exists at present a very influential and powerful institution, named the "Imperial Technical Society." I shall not be very far off from the truth if I compare it to the Society of Arts combined with the Kensington Museum. This society, through its enlightened and highly-esteemed president, P. Kotchoubey, and Secretary, T. Lwoff, offered to the new applicants to accept them as a section of the Technical Society. This arrangement obtained high sanction, and the new photographic society is at present on the way to probable success. The President elected is Lieutenant-General Birkin; Vice-President, General Tchagin; Secretary, W. Sreznewski; Committee, Lewitzki, Denier, Klassen, Lapteff, Shpakowsky, Lorens. It was not decided whether the new society would issue a journal, but Professor Wagner, a distinguished editor of a magazine, *Swet* (Light), recently issued monthly supplements under the title *Swetopis* (Photography), the few first numbers of which I now forward to the library of this Society.

Since January last appeared also a new semi-weekly magazine, *Obzor Graphitzeskich Iskustw* (Review of the Graphical Arts), giving considerable room to photography, and even adorned with specimens of this art.

Photography is largely adopted by many Government establishments for the reproduction of maps and of state papers. Perhaps the largest institution of this kind in the world is the well-appointed photographic establishment under the superintendence of G. Scamoni, who is so well known in the photographic world. Every branch of photography is worked successfully in this establishment, as you can observe by the specimens kindly given to me by Mr. Scamoni and exhibited on the screens. But most original and characteristic are those *heliogravures* produced by the process described in his book, and presenting the same excellence as the world-famed *heliogravures* published by Goupil et Cie. in Paris. Mr. Scamoni's assistant, Mr. Chesterman, is an Englishman. I cannot leave the establishment without taking note of how closely allied with photography is the art of galvanoplasty. In this establishment iron is electro-deposited to any thickness, and by this means letterpress blocks are produced that are able to give millions of impressions without being worn out—a requisite for the impression of rouble notes so largely circulated in the country. I exhibit a fine specimen of an electro-deposited iron plate presented to me by Mr. Scamoni. By the same process old armour, of which excellent specimens are now being exhibited in Paris, are reproduced quite equal to the original.

Another very important Government photographic establishment is in the Depôt of the General Staff, under the able and enlightened direction of Mr. Laptef, chief of the Depôt of Maps. General Shtupendorff is himself an accomplished photographer also, and this contributes to the general success of this very busy and well-organised institution. Photolithography is his principal business. This huge map of the Austro-Prusso-Russian frontier, published for the present war, is certainly a very remarkable specimen of photolithography. However, the most remarkable production of Mr. Laptef is illustrated by this incomparable map, printed from a copper plate, and produced by electro-deposition on gelatine relief. Numerous specimens, not only of prints, but also of negatives used in this establishment, will enable you to estimate fully the excellence and importance of the establishment.

Photography is called in aid by two profusely-illustrated periodicals in the shape of photozincography, which is used for the reproduction of woodcuts published in other countries (copyright in Russia has no effect), but those are generally very inferior.

Among the private establishments that print from gelatine (Alberttype) the most remarkable is that of W. Reinhardt's. Among numerous specimens done by this gentleman I point your special attention to this rare manuscript, produced by the joint labour of himself and Mr. Sreznewsky, who, being an amateur photographer and a learned searcher after vestiges of old civilisation in his country, took all negatives from this unique manuscript, whilst Mr. Reinhardt printed them by photolithography, producing, according to his system, the transfers by Albertype. Here are autographs of Peter the Great and Catharine II., and the first book in the Slavonic language, printed in Cracow.

I have not many specimens of portraits in my collection. These you have often opportunity to see at our own and other exhibitions; but I wish to point your special attention to the production of Mr. Denier. This gentleman employs quite an original system of his own. His work, as you can judge by these specimens, is recognised among all others by its extreme delicacy, comparable to ivory or opal. Strictly, no retouching, either on the negative or on the prints, is introduced. His studio is remarkable for noble proportions, and by the total absence of blinds or curtains. He uses collodion especially prepared by himself, and gives very short exposures.

Mr. Lewitzky, whose universal reputation was established long ago in Paris and St. Petersburg, is not sleeping on his laurels. In his studio special attention is paid to every novelty that appears in photography, and you can find there that every new appliance and every process is investigated. He is the only licensee of Lambert and the Autotype Company in Russia, and his productions are worthy of close examination. I only regret that they are not more numerous.

Many other very remarkable portrait photographers are well known in St. Petersburg, such as Lorens, Bergamasco (the last most successful commercially), and others; but it happens that my collection is lacking in their works.

Next we approach the very numerous studies of Russian life in endless variety. Only attentive perusal of this very extensive series will initiate the inquiring examiner in the outside appearance and general character of the country and its people. The author of this marvellously well-executed collection is an Englishman, Mr. Carrick, who, when presenting to me his magnificent gift, imposed only one obligation—that whenever I showed any one the result of his labour and artistic genius I must couple with his the name of the late Mr. MacGregor, who was his assistant, and became his instructor and best friend till his lamented death, which occurred several years ago. Almost every photograph is a picture of great artistic value.

The fine views of St. Petersburg and Peterhoff are the work of Mr. Felish, who makes street views his speciality, and, by systematic work, has attained the excellence you can here admire without being tired by their great number. The interior of the prison acquired special interest in consequence of the last attempt on the life of the Governor Trepoff. The unsurpassed series of the interiors of the imperial palaces is the work of Mr. Classen. This is undoubtedly the finest result ever produced; but the reason of this excellence is not difficult to understand, since he possesses artistic and technical qualifications coupled with real love of the art and extensive practice. Mr. Classen, like Mr. Denier, does not use blinds or curtains in his studio. The extraordinary panorama of St. Petersburg is also his work.

The next series is the work of Mr. Karelin. You have heard a great deal of discussion respecting these pictures from the time of the last Edinburgh exhibition. I was so struck by them that, without necessity, I went to Nigny Novgorod to pay a visit to this gentleman. The trouble of the long journey was repaid by the cordial reception I received in Mr. Karelin's house, and by the pleasure of seeing a large number of far more important works than these. Unfortunately some very fine specimens have not yet arrived. Mr. Karelin has discovered means to introduce an alteration in portrait lenses which enables him to obtain extraordinary depth of focus without any loss of rapidity. This you can especially observe in the groups I point out to you. But what strikes every observer is that a great many of these photographs are illuminated by direct sunlight, and notwithstanding this they are models of softness. These groups are taken inside the room. I recollect all the fixtures of this rather low and not very light room. I mention this peculiarity for the information of some persons who suppose that these are combination prints. I have also examined the negatives.

Mr. Boldyreff, whose photographs hang on this side, says that he hit upon the same idea as Mr. Karelin. Certainly, some of his pictures approach in beauty those of Mr. Karelin. Quite recently also I received information from a friend in St. Petersburg who has also done the same.

It is possible that we shall soon be obliged to alter our photographic outfit for landscape work, and only be satisfied with instantaneous work. This apparatus is the work of an amateur professor in Moscow, Uzutzewsky. It contains a dozen sensitive plates, which are exposed without the aid of a dark slide. It also reminds one of Jonté's camera, but it is much simpler and has other advantages. The same gentleman has invented a very clever portable stand for the camera, which I hope to be able to show on some other occasion.

The indefatigable secretary of the new society, Mr. Sreznewski, has also constructed a very ingenious box tent.

I introduce next to you a very good apparatus, made in Moscow, to verify the correctness of the position of the ground glass in the camera.

Among *matériel* useful in photography I can only show you at present, in consequence of the shortness of time, this cotton, which is very suitable for making pyroxyline. It is prepared as a substitute for lint, and was used in the late war. Its peculiar property is its permeability by water—a quality very desirable in the manufacture of pyroxyline. The process employed to obtain this quality is not well known, but I heard from a good authority that it is the treatment of the cotton by steam at a very high temperature and under heavy pressure.

I close my notes by publicly expressing my gratitude to those gentlemen who, by their generosity, have enabled me tonight to illustrate my paper by these numerous collections.

Leon Warnerke.

ON THINGS IN GENERAL.

I was standing by the side of my camera the other day, when, upon laying upon it a photographic periodical I was reading, my attention was attracted by what appeared a remarkable phenomenon. Now, cameras have not usually a large range of facial expression, nor have I found them give way to undue levity; but on this particular occasion my Camera solemnly opened his Cyclopean eye and closed it again*—in fact, the nearest approach to a wink of which its features were capable. I almost expected to find it speak, with a suggestion of perambulation. Turning at once to the paper to see what might have caused this unusual behaviour, I read as follows:—"A letter was read from Dr. Richard, of Mannedorf, in which he offers to give instructions in his rapid process at a reduced price. He expressed his willingness to make it known for the sum of seventy-five francs per head, provided ten customers applied together, in order that it might be brought within the means of all; otherwise for a single customer the price would be 300 francs. At the same time he sent a plate with two pictures taken by his process; the first in one, the second in two, seconds, but marked by extraordinary softness."

Excellent Dr. Richard! and his praiseworthy desire to benefit his brethren cannot be too warmly praised! It is true that no evidence appeared to be offered as to the comparative methods of the process, and some members of the society affirmed they could do as well in a good light. But what of that? Some people are *so* particular!

One of the best things I have heard for some time happened in a large town considerably north of London. A young man of prepossessing appearance called a few months ago upon sundry photographers and asked them for specimens to send to the Paris Exhibition. With lamblike innocence they selected a few good impressions and gave them to him, and likewise took a portrait of the young man himself. They heard no more till a few weeks ago, when he walked in, at least into one of his victims' studios, and announced that the proprietors had obtained a diploma. Again were they confiding, and did not attempt to hide from their friends with any great care the news of their newly-acquired honour. I never before thought that human nature was so gullible.

I don't think it was any undue gullibility of nature that caused a drop of fifty-eight pounds six shillings in the present value of the assets of the Edinburgh Photographic Society, owing to the Glasgow bank failure. I was very sorry to see it, and hope they may get some of it back. But the society is certainly to be complimented upon the flourishing state of its funds. How many other societies, I wonder, are there of the same size that could lose between fifty and a hundred pounds and still have a balance on the right side?

What a dreadfully-painful event was that of the death of young Wrench the other day, and from an entirely preventable cause, too! Surely a manufacturer of apparatus in connection with magic lanterns should have known how to make a safe retort! But, no! One was used

* We presume our correspondent trod upon the ball attached to his pneumatic shutter.—Eds.

of the very construction adapted to cause a terrible accident if by any chance the exit got stopped up, as it may so easily do, by falling over as it did in this case, or by the lodging of portions of the materials in the neck through undue heating. It is the old story, though, everywhere—the difficulty in getting workmen to carry out new ideas. They possess a conservatism almost Chinese in its character. It is with the utmost difficulty that they can be got to make anything differing from what they or their fathers before them have made without being asked to change it. Nevertheless, for a death through accident to happen now-a-days in the making of oxygen is well-nigh criminal, I consider. I don't of course refer to those accidents that occur through the ignorance of gas users, *i.e.*, the amateur exhibitors. It was only a few days ago I read an account of such an accident happening, the windows and doors being blown out, a fifty-six-pound weight pitched to the other end of the room, and the wall injured by several heads being violently knocked against it. No one was killed, or very seriously injured. A workman had filled a gas bag with coal gas, and thought a bit of oxygen that was in didn't matter!

I see from the correspondence columns that Mr. S. Fry is telling Mr. J. Werge he has found a "mare's nest." Possibly; yet I must say that I quite thought, in reading Mr. Fry's paper, that he was describing a studio of his own design—a very good one for single figures—but rather, indeed I should think very, imperfect if a group of three or four figures had to be taken in it, especially if one were a squalling babe.

I wonder what sort of albumenised paper it is which, according to Mr. Kirkby's paper, read before the Liverpool Amateur Photographic Association, gives only two and a-half grains chloride to the sheet, and yet produces twelve or thirteen grains of sulphide from the hypo. It must be a very highly-salted paper, with most of the silver washed off after sensitising; for, taking the silver bath at thirty grains, the collodion would only represent about two-thirds of a drachm of solution—a quantity quite insufficient to cover a sheet. FREE LANCE.

PHOTOGRAPHING IN CYPRUS.

WE have already stated that Mr. John Thomson, F.R.G.S., gave, at the last meeting of the Photographic Society of Great Britain, an account of his tour. This we reproduce from the official organ of the Society:—His object in visiting Cyprus, he observed, was twofold—first, to obtain a series of photographs which would convey some idea of the place and the people; and, secondly, to procure such information as would be valuable towards the same end. He took the overland route from Paris to Marseilles and from Marseilles to Alexandria, his only difficulty being with the quantity of baggage he had with him—an item which he advised everyone who contemplated journeying to Cyprus to reduce to as small dimensions as possible. On approaching Larnaca the view struck him as one of the finest in that part of the East. The whole coast of Cyprus could be distinctly seen in the foreground, while in the distance beyond were mountain ranges, which, on looking at with a photographic eye, he could not help thinking denoted much trouble in store. Over these mountain ranges was hanging a haze caused by the heat, and this haze was not at all easy to overcome, so as to give a true idea of the landscape. This heat and haze prevailed in Cyprus during the summer months, and increased as the rainy season approached. The latter season has not yet come on, although it had been expected for some time. The beauty of the view somewhat disappeared on getting nearer to Larnaca, where the visitor saw nothing before him but a Turkish town like many others in Asia Minor or the Levant.

Larnaca is a collection of dilapidated houses, relieved by spires, towers, and minarets, and at first sight the appearance was dreary and depressing in the extreme. There was scarcely any landing places, and altogether the town was just what might be expected after some three or four hundred years of Turkish neglect and misgovernment. Larnaca was certainly not inviting with its tumble-down houses and its dilapidated, groggy-looking piers standing up in the water—very fine indeed for pictorial purposes, but not of much use for anything else.

There was but one English hotel in Cyprus, and, making his way thither, Mr. Thomson found there a number of disconsolate Englishmen, whose only occupation apparently consisted in asking each other after their health, whether they had had fever, whether they liked the place, how long they were going to stay, when they were going back, why they had come to such a place, and altogether the reception was rather dispiriting. As he had not quite got rid of the effects of the sea, he was at first half-inclined to return at once; however, he did not do this, and afterwards found that his first impressions had to be considerably modified. Larnaca was but one place, and he fancied that a good many of the impressions which had been brought to England were only derived from thence. The difficulties of photography in Cyprus were very great; there were no roads to speak of in the island. The only roads, in fact, were one which crossed the island to Nicosia in the centre, and then extended to the mountain ranges at Kyrenia, and one from Larnaca to Famagusta; all others were simply footpaths.

There was but one omnibus in the island, and Mr. Thomson had thought of travelling by it to Nicosia, but afterwards found that it was very small, and did not take baggage. The mode of travelling was by mules, camels, or donkeys, and he decided to hire mules for the purpose. The baggage mule was a very small animal, and when the apparatus was piled on to his back he was almost invisible. The muleteer was a very tall man; indeed, the Cypriotes were, as a whole, a splendid set of fellows, the majority being six feet high. When the mule was packed he deposited himself on the top of the baggage.

Mr. Thomson's apparatus consisted of one of Rouch's tents, as small a quantity of chemicals as he could carry for the wet process, some collodion emulsion for the dry, and a small portmanteau of supplies. Thus equipped, he started for Nicosia, the capital, which lies in a plain between two ranges of mountains. Before reaching Nicosia Mr. Thomson stopped for a night at Athenis, a village peopled by muleteers, who showed him great hospitality, and this was his experience throughout the island. No payment was ever expected for lodgings, and all that was necessary was to make a present to the servants or the children. At Kyrenia he employed a dragoman, an Arab shopkeeper, and a very intelligent man, speaking four or five different languages. As business was bad he gave up his shop for a time, and engaged himself to Mr. Thomson for twelve shillings a day. The dragoman was supposed to know every part of the island, but this turned out incorrect, and Mr. Thomson found him on several occasions to be useless as a guide. Indeed, the dragoman had an important object in joining Mr. Thomson, which was to call upon his customers in the different towns, and remind them of the stock of maccaroni, soap, and matches he had in his store at home. However, on the whole, he managed to attend to Mr. Thomson's affairs and his own pretty well, making himself useful in cleaning glasses, setting up the tent, &c.

With regard to the health of the island, Mr. Thomson remarked, in passing, that it was not nearly so bad as had been reported. The inhabitants in the interior were a fine race of people; there was very little sickness and no physicians. When anybody was ill—say with headache—he made a model of his head—not very artistic, perhaps, but a near enough—and deposited it in the church before some saint as a native offering, so that the saint might be reminded of the cure which was desired. The Cyprus fever was not a very dangerous one. He (Mr. Thomson) had rather a bad attack, but he pulled through it in about a week. His worst photographic experience was when ascending Mount Olympus. He rose very early for the purpose and found the morning very gloomy and threatening. However, about five o'clock he determined to start despite the great masses of clouds gathering up. The dragoman and the chief at whose house he was staying both prophesied rain, but, as he said he should have no other opportunity, they at last started to ascend the mountain. When the summit was reached the rain came down as it only could in those latitudes, and by the time they had set foot on the ancient shrine which crowned the height the hills shook with thunder and the lightning flashed, the whole forming one of the most terrible storms he had ever experienced. The tent was nevertheless erected, and the chief, who was clad in an enormous fur greatcoat, took shelter under it, while the muleteer took refuge under the saddle-bags. However, in spite of all the difficulties, he succeeded in bagging one photograph, and then the party prepared to depart, the chief, owing to the pools of water which had gathered in his huge greatcoat, being with some trouble dragged from beneath the tent.

Mr. Thomson then gave an amusing account of his descent of the mountain, and concluded by expressing his willingness to give any information, to any one who wished it, in reference to his method of working in so hot a climate.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
December 2....	West Riding of Yorkshire	Oddfellows' Hall, Bradford.
" 4....	Photographers' Benevolent	160a, Aldersgate-street.
" 4....	Edinburgh	Hall, 5, St. Andrew-square.
" 4....	Bristol and W. of Eng. Amateur	Museum, Queen's-road.
" 5....	South London (Annual Meeting)	John-street, Adelphi.

AMATEUR PHOTOGRAPHIC ASSOCIATION.

A COUNCIL meeting of this Society was held on Tuesday, the 19th inst.,—Sir Antonio Brady in the chair.

The minutes of the last meeting having been read and confirmed, the following members were elected:—G. G. Baker Cresswell, Esq., Rev. R. O. Yearsley, M.A., J. C. Hannynton, Esq.

The Secretary then read several letters from members expressing their satisfaction at the prizes received by them the previous year; and also a letter from Mr. Gunyon, stating that he had had nearly fifty negatives spoilt by bad varnish. He (the Secretary) mentioned that he had brought this letter specially before the notice of the Council, because he had received several communications from other members complaining of the same thing, and that he himself had been greatly troubled in like manner.

Mr. J. Glaisher suggested that the fault might be in the collodion rather than in the varnish.

After a careful examination of several negatives, it was the general opinion of the meeting that Mr. Glaisher was correct in his surmise.

The Secretary then laid before the Council the prizes, which were as follow:—Three silver goblets, two elegant, illuminated portrait albums, and six oil paintings in gilt frames.

These having been approved by the Council, a vote of thanks to the Chairman was proposed by Mr. Howard, seconded by Mr. Gooch, and passed by the meeting. A. J. Melhuish, *Hon. Sec.*

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

This Society met on the 20th September, when the chair was occupied by Herr Prümm, in the absence of Dr. Vogel, who was in Paris.

The Chairman announced the death of Dr. Schimann (a member of the Association, whose name is favourably known in this country), and, after a few eulogistic remarks upon the deceased, he (the Chairman) placed upon the table a copy of M. Janssen's new work.

Herr Majorkiewitz described an extra roof made of splits of wood for the protection of the roof of the glass-house from sun, snow, hail, &c.

Herr Quidde thought the usual sun blinds answered the purpose very well.

Some further remarks on the same subject followed.

A camera-stand, by Schippang, and one of Cadette's pneumatic shutters were then exhibited. The Chairman was then appointed to arrange for the proper representation of photography at the forthcoming Industrial Exhibition of 1879 at Berlin.

The Chairman mentioned that he had visited the Paris Exhibition along with Dr. Vogel and Herr Schaarwächter; but he had little to add to the reports already made. He (the Chairman) and the latter gentleman had visited the studios of MM. Nadar and Walery. M. Nadar's establishment was very simple and free from ornamentation, while that of M. Walery was quite the reverse. The prices were the same in both places, viz., forty francs per dozen *cartes.*

Herr Schaarwächter showed two of Walery's prints.

The Chairman then gave some particulars as to the extent to which electric lighting is carried in Paris.

Herr Mahlo followed with a description of the Jablochkow candle.

Herr Grimm, of Offenburg, presented to the Society a copy of a pathological work illustrated by enlargements from microscopic objects, such as blood corpuscles, sections of plants, &c.

A pair of colossal panoramas of Sydney and Melbourne, taken and sent by a photographic amateur, Herr Holtermann, were next shown and admired.

Herr van Rouzelen advised the Society to issue a weekly photographic advertising sheet, as the Society's organ appeared at too long intervals to be of much use as an advertising medium.

It was resolved to take the proposal into consideration, and shortly after the meeting was adjourned.

A second meeting of the same Society was held on the 4th October,—Dr. Vogel in the chair.

Herr Schaarwächter showed a number of finely-etched sheets of glass, intended to receive carbon transparencies, which he had brought from Paris; and, further, a number of picture frames in black wood and black and gold with convex glasses.

The Chairman said that in Paris he had seen numbers of very elegant frames for photographs in light bronze, ornamented in the Chinese or Japanese manner, with brownish flowers and leaves.

Herr Hartmann presented a series of 14 × 12 costume portraits of persons who had been present at the Crown Prince's fancy dress ball. He had endeavoured to get backgrounds and accessories in keeping with the various costumes.

Herr Wieske exhibited a design for a show-case. It consisted of an eight-sided pillar, having four wide and four narrow sides—the width respectively of wide and narrow pictures. The bottom of the pillar widens out into an eight-sided table for laying albums or single pictures upon.

Herr. Kannenberg showed some baths rendered water-tight by means of a new cement.

Herr Martini showed a collection of lichtdruck reproductions of celebrated paintings, such as the *Venus*, by Titian, the *Sybil*, by Kaufmann, a *Madonna*, by Holbein, &c.

Dr. Richard, of Männendorf, wrote to say that he would sell and demonstrate his new rapid process for 300 francs to a single individual, and at the rate of seventy-five francs each for parties of ten persons.

The Chairman, by request, related his experience with the new electric light.

Herr Prümm showed Herr Max Fritz's improved sciopticon.

The discussion of a new secret process terminated the proceedings, and the meeting was immediately afterwards adjourned.

Correspondence.

THE RAPID BOISSONNAS' PROCESS.

To the Editors.

Gentlemen,—I think, or I may say I am *sure*, that there must be some mistake in the rapid formulæ given in The British Journal of Photography for November 15, page 549. For instance: a ten-per-cent. solution of acetate of copper is recommended. But, on referring to Fownes's *Chemistry*, I find that acetate of copper is soluble in cold water in the proportion of only one to fourteen.

Is this not sufficient to throw doubt over the accuracy and efficacy of the formulæ given?—I am, yours, &c., A. L. Henderson.

London, November 27, 1878.

PORTRAITS BY ARTIFICIAL LIGHT.

To the Editors.

Gentlemen,—As business in this part of the country is nearly dead, I think it is our duty to do what we can to rouse it up again.

Seeing your notice in this week's Journal of the luxograph patent and the electric lights, I thought perhaps there might be something in them that would have that tendency, and resolved at once to write to you on the matter. I should like very much to ascertain your opinion of photography by artificial light generally, and what you think of the different lights proposed particularly.

Have you any idea how much it would cost to fit up the electric light in a studio, of course inclusive of the engine?

Do you know anything about how the Vanderweyde studio is succeeding? Are they turning out satisfactory negatives, and can they take anything but busts, as that is the only style of portraiture I have seen produced by artificial light?

Could you give me an idea of the relative exposures of the luxograph and electric lights and ordinary daylight?

Do you remember an artificial light which was introduced under the name of the "photogene?" Is this new light not the old one rechristened?

Do you know why the photogene did not succeed, as, according to the inventor's advertisement, it seemed to do all that is claimed for the luxograph?

If I have asked too much in the foregoing queries I beg to apologise to you; but if you could see your way to answering them I can assure you it will give great pleasure to many readers, and to—Yours, &c.,

Glasgow, November 23, 1878. "Glasgowgian."

[The queries of our Glasgow friend are so varied, although on one general topic, that we feel unable to answer them, and therefore publish his letter *in extenso* in order to elicit replies. Our own opinion, stated in general terms, is as follows:—There is no reason, either theoretical or practical, why as good portraits may not be taken by artificial light as by daylight; it is merely a matter of expense. The term "photogene" was applied to a lantern in which was ignited a certain pyrotechnic compound. The luxograph differs from the former instrument, *inter alia*, in having a large translucent sheet interposed between the light and the sitter. No special claim has been made for any description of light. The relative exposures required in the case of the various kinds of light mentioned by our correspondent depends entirely upon the intensity of each; and, as each can be varied at the will of the operator, a definite reply cannot be given to the query having reference to this point.—Eds.]

THE NEW "EMPIRE" PATENT OPAQUE CLOTH FOR BACKGROUNDS.

To the Editors.

Gentlemen,—May we beg the favour of a few lines' space to prevent a mistaken impression as to the above, which might otherwise arise from your report of the Technical Meeting of the South London Photographic Society?

You say that, in reply to a question, it was stated that the "empire" opaque cloth was supplied "in various widths *up to six feet.*" The question put to our representative was whether the material could be had *as wide as six feet*, to which he answered in the affirmative; but this is by no means its extreme limit, eighty-one, ninety, ninety-nine, and one hundred and four-inch widths being also manufactured.—We are, yours, &c., J. Avery and Co.

81, *Great Portland-street, W., November* 21, 1878.

RECENT MEDAL AWARDS.

To the Editors.

Gentlemen,—I only intended to call attention to the fact that the assurance given to the President was incorrect; but I will, at your request, give the grounds for my statement.

1. In more than one of the pictures exhibited by Mr. Payne Jennings, in frame No. 199, the skies are printed in an impossible relation to the horizon of the foreground, revealing at once to competent observers that two negatives have been used.

2. A gentleman in the country wrote to me to obtain him copies of the said prize pictures. They were so obtained and sent, but some short time after were returned to me with the following letter:—

"I have compared the prints sent with those in the Exhibition, and find, to my surprise, that in four out of the eight different skies are printed into the foregrounds in three cases from other sky negatives altogether, and in the fourth the same sky negative was used, but in a different position. I think the Council ought to consider if it is to the credit of the Society that such a thing should be possible, and whether, if it is deemed right to give medals to pictures printed from different negatives, some security should not be obtained from exhibitors *that pictures ordered and bought as copies of the prize medal pictures* should scrupulously and honourably fulfil that condition."

For myself, as this is a new question, and I do not imagine such a thing ever occurred before, I will not at present add any opinion of my own to my correspondent's; but I trust photographers may have something to say on the subject.—I am, yours, &c.,

Rosslyn House, Grove End-road, H. STUART WORTLEY.
London, N. W., November 26, 1878.

To the EDITORS.

GENTLEMEN,—We in Scotland have a proverb relating to the propriety of the "kettle" casting reflections upon the black colour of the bottom of its neighbouring utensil the "pot." Bearing in mind the free criticisms I heard made when visiting a photographic exhibition, not yet a hundred years ago, on certain clouds and seascapes exhibited by Colonel Stuart Wortley, in which the sky and sea seemed to be at such loggerheads as to have allowed the sun to march on through the heavens and its reflection on the water to remain where it apparently was long prior to the photographing of the sun—bearing this in mind, I ask if this well-known artist displays good taste in trying to pick holes in the sea and sky photographs of a *quondam* successful rival?

Who is there at the present day that can plead ignorance of the fact that almost all photographs having skies owe this piece of adornment to separate cloud negatives? I do not see how Mr. Payne Jennings can be held to be responsible either for the assertions of the President of the Photographic Society of Great Britain or for the innocence of such people as imagine that the clouds in photographs are taken at the same time as, and along with, the terrestrial or marine subject. "Those who live in glass houses," &c., &c.—I am, yours, &c.,

Edinburgh, November 25, 1878. AULD REEKIE.

To the EDITORS.

GENTLEMEN,—Replying to Colonel Stuart Wortley's letter concerning my photographs of yachts, &c., in rapid motion, I must first state that I always wished it to be clearly understood that in some cases clouds from separate negatives were introduced; secondly, I am unaware of any rule of the Society forbidding this method of procedure, always considering that it was for the jury to judge whether or not the effect was in harmony.

If the introduction of clouds from separate negatives were forbidden, nearly all the best landscapes at the late Exhibition would have been disqualified. If, however, I am to understand from Colonel Wortley's letter that he wishes to impute an attempt at deception on my part, I must accuse him of a want of gentlemanly feeling in the matter, as he should first of all have made himself clear as to the position I held with regard to the photographs in question.—I am, yours, &c.,

November 27, 1878. PAYNE JENNINGS.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.—The annual meeting of this Society will be held at the House of the Society of Arts, Adelphi, on Thursday evening next, December 5th, when the officers for the ensuing year will be elected, and other business transacted; after which papers will be read—one by Mr. W. T. Wilkinson, of Colombo, Ceylon.

AUSTRALIAN INTERNATIONAL EXHIBITION, 1879.—The regulations for British exhibitors have been approved, and are now obtainable, together with forms of application, from Mr. Edmund Johnson, Honorary Secretary of the London Committee, at the offices of the Exhibition, 3, Castle-street, Holborn. The space at the disposal of the Committee being limited, early application is recommended.

SUICIDE OF A PHOTOGRAPHER.—On Tuesday, the 26th inst., at Dundee, a photographer, named James Porter, residing in Perth, committed suicide by poisoning himself. He had been drinking a good deal, and while in the house of his brother-in-law took two small bottles from his pocket, and drank liquors from them. One contained whiskey, but after he drank the contents of the second he said he had taken poison. Medical aid was summoned, but Porter died in half an hour.

POLICE PHOTOGRAPHY.—The Paris correspondent of the *Baltimore Sun* gives to his readers a graphic account of some of the uses to which photography is put in Paris. Coming, he says, by the back of the Champ de Mars today I was attracted by a group round a photographic policeman, who was making rather awkward efforts to take a picture of an old house wherein an aged woman had suddenly died. I inquired into the subject. It appears that the poor old soul at eighty-seven years of age put out her lamp of life sooner than was expected by her neighbours. A young man had disappeared, and so had a few hundred francs. The police were put on the *qui vive*, and the first thing they did was to photograph the cold old corpse and then the house. Now they are looking for the missing youth to take his picture. It is amusing to see the varied uses that photography performs among the Paris police. First of all, they photograph themselves, from the highest to the lowest. Then they photograph some of their relations, and perhaps friends. They photograph all their first and second class prisoners. In the Exhibition their "rogues' gallery" is quite an array of celebrities, and would form a volume of sketches. Photography is applied in all cases of murder as to persons and places. Before the murdered body is moved it and all the surroundings are carefully photographed. This is done by a special number of the police in uniform, whose entire work is devoted to the subject. Photographs of grand masters of the art of roguery and rascality are exchanged between the police chiefs of all nations. Thus, today, you can see some portraits of the wayward sons and daughters of Baltimore, Washington, Richmond, New Orleans, Charleston, &c., in "places of honour" on the line of the Paris police fine art gallery. They are numbered, and this number is an index, historical and descriptive, book. The days of the dark lantern with the police are changed into hours of the camera, but not *camera obscura*. I am told that the list of crimes detected through the agency of photography is an extremely long one. See to what detective purposes has the original idea of the long-lost Daguerre come at last! Instances of forgery are numerous as being detected by photography. The Bank of France has a special photographic and scrutiny department for the detection of forged notes, bonds, &c. But its invisible portrait gallery for taking the likeness of a person without that person knowing it is unique and full of amusing anecdotes. On one occasion a distinguished-looking person came to the bank desk and presented a little package of bonds of a certain English loan. The bank clerk did not readily relish the looks of the bonds, though those of the person were quite the thing. Stamping a little hand bell—a signal to the photographer, who has his gallery in clear range of the applicant's desk, yet so constructed that it is not easily seen—the clerk engaged the stranger in conversation about the bonds, and in such a way that the photographer should have a good view of his face. This time a country schoolmaster, as honest as the sun of day, thrust his face in by the desk, and he was photographed in company with one of the greatest forgers of France. The sensitiveness of photography is illustrated at this bank when ink marks invisible to the eye on the original document become quite plain on the photograph You cannot alter, by writing, any paper but photography will detect the "meddlesome pen" sooner or later. An erasure on the paper, if done ever so smoothly, is discovered by photography. The character and style of chirography is also well tested by photography. Photograph some of the letters in a sentence, enlarge the photograph, and you have "a big guide" as to style easily followed and made a criterion. The Post-office Department here has its Photographic Director, and many a letter is opened, photographed, compared, and stored away for future evidence. Surrounded by such agencies, how well "honesty being the best policy" is proved to us. In the Exhibition you can see some instances of visitors there being unconsciously photographed. One old lady, however, discovered the police at their proceeding. Up she bounded. Over went, not only her chair, but the three near by ones; down she dashed her umbrella, down she pulled her veil, and she pulled her skirt over her head and turned her back in a triumphant air up to the rash policeman. "What!" she exclaimed; "taking my portrait for a prison! O Jule! Jule! where art thou?" I am sorry to say her spouse, Jule, was in the arms of Morpheus, and cared not for photography. She went and demanded reparation, and was mollified by getting a photograph of her enraged self.

EXCHANGE COLUMN.

Lantern slides, two sets, consisting of ten superior hand-painted, 3½-inch, in exchange for a good portable half-plate camera for outdoor work.—Address, BRADSHAW BROS., 12, Devonshire-street, Stockport-road, Manchester.

Wanted, a 10 × 8 glass bath, large printing-frame, dishes, condenser, argentometer, or any kind of photographic apparatus, in exchange for a magic lantern, a quantity of new photographic lantern slides, and four 4½-inch double convex lenses.—Address, J., 39, Wesley-street, Liverpool.

PHOTOGRAPHS REGISTERED—

John Owen, Newtown.—*View of Newtown.*

Leonard Varney, Buckingham.—*Interior of Buckingham Church.*

A. G. Massey, Armagh.—*Three portraits of W. G. Lyttle, as "Robin."*

R. Jackson, Leeds.—*Monument of the late Dr. Hook, in St. Peter's Church.*

J. B. Platt, Liverpool.—*Four portraits of the Rev. W. H. Dallinger, F.R.M.S.*

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

Tyro.—See page 43 of the present volume.

Pantos.—Not being aware of the composition of Sœhnée varnish, we are unable to indicate with certainty how it is made.

A. Johnson.—The omission was rectified in this Journal, and the complete formula will appear in our forthcoming Almanac.

H. Vermeesch-Adet (Dixmude, Belgium).—The annual subscription to the Journal, including postage to Belgium, is 17s. 4d., payable in advance.

G. Boyd.—Try the following toning bath:—Borax, three scruples; chloride of gold, one grain; water, *quant. suff.* This yields rich, soft, brown tones.

W. M. Phillips wishes to know the best method of making the double chloride of gold and potassium, as recommended by M. Davanne, for a toning bath.

Medicus.—If you attend the next meeting of the Photographic Society of Great Britain you will see conducted the whole of the operations of platinotype printing.

Z. Y. X. (Greenwich).—You are quite correct as to the facts, but wrong concerning the dates, for it was in 1872 that Mr. Crawshay offered prizes for certain large portraits.

H. Manfield.—Our correspondent has favoured us with a very fine transparency, prepared according to the directions for practising the Beechey process given in another page.

An Old Reader.—The cost of the specification is sixpence. It can be obtained at the sale department of the Patent Office. This department is now in Cursitor-street.

C. D. V.—Yes, we are quite conversant with the nature and details of the invention; and in the course of two or three weeks we expect to place our readers in the same position.

G. H. E.—There are no known means by which a wet collodion transparency can be toned so as to resemble the sepia colour of those Woodbury transparencies to which you make allusion.

W. A. J.—Add a few drops of chloride of gold solution alone, and then try again. It is our opinion that the inert condition of the toning bath is due to its having been overworked.

J. Richardson.—In preparing plates by the collodio-albumen process it is not absolutely necessary that the collodion be iodised or excited. The function of the collodion substratum is to a large extent mechanical.

Anxious.—The better way to proceed is to insert an advertisement in the newspapers in the locality in which the individual is supposed to be residing, and take into your account the fact that he may possibly have changed his name.

Henry.—It was a mistake to set about dissolving the gelatine in the manner you did. It ought to have been allowed to steep in cold water for two or three hours, and heat applied after that. By doing so success will certainly reward your attempt.

A. H. A.—None of the constituents of a portrait combination of lenses will answer for a condenser to a magic lantern. As an *objective*, however, a quarter-plate portrait lens answers well and defines a three-inch picture beautifully on the screen.

S. P. S.—Glaze the lower portions of the studio windows with ground glass, and also the whole of the sash marked No. 3 on the plan. By doing so there will be a great gain in the illumination of the sitter; and by a shorter exposure much better pictures will be obtained.

J. B. Neville.—Add to the old fixing bath a solution of sulphide of potassium. The sulphide of silver thus obtained may be converted into metallic silver by first drying and pulverising it, and, after mixing it with twice its weight of nitre, subjecting it to heat in a clay crucible.

A. P.—You are quite right in thinking that the "diary" and record of your photographic experience will be greatly appreciated by our readers. We are in hopes that your name will appear in our forthcoming Almanac as the author of one of the articles to be found therein.

T. M. F.—The condition under which a patent is granted is this—that if the the article patented be not new the patent falls to the ground. You may continue to employ the apparatus described as having been used by you without fear of being interfered with by any person.

G. S. Barclay.—When collodion bursts out and breaks off in layers from the glass soon after it has been immersed in the silver bath it is an indication that the bath is too weak or the collodion over-iodised. If, upon testing the bath, it is found to be of a proper degree of strength the remedy will consist in diluting the collodion with a plain or uniodised sample. On the other hand, should the silver bath be too weak silver must be added until it is brought up to about thirty-five grains to the ounce.

W. W.—The instrument is merely a piece of glass tube bent like the letter U, having a loose plug of cotton wool pushed far down one of its limbs. We do not know where it can be purchased, but you can very easily make one yourself by softening a piece of wide tube in the flame of a spirit lamp and then bending it to the shape required. It will also be advantageous to bend one of the limbs towards its upper end into something akin to the shape of the spout of a teapot, so as to afford facility for pouring out the fluid.

J. R. V.—Do not use any more of that sample of varnish, but pour it out. Try one composed of sandarac instead of dammar. The method you propose for ascertaining the most suitable proportions seems excellent. We here append a retouching varnish which was strongly recommended by a writer in *Mosaics* for 1877:—

Alcohol	32 ounces.
Sandarac	4 ,,
Chloroform	1 ounce.
Oil of lavender	½ ,,

The above varnish may be made more tacky by the addition of more oil of lavender.

H. J. Stuart.—Having burnt all the old filters, clippings, and trimmings of prints (before fixing), place them in a crucible with twice their weight of carbonate of soda and expose to a white heat. The silver will be found at the bottom of the crucible fused into a button. It is quite pure.

Erratum.—In our report of the Technical Meeting of the South London Photographic Society, in last week's issue, a printer's error occurs, in virtue of which the exhibition of a recently-devised printing-frame was credited to Mr. J. L. Lane instead of to Mr. J. *T.* Lane. Mistakes by the substitution or transposition of a letter will sometimes occur. In this case it has resulted in the name of a well-known camera-maker having been substituted for that of a practical photographer, Mr. John Talbot Lane. The name was "right to a T," but that letter makes all the difference.

Syntax.—It is quite impossible for us to say which of the two lenses is the quicker-acting, unless we be made acquainted with the focus as well as the diameter of each. When a lens does not work to focus two courses are open—either make such arrangements in the construction of the camera and dark slide as will ensure the lens working sharp, which is effected by having the ground glass adjusted to a different plane from that of the sensitive plate; or have the lens re-ground. The latter will prove the more satisfactory manner in which to get rid of what is undoubtedly a mild nuisance.

Rev. George Waterston.—An amusing application of photography consists in printing them on albumenised paper and then fixing them in a moderately-strong and freshly-made solution of hyposulphite of soda, special care being taken that they are not toned. After fixing wash *thoroughly*, and place the prints in a saturated solution of bichloride of mercury, which will cause the image eventually to disappear. Wash the invisible prints once more and dry them. In this state they will keep well for months. Next prepare a number of sheets of white blotting-paper by immersing them for one or two minutes in a saturated solution of hyposulphite of soda, after which they are dried. To develope the invisible picture it is only necessary to wet the blotting-paper and apply to it the invisible picture, which instantly becomes developed in a bold, black colour, much stronger than it was previously. You can easily devise other amusing applications of this principle.

Received.—F. York.—In our next.

Experience with Beechey Emulsion Plates.—Just when ready to go to press we received a note from Mr. W. Washam, in which he says:—"I find, in what I had written last week on this subject, one or two errors which rather obscure the sense, and of which I therefore send a correction. Line 17, 'with my moist plates' should be 'with my *next plate.*' From line 33 onwards, 'some from emulsion which I had made towards the end of summer, and I worked with others which had been prepared for me,' should be—'*some from emulsion which I had made. Towards the end of summer I worked with others that had been prepared for me.*'"

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician,

For the two Weeks ending November 27, 1878.

These Observations are Taken at 8.30 a.m.

No. 970. Vol. XXV.—DECEMBER 6, 1878.

ON NEGATIVE VARNISHES AND THE DESTRUCTION OF THE IMAGE.

At the last meeting of the Amateur Photographic Association the question was raised of the destruction of the negative image by the employment of inferior varnish as a protective coating, and a suggestion was put forward by Mr. Glaisher, and obtained the sanction of the members present, to the effect that the injury was rather due to faults in the collodion film than to imperfections in the varnish. This suggestion opens up a very wide question as to the real cause of a by no means uncommon and extremely annoying form of defect in negatives, and one which has hitherto been regarded as a purely physical fault; but if we are to accept the new view it is possible that we may have to consider it, to some extent at least, as chemical.

The deterioration or destruction of a negative after constant use or long keeping assumes different forms, which have been variously attributed to different inducing causes; but, in the majority of cases, damp has been looked upon as the immediately active influence, working, no doubt, in combination with certain physical defects in the film itself. While in many instances the result may indubitably be traced to the effects of damp, it is equally certain that in other cases where the result is almost, if not quite, identical damp can have had no possible part in the matter, and it is only reasonable that we should look to other circumstances to supply the explanation of the change which occurs.

If we divide the possible causes of destruction into two chief classes—physical and chemical—we may place under the first head those forms of the defect which arise apparently from unequal expansion and contraction of the film containing the picture, and under the second those in which the film itself undergoes change or decomposition. The results produced by the first class of causes generally take the form of vermicular markings or cracks over the whole surface of the plate, and are frequently removable by proper means if taken in time. In the second class the film itself appears to undergo a change, in which it loses its transparency and becomes granular, crystalline, and opaque—sometimes uniformly over its whole surface, sometimes only in patches. When this form of the defect is developed it may not unfrequently be got rid of by the removal of the varnish by means of warm alcohol and re-varnishing; but it occasionally happens that the application of such a mode of treatment causes the destruction or solution of the whole picture in such a manner as to lead to the supposition that the collodion film and the varnish had become so thoroughly incorporated in some way or other that the removal of one is impossible without the other.

We recollect a case in point. Some years ago we had occasion to remove the varnish from several negatives owing to the surfaces having become contaminated by continued contact with silvered paper. The whole of the negatives had been coated with the same varnish, and, with the exception of two, were from dry plates. The two exceptions were portrait negatives taken in the studio of a professional photographer but varnished by ourselves, and these two differed entirely in the character of the deterioration they had undergone as compared with the dry plates. The latter were merely discoloured by bronzed surface stains, which had no appearance of penetrating into the film, and which in the unstained portions retained its original transparency; the others, however, exhibited a very noticeable loss of transparency, and the stains were of a matt, sunk-in appearance, in many places spreading in a peculiar arborescent or crystalline form over a considerable area, and showing as brilliant metallic markings from the reverse side of the negative. In every case for the removal of the varnish we employed a warm dilute solution of caustic potash in weak methylated alcohol, and the peculiarity is that, whereas the dry plates withstood the ordeal perfectly and came out as clean and perfect as when newly developed, the two portraits immediately dissolved in much the same manner as we should have expected had ether been the solvent. We were much astonished at the result, and, failing to reproduce it with any other films in our possession, could only attribute it to some decomposition of the collodion film. We regarded it as a case of decomposition rather than of original peculiarity of the pyroxyline, because, had the film possessed the same characteristics when the varnish was first applied, it would seem probable that it would have undergone solution then.

At least the result proved the existence of a very wide difference in the nature of the two classes of films, and the visible change which had taken place further showed a far greater deterioration in the one case than in the other, proving, we think, that the character of the collodion film may have a very important bearing upon the stability of the negative, altogether independently of the nature of the varnish. But whatever the change may be, how is it produced? Pyroxyline, we know, undergoes a gradual decomposition by age—a change which ensues more rapidly, or at least is more evident, if the substance be preserved in a stoppered bottle. This is due no doubt to the fact that the nitrous vapours evolved during decomposition are confined within a small compass, acting and reacting upon the already-decomposing mass in such a manner as to produce more injurious results. An unvarnished collodion film spread upon glass would, however, seem to be free from this excessive tendency to decompose, and when coated with an impervious varnish, and the individual molecules isolated, as it were, from one another, it would seem almost impossible that any decomposition at all could take place. It is quite possible that, under exceptional circumstances, a rotten collodion film and a bad varnish may combine to produce destruction of the negative; but on which are we to lay the blame?—to the collodion or to the varnish? Perhaps neither is altogether in fault, and yet each has its share; in other words, if the varnish be beyond suspicion little danger need be feared from the collodion film.

But at the present day we have, unfortunately, to look with a good deal of doubt upon the varnish; the rage for retouching, and the consequent introduction of so-called "retouching varnishes," has, we fear, brought in a good many chances of danger. We do not speak only of those preparations whose sole purpose is to afford a suitable surface upon which to work with the pencil or other medium; but we look rather at those which are considered capable of serving the double purpose of forming a protective coating to the negative and, where necessary, by means of a little friction, providing a "biting" surface upon which to do the necessary work. It is to the alteration in the constitution of the varnish to meet these purposes that we look for the source of many of the evils of which we hear complaints; and we think photographers who value the stability of their negatives would do well to pay some little attention to the composition of the varnishes they employ.

Shellac, there is no doubt, forms the best protective coating we have, being at once both hard and tough, with no tendency to become soft and stick to the print under a hot sun, and little chance of scratching under ordinary treatment. Its only fault is its dark colour, if, indeed, it can be called a fault, for we know several photographers who employ a pure lac varnish without experiencing any inconvenience from that source. Bleached lac possesses many of the good qualities of the undoctored article without its dark colour; but the treatment it has to undergo to deprive it of its colour does much to deteriorate it for the purpose in question. Sandarac forms a very light-coloured varnish of considerable hardness, and with no tendency to adhere to the print; but it is brittle and easily scratched, and altogether devoid of toughness. These two resins form the basis of most of the varnishes in use at the present time, various other substances being added in small proportions to aid in obtaining special qualities.

Thus, benzoin forms a smooth and easy-flowing varnish, with little strength. Mastic, used in small quantity, gives a brilliant surface, while Venice turpentine, Canada balsam, and other similar substances are sometimes employed to give toughness to the film, but in conferring that property they also increase the chance of producing a "sticky" surface.

If we take a film varnished with a pure lac varnish, or one in which the lac preponderates, and submit it to friction with the bare finger, or even with the aid of an abrasion powder, we find that the polished surface is not destroyed; the varnished film may be worn away to the bare glass without producing a sufficient "tooth" to take the pencil. If, however, we perform the same experiment upon a varnish containing a considerable proportion of sandarac, a very small amount of friction is necessary to produce a dead biting surface upon which the pencil may be worked with as much facility as upon ground glass. The two resins are, in fact, totally different in their characteristics, the one being tough and elastic, the other brittle and powdery; and it is not difficult to comprehend in what manner these qualities may work in the formation of a reliable and trustworthy varnish.

In ordinary varnishes the powdery character of the sandarac is overcome by the addition of turpentine, Canada balsam, or castor oil, and these substances, while adding to the strength of the protective coating, do not to any appreciable degree, interfere with its uses as a retouching surface; moreover, if used in moderation, we do not suppose they produce any ill effect in the varnish or in *the film* when it is newly formed, but we have a very strong opinion that under the action of time their influence is anything but favourable. It is, in fact, to the preponderance of these objectionable ingredients that we attribute much of the fault found with varnishes, and we base our remarks upon experience not wholly confined to their photographic uses.

Of course retouching must be done, and it requires a suitable surface upon which to work. So far as it concerns a negative from which only a few prints are required, it is, perhaps, not material what sort of varnish may be employed to produce the necessary surface; but those who desire their negatives to stand the test of time may, we think with advantage, devote a little more attention to the nature of their protective covering than seems to be done at present. A large section of our readers who are principally interested in landscape work have little need of retouching in its strictest sense, and our advice to them is to shun any varnish which upon moderate friction gives a rough and "biting" surface. Such a quality is not needful, and it brings with it, where it exists, many dangers without any counterbalancing advantage.

A PORTABLE CAMERA-STAND.

The stand to which we here briefly direct the attention of our readers is one that, were it not for a slight misconception on the part of a subordinate, would have been exhibited at the recent Technical Meeting of the South London Photographic Society.

When folded up for travelling it forms a square compound rod, composed of the three "legs" placed in juxtaposition. Each of these legs is, in turn, composed of three elementary square rods hinged together in a peculiar manner to be presently described, a noticeable peculiarity being that the centre element is about four inches longer than those at either side. Having premised so much we must have recourse to the diagrammatic mode of description and utilise this form of graphic delineation.

The diagram represents the camera-stand when folded together. The point at which they are united is at a, where are seen three pins. These pass through a flat piece of brass, forming a hinge upon which the outer portions of the legs can partially rotate. It will be seen that this partial rotation takes place at the ends of the two external rods, but at a little distance from that of the centre one. It will also be noticed that the outer rods are straight, or have parallel sides until within a short distance of the jointed end, when the outside assumes a bevelled form. In this lies the leading feature of this stand.

Let us now suppose that the two outside limbs are being rotated upon their common hinge as far as they can go. What, then, takes place? The bevelled portions lie close up against the side of the centre rod, and cause the two sides respectively to stand at an angle as shown by the dotted lines of the diagram, which represent the form assumed by the legs when opened. In this position we have not shown the legs carried to their full extension, as it is unnecessary.

It now only remains for us to give the dimensions of the stand of which we have above given a description, and with which must be associated the name of Mr. William Morley, of Islington, as its maker, this gentleman having for many years been an enthusiastic amateur landscapist, and therefore fully alive to the requirements of the photographic tourist. The length of the centre limb is thirty-three and a-half inches, that of each of the two outer limbs twenty-nine and a-half inches, the whole, when opened out, measuring fifty-eight inches. It is unnecessary to observe that these dimensions can be indefinitely increased, but the figures here given are those preferred by Mr. Morley for a light, portable stand. With regard to the triangle nothing need here be said, as the means by which the legs are attached will be obvious. No struts or extension bars are necessary to keep the legs apart, for the upper projecting end of the central rod suffices to do this effectively.

From the foregoing description it will be seen that this camera-stand will fulfil its intended functions in a most satisfactory manner.

UNIFORM PYROXYLINE.

One of the most important additions that has of late been made to our knowledge of the means of producing pure and uniform chemicals was the communication from Mr. L. Warnerke, upon a new form of cotton wool, made at the Technical Meeting of the South London Photographic Society the other evening. From a theoretical or practical standpoint it is equally valuable—the latter to a degree only known to those who have been in the habit of making many experiments in pyroxyline manufacture.

There is, perhaps, no substance in the whole range of photographic chemicals more liable to produce disappointment with its working through the utter uncertainty and want of uniformity in connection with its properties. We can go to the dealer in chemicals and buy the rarest salts and chemicals, of the most complicated formulæ, and be able to predicate to a nicety the exact results which would be obtained by their use; but if we go into half-a-dozen of such stores, and buy as many samples of pyroxyline, we should find them, in all probability, to have as many different varieties of action when converted into collodion. If we have our own pet formula, and send it to be made up at half-a-dozen different manufacturing chemists, the probabilities are that each will deliver a product quite different from the rest; while to the occasional amateur the making of a batch of pyroxyline is usually considered a success if it simply possess the power to dissolve with ease in the mixed solvents.

But in the advanced state at which the technical aspect of photography has now arrived — to the emulsion processes we more especially refer—the uniformity and ease of production, with the regularity of a suitable pyroxyline, is a matter of paramount importance. This material plays, as has been repeatedly shown in these columns, a most important *rôle* in the quality of the work; and we cannot but record our impression that Mr. Warnerke has again put photographers under an obligation by bringing before them this new preparation of cotton-wool.

It needs no argument to prove that the true causes of all the variation that occur in the working of the various processes cannot be properly investigated if we work by rule-of-thumb, or if we make use of chemicals of whose properties and conditions we are ignorant. Some of the difficulties in this direction were pointed out by us last week. Of course, if we find that with certain materials treated in a particular manner we obtain success, it is an easy and, perhaps, a wise matter to lay in a large supply of these materials to ensure our being able to go on with similar success; but such a course is most unscientific, and far from being calculated to foster the growth of science.

Now, how stands the matter with respect to pyroxyline? Thanks to the able investigations of men of the calibre of Professor Abel and others we have a very good knowledge of the theoretical aspects of the case; and a host of names rise to mind when we think over those who have examined into the photographic properties of the compound in question. But no one yet has isolated the different impurities, so to speak, which are bound up with the various forms of cellulose as obtainable in commerce, and to which, in most part, we are bound to believe, are due the strong individual characteristics of pyroxyline made from various sources—paper, cotton, linen rags, &c., &c.

Our ideal form of this material is one made from pure cellulose, with a definite formula as to temperature, &c., so that, *if wanted*, we can make special preparations of substances analogous to the results of the acid treatment of the surrounding foreign matter, and be able to add them in the proportions required, though we believe it will be found that all necessary properties can be obtained by variations in the proportions of acids and of water, combined with suitable differences of temperature. If we consult works on chemistry we shall, however, find that to procure pure cellulose is rather a difficult matter, consisting, as it does, in treating cotton, paper, linen, or such like materials, with hot solution of caustic alkali, followed by washing and treatment with hydrochloric acid, then ammonia, more washing, and perhaps the whole treatment repeated once or twice.

We no not mean to infer that Mr. Warnerke's cotton is absolutely and completely pure, but we think it is in such a form that it can be most easily rendered pure. It is, however, in such a state that one most important cause of the varying results obtained in pyroxyline-making is, as his expositor pointed out, got rid of, viz., the difficulty of permeability of commercial cotton wool to liquids. When it is considered that a difference of two degrees in the temperature of the solvent is capable of making such an alteration in the quality of the result as to cause an increase or decrease of one or two per cent. in the weight of the product, the necessity for a material easily penetrated by the mixed acids need scarcely be pointed out, seeing that the immediate action of the acid upon the fibre is to elevate the temperature, and when its action is confined there must be irregularities in the qualities of various portions of the same batch.

We found with others also that the plan—first, we believe, invented and published by Mr. Hardwich—of boiling the cotton in a solution of caustic potash before placing it in the acids added most materially to comfort in working and excellence of results, and we anticipate that to a still greater degree will the new cotton facilitate the manufacture of pyroxyline of uniform quality, owing to the mechanical qualities alone of the material, leaving aside for the nonce the chemical substances with which it may or may not be encased or contaminated.

RECENT PATENTS.

No. XXIII.—WHITE'S HEAD-REST.

It is almost a source of wonler to find a notice of an invention in head-rests that does not emanate from Leeds—a town in which so many improvements in this useful piece of apparatus have had their origin. The present invention, which received provisional protection only, is by Mr. James Paterson White, of Glasgow, and is described as follows:—

This invention relates to improved apparatus to be used by photographers for affording rest or support, and to facilitate the maintaining of steadiness by persons being photographed.

The improved apparatus comprises a horizontal bar or tube, which is to be fixed or held in any convenient way near the floor. To this horizontal bar there is adapted a long arm consisting of two or more pieces fitted to each other telescopically, or in an equivalent manner, so that the arm may be set to different lengths, pinching screws or equivalent appliances being used for fixing or holding the parts when set.

The arm is fitted to the horizontal bar so as to be capable of sliding along it and also of turning round it, and pinching screws or equivalent appliances are provided for fixing it in any position. The arm itself may be made so as by being screwed inwards or outwards in its foot piece which connects it to the horizontal bar to fix or loosen it thereon.

Any position within the range for which the apparatus is constructed can be given to the outer end of the arm (which is formed with or has attached to it the usual head-rest details) by adjusting it in one or more of three different ways, namely, sliding along the bar, turning or moving angularly on the bar, and lengthening or shortening of the arm.

Where an additional support is wished this may consist of a rod capable of being turned on a pin fixed in a piece which is fitted to turn and slide on the arm, pinching screws or other fixing appliances being provided. The overhanging weight of the arm may be counterbalanced by adding weight to the foot piece on the opposite side of the bar. Two or more arms may be mounted on the same bar to be used in photographing groups or otherwise.

If suitable means be adopted for preventing the horizontal bar upon which the head-fork is supported from being seen, which will prove very difficult, the system will be found useful.

No. XXIV.—SCHERING'S PYROXYLINE.

While entertaining the opinion that Herr Schering, on whose behalf the patent has been obtained by Mr. F. A. Zimmerman, somewhat overrates the difficulty of preparing pure nitro-cellulose for collodion, we are still pleased to find such an account of his method of treatment as that described in the following specification:—

The preparation of a pure nitro-cellulose for photographic and medicinal collodion has hitherto been accompanied with great difficulty, although this substance plays a very important part not only in photography but in pharmacy also.

The collodion wool, also called pyroxyline, which has been manufactured up to the present time has always presented many inconveniences; it retains in it an acid compound that cannot be removed by simple washing. But this acid compound is extraordinarily troublesome and detrimental in the application of collodion wool.

When the pyroxyline containing it is employed it yields a red and useless collodion, and the collodion prepared from it for pharmaceutical purposes is irritant to wounds. This acid compound is separated by a new and peculiar method, according to which the pyroxyline is treated for a considerable time at a warm temperature with a dilute solution of potassium permanganate, then with a very dilute solution of sulphurous acid, and finally washed well with distilled water. The celloidin prepared as above described may be in liquid form or in a condensed form, such as gelatine, in which state it is rendered inexplosive, more compact for transport, and more convenient for the consumer, who can regulate the proportions of collodion desired. This preparation is called "celloidin," it being the purest nitro-cellulose. It gives with pure ether and alcohol a collodion that does not become acid, and with sensitive salts of iodine, such as ammonium iodide and sodium iodide, is coloured only faintly yellowish and not brown.

Medicinal Celloidin and Collodion.—This is prepared either direct from the celloidin by dissolving it in a certain quantity of alcohol and ether (according as a one, two, three, or four per cent. collodion is desired) or from the celloidin gelatine by dissolving it in certain proportions of ether and alcohol.

Celloidin Collodion for Photography.—This is prepared with celloidin, according to the degree of concentration required, by the addition of pure alcohol and pure ether, similarly to the preparation of crude photographic collodion. Also as a finished iodised negative collodion, which is remarkable in that it does not undergo change in the iodised condition, and is therefore suitable for exportation.

Other ordinary collodion in the crude condition must be kept apart from the iodising material, and the latter must be transported separately.

Having now described the nature of the said invention and in what manner the same is to be performed, I declare that I claim the treatment of pyroxyline in the manner described, whereby the substance herein called "celloidin" is prepared.

As pyroxyline of the kind described is, we believe, now to be obtained in London, those interested in the subject will be afforded an opportunity of ascertaining the comparative merits of the old and new methods of preparing pyroxyline.

No. XXV.—RENDERING PHOTOGRAPHS TRANSPARENT.

This invention relates to a new method of, and apparatus for, waxing negatives or positive photographs, or other paper articles, which are required to be rendered transparent.

I provide a flat shallow box or closed vessel, of copper or other suitable metal, of a size corresponding with the work to be done, the box or vessel being supplied with a feed opening for supplying the same with water, and an escape valve or opening for the steam. Beneath the box or vessel I arrange a series of gas burners. When the box or vessel is filled with water, and the gas is lighted, the flat top of the box becomes heated to a regular heat all over, and I then take the photograph or other article and lay it upon a sheet of blotting-paper placed on the top of the box, and as soon as it becomes thoroughly heated I take a piece of white wax in the hand and thoroughly wax it all over. I then take a linen or other suitable cloth, and wipe off the superfluous wax from the surface. They are then placed in a press till cold or set, and the operation is complete. This operation will be found more rapid and effective than the usual process, and can be carried on without intermission as long as the gas is kept lighted and the box or vessel supplied with water.

Many devotees of the now extinct waxed-paper process will recognise in the foregoing a method that has often been employed by some of them for waxing their sheets of paper.

We can only add to what has been already said upon the subject of defects in "Beechey" films that we are even yet unable to see any valid reason for supposing that the cause is other than physical; that, in fact, notwithstanding the fresh evidence brought forward by Mr. W. Washam in his article in the present number, we fail in discovering any just reason for attributing the mottling and unevenness spoken of to a chemical source, nor do we recognise in the symptoms described any peculiar feature not perfectly in accordance with the view we have enunciated. Mr. Washam appears to be unable to get over the fact of the presence of mottling upon a dried and *unexposed* film, unless we suppose it to be formed by the imperfect removal of the decomposition salts from the film in washing; but this plain fact is itself, we think, the strongest evidence against Mr. Washam's theory. He speaks of some plates as being entirely free from the defect before exposure; and such films do not, he says, acquire the mottled appearance after exposure and development, showing conclusively that the effect is in the film itself. Now we will ask Mr. Washam to make a very careful survey of the facts, and to say if he can authenticate a single instance of mottling which was not visible immediately after coating the plate and before its immersion in water; in other words, can he state that he has ever had a film which, originally perfect and homogeneous, has developed the defect in question during the operation of washing? It will be quite time to enter fully into the possibility of the removal of the unevenness by the fixing solution and other points when we have established something more than a merely physical cause for the evil; meanwhile we can only look upon the special immunity enjoyed by the plates spoken of in his second paragraph at page 580, and also the entire absence (in Mr. Washam's experience, at least) of the fault in washed emulsions, as accidental circumstances in which there is no connection between cause and effect in the manner he would have us suppose. In the matter of washed emulsions we imagine there are few experimentalists who have not had abundant evidence of the mottling propensities of *washed* emulsion under favourable circumstances. A pyroxyline made at too low a temperature, or solvents containing too much water, will easily produce any amount of mottling without the faintest suspicion remaining of the presence of "by-products" in the film. Many causes operating upon the physical nature of the film may be named, but we do not think the facts justify us in laying the blame to any chemical influence.

PRACTICAL INSTRUCTIONS IN MODERN PHOTO-MECHANICAL PRINTING METHODS.

Part I.—PHOTOLITHOGRAPHY.

VII. Preparation of Transfers from Negatives after Nature.—If a piece of the ordinary gelatinised photolithographic transfer paper be exposed under an ordinary negative taken from nature, and the transfer is inked in the usual way, certain points of interest may be noticed on developing it with slightly warm water. The high lights of the picture will naturally yield up their layer of printing ink almost immediately, while the deeper shades of the subject remain jet black from the presence of an unbroken film of ink. As the development proceeds and successive portions of the gelatine film become softened by the action of the warm water, shades of increasing darkness lose their inky coating; and by increasing the temperature of the water it will be found that the ink may be gradually removed from every part of the transfer. During the whole of this operation a slight indication of half-tone may be noticed to exist in the form of a grain or stipple between the extreme black of the inky film and the clear white of the paper; but the range of gradation embraced by this half-tone is very restricted, as that which is visible at one time does not usually extend over more than one-sixth of the range of gradation existing in a good negative. Notwithstanding this, every degree of light and shade existing in the negative will be successively represented on the photolithographic transfer; but the deficiency of the process is due to the fact that only a fraction of the negative can be represented at the same time. If, for example, the lighter shades of the subject are correctly represented, all the rest is uniformly black; while if the darker shades are properly depicted the remaining portion of the picture is uniformly white.

By the use of the pasted paper recommended in the third chapter of this series a much more extended range of half-tones may be secured; and the extent to which the process is capable of reproducing half-tone depends, among other circumstances, on the nature of the paper employed.* A rough, unsized paper gives a wide range of tone, together with somewhat unsharp outlines, while a smooth paper will give less range of tone.

When it is intended to work from an ordinary graduated negative, the negative should be moderately dense and vigorous, and the process described in the third chapter, The British Journal of Photography, vol. xxv., page 497, is slightly modified, the operation being conducted as follows:—

The flour paste employed for coating the paper should contain eight per cent. of flour, or twice as much as when the process is made use of for line subjects. Instead of Rive's paper ordinary white blotting-paper is employed. This blotting-paper should not be wetted and mounted on glass before the paste is applied, but should be merely laid on a flat surface and coated with the paste by means of a soft brush. This having been done the layer of paste is smoothed by means of a long-haired badger brush, after which the paper is hung up to dry. When dry it is rendered sensitive by being soaked

* Photographic printing processes differ much with regard to the extent to which they are capable of reproducing half-tone, some being able to do justice to a negative having extremes of light and shade, together with all intermediate degrees; while other printing methods are only able to include a more limited range of tone, and, consequently, require a thinner negative. An unfixed silver print, made on moderately-sensitive paper, may perfectly represent all the gradations of a very dense or vigorous negative, but some of the gradations of tone are lost in the operations of fixing and toning. In the case of carbon or antotype printing the same wide range of tone is attainable when the process is properly conducted, although a thin negative is generally preferred for this kind of work. Collotype and most processes for photo-engraving in half-tone have a rather more restricted scale, and fail to do complete justice to a very vigorous negative. It is desirable that some standard scale of degrees of opacity should be recognised, to which the extreme degrees of light and shade in a negative could be referred. If this were the case certain difficulties connected with the varying sensitiveness of carbon tissue, &c., might be removed.

for a few minutes in a three and a-half per cent. solution of potassium bichromate, to which a small portion of ammonia has been added—say about one drachm to each pint. Care should be taken not to damage the pasted surface during the operation of sensitising; and the drying of the sensitive paper should be rather rapid, as slow drying favours an incipient insolubility, which is very prejudicial. The paper ought to be exposed immediately it is dry, and the period of exposure is about equal to that required for making a carbon print from a similar negative, or about half that which would be required in the case of a silver print. The exposure may be regulated by the actinometer, or it may be judged of by a periodical inspection of the transfer. In this latter case it should be continued until the details in the lights of the subject are just visible, and it is scarcely necessary to say that these inspections should be made by yellow light. The exposed paper is next soaked in several changes of cold water in order to remove all traces of soluble matter, and it is then dried, after which it is placed between folds of paper and ironed as directed in the previous case. The directions already given for the subsequent treatment and inking of the pasted paper transfer are applicable in the present instance; but it is generally advisable to employ a rather stiffer ink than in the case of line work, and it is of greater importance that the inking brush should be in first-rate order. The operation of inking affords scope for the exercise of some judgment, as the results may often be considerably improved by a little extra ink being applied to certain parts of the picture, or by reducing the amount adherent to other parts; in fact, this operation of inking with the brush gives one much the same control over the result as is attained by the operation of shading the back of a negative with tissue-paper and blacklead. Any touches of extreme black required by the deepest shadows may be conveniently applied by means of a small hog's-hair brush, while any heightening of the extreme lights which may be advisable is best performed by means of a very small hog's-hair brush rapidly applied; but it must be understood that in each of these cases the motion of the brush is an up-and-down movement, and not of a dragging or rubbing nature.

The transfer being now allowed to dry, any required retouching may be performed by means of the ordinary lithographic chalk or crayon. This having been done, the transfer is laid between sheets of damp blotting-paper until it is sufficiently moistened, after which it should be immediately transferred to the stone. Great care should be exercised in selecting a good stone for our present purpose. It should be rather soft and porous, free from any irregularities of texture, and it ought not to be too highly polished. Generally speaking the surface given by graining sand which has been passed through a sieve having one hundred or one hundred and twenty holes to a lineal inch will answer satisfactorily without any further smoothing or polishing. The picture, having been transferred to the stone, should next be gummed with *freshly-made* mucilage, and when this is washed off the first inking-in must be performed with a roller in first-rate condition, and charged with a very limited supply of stiff ink. The greatest care must be taken that the stone is quite cold when the inking-in is performed, as otherwise the ink will be softened by the heat, and the result will be the same as if a thin ink had been employed, namely, a clogging-up or destruction of the finely-stippled parts of the subject. During the whole of the inking-in the stone must be carefully observed, and should the slightest indication of clogging-up be noticed the conditions of inking must be altered in accordance with the principles already set forth. The first inking-in having been satisfactorily performed, the stone is rinsed, dried, and dusted with resin as in other cases, after which it must be etched with a very slightly-acidified etching fluid; and the strength of this should be generally about one-third of that required by a line subject under ordinary circumstances. During the progress of the etching the lightest shades of the subject ought to be carefully watched, in order that the stone may be immediately rinsed if any deterioration should be noticed.

During the operation of printing the following points must be attended to:—In the first place, the roller which is employed must be in good order—neither so new as to be imperfectly saturated with fatty matter, nor so old as to have lost all its granularity and elasticity. The ink must be very hard and stiff, while the greatest care must be taken to ensure a thin and uniform film of it on the roller. The least tendency towards any clogging up of the closer parts of the device must be immediately combated by the addition of a little acid to the moistening water, or by other means which will be considered under the head of "Failures;" and any difficulty which may present itself should, when possible, be tracod to its immediate cause. Printing from a stone bearing a device in fine stipple is the most difficult branch of lithography, and the beginner will find all his resources severely taxed in keeping the subject undeteriorated on the stone.

Many other methods of photolithography have been devised from time to time, some of these depending on the use of transfers, and consequently requiring direct or ordinary negatives; while other processes involve the direct printing of the photographic image on the stone, and therefore require reversed negatives. There is, however, no occasion to consider any of these numerous methods, as they are less suited to the requirements of ordinary work than those which have been brought under consideration, It is merely necessary to say that first-class photolithographic work may be easily and expeditiously done by Mr. J. R. Sawyer's method of transferring a line subject from a collotype plate to a lithographic stone; but it is obvious that the study of this process belongs rather to the domain of collotypic printing, under which head it will be considered.

The next article will contain a digest of the principal sources of failure incident to the operations already considered, and will conclude our study of photolithography. T. Bolas, F.C.S.

THE NITROGEN COMPOUNDS OF CELLULOSE.

In order to remove the existing uncertainty in connection with the composition and number of the compounds of nitrogen with cellulose, and to exhibit the influence exerted, under certain circumstances, by various acid mixtures upon cellulose, as well as to try to get at the cause of the remarkable properties of soluble pyroxyline, I resolved to nitrify cellulose (cotton wool, hemp, paper, linen, and straw) in various ways, and to examine the products.

In seeking to ascertain the contents of nitrous acid in the nitro-cellulose the usual method of qualitative analysis could not be employed, as it is too inexact and too detailed in practice.

According to Béchamp's* observations, nitro-cellulose is decomposed by ferrous chloride with development of nitrous-oxide gas. According to Schulze, the determination of the nitric acid in spring water rests upon the same reaction. It was, therefore, most convenient to use the apparatus described by Schulze, and to carry out the analysis in this way with but little change in the handling of the apparatus.

A similar but less practical apparatus is used by P. Champion and H. Pellet for the determination of the nitrogen in nitrogenous compounds. They boil the substance with a neutral solution of sulphate of protoxide of ammonia, and, after expelling the air, they add, by means of a funnel-shaped tube and a glass stopcock, a mixture of sulphuric and muriatic acids, and measure the quantity of nitrous oxide in the same way.

The following nitrifying experiments were made, as far as possible, with different sorts of cellulose, such as cotton wool, paper, linen, hemp, and straw, the first three of which had undergone no special previous purification. The cotton wool used was, however, the purest and most crisp which is to be found in the market. Purification by boiling with soda ley, and soforth, with subsequent washing, does not assist the acid mixture to force its way in, as Mr. L. Warnerke thinks. The paper used was a short-fibred filter-paper, which appeared to contain a considerable quantity of woody material. The linen was old bleached linen. The hemp was so far purified, by being repeatedly boiled in soda ley and in calcic chloride with a little muriatic acid, that it looked perfectly white and silky. The strawy substance prepared in the same way from straw was not suited for nitrifying, as it dried together in solid pieces, into which the acid penetrated but imperfectly. On this account straw was used in the form of paper, which was freed from its carbonate of lime (of which it contained three per cent.) by treatment with muriatic acid.

The sulphuric acid used had a specific gravity of 1.8424; the concentration of the nitric acid is mentioned in the respective experiments. On mixing the two acids the temperature rose to 60° or 80°. When the desired temperature had been obtained by cooling the vessel with water the cellulose was introduced, all air-bubbles were removed by pressing against the side of the vessel, and then the mixture was left to cool slowly, so that after standing from twelve to twenty-four hours it had a temperature of from 20° to 23°. Special care was paid to the washing of the nitro-cellulose, which took place either in running water or else by decantation and pressing out of the water—repeated and continued for days.

The pyroxyline was sometimes dried in a vacuum, sometimes in a current of air, and sometimes at an ordinary, sometimes at a less than ordinary, temperature.

The analysed compounds will be best compared with each other by means of the percentage of nitrous acid they contain, and then the tri-nitro-cellulose or its reduplication, the hexa-nitro-cellulose,

* *Zeitschrift für Analytische Chemie*, 1870, page 401.

is shown to have taken up most nitrogen of the six following compounds :—

$C_{12}H_{19}O_{10}$, NO_2, Mono-nitro-cellulose with 12·49 per cent. NO_2.
$C_{12}H_{18}O_{10}$, $2NO_2$, Bi-nitro-cellulose ,, 22·22 ,, NO_2.
$C_{12}H_{17}O_{10}$, $3NO_2$, Tri-nitro-cellulose ,, 30·06 ,, NO_2.
$C_{12}H_{16}O_{10}$, $4NO_2$, Tetra-nitro-cellulose ,, 36·50 ,, NO_2.
$C_{12}H_{15}O_{10}$, $5NO_2$, Penta-nitro-cellulose ,, 41·89 ,, NO_2.
$C_{12}H_{14}O_{10}$, $6NO_2$, Hexa-nitro-cellulose ,, 46·76 ,, NO_2.

The experiments shown in the following table were made with nitric acid having a specific gravity of 1·38 :—

Kind and Quantity of the Cellulose.	Number of the Experiment.	Sulphuric Acid.	Nitric Acid.	Temperature at the time of the dipping in.	Duration of the Action.	Nitrous Acid.	Observations.

(*To be continued.*)

BEECHEY EMULSION PLATES.

In today's number of the Journal I read with interest the editorial remarks on my paper of last week, and I am trying to see how the explanations given are borne out by the facts in my own case. In one respect more especially I am not yet able to do this. Perhaps the Editors will kindly help me a little further. The first I refer to occurred to my mind after I had written my paper last week, and I should have mentioned it in a note had not my paper been already sent off.

Attached to my camera is a sunk box with a flap shutter. I often make use of this to give a considerably longer exposure towards the foreground than towards the sky. But this sunk box prevents my raising the front as much as I often require to do. I then remove it and use a sliding piece or an extra front, and, having no flap shutter with this arrangement, I sometimes neglect to give a longer exposure to the foreground, or, in other words, a shorter exposure to the sky; and it occurred to me, after sending my paper, that some of the negatives most free from the mottled sky were just those in which I had not made this difference of exposure between the foreground and sky. In those, consequently, the sky has received just that relatively better exposure spoken of by the Editors. Of course there is in this case a larger reduction throughout the sky part of the film, and this may render the mottling less perceptible; at least that was the explanation which occurred to my mind of the apparent greater freedom from mottling in those negatives.

By the "by-products" in my paper I mean the same thing as the "decomposition salts" in the editorial remarks. These, of course, are formed *throughout* the film—not merely on the under-side; and my view was that they might be left unwashed from the under-side. The Editors evidently think this not possible. I would still ask, therefore what is the cause of the mottling seen already on the dried, unexposed plate, and how can it be prevented? As I remarked in my paper, after the negatives had been prepared I noticed some of the films quite homogeneous—quite free from the mottling. In these plates it does not make its appearance after exposure and development; the finished negative is free from it. In other cases it is already visible in the film of the prepared plate over a portion or over the whole of it. In this case it may disappear in the fixing with the limitations mentioned in my paper, or it may be rendered worse by the developer and much less easily removed by the fixing agent. I have never seen anything of the kind in any of the washed emulsion plates that I have used; that was another reason which inclined me to think that the fault might rest with the by-products, or decomposition salts, not being thoroughly removed. My having found it also in Capt. Abney's beer and albumen plates seemed to point in the same direction.

I notice another correspondent, Mr. Manfield, speaks of the hardness and want of rapidity in the Beechey emulsion plates. My own experience is rather opposed to this. I spoke of it only in the first plates I prepared, and accounted for it by supposing a large excess of bromide in the emulsion, which I had not made or tested myself. Afterwards I took care to ascertain that only a very slight excess of bromide was present *after the silver had been in excess*, and I had no reason to complain of hardness or want of rapidity, nor yet want of certainty, except where the mottling in the film was excessive. Had these faults troubled me I should not have continued to feel the interest in the process which I do. I am sorry I have no more time to devote to it for the present. A few properly-conducted experiments might make the precautions to be adopted in practice very clear; and no doubt the explanations suggested by the great experience of the Editors in many directions will be valued by all those to whom I thought the few suggestions I could offer might be of interest. WM. WASHAM.

NOTES ON PASSING EVENTS.

BY A PERIPATETIC PHOTOGRAPHER.

THIS is an age for striking into new paths. I "guess that I have struck 'ile" in this direction. Like a good many other readers of the criticisms ou artistic photographic works at any of the exhibitions, both long past and recent, I have frequently been considerably "exercised" when studying the terms employed in the discrimination of merit in its various degrees. Well, to come to a focus, my idea is that of the compilation of an art and photographic critical dictionary. Naturally its circulation will be limited, but its uses will be obvious, and I am a philanthropist. *Every* photograph exhibited in any photographic exhibition during the past dozen of years was good, according to the critics of the two weekly photographic journals. (O! how plentiful and cheap must soap be in the metropolis!) But to say so in plain terms would never do. Bless you! such would be uneuphonious and unheard-of; therefore, the "good" must, like the Edison stream of electricity that is to illuminate our private houses, be subdivided into innumerable verbal ramifications, each of which must convey the spirit of the original in all its force yet in different terms. "Why!" you exclaim, "the 'Peripatetic' must mean a synonymical dictionary?" Good sir, you have hit it. Such a dictionary as applied to the critical notices of photographs, when every one is good, is just the thing that I *do* mean. How does the following "muster roll" of adjectives look by way of a sample? Good — superb — charming — nice—pretty—effective—excellent—beautiful — gorgeous — goodly—brilliant — magnificent — refined—handsome — lovely — fine — able — tasteful — delicate — elegant—classical—chaste—æsthetic—rich—florid — bold — characteristic—graphic—picturesque—truthful—and soforth. How much will critics feel obliged to me when I issue my dictionary of slang art-critical terms, which will also have an obverse side for the special benefit of such as issue bad, smudgy, ill-composed, out-of-focus, flat pictures with or without converging and curvilinear perpendiculars! Having the "cant of criticism" in my mind's eye, I wonder how it would do to have a critical notice of an exhibition with the degrees of merit, as distinguished from the merely descriptive part, conveyed by figures or marks instead of by the interminable "charming" and "fine" so redolent of photographic criticism generally at present.

The Technical Exhibition of the South London Photographic Society was fairly entitled to be considered successful, notwithstanding a statement to the contrary in a letter from one of the exhibitors. That writer does not appear to be aware that this kind of exhibition cannot, from its nature, be one of a highly-organised type. So far as I understand the design of the promoters, all and sundry—including merchants, manufacturers, dealers, and agents—may, and are invited to, send in their wares and make use of that meeting for the purpose of advertising them; it is, in short, a meeting at which "shop" to any extent may be represented. Observing that photographs taken by the "luxograph" were exhibited, I wonder that it did not occur to the introducers of this instrument, or apparatus, to bring it to the meeting and show it in action before the members and visitors. A portrait of the Chairman taken under such circumstances would have been prized by many of the members, and numerous copies would have been purchased.

Now that artificial light is coming somewhat to the front, let me suggest a very nice, intense light, and one that is easily managed. It consists of placing in a saucer a small heap of powdered saltpetre (nitrate of potash), and on the top of it laying a lump of phosphorus. When the phosphorus is ignited the light emitted is so intense as to enable photographs to be taken with great ease by its means. The phosphorus must be kept in a bottle of water, and a bit cut from off the stick when wanted, taking care to keep the knife under water when it is being used. A stick may be lifted out of the bottle and transferred to a flat vessel containing enough water to cover it when laid down on the bottom, in which position it can be cut into suitable pieces with ease. Care must be taken that it be not touched with the fingers, as burns with phosphorus are more serious and painful than those of any other kind.

(To be continued.)

SPOTS ON EMULSION PLATES.

[A communication to the Liverpool Amateur Photographic Association.]

I feel that it almost needs some apology for troubling you this evening with such a well-worn subject as *Spots on Emulsion Plates*, particularly when what I have to say is only in confirmation of what has usually been considered their cause, viz., dust. But it may interest and amuse emulsion workers to hear to what an unlikely and apparently innocent cause I succeeded in tracing that dust.

I have worked the collodio-bromide emulsion process for thirteen years, and spots were by no means a familiar characteristic until three years ago, when an eruption suddenly made its appearance and assumed a chronic form of such obstinacy in spite of all that I could do that but for my former experience, which taught me that they were not inherent in the process, I believe I should have abandoned emulsions altogether.

It would be wearying to you to detail the steps that were taken to subdue the enemy. As the conditions of working were apparently unchanged it was only natural to suppose the spots arose from insufficient filtering, and the changes were accordingly rung on cotton wool, tow, sponge, and cambric, and these were washed in caustic potash and alcohol and then the emulsion was allowed time for subsidence, but all without avail—the spots remained master of the position. It was getting serious, and that fine patience which is such a shining virtue of photographers was nearly exhausted.

One thing was certain, and that saved a great deal of trouble; for, as I worked with portions of the same substances as I had formerly used, it was clearly owing to some undetected error in my method of working. The only change that had been made was in the introduction into the room of a large paraffine lamp, it being more convenient to me, as regards position in developing, than the gas, and it was also used when coating plates. Knowing what a harmless thing paraffine is it seemed like going out of one's way to suspect it. Nevertheless the fact remained that the lamp was the source of my troubles, and a few tests confirmed the suspicion. It may be urged that many photographers use a similar lamp when preparing plates, and yet they are not troubled with spots; they are fortunate, but I still think my experience with the lamp may be of service in helping them to guard against danger.

You have probably failed so far to see the connection between the paraffine lamp and the spots. Let us analyse. In the ordinary paraffine lamp, as everyone knows, a chimney is used for the purpose of effecting a proper combustion of the oil; through this chimney the heated air rushes with considerable force. The column of heated air ascends to the ceiling, and, being impelled forward by the continuous rush of heated air, spreads to the sides of the room, descends, and runs along the floor to the lamp, and thus sets up a circulation more or less active according to the size of the lamp and the room, picking up on its way the particles of dust that, in my case at least, cause the troublesome "emulsion spot." It would appear that the heated air from gas burned in ordinary batswing burners has not the power to displace that in contact with the ceiling, and this explains why, in the upper part of a room, after the gas has been lighted some time, there is such an accumulation of bad air. And it is no doubt better that the bad air does keep to the ceiling; for, if argand burners, which require chimneys, are put on the gas, I am mistaken if the current they would cause would not prevent the accumulation of bad air near the ceiling by driving it into circulation in the room.

Enlightened by my lamp it was necessary to examine more remote parts of the room where I had been accustomed to consider the air, and, in consequence, the dust, totally undisturbed. It needed no great acumen to pitch upon a coil of vulcanised india-rubber tubing, which is generally covered with a fine coating of the sulphur used in its manufacture—sufficient of itself to account for the most virulent outbreak of spots. It was a natural transition from this to the pneumatic holder. If these be made, as mine is, with a ball of vulcanised rubber they must always be viewed with suspicion. The constant pressing of the ball for attaching or detaching the plate must send the dusty particles from the interior into circulation in the surrounding atmosphere. They should be made entirely of pure rubber. As they are exceedingly useful I now fill mine with water and empty it before beginning to work.

I now breathe freely, and the preparation of good, clean-working emulsion plates is once more as easy as plane sailing. Each batch of plates can be prepared with great certainty that spots will not be among their defects. I conclude by saying that I believe almost all spots—except, of course, those produced by free silver in the emulsion—are caused by dust, and, even in the most inveterate cases, a diligent search will doubtless detect their source, although it may not be a paraffine lamp. W. H. Wilson.

SUGGESTIONS FOR WINTER WORK.

I suppose it is an almost universally-recognised fact that, although professional photographers generally "read the journals," and many of them fully appreciate the patience and perseverance of the experimentalists to whom photographic literature is so much indebted, the instances are few and far between in which, as a result of such reading, any material modification has been made in the daily routine of ordinary work. While often admitting the beauty of a new process, or the convenience of a suggested modification, they remain satisfied to let well alone, and both would soon pass into the limbo of forgotten subjects if it were not for the energetic band of amateurs, some of whom are always ready to take up anything new and work it out to a successful issue. The amateur does not, of course, object to this; but the experimentalist, whose sole object is the improvement of the art, cannot help now and then feeling a little sore when he sees his (for the time being) pet process, which he has laboured so long to perfect, and which he *knows* to be more suitable for many of the purposes of the professional photographer than that generally employed, altogether ignored by those in whose interests it has been worked out.

No doubt the main cause of this apparent conservatism of the professional photographer is the alleged want of time for anything but professional work. He knows well that, in most cases, if the "man at the wheel" be not constantly on duty the ship will "come to grief," and his readiness to buy any secret process that may be offered would seem to show that he is quite alive to the advantages improvements would bring, if only they could be obtained without trouble to himself.

There is, no doubt, much force in the plea of want of time during the busy summer months. The photographer must "make hay while the sun shines," or he will not make it at all; but it will not, however, hold good at the present season and for several months still to come, when the time in which good work can be done will hardly average three or four hours a day. I am aware that many have other strings to their bows, but there is no doubt that there are many more on whose hands time hangs heavily. On those, and indeed on all connected with the art, I would strongly urge the propriety of spending some portion of that leisure time in acquiring a *practical* acquaintance with several processes, of which at present they know little more than the name, but which, if thoroughly mastered, would most certaintly increase both their popularity and their profit.

The following incident is a case in point, and fully illustrates the advantages likely to arise, when opportunity occurs, from moving a little out of the beaten path:—During a recent visit to a photographic acquaintance, who has for a number of years done a considerable portrait business in an important manufacturing town, I noticed for the first time a large number of landscape and architectural subjects both in his specimen cases and reception rooms. Knowing his former aversion to that class of work I inquired what had come over the spirit of his dream, and was pleased to learn that it was the outcome of his conversion to a belief in gelatino-bromide emulsion. His explanation of the matter was brief, but instructive. "The fact is," he said, "I had read almost all that had been written on dry plates, and seen many very fine pictures that had been taken on them; but the difficulties and uncertainties I believed to be inseparable from that kind of work kept me from ever giving it more than a slight trial, while I could always rely on making wet collodion do all that I required. But, although wet collodion is admirably adapted for studio work, with the dark room close at hand, it is altogether a different affair out in the field. At first, when sitters were not very plentiful, I was glad of a commission to go off for half-a-day to photograph a house or a landscape; but by-and-by I found it didn't pay. Even when the distance was but a few miles a conveyance of some kind was required and an assistant a *sine quâ non;* and, what with the time occupied in erecting the tent or "rigging up" a dark room, and getting things generally into working order, a single commission usually meant a whole day's work, which, although well paid for from the employer's point of view, always brought in less money than would have been realised from the sitters who were lost in consequence of my absence from home. Now," he continued, "I put a couple of gelatine plates into a double slide, walk if the distance be short, or drive if it be long, give an exposure of a few seconds, and am back again in my studio before I am missed, quite certain that when I develope in the evening I shall have got as good a negative as if I had employed wet collodion, and in less time than it would have taken to sensitise a single plate."

My friend's explanation of the cause of his conversion was no less instructive. One day, in the early summer, an amateur—a stranger to him—called and asked permission to develope one of a batch of plates that had been sent after him, and inquired regarding the proper exposure to be given to the plates, of which he was not quite certain. The permission was willingly accorded and the operation watched with much interest, the result being a negative beautifully clean but, in the opinion of my friend, flat and feeble—an opinion, however, which was soon changed, as on a print being taken from it as soon as it was dry he declared it better than anything he had himself produced, and, to use his own words—"You know I used to consider myself no 'small beer' at that kind of work." He continued:—"The exposure had been so short, the development so simple, and the result so perfect that I at once resolved to get a supply of plates from the same source, and after one or two failures, mainly from over-exposure and over-development, I found that I could succeed as well as my new friend. This gave me a new power, and instead of discouraging outdoor work I now court it, and find both pleasure and profit in its practice, without materially interfering with the proper work of the studio."

It is evident that this is a case in which where precept failed example succeeded. My friend might have read on to the end of the chapter without giving practical attention to the process which he now values so highly; but the practical demonstration impressed itself strongly on his mind, and produced that degree of faith in the process which invariably leads to success. I do not suppose that all photographers may be so fortunate as my friend, and "entertain an angel unawares" in the shape of a teacher of the gelatino-bromide process; but scattered through the pages of this Journal during the present and past year will be found all the information required to enable anyone of moderate ability to succeed as well as he now does. I feel assured that the leisure hours of the approaching winter cannot be better employed than in searching it out, and putting it into practice.

Of course it will be understood that daylight is not essential for this purpose, the practice necessary to lead to perfection being quite as well got by printing under a suitable negative with a gas or paraffine flame. There is, however, one precaution that must not be forgotten, and that is that the light of the ordinary dark room is not sufficiently non-actinic for rapid gelatine work. The experiments should be made with plenty of light, but light of a dark ruby colour; and for this purpose I know nothing better than the gas globes or paraffine chimneys of a deep ruby glass manufactured for Messrs. Mawson and Swan, of Newcastle-on-Tyne. If the former are used they should be covered with some arrangement by which the white light escaping from the top can be prevented from falling on the plate, as it is quite sufficient to destroy results that would be otherwise perfect.

There is another branch of the art to which the profession have never "taken kindly," but which *should* be popular and, consequently, profitable, and which may be practised as well by night as by day, namely, the production of vitrified enamels. A really good enamel is probably the most beautiful, most perfect, and most desirable form of small photograph; and yet these gems have never come into general use, nor attained anything like their deserved popularity. Why this should be so is a somewhat difficult problem; but I believe one cause to be the fact that the production has hitherto been confined to only a few operators. It is true that many have tried to introduce them to their *clientèle*, but when the execution of an order devolves on another the photographer introducing the article is very apt to do so in a half-hearted way, preferring, not unnaturally, to encourage work of which he would enjoy the whole profit to that in which, probably, the largest share would go elsewhere. If every photographer could produce his own enamels there is little doubt that the prices would soon arrange themselves to suit all parties; and, as the work can be done at periods when the operator could do nothing in the studio, an impetus might be given to this beautiful branch that would soon secure for it the popularity and patronage it deserves.

I know perfectly well that the great majority of photographers refrain from trying this kind of work, owing to a belief that it is both difficult and uncertain; but I also believe that opinion to be unfounded. Almost all that is known regarding it has been published again and again; and I feel certain that any artist who succeeds well in other branches of photography would, by a little patient practice and perseverance, succeed equally well in this department of the art. For this the long winter nights are admirably suited, the only light required being to produce the transparency, and that, as everyone knows, can be as well done by artificial light as during the day.

Without in any way implying that it is the best, or even as good as some other articles which have appeared on this subject, I may here refer to a description of the process I published in this Journal at page 486 of the volume for 1876. I have perfect confidence in my opinion that anyone who will carefully follow the directions therein given, and adhere to them till he acquire the necessary dexterity, will ultimately succeed in producing such specimens as cannot fail to attract the attention of his customers, and enable him to add a new and profitable branch to his business.

John Nicol, Ph.D.

THE REACTIONS OF CHROMIC ACID AND CHROMATES UPON SUBSTANCES OF ORGANIC ORIGIN, CONSIDERED WITH REFERENCE TO THEIR USES IN PHOTOGRAPHY.*

Influence of Temperature on the Sensibility of Chrome-Gelatine.

Temperature has but little influence on the sensitiveness to light of dry chrome-gelatine—much less than upon the still damp chrome-gelatine whose spontaneous insolubility it really accelerates. I exposed two exactly similar pieces of air-dried carbon tissue, sensitised upon a three-per-cent. bichromate bath, under two similar photometers—one placed in a room heated to 30° C., the other in a similar room the temperature of which was only 10° C. The experiment when repeated showed that both pieces of tissue possessed the same degree of sensitiveness. Wilson's[1] dictum that if in summer one expose chrome-gelatine one minute, in winter one must expose it three in consequence of the *difference of temperature*, must, I believe, be almost exclusively referred to the decrease in the chemical intensity of the light,[2] and not to the fall in the temperature; also, perhaps, the far higher absolute quantity of moisture in summer may have a part in producing that effect.

To a similar confounding of causes I believe the following opinion of M. Vidal's[3] must be attributed:—A negative requires one minute's exposure with a five-per-cent. bath and a temperature of 15° C., three minutes at a temperature of 10° C., four minutes at 5° C., two minutes at 20° C., and one minute thirty seconds at 25° C., when the concentration of the bath is one per cent. At a concentration of six per cent.

* Continued from page 546.

[1] *Photo. Archiv.*, vol. ix., page 181.

[2] Holitscheck's Tables of the Intensity of Light. *Photo. Corr.*, vol. xiv., page 51.

[3] *Photo. Monatsblätter*, vol. ii., page 363. *Bull. Soc. Franc. Phot.*, 1875, page 92.

Vidal would give the following exposure:—One minute fifteen seconds at 5° C., one minute at 10° C., forty seconds at 15° C., thirty seconds at 20° C., and twenty seconds at 25° C.

As already mentioned I could distinguish no influence exercised by temperature when the experiments with the different temperatures were made simultaneously with the *same tissue, same light*, and the *same length of exposure.* It is also supposed that previous to the experiment the tissues used have been stored together. To the foregoing remarks I shall yet add, with respect to the increase of the sensibility with the temperature, that the increase of the temperature of the air generally runs parallel to that of the intensity of the light of the sky. The fewer clouds the more light and the more warmth, in consequence of the sun's rays not being weakened. In this way the proportion between the increase and decrease of the intensity of the light, and the changes of the seasons with their accompanying temperatures, lead to erroneous conclusions.

The special difficulties of manipulation which accompany the various photographic methods at the different seasons of the year cannot be entered into here more minutely. It may not, however, be uninteresting to remark that it has been found necessary by experience to use in the carbon process a weak bichromate of potassium bath (about two per cent.) in summer and a stronger one (about five per cent.) in winter. If as strong a solution be usedin summer as gives good results in winter flat pictures totally devoid of brilliancy will result. I observed that a similar difference existed between printing in the sun and that done in diffused light; that is, that a negative which in the cool season of the year would be printed in the shade on tissue prepared in a five-per-cent. bichromate solution would not print well in the sun, or, at least, a brilliant print could only be got when the tissue was sensitised on a from one to two per cent. chrome bath[1]. Upon this fact, in conjunction with that mentioned at the beginning of this article, I believe the different preparations required in summer and in winter to be based. The difference of temperature principally affects the time which the prepared paper may be kept before printing.

Hannot[2] makes an important remark on the photolithographic (chrome-gelatine) process which has reference to the above:—"Photolithographic prints become harder in the shade than in the sun—a fact which may be utilised so as to suit the peculiarities of the negative."

Influence of the Commencement of Spontaneous Insolubility on the Sensitiveness of Chrome-Gelatine.

I have already mentioned that the *commencement of insolubility in chrome-gelatine decreased its sensibility.* Chrome-gelatine becomes insoluble not only through long lying in the dark or long heating, but also by the action of chemical agents, such as chrome-alum, tannin, gallic acid, &c. Such chrome-gelatine films behave differently towards light from freshly-prepared films, which still retain unchanged the solubility of the gelatine. On comparison of the relative sensitiveness of the two sorts of gelatine it appears that those sorts of chrome-gelatine which already contain, in consequence of the presence of certain agents, the elements of insolubility in the glue will become insoluble much more rapidly than those which have not yet begun to undergo that change. It does not, however, follow that in consequence of a certain degree of insolubility in the chrome-gelatine the latter will give a foggy picture; it can usually be developed as clearly as a fresh film, but a more powerful picture results.

It is an undeniable fact that chromated carbon tissue is distinctly less sensitive immediately after being dried than three days later.[3] This is because through the whole mass the spontaneous reduction of the chromic acid to chrome oxide has set in, as well as the consequent insolubility, which is at first slight, but which is increased by the action of light. When the reduction has taken place entirely in the dark a very slight impulse from light suffices to carry it on to its end, while with a perfectly-unaffected chrome-gelatine the light has more to do to produce the reduction. When a piece of tissue is sensitised with potassic bichromate and divided into two parts—one being stored over water and the other in common air—at the end of four days there will be a considerable difference in the degree of solubility of the two pieces in hot water, the one kept in damp air being the most insoluble. In order to eliminate the influence of the varying moisture contents upon the sensibility I next allowed both pieces of paper to lie in ordinary air, so that in two days they both contained the same quantity of moisture. When exposed and developed the piece which had first been kept in moist air, and which was much the most difficult of solution, proved considerably more sensitive than the air-dried and more soluble. The tissue difficult to dissolve printed two to three photometer degrees deeper, but required hotter water to develope it than the other.

Here the accelerating influence of the commencing insolubility (reduction) was evidently shown. This can be demonstrated by dividing a piece of tissue and exposing one half for a few seconds to clear daylight, and allowing the other to lie for twelve hours. By the progressive action of the light the insolubility penetrates pretty equally through the whole mass, and an experiment made with the tissue continuously kept in the dark and that exposed to the light for a few seconds shows that the latter is the more sensitive and furnishes denser prints, which, when developed with water of the proper heat, are perfectly free from fog.

Another confirmation of my view is that the addition of chrome alum to the bichromated gelatine actually increases its sensitiveness. Thus, if one per cent. of chrome alum be added to a sensitising bath containing three per cent. of potassic bichromate, the tissue chromated upon it will be about one-eighth more sensitive than tissue sensitised upon a bichromate bath without that addition; that is, the former tissue would print to the ninth degree of the photometer, when the latter prints to the eighth degree. Such tissue containing chrome alum is, however, less easily kept than the ordinary sort, since, as a rule, it loses so much of its sensibility as to become unusable on the second or third day, and at the same time it loses its solubility in hot water.

The slightly-begun insolubility of the chrome-gelatine, which is induced in various ways, has the same effect: it increases the sensibility to light. Still, it is not advisable to induce intentionally that commencement of insolubility as a means of accelerating the exposure; for it is a veritable two-edged sword, since the intentionally-developed difficulty of dissolving the chrome-gelatine might easily progress so far as to render it quite insoluble, and then the picture produced by the light could not be developed. To this division of the subject also belongs the observation that slowly-dried chromated tissue is more sensitive than rapidly-dried, so that it is difficult to hit at first upon exactly the proper length of exposure, as that depends also partly upon whether the tendency to insolubility has begun to operate.

It is very interesting also to remark that those parts of the chrome-gelatine film which light has reached become more rapidly insoluble when allowed to lie subsequently in the dark than those parts which have remained unexposed.

Under-exposed carbon pictures or lichtdruck plates, when allowed to lie in the dark for several days, gain in intensity in the exposed places. Abney's[1] discovery, which has been frequently substantiated, is worth noting. It is that carbon tissue only requires a quarter of the full exposure if it be subsequently allowed to lie fourteen hours in the dark.[2] In this way some splendid carbon effects have been produced.[3] According to Scamoni this intensification is more rapid when the air reaches the prints freely (that is, out of the printing-frame) than in the frame; therefore the box in which exposed prints are laid to wait until they can be developed should not close hermetically. This after-action of the light can only be prevented by washing out the undecomposed potassic bichromate.

According to a private letter from Leipold, he found that when chrome-gelatine films for photogalvanography and heliography were quickly (in about two or three hours) dried and then at once exposed and developed, they were never so sharp as those which were allowed to lie from six to ten hours in the dark after drying.

I consider this appearance of old chromated films difficult to dissolve, being more sensitive than fresh ones to be analogous in its whole range to the results of pre-lighting in the negative process. In this case the reduction is produced by an exposure of short duration, and yet the action on the exposed parts, which are afterwards to produce the picture, is sufficient. J. M. Eder, M.D.

(To be continued.)

[1] Thin negatives furnish very brilliant and powerful carbon pictures, which are as beautiful as those from dense negatives printed in diffused light. (Rowell, *Photo. Archiv*, vol. viii., page 290.)

FOREIGN NOTES AND NEWS.

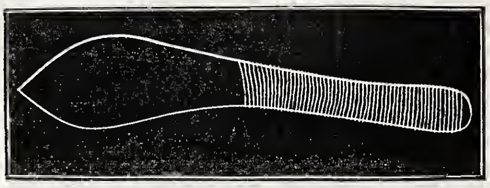
Wieske's New Show-Case.—Reprint of Eder's Treatise.—A Handy Retouching Knife.

Herr Wieske, of Berlin, lately exhibited a design for a photographic show-case, consisting of an octangular pillar, having four wide and four narrow sides corresponding in width to that of large and small pictures. At a convenient distance from the ground the pillar is surrounded by an eight-sided sloping desk-table, upon which separate pictures or albums may be laid. Another sketch showed a half pillar arranged on the same plan, and intended to be fixed against a wall. Herr Wieske thinks that one of these pillar cases, 2·5 metres high, and finished so as to stand in the centre of a room, would cost about 700 marks (say about £35), and for a wall case less in proportion.

Dr. Eder's treatise on the *Reactions of Chromic Acid and the Chromates upon Gelatine and other Substances of Organic Origin*, &c., which has been coming out in parts in the *Photographisches Correspon-*

denz, is about to be reprinted in a separate form. This treatise was "crowned" by the Photographic Society of Vienna.

The accompanying figure, taken from the *Photographisches Wochenblatt*, represents a handy knife used in the establishment of MM. Braun



and Co., Dornach, for pricking dark specks out of a *carte*-sized negative which is intended to be enlarged, or to lighten up dark places in the background.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
December 10 ..	Photographic Soc. of Gt. Britain	5a, Pall Mall East.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

The annual meeting of this Association was held on Thursday evening, the 28th ult., at the Free Library, William Brown-street,—Mr. Thomas Clarke, Vice-President, in the chair.

The minutes of the previous meeting were read and approved.

Messrs. H. Norwood Atkins, T. W. Bruce, E. Bucknall, and Dr. Kenyon were elected members of the Association.

The Secretary then read the following—

ANNUAL REPORT.

The prosperity of our Society still continues, and though this is the fifteenth annual report there is no falling off in the number of its members, which is now sixty-three.

The meetings have been well attended, more especially when any practical illustrations have been announced, showing that, however interesting it is to hear a paper read on photographic subjects, it is still more so to be able to see the practical demonstration of them.

At the close of last year the Association joined with about twenty-two other societies in an associated *soirée* at St. George's Hall. The result was such a success that a general desire was expressed that another should be held this year. This was found to be impracticable, but the hall has been secured for the 19th February next, when it is hoped that a *soirée* more attractive and interesting than the last may be held.

The numerous dry processes have been well illustrated by different members, but the past season has shown the marked advance in the use of gelatine plates, as proved by the numerous specimens exhibited at the meetings.

Several papers have been read by the Rev. H. J. Palmer, which have no doubt attracted attention to the value of gelatine, viz.:—*A Further Improvement on the Gelatine Process; Cardboard Slides for Gelatine Films; Practical Demonstration of Palmer Films; Switzerland, from a Photographic Point of View;* and *A New Cure for Blurring.*

Mr. Kirkby read a paper on *Recovering Waste Silver in Printing*, and Mr. Wilson will read one on *Spots on Emulsion Plates.* In addition several novelties have been introduced by Messrs. W. J. Chadwick, Houlgrave, Ellerbeck, and others.

The Society's lantern has been much appreciated, and proved an attraction. By the addition of Chadwick's oxygen generator Mr. Weber was enabled to illustrate Mr. Palmer's paper on *Switzerland from a Photographic Point of View* most effectively.

The report would be incomplete did it not record the pleasant visit of several of the members of the Manchester Photographic Society to one of our meetings, who showed us several very interesting novelties. Some of our own members also made a return visit to Manchester, bringing back with them very pleasing reports of their hearty reception. These friendly meetings caused a desire to meet again on an outdoor excursion, and the result was a most enjoyable day spent together at Hawarden. Our own members had previous to this held an excursion to Speke Hall, which, notwithstanding the unpromising weather, proved a success, and Mr. Potter had the pleasure of carrying off the album which Mr. Forrest had kindly offered as a prize for the best negative taken that day.

The thanks of our Society are due for the presentation to them of the *Autotype Notes, Bulletin Belge, Journal of the Photographic Society*, and also to the Edinburgh Photographic Society for their presentation print.

The Secretary then read the Treasurer's report, showing a balance in favour of the Association after paying all expenses, and which after being audited was, together with the Secretary's report, duly passed.

The undermentioned officers were then elected for the year 1879:—*President:* Thomas Clarke.—*Vice-Presidents:* J. H. T. Ellerbeck and W. Horsman Kirkby.—*Treasurer:* A. Tyrer.—*Hon. Secretary:* Wm. Murray.—*Council:* Wm. Atkins, Rev. T. B. Banner, J. A. Forrest, Wm. King, Rev. H. J. Palmer, E. Phipps, W. E. Potter, E. Twigge, J. W. H. Watling, Ed. Whalley, H. A. Warmby, and W. H. Wilson.

Mr. W. H. Wilson then read a paper on *Spots on Emulsion Plates* [see page 581], after which a discussion followed, in which Messrs. Boothroyd, Palmer, and Twigge took part, it being the general opinion that no spots resulted from an enclosed paraffine lamp.

Mr. Potter exhibited his album, which contained a collection of prints with some very fine natural sky effects.

Some exceedingly successful photographs of children, taken in an ordinary room, and some taken out of doors of animals, on Swan's plates, caused considerable attention and inquiry respecting exposure, &c.

The Rev. H. J. Palmer then gave a very successful demonstration of enlarging with the lantern, and afterwards developed the resulting negative and some transparencies with the ferrous oxalate developer, using a fine specimen from one of his film negatives to enlarge from.

Mr. Wilson said he was always pleased to find old members still taking an interest in the Association, and it was with pleasure he welcomed back Mr. Guyton, who had formerly held the office of hon. secretary.

Mr. Guyton briefly thanked the members for their kind greeting.

Hearty votes of thanks were then passed to Mr. Wilson and Mr. Palmer for their contributions to the interest of the meeting, and to the various societies who had presented their journals and prints to the Association.

The meeting was then adjourned until the last Thursday in January next.

Correspondence.

HEATING A SMALL DARK ROOM.

To the Editors.

Gentlemen,—I notice in your issue of October 25th an inquiry for an apparatus for heating a small dark room, also your reply to J. James on the use of paraffine oil as a fuel for making heat in drying bichromatised gelatine.

There are various patterns of stoves made in America for burning "coal oil," which I take to be equivalent to the parraffine oil you speak of. The best oil-burning stove I have found is called the "hot blast." I have two such in use for a long time, both for heating a room and for heating the drying-box for drying gelatine plates, and can speak in the highest terms of their efficiency. The tank is of cast iron, and the lamp has two flat four-inch wicks. It is so constructed that the tubes can be surrounded with cold water, and the stove gives a very powerful heat.—I am, yours, &c., Jno. Carbutt.

54, *North Ninth-street, Philadelphia, U.S.,*
November 13, 1878.

"FREE LANCE'S" CRITICISM.

To the Editors.

Gentlemem,—I notice that "Free Lance," in your last number, alludes to a paper read by me before the Liverpool Amateur Photographic Association. He has not expressed himself very clearly, but presuming that the word "collodion" is a misprint for "chloride," he seems to infer that I made out that the paper contained only two grains and a-half of chloride of silver, and that this amount was converted into twelve or thirteen grains of sulphide of silver, which is absurd.

If he refers he will find that I obtained about two grains and a-half of chloride *and* twelve grains of sulphide of silver from each sheet (= to about nineteen grains of Ag No_3), and this after printing from average landscape negatives; consequently the paper must have absorbed nearly an ounce of his imaginary thirty-grain bath.

I am surprised that my statement should have been so misunderstood; and, "sharp" as "Free Lance" usually is, he seems to have missed the "point" this time.—I am, yours, &c., W. Horseman Kirby.

Liverpool, December 2, 1878.

[We have little doubt that "collodion" is a clerical error for "chloride." "Free Lance's" meaning is rather "involved," but we presume he intended to indicate that, with the use of a thirty-grain bath, two and a-half grains of chloride from the washing of a sheet indicate that only two-thirds of a drachm of bath solution adhered to the paper upon withdrawal from the bath.—Eds.]

HEMERY'S PRINTING-FRAMES.

To the Editors.

Gentlemen,—With regard to Hemery's printing- and tinting-frames: they are certainly ingenious and, no doubt, will do all that is claimed for them, but it is only what has been done before.

In December of last year you published a description of my carbon printing- and tinting-frames; but in a letter in the previous week's Journal I directed your attention to a frame described by Mr. James Harris at page 176 of your Almanac for 1877. With this frame I can do any sort of printing in carbon. A landscape background, clouds, or anything else can be printed-in with the greatest ease; and when once the masks are set you may print away as fast as you like without any fear of the registering.

I use Ford Smith's waxed landscape negatives regularly, and I find no more difficulty in carbon printing than in silver printing; in fact, not so much, as I have only once to fix the mask to the glass, then I can print any number of proofs and introduce as many landscapes as I like.

The only objection I have to the Harris frame is the mode of fastening the paper to the back; but I am at work with a pair of frames in which I think I shall get over this.

Who Mr. Harris is I do not know, but personally I feel very much indebted to him for introducing a frame so useful for combination carbon printing.—I am, yours, &c., SAM. BAMFORTH.

Hollingworth, Hadfield,
Manchester, December 2, 1878.

RECENT MEDAL AWARDS.

To the EDITORS.

GENTLEMEN,—I had not any intention to impute "deception" to Mr. Jennings. Directly after the meeting I wrote to the President, asking him to tell me who *assured* him. He declined to tell me. Feeling it a matter of public importance that such a statement should not go forth uncontradicted, I called attention to it through the press. I beg, therefore, Mr. Jennings to dissociate my action from himself personally, and to believe that I raise the question on public grounds solely.

I regret that a personal attack on me appears, signed "Auld Reekie." I will remark only that *I* have at least the courage of my opinions and sign my name to them, be they right or wrong, and that of all things the most contemptible and cowardly is an anonymous *personal* attack.—I am, yours, &c., H. STUART WORTLEY.

Rosslyn House, Grove End-road,
London, N. W., December 3, 1878.

NATURE AND ART.—A person untutored in the art of painting might be induced to suppose that the perfection of art would be to depict nature as it really is; the more lifelike the resembles the higher the standard of the work. In sculpture this doctrince will, we believe, be freely admitted; the whole aim of the sculptor is to reproduce in his marble the exact poses, the same mouldings of limb and of feature, which would be looked for in the living subject. But when we pass from the reign of the chisel to that of the paint brush, we find a different principle guiding the hand and eye af the artist. The first desideratum seems to be that of effect, and the height of art appears to be to produce the greatest effect in colour and pose with the least amount of direct violation of laws of nature. Some violation is expected almost as a matter of course; it becomes a question of degree, and the talent of the painter lies in the real subservience of nature to his art, while the art is deluded into the belief that it is viewing an exact reproduction of nature. For example: a leading artist remarked to us the other day, in horror at the bare suggestion of shorn sheep figuring in landscape, "We never think of painting sheep without their fleeces." The natural question then arose, "What then do you do, when you depict an August landscape in England? Do you ignore the existence of sheep, and keep them out of the picture?" "Certainly not," was the reply; "if they suit the effect of the landscape, we should introduce them, and should paint them with their fleeces as a matter of course, for the sake of the effect." Again: bright green foliage, such as is seen in the month of May, is held by most artists to be crude, too glaring in its effect upon the eye, to harmonise well with the tone of the rest of a landscape. For this reason autumn scenes, with varied tints of the leaf in the fall of the year, are favourite subjects for the brush. But if it is thought necessary to date the scene of a landscape in spring time of early summer, the rules of colour are then too often found to predominate, to the destruction of nature. A certain amount of yellow and orange is necessary to the "tone" of the foliage; it may be thoroughly anachronistic, but anachronism is a secondary consideration when art is the object in view. As an instance of this doctrine, we have heard and read divers criticisms of a picture which is certainly one of the leading productions in the exhibitions of the year—to wit, Mr. W. Field's *Henley Regatta*. Some art-critics have remarked that the foliage is too "cold" or too "crude," because it shows hardly any other tint than that of midsummer green. We have heard that Mr. Field was advised in many quarters by artistic friends, who visited his studio while the work was in progress, to tone his foliage with a certain amount of autumnal tint for the sake of the effect upon the eye. But the artist, having studied the scene from life, and being aware that Henley regattas invariably fall at midsummer, or within a very few days of that date, was bold enough in this instance to stick to pure nature as his text, and to represent a Henley scene such as it really is, to anyone who has been in the habit of witnessing it. Perhaps "sea pieces," which depict waves breaking on shore in fair weather and in sunlight, present the greatest violations, as a rule, of the laws of nature. Two details are especially desired by the artist to give due effect to his pictures—the one the sudden curl of a good-sized breaker immediately in the foreground; the second, a deep tint of blue or of green in that breaker. As a contrast to that colour, a foreground of sandy beach is often the best. The natural results of a sandy bottom would be twofold. In the first place, the shore being thus gradually shelving—for sandy beaches seldom lie on a steep incline—the breakers, if of any large size, would begin to break some distance out to sea, and would then roll in one after the other, in broken foam; no large breaker, preserving its intregity to the very edge of the beach, could possibly exist under such circumstances. Secondly, the sandy bottom would be stirred up by the action of the waves, and the colour of the breakers would be brown. Yet to follow nature in these two details would mar the "effect" of the picture, and, as a natural sequel, nature and the law of fluxions are made subservient to the requirement of art.—*The Field.*

ADVICE TO INEXPERIENCED PHOTOGRAPHERS.—Mr. E. H. Train, of Montana, in the *Phil. Phot.*, gives some advice and directions of a thoroughly practical character to some of his brethren less experienced than himself in the art of taking good negatives:—Arrange your dark room so that it can be kept cool in summer and warm in winter, and be well ventilated (for health). Learn your light, and get control of it so that you can get your lights and shades to fall to suit you, taking care that the light on the eye is right, and do not get a "blind light" over the pupil. Buy none but the best chemicals, of reliable dealers. Now take a gallon of distilled water (more if your bath dish will hold it, and it should not hold less); add nitrate of silver enough to make it thirty-five or forty grains to the ounce. When it is all dissolved, separate one-third from the rest and saturate the two-thirds with iodide of silver; filter well and pour back the other third; sun a day or two if you have time, or it will work without. Prepare your collodion after any good receipt. Next put four ounces of protosulphate of iron in a two-quart bottle, add sixty-four ounces of water, cork tightly, and lay it on the table or floor, where you can give it a roll semi-occasionally, and it will soon be dissolved; let it settle and filter off sixteen ounces, to which add one ounce of acetic acid No. 8, and just enough alcohol to make it flow (which will be very little at first, and more as the bath accumulates alcohol from the plates dipped), and you have a reliable developer. Now try a plate, and see if it works clear. If there is any fog add nitric acid, C. P., a little at a time, to your bath until it works well. The above is probably not the best formula in the world, but it is a thoroughly reliable one. Now your chemicals are all right place your sitter so that his pose looks easy and graceful on the ground-glass (pay no attention to anything else). Slide your head-rest up until it just steadies his head without changing its position; talk him into a good humour with himself and the world. Now "shoot your gun off," and if you do not get a good picture it is your own fault; if you do you can do the same thing every time, as long as the conditions remain the same. The next thing is to know where to look for trouble when trouble comes. I see that some writers (who, by the way, are fine artists, and have had much experience) say they always look for it in their collodion. With me, on the contrary, if the trouble is not in the temperature of the rooms or chemicals, in ninety-nine cases out of a hundred I find it in the bath. Heat causes various and sundry troubles and cold some, although it is not so much to be feared. In hot weather keep your bath, developer, and plate-holder cool. Immerse your plates with a very slow but even motion, and let as little time as may be elapse between the sensitising and developing of your plates, and you will have little trouble from this source. But, to return: the change in collodion is very slow and always in the same direction, and any sample that will work clear once ought to do so always, or at least for a long time. Of course it will lose sensitiveness with age, and will, from evaporation, grow thick in the bottle you pour from, but that is about all, while the change in the bath, particularly if it is a small one, may be rapid, from the foreign matter introduced with the plates. I know that a change of collodion will sometimes remove a difficulty for the time, when, if the bath was all right, both samples would work. To illustrate: I once left my gallery in Montana (it is a long way from any place) in charge of a friend for some time, and when I returned he complained that none of the cotton I left him would make collodion that would work, and he had to send to Philadelphia for some. He showed me several bottles he had made at different times and condemned. I told him that it ought not to be "thusly," so I renovated one of his baths, and went to work and produced excellent work with every sample of his condemned collodion. But for all this I do not want you to infer that I would advise you to be always doctoring your bath; on the contrary, having got it into good working order I recommend that you let it severely alone; put into it absolutely nothing but the cleanest of plates, and these only when necessary. Do not call in every paper by which to try your "kimicles" on; so long as it works satisfactorily do not change its quantity or quality. If a scum gathers on it skim with blotting- or filtering-paper; filter it only when necessary, and it should work for a long time. When, however, you do get into difficulty, be sure first that it is not caused by the temperature of your rooms or some similar cause, and that your collodion and developer are the same that have been giving good results; and then if a little more acid in your bath will not set you right I know no remedy but to renovate your bath by neutralising and boiling, and that is a remedy that has never failed me for twelve years. To be sure "that none go away dissatisfied" you should always have two or more baths in good working order; for it does not improve your reputation as an artist to tell people that your bath is not working well today, and they will have to come again. Usually they will come no more for ever. To albumenise plates, soak them for a few hours in dilute nitric acid, wash thoroughly, rinse with dish-water, and flow with albumen. While wet flow them with about one-fourth of an ounce of albumen to four ounces of distilled water. Letting your plates dry after they come out of the acid will make the albumen refuse to flow.

EXCHANGE COLUMN.

An extra-rapid *carte* lens by Squire, cost £7 7s., will be given in exchange for a landscape lens by a good maker.—Address, F. Wright, photographer, Northampton.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

PHOTO-MECHANICAL CORRESPONDENCE.

Hope.—Try the experiment. If you do not get the desired result you can hardly fail to learn something.

Lampblack.—The oil colours sold in tubes for the use of artists make excellent coloured inks for lithography; but as they usually dry rapidly clean your rollers immediately after use.

J. Carr.—The stone which you have been using is probably very porous, and thoroughly saturated with gum. Either prepare yourself for some hard work in grinding it down, or make an ink slab of it.

GENERAL CORRESPONDENCE.

F. C. S.—Of the two iodides that of magnesium is the more deliquescent.

W. H. Wright.—We have no means of knowing anything about the work to which you refer.

G. P.—We have not yet ascertained the address required. We shall send you a post card when we do so.

G. F. S.—The sulphuret and sulphide of silver are the same. The latter term is more generally employed.

Heaton Mersey.—1. The slight discolouration of the salt will not produce any deleterious effect.—2. Let the alcohol be made quite hot.

F. W. N.—So far as we can judge there is nothing in the colouring matter of the mount that will act injuriously upon the print.

F. L. S.—Let the organifier consist of an alkaline solution of gum arabic, sugar candy, and tannin, and you will obtain all the rapidity required.

Bargo.—By the addition of more kaolin the solution will rapidly become limpid and colourless. Shake well up previous to placing the bottle in the sun's rays.

"Client."—So far as we have been able to ascertain, the toning bath employed by the artist mentioned is the ordinary acetate bath, but care is taken not to carry the toning too far.

T. Smith.—As you obtain such uniform success when making use of the formula you enclose it is unwise to give it up in favour of something else, the nature of which is coquettish, to say the least.

Colonel Barclay.—It is difficult to account for the prints not toning, unless on the assumption of the sensitising bath being very acid, or of the paper having been excited on an old negative bath charged with iodide of silver.

A. B. Slater.—Let the water be boiled previous to its being used. This liberates carbonic acid, and the lime is deposited on the sides and bottom of the vessel in which it is boiled. It is this that causes boiled water to be "softer" than ordinary well water.

"Transparent," (and other querists).—No questions are answered in this department of the Journal unless they are accompanied by the name and address of of the correspondent, in addition to the initials or *nom-de-plume* under which he desire his answers to appear.

W. Weston.—Our correspondent has been employing gelatine emulsion from a sample of gelatine which cost only three shillings per pound, and with so much success as to have induced him to lay aside his silver bath In his estimation the drying, as regards its quickness or slowness, is not a factor in the production of blisters or frilling. We shall be glad to receive details of the process employed by our correspondent.

A Country Photo.—The posing of your *cartes* being very stiff, and the heads of your unhappy-looking sitters so very constrained in position, render it quite apparent that you do not use the head-rest as it ought to be used. Everything seems to indicate that you have first of all placed the head-rest in what was considered a good position, and that the head of the sitter has then been posed to suit the head-rest.

F. B. H.—1 The chief objection to the use of a portrait lens having a short focus consists in the necessity for placing the camera too near to the sitter, by which the projection or "drawing" of the figure is not so pleasing and harmonious as when the point of sight is at a greater distance.—2. The dimensions assumed by the image on the ground glass depend entirely upon the focus of the lens. The shorter the focus the smaller will be the scale of delineation, and *vice versâ*. See our Almanacs for 1870 and three following years.

Caution.—We are requested by Mr. S. S. Crewdson, of Union-street, Ulverston, to caution photographers against the blandishments of one of the fraternity who, having an abnormally "stiff leg" and professing to be an artist, has been obtaining photographs to colour. These he appears to be addicted to pledging, or otherwise disposing of in order to "raise the wind," preferably after having received payment in advance from those too-confiding photographers who entrust him with their money as well as their work.

An Operator.—There being no patent for the production of opal enlargements by the "camera" process, you are at liberty to practise it without any fear of hindrance. True, a patent did exist at one time, "but that was a long time ago"—certrinly over a quarter of a century.

T. M. F.—The *lichtdruck* process, by which works similar to your enclosed print was produced, has frequently been described in the pages of The British Journal of Photography, and also in several volumes of our Almanac. We cannot in this page go into such matters again.

M. A. B.—When ammonia is added to a nitrate of silver bath containing acetic acid, the precipitate that takes place is acetate of silver. The best method of treatment in such a case is to filter off the precipitate, and add a few crystals of nitrate of silver to make amends for the loss occasioned by the precipitation.

An Ardent Oldster.—1. The collodio-albumen process of Mr. R. M. Gordon has never yet been published—at least no such publication has been made in connection with the name of that gentleman.—2. The bromide emulsion and hot water processes may very easily be combined.—3. See our issue of August 22nd, 1873.

Ajax.—The invention appears to be one of a meritorious character; but whether it is of sufficient importance to be patented, or whether the patent would be valid, are matters upon which we must decline offering any opinion unless the proposed specification be placed before us, or at anyrate until the whole matter has been fully explained.

G. S. Sharpley.—Intense cold may be produced by mixing equal parts of nitrate of ammonia, carbonate of soda, and water. A simple solution of nitrate of ammonia in water (equal parts of each) will prove much more convenient than the foregoing, because the salt may easily be recovered by evaporation. This is much employed in India.

W. H. Langley.—The experiments appear to have been fairly conducted, and the degree of success obtained is quite encouraging. We cannot suggest any better method of procedure than that which you have adopted. By obtaining enamel tablets of a different kind of manufacture from those hitherto employed other and, perhaps, superior effects may be secured.

Geo. Davis.—The lens gives good definition on the ground glass, and the picture is as sharp all over the field as that given by any lens we have ever examined; but the over-correction for colour is so great that you will be compelled to rack out the lens to a considerable extent after focussing in order to get a sharply-defined image. The lens has been returned as directed.

Lethe.—The triple combination of lenses will certainly work when the central lens is removed; but the focus will be short, the field round, and the picture small. The central lens forms an essential element in the working of the combination, as it lengthens the focus, flattens the field, and to a certain extent equalises the illumination. From the foregoing you will be enabled to deduce an answer to your query.

Received.—T. G. Hemery, A. Ward, Alder and Clarke, and other correspondents. In our next..

Photographic Society of Great Britain.—The next meeting of this Society will take place on Tuesday next, the 10th instant, at 5a, Pall Mall East (the winter exhibition of the Water Colour Society being on view), when papers will be read by Mr. Henry Cooper on *An Emulsion Process*, and by Mr. Leon Warnerke on *A Case of the Destruction of the Latent Image on Washed Emulsion, and a Method of Revising the Same*; also, a practical demonstration of the working of his new platinum process, by Mr. William Willis, Jun.

OUR ALMANAC.—We once more venture to invite our readers to forward details of any unusual or interesting experiences in the various phases of photography which have occurred in the course of their practice during the past year, addressed to the Editor.——Our business friends who have not yet sent in their Advertisements are requested to do so before Monday, the 16th December. It should be remembered that *priority of position will be given to Advertisements according to the date at which each order reaches the Publisher.*

JOURNAL OF PHOTOGRAPHY.

No. 971. Vol. XXV.—DECEMBER 13, 1878.

ON THE ARTIFICIAL LIGHTING AND HEATING APPARATUS EMPLOYED IN THE DARK ROOM.

The attention of photographers, more especially those who work chiefly with dry plates, has been directed by Mr. W. H. Wilson's article in our last number to a hitherto unsuspected source of annoyance in the preparation of the sensitive film; and, from the systematic explanation of the facts given by the author of the paper in question, there seems to be every ground for looking with suspicion in the direction he indicates.

It is not only, however, in the production of spots that a careful survey of the facts connected with our lighting and heating arrangements will afford a prospect of trouble, as we shall point out in the course of our remarks; and, without denying the accuracy of Mr. Wilson's observations, we think we can discern the possibility of spots arising under the circumstances he mentions otherwise than by the disturbing influence of a strong current of hot air. The strength of the upward tendency of the column of air rising from a lamp chimney is very plainly exhibited by simply turning up the wick to such a point as to cause the flame to smoke badly, when the stream of unconsumed carbon will be seen to pass from the chimney, and will rise in a perpendicular column for some distance before it commences to diffuse itself into the surrounding atmosphere. There must, however, we should imagine, be something almost volcanic in its violence if its lateral and downward progress be sufficiently rapid and concentrated to cause so complete a disturbance of dust particles as that described; and we think at least a good portion of the result may be ascribed to different causes.

If we interpose a sheet of glass or metal or any cold substance, and arrest the rising column of smoke, we shall find a very rapid deposition of particles of unconsumed carbon or lampblack, and as the deposit increases in quantity it assumes the character of feathery flakes and tufts, which after a short time gather sufficient weight to detach themselves from their support and float away in the current of circulating air. Now, it seems more than probable to our minds that the same sort of action may go on, on a smaller scale, without the interposition of any arresting surface, and that the particles of carbon, when they reach a cooler atmosphere, or wander out of the influence of the heated current travelling in an upward direction, become subservient to the ordinary laws of gravity, and gradually subside, attaching themselves to any surface, sensitive or otherwise, which may present itself.

Then, again, the gradual accumulation of smoke and dust upon the ceiling or upper portion of the walls within reach of the ascending current is liable to dislodgment, and cannot fail to add its quota of annoyance. Yet, in spite of this, we are aware of many instances where a paraffine lamp is employed invariably without any unusual amount of trouble on the score of spots; but then the circumstances attending such employment differ from those which prevail in Mr. Wilson's case. Owing to the vastly-increased sensitiveness of modern dry plates it has been found necessary to get rid of all chances of fogging by extraneous light reflected from the ceiling or other parts of the room, and this is usually done by entirely enclosing the lamp or other source of light in a "lantern," or chamber, provided with suitable means of ventilation. Under such circumstances the solid products of combustion, if any, will be to a very large extent confined within the lantern, and the small portions which may escape will take such a direction as scarcely to present any danger of reaching the prepared films during coating. With the older form of collodio-bromide plate, which affords a comparatively low degree of sensitiveness, the small amount of reflected light coming from the unprotected chimney does not form a serious difficulty, though the arrangement may be dangerous in other ways.

Another phase of danger in connection with the ordinary modes of illumination is found in the accumulation of foul air arising from the combustion of the illuminating material, whether it be paraffine or gas; and there is no doubt that far too many dark rooms are but poorly provided with the necessary means of ventilation for the removal of the foul gases. Two or three hours' work (a by no means unusual period) in a close and badly-ventilated apartment, in which the products of combustion are afforded no adequate means of escape, will produce such an impure atmosphere as to be almost unbearable to the operator, and we can scarcely doubt its injurious action upon sensitive films long exposed to its influence.

In addition, moreover, to any chemical action it may have, the vitiated and heated atmosphere also produces trouble in connection with the physical character of the film, especially when an emulsion is employed. It will often be noticed, in preparing a number of plates, that the first few films will be even and free from structure, but gradually a strong tendency to irregular markings and mottling will be developed, apparently from the rapid evaporation of the solvents and consequent thickening of the collodion or emulsion. But this does not constitute the whole of the cause, as thinning the preparation with ether and alcohol will prove. It arises rather from the effect of the heated atmosphere upon the fluent properties of the collodion, or, rather upon its "setting" powers, by which the surface of the film that is exposed to the over-heated air sets more rapidly than the under portion, which is in contact with the comparatively cooler glass.

For these, no less than for hygienic reasons, the question of ventilation becomes one of paramount importance, and it can only be thoroughly met, we think, by so modifying the illuminating arrangements that the products of combustion are altogether excluded from the operating-room, and with such products will also be removed that oppressive "stuffiness," together with much of the heat, which render the preparation of dry plates too often so unpleasant.

We have said that the modification of existing arrangements is the only means of thoroughly meeting the evil, and for this reason:—Ventilation in its ordinary sense means a continuous and perfect circulation of air, and this, in turn, is scarcely separable from an equally continuous circulation of dust, if the ventilation is to be efficient. A continuous circulation of pure air free from dust particles may be a scientific possibility; but it is not practically within the reach of the amateur, or even the professional, photographer. It is, therefore, necessary to isolate the causes of the evil, and to treat them separately. By excluding the products of combustion altogether from the apartment we decrease the quantity of impure matter to be removed therefrom, and consequently lessen the necessity for so violent a circulation of dust-loaded air.

To many of our readers the carrying out of this suggested modification may perhaps present some serious difficulty, but such is not the case, all that is necessary being the removal of a single brick from the wall in order to open a communication by means of a small tube or pipe with the flue or with the open air. The diameter of the escape tube need not be large, as we have seen an arrangement of this description which worked admirably, and from which the heated products escaped through a half-inch gas tube. It follows also that if the position of the lantern cannot be so arranged as to secure direct communication with the flue, the current of hot air may be conducted along a leaden pipe fixed to the wall like an ordinary gas pipe; but this tube must be so fixed that the current may have a generally *ascending* direction until it makes its exit.

A convenient form of lantern consists of a square or oblong box of wood of suitable dimensions, glazed on one or more sides with ruby glass, and provided with a door by which communicate with the lamp inside. This is surmounted by an overlapping lid or cap of sheet iron, which fits, not too tightly, upon the upper portion of the woodwork, in such a manner as to permit the door to be opened while it is in position. If a gas flame be employed it will be well, especially if the lantern be of small dimensions, to give a considerable depth to this surmounting cap, in order to keep the lower portion of the lantern cool, and to prevent the glass cracking. A lantern one foot square on the base, and fifteen inches to the top of the woodwork, surmounted by a conical-shaped lid eight inches deep, will be found quite roomy enough to stand the heat of a large gas flame without any chance of fracturing the glass or igniting the woodwork, *provided the ventilation be sufficient*. For the inlet of fresh air a number of holes are bored in the bottom portion of the woodwork, and the escape pipe is, of course, fixed in the sheet-iron cap. To prevent any escape of light from the inlet holes a few short lengths of three-eighths lead piping, bent to a curve or "elbow," may be inserted, and will prove a cheap, easily fitted, and efficient means of effecting the object.

An arrangement of this sort will also combine the advantages of a drying stove for small plates, as by adding a shelf to the sides of the sheet-iron cone the plates may be reared up to dry against the heated metal, proper precautions being taken to prevent their touching in any part, which would probably lead to drying marks. If further provision be made for regulating the ingress of cold and the egress of hot air the temperature of the cone may also be considerably varied to suit the different requirements of a drying-stove; but if the lantern be required for lighting purposes only it will be advisable to keep it as cool as possible.

In conclusion: when it is absolutely necessary to employ artificial light, the erection of a contrivance such as we have described will be found to add most materially, not only to the comfort of working, but also to immunity from many dangers and inconveniences which arise from a badly-planned light; all extraneous actinic light is avoided, while noxious fumes and unnecessary heat are reduced to a minimum; and last, but not least, a second source of heat for drying purposes becomes, in many cases, quite unnecessary, and the whole affair may be constructed for a few shillings.

MR. HENRY COOPER'S "RELIABLE" PROCESS.

Such an amount of interest is attached to the collodio-bromide emulsion process that we believe many readers will thank us for giving even an epitome of the process described by Mr. Henry Cooper at the meeting of the Photographic Society of Great Britain held on Tuesday evening last. Such an outline we shall now present, premising that the paper will be published *in extenso* in our next number.

The process is, of course, a washed emulsion one, this being the leading feature in almost every dry process that is now being introduced; and, to prevent misconception, we state that we here employ the term "process" as synonymous with "modification." From the fact that Mr. Cooper has been an assiduous emulsion experimentalist during the past thirteen years, and from the further fact that he has produced numerous exquisite photographs by this process, the outcome of his experience will be received with profound respect.

A stock collodion is made by dissolving 160 grains of pyroxyline in ten ounces of ether and six ounces of alcohol. A stock bromide solution is also prepared by dissolving bromide of zinc in alcohol in the proportion of ten grains to each drachm.

When preparing ten ounces of emulsion, five ounces of the stock collodion are placed in a twenty-ounce bottle, to which are added an ounce of the bromide of zinc solution and twenty minims of syrupy lactate of ammonia. One hundred and fifty grains of nitrate of silver having been dissolved in eighty minims of water, three ounces of alcohol are added to dilute this solution, and the whole, having been heated to the boiling point, is added to the collodion, the temperature of which is kept at a moderate degree of heat for some time. In a period of time varying from twenty-four hours to three days, twenty minims of nitric acid are added. Having been well agitated the emulsion is poured out into a flat dish to set. When dry the pellicle thus prepared is dissolved in a mixture of five ounces of absolute alcohol and five ounces of ether, ·720.

On the method of preparing plates we need not here speak, merely observing that Mr. Cooper makes use of the gelatine substratum described by him a short time ago in this Journal.

The development is effected by an extremely weak solution of pyrogallic acid, commencing with a half-grain to a one-grain solution, with one drop of a ten-grain solution of bromide of ammonia and one drop of a saturated solution of carbonate of ammonia.

As we have already stated, the full details will be given next week, but, we have said sufficient at present to enable our readers to try the process, the proportions here given being believed to be quite accurate. Mr. Cooper lays great stress upon slow development, believing that in this is to be found the most important means of securing soft, delicate negatives, full of charming half-tones while possessing all the requisite printing vigour. Indeed, he expressly sounds a note of warning respecting the importance of avoiding too much intensity, which, he correctly thinks, is the cause of thousands of negatives being spoiled.

We shall have more to say regarding this subject after we have been enabled to peruse Mr. Cooper's paper.

VARIETIES OF TONE.

The use of the word "tone" in connection with the colour of photographs has now become so fixed that any attempt to substitute another term in its place would meet with but scant success. The employment, however, of critical terms—indeed, of any descriptive expressions whatever—should be rigidly guarded in order to prevent that loose, inexact mode of stating artistic truths which, by substituting mere verbiage for instruction, is so liable to clog the wheels of progress. The word "tone," however, as used by photographers, is applied in such a special sense that, though it may be regretted a more suitable one had not been selected, there is no fear of confusion when only the technical aspect of the process is in consideration.

It is, comparatively speaking, but a few years ago that the aim of most printers—when alkaline toning was fairly accepted—was to get a rich black or purple black, and, concurrent with white skies, it was the prevailing tone of most pictures exhibited. The formula as first published may have had something to do with this; but, be that as it may, most of the warmer-toned pictures then seen were the products of old toning and fixing baths, still not entirely banished. After a time this purple tone, to some extent, was talked and written down, and a warmer one aimed at by many workers of the day; not in the sense of suitability for particular cases, but rather as a panacea—a sort of process, fine-art by rule—a given tone to be obtained and artistic excellence to follow at once. This is the bane of photography in a multitude of instances. Instead of thoughtful adaptation of known rules, in combination with the application of the ever-increasing store of new facts and new processes, the tendency is to seize hold of a new process and work it entirely to the exclusion of the old, which has so much of good in it, in the expectation that, by the use of a new formula, process, or secret, a high standard of excellence will be obtained, but which never can result, and never will, except from culture and experience, helped, it may be, we will not deny, by new inventions and methods of manipulation.

A marked and very gratifying change has, however, taken place of late, thanks, perhaps, to the aid of journalistic criticism and the presence of more cultivated minds among the rank and file of photographic workers; and now a glance at any large collection of photographs will show a great and pleasing variety in this quality of such work.

An attentive frequenter of exhibitions will, however, note two allied points in their connection—the increase of variety of tone in the works as a whole, and the adhesion to particular tones by the several workers. While character is thus given to a series and their individuality emphasised, there may be thought to be a danger of reverting to a specific process to entail artistic effect; but we think a closer examination would show that in few cases could the actual tone obtained be improved upon by the substitution of another, and for the explanation of this apparent contradiction to the scope of our remarks we must look not to the results but to the means. We think it will be found that, possessing a fancy for an especial tone, the artist has bent his means to that end. He has had in view, in mixing his solutions, selecting his paper and the formula for using it, and, above all, in taking his negative, the ultimate tone he wished to obtain, and made everything work in accordance. But, even then, it will be found that by high-class workers there are cases where the selected tone has been departed from when a particular effect has been desired.

Thus, in the so-called "Rembrandt" pictures—another improperly-used expression—nearly every printer eschews the use of a cold tone; for, unless negatives and everything in connection is in a state of perfect excellence and accordance, cold pictures with heavy-looking shadows predominate. So in all pictures couched in a dark key will warmer tones be found more desirable, the shadows especially being then so much more transparent. A cool, purplish-grey, on the contrary, is very suitable for delicate, light-looking subjects possessing but a small amount of dark points. Children in light dresses, busts of fair women with light drapery, and cognate subjects lend themselves in a delightful manner to this kind of treatment, and more particularly on a small scale.

On a large scale a greater variety of treatment of all styles is allowable. The wonderfully-beautiful studies in red, by Faulkner, are doubtless familiar to all our readers. This is, however, such a bold flight that we would not recommend it for imitation to any but a master, for this tone adapted to a pretentious portrait with no other qualities to recommend it would be *bizarre* and laughable. Thanks to the facilities which autotype printing offers there is now no practical limit to the tone obtainable; but this point will fall more particularly under the head of the technical means of varying the tone, which will be treated of in our next number.

RECENT PATENTS.

No. XXVI.—TYPOGRAPHICAL ETCHED PLATES.

This invention is the joint outcome of Messrs. Capron, Duvivier, and Ponsolle, all of Paris. It is entitled "Certain Improvements in the Production of Typographical Etched Plates Reproducing Photographs from Nature or from Copy," and is described in the following specification:—

This invention relates to an improved process for obtaining typographic plates, reproducing photographs from nature, or from copies, with their mezzotints.

In carrying out this invention we proceed in the following manner:—We prepare, by the application of a layer or coating of the composition hereinafter described, a metal glass or ceramic plate, which, under the action of the light, receives the impression of a photographic plate; the image thus obtained transferred to the metal or other plate, as before mentioned, is submitted to the action of acids according to one of the usual and well-known processes, and the plate is then ready for printing.

The layer or coating hereinbefore referred to is composed of the following ingredients or others possessing equivalent properties in about the under-mentioned proportions, which may, however, be varied according to circumstances, and it is prepared in the following manner:—We steep in a porcelain or other vessel fifteen parts by weight of ambergelatine, three parts by weight of loaf sugar, and 125 parts by weight of distilled water; and we introduce into another vessel, composed, by preference, of glazed fireproof ware, three parts by weight of isinglass (first quality), and 175 parts by weight of distilled water. These two solutions are allowed to stand for (say) from ten to twenty hours in an atmosphere of a temperature of (say) about 3° Centigrade, after which the isinglass is boiled (whilst being kept stirred) on an open wood charcoal fire for (say) about twenty minutes, and placed aside, and the gelatine is dissolved with a water bath at a temperature as low as possible. To the gelatine solution is then added about four parts by weight of bichromate of potash, the mixture being well stirred in order to accelerate the solution and prevent cooling. The solution thus obtained is then added, whilst being stirred, to the isinglass solution in its vessel, and the whole is filtered through suitable flannel free from traces of soap, care being taken to accelerate the filtration by pressing the flannel, in order to cause the thickess portion of the composition to pass. This operation is performed over a glass having a spout or lip, and the mixture is then poured over an unpolished plate of copper, zinc, or plate glass.

The plate employed should be slightly warmed before the mixture is applied, and afterwards laid flat upon a marble in a stove maintained for about three hours at a temperature of (say) about 40° Centigrade, after which, when cooled, it may receive an impression by the action of light behind a photographic plate.

The process is then continued as for ordinary printing with fatty ink upon gelatine, employing transfer ink and transfer paper. The image obtained is then to be transferred to a plate of zinc, for example, and bitten in.

The grain obtained by means of this process enables a plate to be produced suitable for typographic printing.

The place in which all the hereinbefore described operations are to be performed must be maintained at a uniform temperature of (say) from about 25° to 30° Centigrade.

We are glad to find that the patentees had the good sense not to carry their invention beyond the provisional stage. Had they done so it would have been our duty to have indicated the number of times (if that were possible) the process has been brought before the readers of this Journal and the public at large.

M. Ernest Boivin has just completed in the *Moniteur* a series of articles upon gelatino-bromide which do not present any features of novelty for English readers. In the last number, however, he speaks of various physical defects in the gelatine film, and the methods of obviating them. Frilling of the edges, which he attributes to the use of unsuitable water for dissolving the pellicle, too slow drying of the film or over-heating of the emulsion or glass before coating, is cured in the first case by the addition of slight traces of alum or Epsom salts to the water employed (we presume) in moistening the film before development; in the other cases by removing the inducing cause. He further states that *ordinary* water only should be employed, distilled or rain water leading to failure. Blisters are prevented by adding "a few drops of solution of chrome alum" to the emulsion, or traces of tannin or alum to water used to soak the film before development. As regards the chrome-alum treatment the particulars are surprisingly vague; but it is possible that this very vagueness may account for the supposed advantage; or, in other words, that by using a sufficiently weak solution of chrome alum and a sufficiently limited number of drops no ill effect may accrue, while the faith of the operator leads him to imagine a beneficial action. In the course of a few experiments in this direction made some time ago we found that, if a sufficient proportion of chrome alum were used to produce an appreciable effect upon the solubility of the film after once drying, it was almost impossible to work the emulsion owing to the tendency to become lumpy, if not actually to gelatinise, unless the temperature were kept dangerously high for the production of perfect films in other respects; and that once developed this fault was irremediable. Infinitesimal proportions of the chrome alum, while not interfering with the fluidity of the emulsion nor with its solubility after gelatinisation or desiccation, worked most injuriously upon the structural character of films prepared from an emulsion which had been allowed to solidify and were re-liquefied by heat. Though the gelatine became perfectly fluid, the emulsion appeared to conglomerate into minute clots, which contributed a decidedly objectionable grain to the film when dried upon glass. For this reason we think the use of chrome alum is to be deprecated, except when facilities exist for preserving the emulsion at an uniform and sufficiently high temperature to retain it in a fluid state for any desired period, or where it is the practice to work up the whole quantity in one operation without permitting it to solidify.

RAISING THE FRONT OF THE CAMERA.

At last year's Technical Meeting of the South London Photographic Society I exhibited a camera having a movable front for raising the lens, and pointed out its many capabilities. As the makers of cameras have not taken advantage of the plan, I conceive it was not sufficiently seen at the meeting to be properly appreciated.

The invention is not my own, so I may therefore be excused for saying that it is, in my opinion, the very best method of raising the lens at present known. I enclose a small model, in case you should think it worth preparing from it a woodcut for your forthcoming Almanac.

Cameras are very frequently made square—thereby increasing considerably both bulk and weight—simply for the reason that when placed on their ends there is no method of raising the lens, and it is in that position it is most generally required for taking towers, steeples, and other lofty buildings. The fixed camera front has an aperture of the shape shown to enable the lens to traverse perpendicularly or horizontally, and two fixed screw bolts which pass through the L-shaped slots in the movable front carrying the lens, and which is fixed *in situ* by means of milled nuts.

I should not have brought forward this contrivance a second time, but it is really so simple and effectual that I should suppose no one who had ever tried it would think of adopting any other plan.

Baynham Jones.

ON THE RECTIFICATION OF SILVER BATHS, AND OTHER SUBJECTS.

[A communication to the South London Photographic Society.]

In the *Pharmaceutical Journal* of September 21 there is a paper, by Mr. W. C. Stables, treating upon permanganate of potash as a water purifier, and proceeding to point out that, although permanganate was very useful in getting rid of many organic compounds in water, its influence upon albumenoid compound was *nil*, and recommending hydrate of potassa as well as permanganate to purify water containing albumen.

Now, as it is very desirable in silver printing to keep the sensitising bath clean and as free as possible from albumen and other organic matter, I concluded to try the effect of Mr. Stables' solution upon my printing bath, and am much pleased with the results, the bath working like a new one after each clearing.

Having a small quantity of negative bath that would not work and an hour or two to spare I tried Mr. Stables' solution on it, and again met with success—such success, indeed, that when my working baths are in want of the "doctor" they have a dose of the following solution:—

Permanganate of potash	1 ounce.
Hydrate of potash	4 ounces.
Distilled water....................................	100 „

The application is the same as plain permanganate, viz., add until the colour is a permanent one.

What the reactions are I, of course, am not in a position to say, but if any photographer will kindly look up the article in the *Pharmaceutical Journal*, and give us the reactions, I as well as others will be grateful.

I have mentioned above some negative bath that would not work. Now that bath has been the cause of a great deal of anxiety to me and some loss of time. It was a new, specially-made bath for clouds and other pictures, and of course worked splendidly at first; but in a day or two *fog* set in, and the bath was neutralised, strengthened, and after the addition of a little acid was again in good working order. After the trial plate I could not use the bath for a fortnight on account of bad weather; judge, then, my surprise when, again trying a plate, I secured black, dirty, foggy pictures, instead of nice, clean ones as before. This was repeated twice more; then I thought something must be wrong, and at last pitched upon my ebonite dipper, which, although perfect below the water line, had the smooth skin peeled off above, and in my outdoor bath this bare part was below the solution when the top was screwed on, consequently the bath was fouled. The dipper was banished and the bath kept for experiment, as nothing seemed to make it come right until the present time, when it is working splendidly.

I myself shall not very likely have to use the solution again for the bath (except only for the purification of the water), as it is very seldom indeed my bath gets out of order sufficiently to require anything except *cyanide* and *sunning*, so I should like to hear from some one else how it works.

From the bath to the developer is but a natural step, and I again reiterate my partiality for collocine instead of acetic acid. I have tried experiments without number, but the result has always been the best from collocine. W. T. Wilkinson (Colombo).

NOTES ON PASSING EVENTS.*

By a Peripatetic Photographer.

Observing that the subject of the blistering of prints has been recently introduced upon several occasions, I beg to place on record a method of printing which gives immunity from this trouble—if one may be permitted to make such a bold statement on the strength of a trial of a few days. It consists in rinsing out the free nitrate of silver from the albumenised sheet, and subsequently sprinkling a little carbonate of ammonia over the pads of the printing-frame. This method of preparing paper for printing is already well known to the older and more experienced photographers; but my object in treating of it at present is to direct attention to the fact that a sample of paper addicted to blistering, when sensitised and made use of in the usual way, was quite free from this tendency after it had been subjected to the foregoing treatment. The method in detail is as follows:—After sensitising the paper the usual time draw it over the edge of the flat bath to get rid of as much silver solution as possible, and then float it upon a second bath containing water only, by which the bulk of the nitrate will be diluted and removed. It is then dried, and in this state it will retain its whiteness and purity for several weeks. To use it, all that is necessary is to impregnate the pads of the printing-frame with the vapour of ammonia. This may be done either by sprinkling a little ammonia (in the form of spray) upon the pads, by dusting over their backs a small pinch of carbonate of ammonia, or by placing the pads previous to their being put in use for the day in a close vessel or drawer containing ammoniacal fumes. Prints obtained upon paper thus prepared are very vigorous, and they tone to a rich colour.

The name of William H. Rulofson, of San Francisco, is well known all over the world, and photographers will hear of his sudden death with emotion. He lost his life by falling from the wall of his studio into the street below—a height of fifty-five feet. He was an artist of great taste and general ability, the business over which he presided being large and flourishing at the time of the sad and fatal accident.

Are photographers aware that the electric light can be produced without either a steam or a gas engine? Yet such is the case. It has been found that by the aid of a large flywheel, which can easily be driven by one man, a degree of rapidity and power can be obtained quite sufficient for utilisation in the production of the electric light. A large "machine" requires, of course, a powerful motor; but a machine of moderate power will suffice for the requirements of the photographer who desires to make use of it either in the production of portraits or enlargements. I am aware of a machine of this kind having been constructed by an amateur mechanician, and it answers well. What is now wanted is a machine of similar power, that can be obtained in the usual course of business at a moderate price—say for forty or fifty pounds, all complete.

Personal.—I, the "Peripatetic Photographer," feeling myself becoming lazy, have petitioned my good friends the Editors of this Journal to suspend the publication of these "Notes on Passing Events," which, with the exception of two paragraphs, have been regularly contributed by me every month during the past eleven and a-half years. The Editors permit me to be their mouthpiece on this occasion in informing the numerous readers of this Journal that these "Notes" by the "Peripatetic Photographer" will, with the commencement of the forthcoming volume for 1879, be succeeded by *Notes on Men and Things*, which will appear, with as much regularity as possible, on the first and third weeks of each month. Whether I "turn up" again under any other *nom-de-plume* or not is a matter of little concern at present; but as the "*Peripatetic Photographer*" I now take leave of numerous readers and many friends to whom in my assumed name I have not been unknown. I have only further

* Concluded from page 581.

to say that in these "Notes," while I have never omitted handling in the freest possible way such subjects as in my estimation deserved a little "touching up," I have ever endeavoured to do so in such a manner as to leave no sting of a personal nature behind. How far I have succeeded in doing so the readers can judge for themselves. It only now remains for me to say—*Farewell*, and subscribe myself, THE PERIPATETIC PHOTOGRAPHER.

NOTES FROM AMERICA.

KENT'S HAND-SCREEN.—RETOUCHING.

IN the *Philadelphia Photographer* Mr. E. J. Hough describes a visit paid by him to Mr. Kent, of Rochester, N.Y. He says:—

The point of most interest for me was his use of the celebrated "hand-screen." I saw him make five positions, using the hand-screen, as I understand he does with every subject for bust portraits, and in neither case did the movement of the screen over the sitters' heads exceed ten or twelve inches—just enough to slightly modify the toplight, shutting out or letting in a little more or less on either side. My misconception of its use was almost as great as that of the editor of an English journal who, in a recent article, described Mr. Kent as swinging his screen around his sitters' heads in a style quite likely to make them frightened and nervous. In speaking of how little its use was understood, I asked Mr. Kent if he had read the English editor's article. He said "Yes," laughingly, "and he must think I use it something like a windmill." I think the prevailing idea of it is something about as vague and wild, while in fact it is only a more convenient and controllable form of the old stationary head-screen; and the advantages sought and attained by its use are precisely the same—shutting out sharp high lights, and giving a softened and diffused effect to the light. Yet Mr. Kent's pictures have none of the flat look of pictures taken under an umbrella; they are full of detail in the lights and very transparent in the well-defined shadows. Mr. Kent makes his bust pictures mostly under the light, working the camera all round the room looking towards that centre. Four out of the five sittings I saw were made with the camera nearly facing the side light, the subjects sitting with their backs to the light, or nearly so. The side light was quite heavily screened although the day was cloudy, being covered up two-thirds its height with both white tissue-paper and white muslin. The exposures were somewhat prolonged—from thirty to forty seconds—with what must have been very sensitive plates, for the light was very subdued; yet the negatives were vigorous and full of printing quality. The hand-screen used was a thin, white muslin, about two feet at the widest, stretched over an egg- or pear-shaped willow hoop at the end of a light pole, about the length and weight of an ordinary jointed bass fishing-rod; in fact, I am now using my rod in that way, and it answers admirably. Having used it since my return to business I can confidently affirm that it is a very handy and useful implement for general use under the light, and almost indispensable for the best class of Rembrandtish effects. Its cost is almost nothing, and any one can make it; facility of using it is easily acquired, and the right to use it has, I believe, been freely given. I would, therefore, candidly advise every photographer who wants to increase his power of controlling the light to make one and try it.

Mr. E. H. Train, of Montana, in the same journal, makes the following observations on retouching:—

Now, we can make good negatives; but about retouching—"aye, there's the rub!" That takes long and careful practice to do it well; but a few hints may not be amiss here. Round up and smooth your negative nicely, being very careful always to preserve but beautify the likeness. Soften and blend, but do not obliterate, your shades. Look to the end of the nose. It usually wants some retouching, and is often overlooked; also to the eye, but here you must be very careful. In all your retouching strive to make it so fine that your prints do not show it.

ON PROCESSES OF MAP PRODUCTION BY PHOTOGRAPHY.*

PHOTOGRAPHIC ENGRAVING.

THE earliest practical process of photography was a method of photographic engraving invented by Nicéphore Niepce, and since his time nearly every great improvement in photography has been applied to this object. Thus, no sooner was the daguerreotype invented than essays were made by Fizeau, Donné, and others to engrave the images produced on the metal plates. In like manner the earliest application of the peculiar action of the alkaline bichromates upon colloid substances was Fox Talbot's photoglyptic process, which was soon followed by the photogalvanographic and helioplastic processes of Pretsch and Poitevin. Engraving processes have also been based upon Swan's pigment-printing process, the Woodburytype, and the collotype. With the exception, perhaps, of the second, all these methods, from the earliest to the latest, are in use at the present time in a more or less modified form.

* Continued from page 547.

The object of engraving maps upon copper is to obtain a plate taking but little storage room, and not liable to break, which shall yield a large number of impressions of uniform quality, and, with due precautions, be capable of being preserved in a good condition for printing during any length of time.

Copperplates have the further advantage that they may be multiplied to any extent by electrotyping, and corrections may be made when required, either on the original plate or on the electrotyped matrix or copy. Transfers may also be made from them to stone or zinc, and printed in the same way as ordinary lithographs. This procedure is specially applicable when very large numbers are required or when the subject is to be printed in colours.

Besides these more practical advantages, the superior beauty and finish of copperplate engraving give it the preference for all maps of a permanent or standard character.

With these objects in view nearly every civilised nation has at least one engraved map giving the results of the state surveys on a convenient scale for general use. For the same reasons map-publishers generally engrave the maps composing their atlases and other standard publications.

Notwithstanding its many advantages copperplate engraving is a very slow process and is also expensive, because the art of the engraver is one requiring great artistic and manipulative skill, only to be fully acquired by an almost life-long apprenticeship. Map-engraving, it is true, does not require so high a degree of artistic skill as line or aquatint engraving, but it nevertheless requires a long training, parcicularly in the more difficult branch of hill-etching, which demands almost as much skill to produce first-rate results as ordinary line-engraving.

Although the advantages of photographic engraving as a means of avoiding the long and costly labour of engraving maps by hand are obvious, for various reasons these processes have not yet come into general use. A successful commencement has, however, been made by the Italian and Austrian governments of employing photography in the production of their engraved maps, and there is little doubt that before long photographic engraving will be more extensively used for this purpose than it is at present, especially as processes are now available by which gradation of shade may be obtained without difficulty, and the expensive hand-work of the engraver in biting in or finishing may to a great extent be dispensed with.

The processes of photographic engraving that have been proposed from time to time for producing incised images on metal plates capable of being printed in the copperplate press are very numerous. I shall, however, confine myself to those which have been most successfully worked, and of which the details have been more or less fully published. Further information on the subject will be found in the special works referred to in the footnotes, and also in Hammann's *Des Arts Graphiques Destinés à Multiplier par l'Impression*, and A. Martin's *Handbuch der Email-photographie und der Phototypie order des Lichtdruckes*, which both give very complete *résumés* of the early progress in this branch of photography, with details of many of the processes. The photographic journals and the Patent Office records may also be consulted.

The principal methods of obtaining an incised image on a metal plate by means of photography are—

1. Obtaining a photographic image on a metal plate coated with asphaltum and then etching or "biting in" with acid.
2. Obtaining a photographic image in gelatine on a metal plate, and etching the latter with some substance that will not attack the gelatine.
3. Obtaining an image by the direct action of light on a metal plate, as in the daguerreotype process, then forming a metallic reserve to protect either the lights or shadows of the image, and etching with a suitable mordant.
4. Electrotyping from a relief obtained by the swelling or partial solution of a chromated gelatine film, either directly or by the intervention of a cast in wax or plaster.
5. Electrotyping from a relief in insoluble gelatine obtained in the same way as in the autotype or pigment-printing process.
6. Electrotyping from a leaden plate on which an image has been impressed from a gelatine relief, as in the Woodburytype process.
7. Electrotyping from a relief obtained directly on a collodion positive *cliché*.

It will be seen that these methods divide themselves into two principal groups of etching and electrotyping processes.

Etching Processes with Asphaltum.—We have already seen that Niepce, in his experiments to find a substitute for lithography, made use of the property possessed by bitumen of Judæa, or asphaltum, of becoming insoluble in oil of lavender and other solvents, after exposure to the action of light, to obtain photographic images on metal plates, which were then bitten in with acid, so as to form engraved plates, usually copies of engravings, though he also obtained images from nature.

Owing to the imperfection of photographic appliances in those early days of the art, the results obtained by Niepce could not have been very satisfactory; but with better appliances the same process has yielded in the hands of Niepce de St. Victor, the nephew of the inventor, Amand Durand, and others, results which prove its practicability and its capabilities for reproducing images direct from nature or for copying fine line engravings and similar subjects, for which latter it is much better adapted.*

A process on this principle has been very successfully used at the Imperial State Printing Office, Berlin, for the engraving of plates for bank notes and other purposes, and I have also tried it myself with fair success.

The following outline will give an idea of the operations:†—A perfectly smooth copperplate, having been thoroughly cleaned, and polished is coated with a solution of asphaltum in turpentine, to which a little oil of lemon is added. It is then carefully dried in the dark, so as to preserve an even coating, free from dust.

The image may be impressed upon the sensitive surface by sunprinting through an ordinary negative on glass; but as there is by this plan great risk of losing perfect sharpness by want of close contact between the glass and the copperplate, it is better to remove the collodion film from the negative and transfer it on to the surface of the asphaltum, so that it may be in absolute contact with it all over, and thus secure the utmost possible sharpness of the image. The collodion film is loosened from the glass in an acid bath, containing one part each of sulphuric and acetic acids in 320 parts of water, and the transfer is then effected in a bath of one part of glycerine and four parts of water. The transferred film being dry, the plate is ready to be exposed to light, and as the asphaltum is not very sensitive the exposure is somewhat long—extending from six to thirty-six hours; but it is better to over-expose and to work in diffused daylight rather than in the full sunshine.

When the plate is judged to have been sufficiently exposed, the collodion film is removed and the asphaltum surface is rubbed lightly with a tuft of cotton dipped in olive oil, to which after a short time a little turpentine is added. The image gradually begins to appear, and by degrees the unaltered asphaltum is all removed, so that the design appears in clear brown upon the polished copper. The plate is then washed with soap and water and allowed to dry.

The next operation is the etching or biting-in of the image. The back of the plate having been well coated with a thick varnish of asphaltum, to protect it from the action of the acid, the plate is plunged into a trough containing a mixture of one part of chlorate of potash, ten parts of muriatic acid, and forty-eight parts of water, and allowed to remain till the weakest lines of the drawing begin to appear. It is then well washed and the asphaltum covering the lines is removed with benzole. The design will now be seen standing in a slight relief, and an electrotype must be made in order to obtain a printing-plate, from which impressions may be taken in the ordinary way. The sharpness of the lines is better preserved by making a relief and electrotyping than it would be by biting-in.

The best results by this process are obtained from subjects in line, and even with these the operation of biting-in demands a little manipulative skill. Good results have, however, been obtained in reproducing half-tone subjects, but they require the greatest skill on the part of the operator, and generally much retouching by a practised engraver.

Etching Processes with Gelatine.—In 1852, Mr. Henry Fox Talbot brought forward a method of photographic engraving called "photoglyphy," which is of some interest as being the first practical photographic process founded on Ponton's discovery of the decomposition of bichromate of potash in contact with organic matter under the influence of light. Talbot found that by the action of light a dried film of gelatine mixed with an alkaline bichromate became impermeable to certain fluids in proportion to the intensity of the action of the light upon it. He coated steel plates with a thin film of gelatine and bichromate of potash, and after exposure to the light under a photographic positive he etched the image so produced with a solution of bichloride of platinum, which, penetrating the unaltered gelatine in the parts protected from the light and attacking the underlying metal, produced the shadows of the resulting picture. Some very promosing results were obtained in this manner, and great expectations were entertained of its utility in producing engraved plates for book illustration and other purposes. These hopes, however, have not been fulfilled, and the process, though remarkable as the first of the many valuable methods of photographic press-printing dependent on the use of gelatine and the alkaline bichromates, has inherent defects and difficulties which seem to render it of little practical value.‡

M. Baldus has successfully employed a modification of the photoglyphic process for line work.§ He coats a copperplate with gelatine and bichromate and exposes it under a negative or a positive, then etches in a solution of perchloride of iron, which attacks the copper in all the parts not acted upon by the light, and thus a first relief is obtained. As this relief is not sufficient, the plate is inked in with a printing roller, when the ink attaches itself to the parts in relief and protects them from the action of the etching liquid. This procedure is repeated till the desired effect is produced. If a negative be used an incised plate is obtained, which may be printed in the copperplate press. If a positive be used the image is in relief and suitable for being printed with type. I have found that the reliefs obtained in this way are exceedingly sharp, though the gelatine films will not stand the action of the etching fluid very long.

Messrs. Leitch and Co., of London, have lately introduced a similar process, called by them "photogravure." It appears to be due to M. Garnier, who has had great experience in these processes, and produced some very fine results. The method of working is a secret, but it is said that a metal plate is coated with a sensitive composition capable of resisting the action of acids. The photographic image is impressed on the sensitive surface through a negative, and is then etched with perchloride of iron. The etching is said to be to a certain extent automatic; that is to say, the etching action on the lines ceases at different periods in proportion to their fineness.

J. WATERHOUSE, *Capt.*

(To be continued.)

† Full details will be found in my *Report on the Cartographic Applications of Photography*, p. 79.

‡ A full description of Talbot's process, with specimens, will be found in the appendix to the English translation of Tissandier's *History and Handbook of Photography*, edited by J. Thomson.

§ See the above work, p. 207.

IMPORTANT LAW CASE.—DECISION.

THE nature of this suit, brought by Simon Wing, Albert S. Southworth, and Marcus Ormsbee, against Edward Anthony, Henry T. Anthony, and Vincent M. Wilcox, will be ascertained from the following:—

This suit is brought upon re-issued letters patent, No. 1,049, dated September 25th, 1860, to Albert S. Southworth, for "certain improvements in taking photographic impressions." The validity of this re-issued patent is denied for want of novelty in the original, and because it is for a different invention from that in the original. Infringement is also denied.

The patent has been held to be valid by Mr. Justice Clifford in Wing *v.* Richardson, 3 Fisher, 535, by Blanchford, J., following that decision as an authority, in Ormsbee *v.* Wood, 3 Fisher, 372, and by Shepley, J., in Wing *v.* Dunshee, district of Massachusetts, without delivering any opinion. And it has been held to be invalid by Mr. Justice Nelson in Wing *v.* Schoonmaker, 3 Fisher, 607, and by Withey, J., in Wing *v.* Tompkins, western district of Michigan. The decree of Mr. Justice Nelson was affirmed by the supreme court, equally divided, on appeal. It is understood that this decision of the supreme court was accompanied by a statement showing the manner in which it was made, that the question might be left open in other cases, and that decision did not appear to be an authority upon it either way. Durant *v.* Essex Company, 7 Wall, 107. In this state of the decisions upon this patent it seems necessary to examine this case in the light of the evidence in it and such recognised principles of law as appear to be applicable, however much easier and pleasanter it might be to follow implicitly one or the other of these decisions.

In the specification of the original patent the inventor said that the object of his invention was "to bring in rapid succession different parts of the same plate, or different plates of whatsoever material prepared for photographic purposes, into the centre of the field of the lens, for the purpose of either timing them differently, that the most perfect may be selected, or of taking different views of the same object with the least delay possible, or of taking stereoscopic pictures upon the same or different plates with one camera." That it consisted "of a peculiarly-arranged frame in which the plate-holder" was "permitted to slide, by which means" he was "enabled to take four daguerreotypes upon one plate and at one sitting, different portions of the plate being brought successively opposite an opening in the frame, the opening remaining stationary in the axis of the camera while the plate-holder and plate are moved." He then described the construction of the plate-holder by which a smaller frame holding the plate could be readily moved into and held in the four corners of a larger one, during the required space of time, by an ingeniously-constructed guide-piece designated L, and then stated that the "guide-piece, L, or some equivalent thereof is absolutely essential, as the attempt to hold the block, I," by which the smaller plate was moved, "by hand would shake the camera or move it from its normal position whilst the picture was being taken." The claim was for "the within-described plate-holder in combination with the frame in which it moves, constructed and operating in the manner and for the purpose substantially as herein set forth." In the specification of the re-issue the inventor stated that, in carrying out his invention, he had "made use of a peculiarly-arranged frame in which the plate-holder is permitted to slide, and in which the position of the plate holder is definitely indicated to the operator so that he can quickly and accurately adjust the plate or plates, and described the mechanism and construction substantially as in the original, and making the same statement as to the guide-piece being absolutely essential, and added—"It is evident that my improvement may be embodied by causing the lens of the camera to be made adjustable in different positions with respect to the plate while the plate remains stationary, so that different portions of the plate may be brought into the field of the lens. This I have tried, but do not consider it practically so good a plan as the foregoing, as it necessitates a change of the position of the camera itself or of the objects."

The claim was :—"What I claim as my invention and desire to secure by letters patent, is bringing the different portions of a single plate, or several smaller plates, successively into the field of the lens of the camera substantially in the manner and for the purpose specified."

It is quite obvious that the original patent was for the plate-holder of a camera, in its peculiar construction with its peculiar mechanism, and not for anything more. There was nothing whatever in it about moving the lens of the camera, or making it adjustable in different positions in respect to the plate, in order to accomplish the purposes of the invention. In the re-issue there are no means whatever described for adjustng the lens in different positions in respect to the plate, with the plate stationary, to bring different portions of the plate successively into the field of the lens. It is argued that bringing this subject of moving the lens into the re-issue constitutes a different invention from that in the original. If the mere statement here that it was evident that this might be done, without stating at all how, could be said to specify any manner of doing it, then the claim would include that manner, and the invention sought to be covered, as to so much, would be for what was not in the original, and essentially different from that, and the patent would be void. (Seymour *v.* Osborn, 11, Wall, 544); but whatever may have been intended by putting it in, this statement is not of anything essential to the invention, otherwise described, and describes nothing amounting to an invention by itself. It is not definite enough, so that it can fairly be said to add to or vary that with which it is put. It is said Mr. Justice Field, in Russell *v.* Dodge, 93, U.S. 460, that where a useful result is produced in any art, manufacture, or composition of matter by the use of certain means for which the inventor or discoverer obtains a patent, it is too plain for argument that the means described must be the essential and absolutely necessary means, and not mere adjuncts which may be used or abandoned at pleasure.

If the claim was for bringing different portions of plates successively into the field of the lens, without regard to the means by which it was done, as the central part of the film is mentioned in the original and not in the re-issue, the invention sought to be covered by the re-issue would then be broader than that in the original, and void, as that in Russell *v.* Dodge was held to be. But that does not seem to be the true construction of the claim. It is for so bringing the different portions of the plate into that field "substantially in the manner and for the purpose specified."

This is the same as if it had been for the manner or means specified of accomplishing that result, and it is for the means and not for the result. The means described must always bring the portions of the plates to be used into the central and best part of the field of the lens, the same as when described in the original; so that, in effect and in fact, the invention specified in the re-issue is the same as that specified in the original.

In taking pictures with a camera—theoretically, at least, and practically to a useful extent—probably the best are taken in the central portions of the field of the lens. If several are taken on the same plate they must be successively so taken in order to obtain the best results. This patentee may have discovered that they could be so taken, and would be better when so taken; but if he did, neither that principle nor the mere taking them so would be patentable, Boulton *v.* Bull, 2 H, Black, 463; Hornblower *v.* Boulton; 8 T. R. 95; Le Roy *v.* Tatham, 14 How. 166; O'Reilly *v.* Morse, 15 How. 62, although if the view of Mr. Justice Nelson in Le Roy *v.* Tatham, 185, "that where a person discovers a principle or property of nature, or where he conceives of a new application of a well-known principle or property of nature, and also of some mode of carrying it out into practice so as to produce or obtain a new and useful effect or result, he is entitled to protection against all other modes of carrying the same principle or property into practice for obtaining the same effect or result," had been adopted by the court, and this specification had not been limited, the patent might be held to cover that principle and the application of it. But that was not according to the opinion of the majority of the court in that case, and was not adopted then nor in O'Reilly *v.* Morse, in which the same question arose at the next term, when the same Justices, Nelson, Wayne, and Grier, dissented again, nor does it appear to have been adopted since. In the latter case Mr. Chief Justice Taney, at page 119, said :—"Whoever discovers that a certain useful result will be produced in any art, machine, manufacture, or composition of matter, by the use of certain means, is entitled to a patent for it; provided he specifies the means he uses in a manner so full and exact that any one skilled in the science to which it appertains can, by using the means he specifies, without any addition to or subtraction from them, produce precisely the result he describes. And if this cannot be done by the means he describes the patent is void. And if it can be done, then the patent confers on him the exclusive right to use the means he specifies to produce the result or effect he describes, and nothing more. And it makes no difference in this respect whether the effect is produced by chemical agency or combination; or by the application of discoveries or principles in natural philosophy, known or unknown before his invention; or by machinery acting altogether upon mechanical principles. In either case he must describe the manner and process as above mentioned, and the end it accomplishes. And any one may lawfully accomplish the same end without infringing the patent if he uses means substantially different from those described."

If the views of Mr. Justice Nelson had been adopted they would apply as he said, 14 How. 189, only to cases where "the inventor has not tied himself down in the specification to the particular mode described."

This patent seems to be limited carefully to the particular means specified in it for producing the desired result. In this respect it is quite different from that of Watt in Boulton *v.* Bull, and Hornblower *v.* Boulton. He describes his general method of arranging his engines without descending into particulars at all. In this the particular means are minutely pointed out. It is like that in Russell *v.* Dodge, which set forth a process of heating bark-tanned lamb or sheep-skins by means of a compound of which heated fat-liquor was an essential ingredient, and which was held not to cover the use of the same liquor, hot or cold, in the same manner otherwise. This view, that the scope of this patent is such that it covers only the means employed, is supported to some extent by the judgment of Mr. Justice Clifford in Wing *v.* Richardson.

The inventor himself has testified fully concerning the various steps by which he succeeded in accomplishing the invention patented. His testimony is corroborated by that of other persons, but is not essentially varied. According to it he conceived his idea of bringing different parts of the plate successively into the central and best part of the field of the lens when taking several pictures on the same plate, in 1846, and embodied it to some extent in the camera frame, which is exhibit 6, and the accompanying parts, which are exhibits 7, 8, 9, 10, and 11. But the method there adopted was very different from that described in this patent. That accomplished what it did accomplish by moving the lens with reference to the plate, not the plate with reference to the lens. In ascertaining the time of the invention the inquiry must necessarily be directed to the one patented. As to the time when that was perfected the inventor is directly inquired of at page 60, by cross interrogatory 36. When did you first devise and make an apparatus having the piece, L, described in your patent?

Ans.—I should say, in the first place, I know I made one in 1854; whether either of my sliding movements made previously had a stop that answers to piece L I cannot say. I know that there was one made in the autumn of 1854. I am sure I had a frame that had a guage or stop to it some time previous; whether it is possible to find that I do not know.

37. When did you first use in your business and when first sell an apparatus like that described in your re-issued letters patent?

Ans.—I cannot say when we first began to use it, but I judge about the time the patent was granted: not long previously. I think there were but two or three sold before 1859, 1860, or 1861; the exact time of these sales I cannot say.

He nowhere fixes the date any earlier, and the fall of 1854 seems to be the time the proof fixes upon as the date of this invention. This is according to the time found by Mr. Justice Nelson in Wing *v.* Schoonmaker.

If the patent was for taking several pictures on the same plate by bringing different portions of it into the field of the lens successively, the old and well-known method of doing that by swinging and tipping the camera would be an anticipation.

If it was for so taking pictures in the centre of the field it would be necessary to examine the proofs to ascertain whether, in the cases set up in the answer and claimed on the evidence, that method was known and practised prior to the discovery and use of it, by this inventor, in 1846. It might be difficult to find, by the requisite measure of proof, such use as would amount to an anticipation in this respect. If it was for a smaller plate-holder movable into the corners of a larger frame merely, it would clearly appear that several persons made use of that arrangement previous to the date of the patented invention in the fall of 1854. But the patent seems to include the arrangement of the guide-piece, L, in combination with a small plate-holder into the corners of a larger frame. This arrangement, taken altogether, appears to be substantially different from any other shown to have been made or in use prior to that time. This seems to be the effect of the testimony of the defendant's expert, Hicks, as well as the result of an examination of the testimony describing the various contrivances more or less relied upon, and the models and exhibits illustrating them. From these considerations the patent appears to me to be valid for that arrangement, and for that only.

There remains the question made as to whether the defendants infringe the patent, in its extent, according to this construction of it.

They have in their cameras smaller plate-holders movable into the corners of a larger frame substantially as described in the patent. But they are not shown to have the guide-piece, L, nor anything substantially like it, or substantially an equivalent for it. If the patent covered a sliding plate-holder moving into the corners of a larger frame as well as the guide-piece, the use of the former would be an infringement; but it does not. Such a plate-holder was old at the time of the invention. The patent is really for the method of moving the plate-holder and plate from corner to corner, and holding it in position there for the required length of time, without disturbing the camera as focussed; or the relative positions of the object to be pictured, the lens, and the opening to admit the image in the best part of the field of the lens in front of the plate. The inventor accomplished this by the

guide-piece, hinged to the larger frame, and controlling the movements of the smaller one within it. The defendants accomplish the same thing by another mode. In the language of Mr. Chief Justice Taney, before quoted, they use means substantially different from those described, and lawfully accomplish the same end without infringing the patent. Let a decree be entered dismissing the bill of complaint, with costs. (Signed) HOYT H. WHEELER.

Meetings of Societies.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

THE usual monthly meeting of this Society was held on Tuesday evening last, the 10th inst.—Mr. James Glaisher, F.R.S., President, in the chair.

The following gentlemen were elected members of the Society:—Messrs. Guttenburg, W. Hoar, Thos. Marsh, J. Milman Brown, Capt. Reeves, N. Broderick, Ezra Greaves, W. M. Harrison, and Alfred Pettitt.

A paper, *On a Really Reliable Emulsion Process*, was then read by Mr. Henry Cooper. Some observations on this will be found in another page.

The above was followed by a paper, by Mr. Leon Warnerke, *On a Case of the Destructian of the Latent Image on Washed Emulsion and its Restoration.*

In the absence of these papers from our columns the short discussion which followed could not well be understood. We therefore defer the publication of the discussion till next week, when the papers will also appear. It will be sufficient to here state that Captain Abney's remarks had reference to spots on emulsion plates, to the importance of making the emulsion with a hot solution of nitrate of silver, of the advantage of evaporating the solvents of the emulsion at a raised temperature, and of making use of lactic acid instead of the lactate of ammonia recommended by Mr. Cooper. Sulphite of soda was also recommended by Captain Abney as a preservative.

Mr. T. Sebastian Davis made allusion to his having, last year, in the course of experiments with bromide emulsion, used as a preservative that which he had formerly recommended in connection with the tourist's dry-plate process. It was rather interesting to notice the similarity between it and that in Mr. Cooper's process. He concluded with some observations on the mottling of the film in the high lights, on which subject Mr. William Bedford made a remark to the effect that mottling was solely owing to an unsuitable pyroxyline having been employed in the preparation of the emulsion.

Mr. WILLIAM WILLIS, Jun., then read a paper in which he described the reactions in, and process of printing by, his new platinum process. Having so recently given a full account of this process we shall assume our readers to be conversant with it, and hence shall not here anticipate by a recapitulation the publication of the paper next week. Mr. Willis demonstrated the working of the process and developed several specimens, the success of the whole being of such a marked character as to elicit the hearty applause of the members. Among other observations following the demonstration,

Mr. JABEZ HUGHES directed special attention to the fact that Mr. Willis had, since the original introduction of his platinotype process, made such decided and important advances as to have eliminated from it the necessity for using silver and its concomitant, hyposulphite of soda. These, he was happy to perceive, were now entirely discarded.

Mr. EDWIN COCKING then read a paper on *Subjective and Objective Photography*, which, with the other papers read, will also appear in our next number.

Votes of thanks were awarded to the authors of the various communications.

It was intimated that the next meeting would be held on January 14th, when Captain Abney would read a paper on *The Sensitiveness of Spots in Emulsions*, and Colonel Wortley would exhibit an instantaneous shutter.

The proceedings then terminated.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

THE annual meeting of this Society was held on Thursday, the 5th inst.,—Mr. P. Mawdsley, Vice-President, in the chair.

Messrs. E. Benthen and W. J. Anckorn Lowrie having been elected members, the Secretary read the following

ANNUAL REPORT.

YOUR Committee, in presenting the annual report of the South London Photographic Society for the session 1878, have reason to think that the amount of work done has been more than could have been expected, after taking into consideration the disturbing influences in political and commercial circles which have characterised the past year, and which, to some extent, must interfere with the careful consideration of scientific subjects, more especially as respects those who, whilst engaged in the daily routine of work, come forward voluntarily to supply subject matter for discussion at your monthly meetings.

Whilst all praise should be awarded to those few members who, by writing papers, have endeavoured to maintain the prestige of the Society, your Committee cannot but express a desire that others, and especially the new members who have hitherto not done anything in the same direction, should seriously try to commit to writing any thoughts that may arise whilst engaged in the practice of the art-science.

It frequently happens that in simple statements of any variation in what appear to be ordinary facts there lies concealed something which discussion often brings to the surface and throws a light upon, thus resulting in the communication of useful information, and for which your Society offers suitable facilities by its conversational mode of investigating details. It is hoped that the future will show that such opportunities have been taken advantage of.

Your Committee, in referring to the annual recurrence of the Technical Meeting, would wish to call attention to the fact that all your Society can do is to afford an opportunity (perfectly free) for new inventions and appliances to be published and explained; but the value of each Technical Meeting must depend upon the inventive power which has been at work since the previous meeting. Whether it be much or little, your Society, at the same time, deserves credit for giving inventors so desirable a privilege.

The opening meeting of the session was again devoted to a lantern exhibition, when readings were introduced for the first time—one from the *Pickwick Papers*, "Gabriel Grub," being given by Mr. S Statham, and a very dramatic reading of "Jane Conquest," by Miss Alice Burnelle.

The following papers have been read during the session:—*Educational Uses of Photography*, by Edwin Cocking; *On the Elimination of Soluble Salts from Gelatine Emulsions*, by F. Wratten; *The Use of Alcohol in Gelatino-Bromide Emulsions*, by E. W. Foxlee; *On the Reproduction and Enlargement of Negatives by the Collodio-Emulsion Process*, by W. Brooks; *Varieties*, by Edward Dunmore; *Photographic Experiences in Paris*, by F. York; *A Curious Incident in Connection with Paper Enlargements*, by F. A. Bridge; *Special Cotton for Making Pyroxyline*, by Leon Warnerke; *On the Rectification of Silver Baths*, by W. T. Wilkinson.

Photographs, apparatus, and appliances have been exhibited by the following gentlemen:—Messrs. W. M. Ayres, T. Avery, W. Atkins, C. Bennett, F. A. Bridge, W. Brooks, T. Bolas, W. Cobb, F. Cowan, A. Clarke, E. Dunmore, T. Harrison, T. G. Hemery, Baynham Jones, J. T. Lane, R. Kennett, Lieut. J. D. Lysaght, P. Mawdsley, J. Nesbitt, J. Penny, C. Smith, L. Warnerke, J. Werge, F. Wratten, W. Woodbury, and F. York.

In conclusion: your Committee hopes that the forthcoming session will be valuable from the subjects brought forward for consideration, and that the younger members of the profession will recognise the importance of giving material support to a Society which affords so pleasant a medium for the discussion and elucidation of all art and scientific matters connected with photography.

The report was unanimously adopted.

The Treasurer then submitted an interim report of the state of the finances of the Society, and it was agreed that the complete report be submitted early next year.

The following officers and committee were then elected:—*President:* Rev. F. F. Statham, M.A.—*Vice-Presidents:* Messrs. W. Brooks, E. Cocking, F. Howard, Jabez Hughes, P. Mawdsley, and G. W. Simpson.—*Committee:* Messrs. W. Adkins, T. Bolas, C. G. Cutchey, E. Dunmore, J. Nesbitt, L. Warnerke, and F. York.—*Treasurer:* F. A. Bridge, 9, Norfolk-road, Dalston-lane.—*Secretary:* H. Garrett Cocking, 7, Mount Eliot-terrace, High-road, Lee, S.E.

Votes of thanks were unanimously awarded to the retiring officers, especially to Mr. Edwin Cocking, the Honorary Secretary, for his valuable services during a number of years.

A paper by Mr. W. T. Wilkinson, of Ceylon, *On the Rectification of Silver Baths, and other Subjects* [see page 590], was then read; but, owing to the lateness of the hour, no discussion ensued.

The meeting was then adjourned.

EDINBURGH PHOTOGRAPHIC SOCIETY.

THE second ordinary meeting of this Society was held in 5, St. Andrew-square, on the evening of Wednesday, the 4th instant,—John Lessels, Esq., President, in the chair.

The minutes of the previous meeting having been read and approved, the following gentlemen were unanimously elected ordinary members:—Mr. G. W. Danter, Mr. John Hay, Mr. William Steaurt, Mr. John Reid, and Mr. James Dall.

The PRDSIDENT proposed that a presentation print be provided for the current year, and suggested that the subject should be chosen from nature.

The Treasurer (Mr. Alexander Mathison) having intimated that the funds would support the necessary expenditure, the matter was unanimously remitted to a small committee with full powers.

Mr. W. H. DAVIES next intimated the death of Mr. Carrick, an honorary member of the Society, and after a few appropriate remarks moved that expressions of sympathy be sent to his widow through the Corresponding Secretary of the Society. This was agreed to.

Mr. W. Neilson then read a paper entitled *Art in Landscapes*. This paper had been prepared for the forthcoming BRITISH JOURNAL PHOTOGRAPHIC ALMANAC and not for reading to the Society, but after some pressure Mr. Neilson had consented to read it on condition that a full report of it was not published. The paper was in the form of a dialogue intended to show (a) "art is not an imitation," and (b) "pictorial grandeur depends wholly on shade."

Dr. HUNTER said he had felt great pleasure in listening to such a poetically-expressed and practical paper. He considered that artists, as well as photographers, did not pay sufficient attention to the shades of their pictures. He also would particularly urge upon photographers the desirability of looking pre-eminently to the general form of their subjects, leaving the details to take care of themselves.

Mr. Denovan Adams remarked that artists endeavoured to put into their scenes not so much what they saw as what they *felt* to be there; they thus succeeded, more or less, in representing the emotions. He (Mr. Adams) considered the photographer to be so hampered by mechanical details that he would never attain to the production of pictures possessing the highest art qualities, and so would have to be content to rest within the more modest sphere of the possible.

Mr. J. Craig Christie believed the difference between an artist and a photographer to be—that an artist is able to give the sum total of his experience of nature, both past and present, while the photographer is bound to represent a phsae of nature only existing during a very limited period of time.

Mr. M. G. Dobbie moved a vote of thanks to Mr. W. Neilson for the very kind way in which he undertook to bring this paper before the Society, and which had led to such an interesting discussion. This was carried by acclamation.

Mr. Moncrieff (Secretary of the Society of Arts) exhibited a fine photographic copy of an old painting, showing the peculiarities of the German school as modified by Italian influence.

Mr. R. Murray, C.E., exhibited a large series of photographic views taken by the coffee process during the past season. They possessed considerable merit, the softness of the pictures being particularly noted, as also, in several instances, the happy selection of the point of view.

Mr. Neilson concluded his criticism of the series by remarking that he had often enjoyed coffee, but never more than he had that night while looking over these pictures.

Mr. J. M. Turnbull next exhibited Mr. Chadwick's oxygen generator, prefacing his illustrations with a short account of it, as gleaned from the published proceedings of the Manchester Photographic Society. The apparatus was an object of very marked interest, everyone present seeming anxious to see it in all its details, its extreme simplicity and freedom from danger being highly commended. Considerable surprise was also manifested by its decided economy over the old method, the evolution of gas being almost exactly equal to what it ought to be theoretically. The small cake of composition employed produced a cubic foot of oxygen in about seven minutes after the Bunsen flame was lighted, and that without any attention, trouble, dust, dirt, or annoyance of any kind whatsoever. A set of transparencies by Mr. York, illustrating the late Paris Exhibition, were thrown on the screen by the aid of this apparatus. It was suggested that a useful addition would be some simple means of working the generator when ordinary house gas was not available.

Votes of thanks to Messrs. Moncrieff, Murray, Turnbull, and to the President terminated the proceedings.

BRISTOL AND WEST OF ENGLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

The ordinary monthly meeting of this Society was held as usual at the Museum, Queen's-road, on Wednesday, the 4th instant,—Mr. E. Brightman in the chair.

The minutes having been read and passed, Messrs. R. Biggs and G. F. Powell, of Bath, were, on the motion of the Secretary, seconded by the Chairman, elected ordinary members.

The Hon. Secretary (Mr. H. A. H. Daniel) then handed round some samples and copies of price list of the "empire" opaque cloth for backgrounds made by Messrs. Avery and Co., of London. They were much admired, the texture being beautifully fine, and the colours chosen with great judgment.

The Chairman remarked that as the cloth was coloured on both sides it was a good plan that the manufacturers placed a different colour on each side, such as a medium dark one for three-quarter length figures and a light one for vignettes. He thought it capital material, as it could be washed.

Mr. Steevens remarked as to the inexpensiveness of the cloth.

Mr. Daniel introduced the subject of drying carbon tissue. He said that some few weeks back he prepared some 10 × 8 pieces, and hung them up in his laboratory to dry during the night, leaving his petrolene stove slightly burning to keep the air as dry as possible; the stove emitted no smell. After printing the next morning it was found utterly impossible to develope the tissue the ensuing evening. Fearing that the bichromate solution might have been acid he prepared some more sheets, sensitising with the Autotype Company's own powder dried in the same manner, and yet with the same result. Seeing the Editors of The British Journal of Photography had recommended drying by a petrolene stove, he wrote and stated his experience. In a recent number this was printed, the Editors saying they had used a petrolene lamp without the evil effects spoken of, and that they should like to hear of the matter being discussed. He (the Secretary) therefore brought it before the meeting.

The Chairman suggested that possibly some acid fumes might have existed in the operating-room at the time, and, if so, that would be a sufficient reason for the occurrence.

Mr. Steevens presumed that the Autotype Company used a different means of drying.

The Chairman replied that he believed revolving fans and other specially-constructed apparatus were used. He once was anxious to dry some sheets of carbon tissue by the next morning, and hung them near the ceiling of a room where gas had been burning all the evening, and shut the door. It was impossible to develope the pictures, the acid fumes of the gas rendering it quite insoluble. He now adopted the plan of using the kitchen grate, placing tissue on bamboo rods across it, letting the fire out, and using the heat from the iron plate at the top; in an hour or two it was quite dry.

Mr. T. Davey thought one of the "cherful" gas stoves would be a good thing to use for drying, the fumes being carried off by a small pipe at the back. The hot iron of the stove would be the means of doing this.

Mr. Daniel had some hot-water pipes passing through some rooms in his house, and he was making a drying cupboard to fit round them, with light-tight draught holes at top and bottom. This arrangement he hoped would be practically perfect.

Mr. Davey inquired whether those present had been satisfied with the past summer's experience in the working of the triangular-shaped black tent which the operator entirely entered, and which some of the members, like himself, had adopted.

The replies were in the affirmative, and

Mr. Daniel said that so far as he could see he should not work in a box-tent again. He considered, however, that the following improvements might be made, viz., that, instead of the present plan, short metal pins with cross swivel tops might be pushed into the ground through eyelet holes in the material at the base; and that, instead of the water bags which many used as tanks, a zinc tank with a cover should be used, as that could be filled from a stream at once. Filling water bags from a stream was not only a difficult but also a very time-wasting operation. The zinc tank would not occupy extra space in packing, as it could be made exactly the size to hold a plate-box.

Mr. Davey made some other suggestions as to head room and fixing the base in the tent in question.

Preparations were then made for carrying out one of the attractions of the evening, viz., the exhibition of Woodbury lantern slides. The lantern used was Newton's phantasmagoria lantern, and the new three-wick refulgent lamp.

Mr. Daniel said that he had had a communication from Messrs. Newton and Co. stating the result of their experiments since last season. They had constructed a three-wick lamp of great power and brilliancy. This lamp he had sent for, and they would use it for exhibiting the Woodbury slides. He had with Mr. Kitt, the Bristol Gas Company's engineer, tested the old two-wick and the new three-wick lamps most carefully, and found that the light of the former to the latter was as 45 was to 64½, which was a very great increase of illuminating power. This does not at all imply the candle-power of the light. The light was then turned on, and was much admired for its power and evenness.

The Chairman then exhibited a large number of slides of foreign scenery and characters, which fully maintained the reputation they have so deservedly gained. A few carbon tissue slides were also exhibited, and certainly proved the suitability of this process for making transparencies for the lantern.

Mr. Daniel said that the Autotype Company would be conferring a great boon on lantern exhibitors if they would not only supply a filtered black but also a filtered *purple* tissue for transparencies, as that colour was, so far, more harmonious and pleasing on the screen, the Woodbury slides always looking so agreeable in colour.

All the slides having been shown, votes of thanks to the Chairman and the Secretary were accorded, and the meeting was adjourned.

WEST RIDING OF YORKSHIRE PHOTOGRAPHIC SOCIETY.

The above Society held its annual meeting at the Oddfellows' Hall, Bradford, on Monday, the 5th ult.,—Mr. E. Greaves, President, in the chair. There was a fair attendance of members.

The Secretary read the following

ANNUAL REPORT.

The Council, in presenting this, the fourth Annual Report, have to congratulate the members upon the completion of another year's work. The Society still numerically advances, its numbers having considerably increased during the year, and few resignations have been received. We have to lament the death of Mr. E. L. Suddick, one of the oldest amateur photographers in the district.

The number of papers read has not been so large as in former sessions, but the Council hope to have more matter on hand for next year. The papers read have been as follow:—*On Secret Processes*, by Mr. Gregson *On Silver Waste*, by Mr. Garbutt. *Our Society*, by Mr. Crosthwaite. Several pieces of apparatus for facilitating oarbon printing have been exhibited by Mr. E. Greaves.

One outdoor meeting has been held at Bolton Abbey, where the Sheffield Photographic Society joined us, and an excellent day's pleasure was enjoyed.

The Council have once more to reiterate their wishes for more voluntary contributions to the Society's meetings. A paper produced from love of the subject and a desire to inform and benefit the members, is more valuable than one extracted only at the expense of much solicitation and entreaty. The old saw that "one volunteer is worth two pressed men" is as applicable to the peaceful art of literary composition and the conveyance of information as to the more violent arts of war.

In conclusion: the Council beg the members to bear the Society's interest at heart, to endeavour to develope the latent talent existing in our midst, to bring more personal feeling to bear upon the meetings, to provide more material for discussion, and in every way possible to add to the success of the Society.

The financial statement was presented by the Treasurer, and passed.

The election of officers for the ensuing session was then proceeded with, the President, Mr. E. Greaves, declining to fill the presidential seat for the next year. The result was as follows:—*President*: Mr. Jno. Howarth.—*Vice-President:* Mr. E. Wormald.—*Treasurer:* Mr. W. T. Burrow.—*Auditor:* Mr. A. Megson.—*Secretaries:* Mr. J. Crosthwaite and Mr. R. Holgate.—*Council:* Messrs. R. Broadhead, Gunstone, J. Smith, A. Sachs, E. Jenkins, E. Passingham, E. Greaves, W. E. Thompson, and J. Shaw.

The meeting was then adjourned.

THE annual *soirée* was held on Wednesday, the 27th ult., at the Market Tavern, Edwin-street, Bradford, at which there was a large attendance of ladies and gentlemen. Owing to the considerable cost which attended the exhibition of pictures last year the Council determined not to make any special effort in that direction on this occasion, but to reserve it for another year, when it is proposed to hold one on a more extensive scale. The number of pictures exhibited was therefore small, but of a very interesting character. To the tea, which was provided in admirable style by Mrs. Town, full justice was done by the assembled guests, after which the proceedings, under the able presidency of Mr. Howarth, took the form of social entertainment. Music, recitations, and dancing served to keep the company alive with enjoyment. Duetts were sung by Mrs. Crosthwaite and Miss Smith, Mr. Greaves and Mr. Kilner; songs by Mr. Burrow, Mr. Crosthwaite, and Mr. Hanson, and excellent recitations by Mrs. Illingworth and Mr. Howarth. The meeting broke up at a late hour, with good wishes for the Society's career and an earnestly-expressed hope of meeting again at the next annual gathering.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

THIS Society met on the 18th October, the chair being taken by the President, Dr. Vogel. He (the Chairman) laid upon the table a number of books and periodicals, amongst others a number of the *Patentblatt*, containing the report of a meeting of the recent International Patent Congress at Paris, where the subject of photographic copyright was considered, and at which the following opinions were expressed:—That photographs ought to be divided into two classes, namely, those of an artistic character and those having a purely trading value; and that the latter should be protected by a special law, while the former should come under the law of copyright as applied to works of art.

The Chairman remarked that it was gratifying to see the artistic value of photographs thus recognised, while the German Reichstag denied that photographs had any artistic value. He (the Chairman) then laid upon the table a copy of Husnik's work upon heliography, and a communication from Herr Schlösser, of Breslau, in which he gave an account of an exhibition of art-manufactures in that town, was read.

The new postal regulations were then discussed.

The CHAIRMAN presented a report on the Klary-Boissonnas' process in which he said he had arrived at the same conclusion as Mr. Rocher, viz., that by using it one gains a few seconds of time in the exposure, but that one loses in the quality of the negative.

Herren JACOBI and MARTIN said that some other photographers of their acquaintance had bought the process and had arrived at the same conclusions as Dr. Vogel.

Herr SELIGMANN had made a journey in Switzerland, taking with him some of Warnerke's and Wilde's emulsion plates, and some of Kennett's gelatine emulsion plates. He was most successful with the two latter.

Herr PRÜMM wished to know the percentage of really good plates which Herr Seligmann had obtained with the emulsion process as compared with the wet process.

Herr SELIGMANN replied that had he not made some mistakes in the management of the collodion emulsion plates he thought he should have been successful with about ninety per cent. of them. The gelatine plates had been nearly all successful. He could, however, make no comparison with the success of wet plates, as he had not used the latter on the particular excursion in question.

The CHAIRMAN, who had had considerable experience both with wet and dry plates, explained that he had found the percentage of failures about as great with the wet process as with a good dry process. Because, though the wet process itself was very reliable, still heat, dust, bad water, insects, light getting into the tent, &c., were great causes of failure which were absent from the dry process. He had once taken a bottle of emulsion with him on an excursion to the Baltic, prepared the plates in the evening, dried them for half-an-hour or so in the drying-box, exposed them the following day, and then developed them in the evening. Out of a dozen plates he had only *one* failure in consequence of faulty preparation. The other failures were caused by under-exposure, wind shaking the camera, &c.

The invitation from Herr Schwier, the President of the German Photographic Society, to join the latter body in holding a photographic congress at Dresden, in August, was then read, but the locality was not considered central enough.

The meeting was shortly thereafter adjourned.

THE Berlin Society met again on the 1st November,—Dr. Vogel occupying the chair.

A number of negatives on tissue paper, sent by Herr Sandtner, of Tetschen (Bohemia), were laid upon the table. The negatives looked very clean and dense, but the prints which accompanied them left a good deal to be desired. They were mostly reproductions. Herr Sandtner's object was to save the expense of glass negatives.

Dr. FRIEDLÄNDER, who had recently visited Herr Husnik, of Prague, said the process of the latter was suitable for pretty large negatives, and that equally good prints could be secured from either side of the negative.

The general impression of the members was that the process was better adapted for reproductions than for portraits.

Herr Hartmann exhibited a Klinkerfues' hygrometer, which was examined with great interest.

Herr Rückwardt showed two views, interiors of the dining-room of Herr Siemens' villa at Charlottenburg—one taken by daylight, the other by a mixture of daylight and electric light, both with an exposure of an hour and a-half. In the former those parts of the room which were not directly lighted appeared considerably under-exposed; while in the view taken with the aid of the electric light even the darkest parts of the room were shown in the most brilliant detail. Both pictures were taken with a pantascope. The electric light consisted of two flames, each equal to the light of 1,500 candles. An attempt to take the same view by electric light without any daylight failed completely. The electric lamps were used without reflectors.

Herr SELIGMANN thought it would be better to use a Ross's wide-angle symmetrical lens for photographing by electric light than a pantascope.

A discussion on Martini's new head-rest was followed by Dr. Vogel and Herr Schaarwächter's report on Dr. Richard's rapid process.

Dr. VOGEL had prepared some plates with his own preparations and some with those sent by Dr. Richard and had exposed a dozen of them, in pairs, in a stereo. portrait camera. The results were laid before the meeting. The exposure of one half of the plates was ten seconds, that of the other fifteen seconds. The result was that the plates prepared with Richard's chemicals were considerably denser in the lights than those prepared with Dr. Vogel's own chemicals, but they did not possess any more detail in the shadows than the latter. He (Dr. Vogel) also tried the double silvering, as recommended by Dr. Richard, and then the baths B and A, each by itself, but without any better results.

Herr SHAARWÄCHTER had also found greater density in the lights, but no greater sensitiveness in Dr. Richard's chemicals than in those in ordinary use.

Dr. VOGEL had communicated this result to Dr. Richard, who replied that probably the transport had had an unfavourable influence on the sensitiveness of the chemicals.

This explanation, Dr. Vogel thought, might not be improbable, but, if true, what a drawback to the usefulness of the process!

Herr SELIGMANN gave some further details as to his experiences with emulsion dry plates, and shortly afterwards the meeting was adjourned.

Correspondence.

THE "MANAGEMENT" AT THE RECENT PHOTOGRAPHIC EXHIBITION.

To the EDITORS.

GENTLEMEN,—As the eight pictures I contributed to the recent Exhibition have mysteriously disappeared, and under peculiar circumstances, I shall be glad if you will allow me to state the facts of the case in the Journal, in the hope that some clue may be found as to their whereabouts.

As no packing-cases were allowed at the Gallery I sent my pictures to a friend in London, who unpacked and delivered them at the Gallery. My friend (Miss R.) was told nothing as to the fetching them away by the people at Pall Mall; but at the close of the Exhibition, of which I received no notice, I wrote to her asking her to call for the pictures and send them back to me. She thought they would not deliver them without a written order from me, and the posting of this order caused two days' delay. It thus happened it was not until the Thursday after the close of the Exhibition that the pictures were asked for. On application at the Gallery my friend was told all the unclaimed prints had been sent to Mr. Bourlet, of Nassau-street. On going to him nothing could be heard of the pictures, and after waiting until now for inquiries to be made, I have just received a letter from Miss R., in which she says —"I am so vexed about your pictures, but do not know what to do. They say at Pall Mall every picture was sent away the day after the Exhibition closed, and Mr. Bourlet, in Nassau-street, says he has never seen them." I understood the Exhibition closed on a Saturday, so by the "next day" I suppose they mean Monday.

I make no comments on the dreadful want of management shown by some one; but, as I cannot help thinking the pictures have been stolen, I should like to know who is responsible. Occurrences of this kind are not inducements to exhibit.—I am, yours, &c., HENRY COOPER.

Homehurst, Torquay, December 7, 1878.

CONTINENTAL PHOTOGRAPHIC LITERATURE.

To the EDITORS.

GENTLEMEN,—Having been enabled to hand over to a successor the direction of the photochromic works of the *Moniteur*, which absorbed the whole of my time, I am at last free to devote myself afresh to my experiments and photographic publications.

I have just undertaken to edit the whole of a series of distinct works on phototypy, photogravure, photoglyptie, photochromy, phototypography, photolithography, enamels, &c. I wish to communicate this fact to the *savants* and those who study or practice these various processes industrially in order that they may, if they think proper, assist me either in my judgment or in my work of popularisation by supplying me with any information they may desire to see figure in my various volumes. These volumes will form a grouped series under the collective title of *Annales de la Photographie*, and they will be edited and published separately, and as soon as they can be got ready, by the firm of Gauthier-Villars.

I shall be grateful, gentlemen, if you will give publicity to this letter in THE BRITISH JOURNAL OF PHOTOGRAPHY, as I am certain that it will thus be brought before the notice of all whom it may interest throughout the photographic world.—I am, yours, &c.,

28, *Rue Jacob, Paris, December* 6, 1878. LEON VIDAL.

THE *FIELD* ON THE SEA.

To the EDITORS.

GENTLEMEN,—In your issue of yesterday, on page 585, in an extract from the *Field*, it is said that painters err in painting large breakers immediately in the foregrounds of their pictures, in making *these* transparent instead of muddy, that they should begin to break out to sea and come inshore as foam, and that no large roller can exist in its perfect form close onshore.

In contradistinction to all this I beg to say that they can and do, for in bright and calm weather rollers six to ten feet high may be seen breaking at the very edge of the sea, so to speak. They may be noticed coming in and in, and then rolling over with a grand bang close to your feet, and are often wonderfully transparent and *not* muddy, as the *Field* would have us believe. Of course, when there is a heavy sea on the rollers do break out to sea and come in as foam, and after heavy seas the whole sea along shore is often brown, but not always. Let the *Field* stick to the "field," and not tell "crams" about the sea.—I am, yours, &c., FRANK M. SUTCLIFFE.

High Stakesby Cottage, Whitby, December 7, 1878.

P.S.—I also notice that the *Field* says that spring foliage is bright green. Surely the writer must be colour blind; it is often yellow and brown. Look at an oak, for instance, bursting into leaf.—F. M. S.

THE LUXOGRAPH.

To the EDITORS.

GENTLEMEN,—In reply to the inquiries of "Glasgowgian" in your issue of the 29th ult., permit us to supplement what you have said on the subject of the "luxograph."

Respecting the expense of fitting up the electric light, we believe that it will cost very little under three hundred pounds to have it fitted up properly. This, of course, includes the price of an engine. It is not for us to say how the Vanderweyde studio is succeeding; but from all we can learn its success at the present time is undoubted. Similar studios will soon be opened in connection with the luxograph.

With regard to the exposure required by the luxograph: we have obtained good negatives on gelatino-bromide plates in three seconds, although when working with wet collodion we prefer to and always give a much longer exposure—say fifteen to twenty seconds. In this time we obtain good negatives.

The "luxograph" and "photogene" are quite different instruments, both, however, having this point in common—that they may be used with pyrotechnic compounds; but they differ in this respect—that such compounds must be used in the one case, while in the other any powerful actinic light may be employed. Any further information we can supply to your correspondent is at his service.—We are, yours, &c.,

December 11, 1878. ALDER AND CLARKE.

THE RECENT MEDAL AWARDS.

To the EDITORS.

GENTLEMEN,—I forbear making any remarks as to Colonel Wortley's criticism of my seascapes, and wish to state that whatever my private opinion may be of the gallant Colonel's own work in this direction I do not elect to air them in a public journal.

A few words are, however, necessary respecting the particular copies he mentions, which were required for his "friend in the country," and about which he (Colonel Wortley) asks the aid of the Photographic Society of Great Britain. The prints were obtained in this wise:—A special messenger was sent down to my printing works in hot haste for a set of the photographs in question, with instructions to say they were for a "gentleman going to India," and unless they could be delivered immediately they would be of no use. In my absence my assistants sent him the only prints that were available, two or three of them being trial impressions as to whether double printing would improve them or otherwise. I heard nothing more of the prints until Colonel Wortley's name appeared in connection with them. I should, of course, have much preferred to have sent prints in every way similar had reasonable time been given for their production.

In conclusion: I may inform your readers that Colonel Wortley has really no *sole right* in the production of seascapes, and that any photographer is at liberty to produce them providing he has courage enough to submit them to the criticism of the gallant Colonel.—I am, yours, &c.,

December 9, 1878. PAYNE JENNINGS.

RECENT MEDAL AWARDS.

To the EDITORS.

GENTLEMEN,—As the "personal attack" alleged by Colonel Wortley to have been made upon him by me consists in a very mild criticism of one point in one of his pictures, I leave you to judge what importance I ought to attach to his deductions.—I am, yours, &c.,

Edinburgh, December 10, 1878. AULD REEKIE.

THE LATE MR. WILLIAM H. RULOFSON.—The late Mr. William H. Rulofson, for many years a leading photographer of this city, was almost instantly killed, about four o'clock yesterday afternoon, by accidentally falling from the fire-wall on the roof of his photograph building, on Sacramento-street, near the corner of Montgomery. It appears that he was standing on the fire-wall looking at some workmen who were lowering old lumber by means of a pulley, and while in that precarious position his foot slipped, and he instantly lost his balance and was precipitated to the sidewalk, a distance of about fifty-five feet. The building is four stories high, without awnings. He was heard to exclaim "I am killed" during the descent. He struck on a pile of tin, which arrested the force of the fall and prevented a mutilation of the body. He was taken up and removed to Burnett's drug store, and thence to the office of Dr. McNulty, his family physician, who pronounced him dead. The only external injury to the head was a bruise on the forehead. The ribs had been crushed by the fall. Mr. Rulofson was a native of Maine, and 52 years of age. His widow and several children survive him. He was a gentleman of pleasing manners, and highly esteemed by a large circle of private acquaintance. Professionally his standing was of the first rank. He had been a photographer in this city for over twenty years, during which time his efforts to improve his art were indefatigable and eminently successful. He was a member and promoter of the Photographic Society of the Pacific, and at one time was its President. No small part of his professional reputation was due to the artistic galleries of celebrities, which he cultivated with great care and taste. Few persons of note visiting this city were exempt from facing his cameras; and his photographs of that class became famous abroad and took prizes. He was intensely devoted to his art, but, in addition, he was fond of polite literature, and made some successful efforts in literary authorship. A work, entitled *The Dance of Death*, though its authorship was mooted, was generally ascribed to his pen.—*San Fransisco Alta.*

A NEW MADONNA.—On many of the boulevards, and on all the chief streets in Paris, are found pretty shops where they sell nothing but photographic pictures. During the exposition an unusual display is being made. Everybody finds pleasure in examining the attractive exhibits found in these shop windows. Throngs are about them all the afternoons and during the evenings, as they light up brilliantly real crowds. Such artistic pictures of actresses! Such clear and sharp pictures of the wonderful buildings in the public squares, and such views of the exposition! Just out of the Rue De l'Opera, in the Boulevard Des Italiens, is one of these picture stores. We often looked in the windows, and one day saw, oh! such a face! 'Twas that of a Madonna. Everybody looked at it and spoke about it. The dearest cabinet photograph sold in Europe is that of Queen Victoria, taken by Bergamasco; price, 75 cents, everywhere the same. The price of this Madonna was 90 cents. It seemed like a familiar face—a photograph we had seen in New York; but it was on a card with the name and address of this Paris establishment. Several Americans had been heard to exclaim as in the crowd we looked and admired together, "Oh, *that's* a picture;" "Oh, what a photograph that is!" "Ah! if our American photographers could only take such pictures!" "Did you ever see anything anywhere so fine?" One day, after hearing these expressions for the hundredth time, making up our minds to "*see*" about that, we went into the shop and said—"Now be frank about that photograph. Is it not made in the United States?" The Frenchman answered—"Oh, Monsieur, he is such bootiful piczure." "Ze artists he raves; oh, ze bootiful Madon!" "But isn't it made in the United States? And didn't you get it through Anthony's? And isn't it one of Sarony's?" "Let me assure you, Monsieur, it is ze finest photograph in ze world!" and then the fellow went into a dozen exclamations as to the perfection of the artistic effect, the light, the shade. It took a long time, but to persistent questioning at last he said—"We, we, Monsieur; he is Sarony!" "He is Anthony!" To get "*good* photographs," however, you must go to Paris (?); and "if American artists only *could* take *such* pictures" it would be so much *more* to our credit (?). The face was that of Maud Branscombe, and the photographer was Sarony, of Union-square. Look out for pictures taken over unmounted or stripped from the home card and remounted again. Beware of *artistic* photography in Paris.—*Anthony's Bulletin.*

EXCHANGE COLUMN.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

Fabronius.—There is no copyright in the name.

F. L. C.—Three and a-half feet of opaque covering over the sitter's head will be quite sufficient.

T. Lewis.—The subject is alluded to in several manuals, but there is none devoted to it exclusively.

H. G. G.—M. Despaquis, of Paris, is the patentee. On the merits of the invention we are not in a position to speak.

S. P. L.—Your chrome alum has not behaved in an exceptional manner. The colour, although blue when the solution is cold, becomes green when heat is applied.

Alpha.—Seeing you have tried all the other methods that have been proposed, why not devote a few hours to that in which alum is alleged to be an element of success?

D. W. (Leith).—A tall figure may be obtained in even your low studio by suspending, at a little distance in front of and overhead the sitter, a cloth which when photographed will be of the same colour as the background.

A. B. C.—The process of silvering glass globes, similar to the sample enclosed, is a secret one. We hope, however, to obtain some information concerning it, and, if we are so fortunate, shall publish it under the initials at the head of this answer.

J. W. B.—We have made inquiry respecting the standing and general character of the firm named, and the report is highly favourable. Should you not hear from them in course of a few days, we can, if you prefer it, submit your letter to the principal.

The Luxograph.—Just before going to press we have received a letter from Mr. Robert Faulkner, in which he says that a statement in Signor Lombardi's "testimonial" advertised in our issue of last week is incorrect, so far as Mr. Faulkner's immediate intention is concerned.

Thomas Tulloch.—Strain tightly the fabric which is to form the background, and give it a coating of weak size. Next apply a powder composed of burnt umber and lampblack or other pigment, using for this purpose a soft pad. When the desired effect has been produced the spray of water, judiciously applied, will suffice to fix the colour.

Geo. Beck.—Both of the lenses named are perfect in the sense of producing pictures free from distortion. But one of them—that having the shorter focus—must be used with a *small* diaphragm, otherwise the definition, both in the centre and all over the field, will be defective.

R. C. M.—On the principle that "desperate diseases require desperate remedies," we suggest that you give your bath a dose of cyanide of potassium, seeing that all other means of rectifying it have failed. We have known a similar case cured by the addition of a weak solution of permanganate of poaash. See, also, a paper by Mr. W. T. Wilkinson in the present number.

F. Smith Bell.—The markings on the plates are evidently owing to their having been rested, whilst wet, upon a bare shelf or other non-absorbent surface. In future let your shelf be prepared by being first of all thoroughly well scrubbed, and then covered from end to end with three or four thicknesses of blotting-paper. This will absorb all the drainage from the surface, and keep the plates clean.

Rev. F——.—Far better will it be to have a divided rule placed on the baseboard, and have it graduated to tenth parts of an inch. Let there be an index point or finger outside the sliding back of the camera and corresponding with the plane of the ground glass. By having such an arrangement as that described, and aided by the tables of enlargement and reduction to be found in our Almanac, your further proceedings will be rendered quite easy.

G. S. J. G.—The greasiness of the surface of the albumenised paper print may be effectually obviated by applying your tongue to it.

A Printer.—A mixture of chloride of platinum, essence of lavender, litharge, and borate of lead is said to be that employed in the platinising of glass. We are not aware of the best proportions, but we know that the mixture is applied to the surface of the glass by means of a camel's-hair brush, after which the plate of glass is heated in a muffle, with the result that the surface treated in the manner described becomes quite resplendent.

Subaltern.—The best process by which to take the series of pictures mentioned in your second note is the "moist" process of the late Mr. Sutton. So far as we are able to speak from experience it will answer admirably when used uuder the circumstances described. The process, in brief, consists in adding an extra grain or two of bromide to any ordinary collodion, sensitising the plate in the usual nitrate of silver bath. After undergoing a washing the plate is then coated with a mixture of albumen, glycerine, and water. Plates prepared in this manner remain good for a whole day. In reply to the query in your former note: a photometer of the nature suggested has already been tried, but up to the present time it has not proved successful. It would, doubtless, be highly convenient if the actinic power of the light could be ascertained by means of instruments having an index similar to those of the thermometer and barometer; but such an instrument has not yet been successfully introduced.

Death of an Amateur.—We much regret to announce the sad death of Mr. Frederick Gye, which took place on the 4th inst., at Dytchley Park, Charlbury, Oxfordshire. The deceased gentleman was on a visit to Viscount Dillon, and while out shooting with a party of friends was accidentally shot in the groin, from the effect of which, after a few days' suffering, he succumbed. It is scarcely necessary to say that Mr. Gye was proprietor and director of the Royal Italian Opera, Covent Garden, where for nearly thirty years he was so well known for the liberal and splendid manner he produced many new operas to the English lovers of music, that any details of Mr. Gye's management as *impresario* of that great lyric temple would be here out of place. In Mr. Gye's death we lament the loss of one of the early amateur photographers. Many years ago he was most successful in the production of stereoscopic glass positives, for delicacy of detail in which we seldom ever saw anything to equal, and up to a recent date he was a warm patron of any high-class photographic work. The funeral of Mr. Gye took place on Monday last at Norwood Cemetery, the ceremony being one of quite a private character. We simply add that the deceased was universally respected by all who knew him, and his loss will be deeply regretted for many years to come.

Photography in Court: A Faded Photograph.—Larkin *v.* Suchbery.—This was a claim heard in the Clerkenwell county court before Mr. Judge Whitbread, in which the plaintiff, a private gentleman and a yacht owner, sued the defendant, a photographer in Canonbury, to recover the sum of £5, being for money paid to defendant for a marine photograph. The plaintiff said that on the representation of the defendant he gave him instructions to execute a photograph of his yacht, and to go to her moorings for that purpose, and that on receiving a proof of the photograph he paid the defendant the sum agreed upon, and had the photograph framed and hung in his yacht; but the plaintiff subsequently discovered that the photograph had become so obliterated as to be perfectly indistinct, and under these circumstances he had applied to the defendant to return the money he had received, as, in fact, the photograph was perfectly worthless. The defendant in reply said that the fault was not attributable to himself, as the photograph was carefully mounted, well washed, and could not have faded, and if it had been properly framed the action of the sea air would not have affected it. At this stage of the case the learned judge considered that a delicate photograph would be materially injured by exposure to sea air unless properly framed and protected, and as the plaintiff did not appear to have done this judgment would be entered for the defendant with costs.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician,
For the Week ending December 11, 1878.
These Observations are Taken at 8.30 a.m.

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 972. Vol. XXV.—DECEMBER 20, 1878.

PERSONAL.—EDITORIAL CHANGES.

Seldom indeed, in these pages, has any editorial announcement been made in the first person singular. It is believed, however, that the intimation now to be given may fitly assume that form.

After having for nearly fifteen years occupied the well-known "old arm chair" in the editorial *sanctum* of The British Journal of Photography, the connection thus intimately established between the readers, the proprietor, and myself is about to be severed; for with the last number to be issued this month I retire from my editorial position, during the tenure of which I have secured many valuable friendships. I wish cordially to acknowledge the numerous courtesies I have received, and which I have ever endeavoured to reciprocate, although from the exceedingly heavy correspondence to which I have had to attend, as indicated only to a small extent by a perusal of the "Answers'" page in each number, some may have unintentionally been overlooked.

With respect to my successor, the position of editor-in-chief will be occupied by Mr. W. B. Bolton, of Liverpool—a gentleman whose intimate connection with emulsion photography will secure for him universal respect. Not merely as the initiator of the now generally-practised washed emulsion process, and in a less-exclusively individual sense of the original collodio-bromide process, but also as a lucid writer and intelligent experimentalist, Mr. Bolton is already well and favourably known to the readers of this Journal. I wish, therefore, to bespeak for my immediate successor a continuation of those courteous attentions of which I have been the recipient. Mr. Bolton will be assisted in his editorial work by those able writers, on every phase of photographic art-science, who have for such a lengthened period aided the chief editor in rendering The British Journal of Photography worthy of the high position which it has so successfully aimed at securing.

It is, perhaps, wrong to speak, as I have done, of my *severance* from this Journal, for it is far from being improbable that its readers will frequently hear from me shortly after the commencement of the new year, when I shall have settled down in my new home in the chief city of the United States of America.

J. Traill Taylor.

ON MOTTLING AND ITS CAUSES.

In the course of the discussion which followed the reading of Mr. Henry Cooper's paper, at the last meeting of the Photographic Society of Great Britain, the question of "mottling" was introduced, and Mr. William Bedford expressed the opinion that the defect arose solely from the employment of an unsuitable pyroxyline. It seems to us, however, that there are two distinct forms of mottling—not perhaps very easily distinguishable by their mere appearance, but readily so if the conditions under which they are developed be taken into consideration.

We agree so far with Mr. Bedford in his view that we are prepared to place an unsuitable pyroxyline in the foremost place amongst the causes which induce mottling; but, at the same time, it can scarcely be denied that the defect frequently makes its appearance under circumstances which preclude all possibility of laying the blame to that cause. When such is the case the origin of the fault is nearly always traceable to purely physical causes—such as too thick an emulsion, the presence of too much water in the solvents, or an excessively high temperature at the time of coating the plate. When, therefore, the defect makes its appearance under any of these conditions it will be advisable, before completely condemning the emulsion itself, to make a searching inquiry into the whole of the circumstances, with a view, if possible, of reaching the true seat of the evil; and for this purpose the nature of the mottling forms a tolerably good guide.

If the result arise from a too thick emulsion the markings will be large in size, and will have the character of waves or streaks running somewhat in the direction in which the emulsion is poured off the plate. The excessive thickness of the emulsion may arise from different causes. It may be due to too great a quantity of pyroxyline in proportion to the bromide, or *vice versâ;* or, those two constituents being in correct proportion, the quantity of solvents may be too small, as in the case of an emulsion which has been employed for coating a number of plates, without any addition of fresh ether and alcohol to replace that lost by evaporation.

When the pyroxyline is in undue excess of the bromide it becomes necessary, in order to obtain a sufficiently dense film, to form a thick coating by reducing the solvents to the lowest possible limit; but the sort of marking which results from this course can scarcely be classed under the head of "mottling," as it partakes more of the character of "crapiness" of a very pronounced description. Under the reverse conditions irregularities in the film are scarcely of the nature of mottling; and as this phase of the evil is not likely to be of very common occurrence under ordinary circumstances we need scarcely dwell upon it here.

The first type of mottling, then, may be considered to arise either from dissolving too large a portion of "pellicle" in a given quantity of solvents, or from using the same emulsion for a large number of plates without "thinning" it by the addition of ether and alcohol to replace that lost by evaporation. The next form of the defect caused by weak solvents is similar in physical characteristics to the first, the markings being large and distinct, but partaking less of the character of streaks. It is, however, distinguishable from the first-named by the peculiar glassy appearance of the surface of the film when "set," and by a tendency to further irregularities in drying.

When mottling occurs from too high a temperature in the operating room it is of an entirely different kind. The individual markings are smaller in size, and approach more closely to a circular shape; they are frequently also spread unevenly over the surface of the plate, one end of which may be perfectly clear, while the other (that at which the emulsion is poured off) is entirely covered with them. Working under such unfavourable conditions as regards temperature, the most perfect emulsion will frequently prove incapable of forming an even film; but, if other predisposing causes exist, it will be found absolutely hopeless to attempt the preparation of plates without resorting to some means of cooling the atmosphere.

When mottling arises from physical causes the results are, to some extent, remediable; but such is not the case when the pyroxyline is at fault, as by no amount of care in coating the plate, nor by any modification in the proportions of the different constituents of the emulsion, can the irregularities and imperfections of the film be avoided. It is, therefore, desirable to consider what are the conditions which lead to the production of this objectionable description of pyroxyline. For emulsion purposes—especially since the introduction of washed emulsions—the chief aim in the preparation of pyroxyline has been the formation of a product capable of rendering density and of resisting the washing or precipitation which the emulsion has to undergo previous to re-solution. The difficulty consists, not in securing density and resistent power, but in combining those properties with others of equal importance, and which require a different course of treatment for their production. Thus it is a matter of the greatest ease to produce a sample of pyroxyline capable of forming images of the greatest possible density, but wholly useless on account of structural defects; and, as we have had some experience in this direction, we propose to mention briefly the causes which operate, in the preparation of pyroxyline, in producing mottling and other similar defects in the finished film.

First, we will speak of the temperature of the acids. In the preparation of cotton for ordinary collodion purposes—that is, for use in connection with the bath—a high temperature produces a fluent, structureless collodion; and the same rule holds good, to a certain extent, when the pyroxyline is intended for emulsion purposes. If, however, the temperature, taken in connection with other circumstances, be too high the result is that the collodion—or, rather, the emulsion—possesses excellent flowing properties, but exhibits an apparent incapacity to carry the suspended bromide evenly over the plate. Thus: we coat a plate with an emulsion of this description, and upon pouring off the surplus we probably have a beautifully-even film; but, on the point of setting, as it were, the evenness suddenly gives place to a regular series of fine mottled markings, differing most completely from the appearance described in connection with mottling from physical causes, and answering, probably, to the defect designated by Mr. H. Manfield "flocculence."

High temperature alone, however, does not produce this result, but only in connection with some other variation from the normal conditions observed with regard to the mixed acids. The proportion of water present in the acids, on the other hand, seems to work independently of other conditions, and quite irrespective of the temperature, producing a marked effect upon the character of the resulting pyroxyline. In proportion as the quantity of water is reduced beyond certain bounds (dependent, of course, upon the raw material to be operated upon), so does the tendency to mottling, as well as other forms of marking, increase, and this is the direction in which, we believe, the gravest errors are made. With a view of securing the greatest amount of density the temperature of the acid mixture is raised to the utmost limit, and then, in order to avoid solution of the cotton, the *strength* is also raised; hence the trouble.

Our observations are chiefly based upon experiments made with paper and linen, though we have noticed the same results when working upon cotton. With the former class of substance we have found it extremely easy to produce a collodion possessing any degree of density combined with sensitiveness, but failing in the one quality—evenness of film; and in nearly every such instance we have been able to lay the blame to an insufficient proportion of water in the acids.

VARIETIES OF TONE.

Last week we dealt with the æsthetic bearing of the various "tones" in which photographs are printed, deferring to the present time the discussion of practical modes of bringing about these desirable varieties.

Naturally carbon printing first presents itself for notice, though the work for the operator in producing the desired result is practically *nil*, seeing that the manufacturer does for him all the mechanical part, the duty of selection alone belonging to the former. It is possible now to purchase not merely a few well-marked colours, but also—to assimilate their appearance as much as possible to silver prints—a considerable number of tissues of a brown or purple character, all varying slightly but each possessing marked characteristics. We have already alluded to a red tissue made similar in colour to the red chalk of the draughtsman. There are also sepia and other similar colours to be had, and there are few which, if they are required, cannot be produced. This is not the occasion to enter into a disquisition as to their qualities in the direction of permanence, but there is no doubt that the fullest necessary information will be freely given on any required point by the manufacturers.

The treatment by the printer of any given tissue has no practical effect upon the colour—hence, as we have said, his share in the toning is merely selection; but if for any special purpose he wishes to make a difference in the colour of a given picture it is open to him to do so by dyeing the print afterwards, the gelatine of the print lending itself in a very easy manner to tinctorial treatment by a variety of substances—the aniline dyes in particular, which may now be purchased very readily, either in solution or crystals.

The toning process, *par excellence*, however, is the time-honoured treatment by gold of a silver print—an almost inexhaustible topic. The present taste of photographers seems to be decidedly for a brown, as rich as possible, and inclining rather to yellow than to red. There are many causes for this preference, the main one, we believe, being this—the use of heat in hot-pressing, by burnisher or otherwise, which, as we have on a former occasion pointed out, has the effect of increasing the brilliance and depth of the shadows to a most exalted degree, the colour at the same time changing in the direction of a brown, a rich burnished print of a purplish-brown tone being rarely seen. No existing process gives the excessive beauty and transparency of the darks that hot burnishing or pressing produces, and it is obvious that such most desirable qualities should determine the tone to be aimed at in many instances.

The production of a brown tone, when first it became a fashion a number of years ago, was aided by the introduction of a special paper salted with a barium salt, which has the character of limiting the range of colour to the region of reds and browns, any attempt to force a good purplish tint with it being unsuccessful.

Earlier in the days of our art chloride of sodium was the chief salting material, and with that, too, the range was limited and outside of the bluish colours, the introduction, at a later day, of chloride of ammonium being one of the most striking of those many apparent insignificant changes in modes of working which have wrought such important improvements in the general character of photographic work. With an ammonium-salted paper the richest purples, almost approaching to black, may be obtained, while the browns also are within its capabilities; but not, we are bound to say, with such thorough success as the papers specially prepared for those colours.

Turning now from the make of the paper to the gold bath: we find we have in our hands still further powers of stamping a distinctive character upon our prints by varying its composition. Carbonate of soda and gold was the first formula published as the alkaline gold toning; this was quickly followed by one which substituted phosphate of soda for the carbonate; and after that nearly every salt under the sun has been tried and recommended. In common practice, however, the carbonate, phosphate, and acetate of soda, and the so-called chloride of lime, are employed almost to the entire exclusion of any other. For quickly-extemporised baths, capable of producing most varieties of colour, the carbonate is a general favourite; but the colour it produces is rather rawer in character than the others give, and the bath does not retain its properties unaltered for many hours—in fact, if not specially acidified after use it shortly ceases to be able to tone.

Phosphate of soda is very similar in action to carbonate, giving rather more delicate colours; but it also is liable to quick change, though not so quick as the carbonate. Biborate of soda, or borax, enables a particularly blue hue to be produced—one not to be recommended for general use, but perhaps useful in special cases.

The favourite salt of all is, however, the acetate of soda. With it every tone from brown to purple can be obtained, and of such a soft and delicate character as to thoroughly deserve the general favour with which it is regarded. There is scarcely any feat in gold toning which cannot be performed upon an albumenised paper print with the acetate of soda gold bath. The solution keeps for weeks—we might say months—in good and even working order, and is freer than any other from the many difficulties of mealiness, uneven toning, &c., &c., so often a nuisance to amateurs and professionals in printing operations.

There remains to be noticed the chloride of lime bath. We may here, *par parenthese*, note that "bleaching powder" is the best name for this substance, the term "chloride of lime" being a chemical absurdity. Chloride of calcium is another substance altogether; although, through these improperly-selected terms, confusion has often been caused with regard to this particular bath. Its properties are to give a rich blue or black, such as cannot be obtained fully with any of the before-named substances, and for those who like to give this tone to their prints it is invaluable. When carefully worked, and not made too strong, it gives a delicacy and an engraving-like appearance which no other toning bath known can rival. In its tone it is most like the beautiful colours of Mr. Willis's platinum process, which, upon plain unglossed paper, surpass anything else in the region of photographic "tones."

THE "CONTINUATING ACTION" OF LIGHT APPLIED TO CARBON PRINTING.

Since the commencement of the present month residents in the metropolis have had no occasion to be reminded that the proverbial "dark days before Christmas" have already put in an appearance; especially will this be the case when they read the Astronomer-Royal's report, which shows that the actual duration of registered sunshine in London during the first seven days of December was less than three and a-half hours, or about six per cent. only of its possible duration. We have reason to believe that many provincial towns have not fared much better as respects weather than has the metropolis. One of the first to experience inconvenience from such a state of the light is the photographer; for, not only is it impossible for him to produce negatives, but he is also unable to execute such orders as he may have for prints. He may put out his frames day after day, but the number of prints obtained will be far short of his requirements; and he frequently finds that after a print has been exposed for two, or even three, days he is compelled to destroy it owing to the discolouring of the paper. Especially is this the case with vignettes, thus entailing considerable loss not only in time but in material. It is true that he may, to some extent, ameliorate matters by using permanent sensitised paper, which is not so liable to change colour in the frame, and is generally more sensitive than that in ordinary use; and he may, to some extent, increase the sensitiveness of his ordinary paper by more heavily salting and sensitising it on a stronger bath. Fuming with ammonia also increases the sensitiveness. But with all that he can do he cannot effect much in shortening the exposure.

In these remarks we have only referred to silver prints; but, as we shall presently show, the carbon printer has many advantages over his argentic *confrère,* inasmuch as carbon tissue is much more sensitive than silver paper, and only requires from one-third to one-half the exposure. Thus it will be seen that at least double the number of prints can be produced in a given time from any negative when carbon is employed than it is possible to obtain when silver is used. Added to this advantage it is possible to still further shorten the exposure by taking advantage of the so-called "continuating action" of light—a property possessed by exposed carbon tissue. It is to this property we are now about to direct attention.

In the early days of the carbon process it was frequently noticed that prints which had been kept for some time after printing and before development often turned out to be much darker than was anticipated; but not always. This at that time was attributed to one of the *uncertainties* of the process, and naturally caused much disappointment amongst experimentalists. Some five or six years back Captain Abney brought the subject before the Photographic Society of Great Britain, and showed that carbon prints which had only been partly printed would, if kept in the dark, gain in exposure, and that a print which had received but half the requisite time in the printing-frame would, if the development were deferred some twelve or fourteen hours, prove to be quite as good as if it had received the full exposure. This fact was denied by many, and if our memory serve us rightly even the Photographic Society of France disputed that any such property existed. At the June (1877) meeting of the Photographic Society of Great Britain Mr. J. R. Sawyer read an able paper on this subject, which he illustrated with some well-chosen examples that showed incontestably not only that this action did exist, but that it went on much more rapidly when the printed tissue was freely exposed to the air than when it was protected from its influence. He also showed that prints which had only received one-sixth the requisite exposure would yield quite as good results by keeping some days as if they had been fully exposed in the frame.

Our readers will, doubtless, remember that in an article which appeared in The British Journal of Photography (No. 897) for July 13th, 1877, we gave details of some experiments we made when on a visit to Mr. Viles, of Pendryl Hall. We, in conjunction with that gentleman, found, when using the solar camera for making enlargements, that by substituting carbon tissue for silver paper the requisite time of exposure was reduced from one hour to twenty minutes. That was when the picture was finished at once; but it was still further reduced to six minutes when the picture was kept for twenty-four hours before development. Thus we see that, by taking advantage of this property, ten times the number of prints can be made in carbon that can be produced in silver; and, by taking still further advantage of this continuing action, as Mr. Sawyer has done, a still larger number can be obtained.

We have now shown that the carbon process possesses many advantages over silver in the rate of production. Being anxious to know how far this continuating action was utilised in actual practice, we applied to several workers, and they all informed us that the action was too uncertain to be of any practical value, as they found that, occasionally, the requisite gain was sometimes obtained in twelve hours, which at other times required as much as twenty-four or even thirty-six hours to bring about the same results; hence they had not been able to take that advantage of it in practice which might have been expected. Now, from this it would appear that some factor was at work which had not been taken into consideration.

In a recent conversation with Mr. E. W. Foxlee, who is well known as an ardent experimentalist as well as a worker in the carbon process, that gentleman informed us he had found that the so-called "continuating action" was entirely due to moisture in the tissue, and that if it were made thoroughly dry after exposure, and kept so, no darkening of the picture occurred, the "continuating action" being totally arrested, so that a print might be kept a month or more after exposure and before development in so far as this action was concerned. He also informed us he had found that this action was most energetic when the exposed tissue was kept in a warm and damp atmosphere, and least so when in a cold and dry one. If this theory be correct—and our experiments, as far as they have been carried, fully endorse it—there can be no doubt this will very materially aid in the production of carbon prints by making this hitherto uncertain action better understood, and enabling printers to bring it more under control.

That our readers may better understand the matter we will here detail one of Mr. Foxlee's experiments. He took a piece of tissue and placed it on six test negatives which had been found by experiment to require exactly the same time to print. These were then exposed to light for only half the time that would be required if they had been finished at once. The insolated tissue was then divided into six pieces, each piece being a complete picture. One of these was developed at once, and it proved, as was expected, to be only half done. Two other pieces were put into an air-tight metal case, and the lid secured by means of gum paper, so as to prevent the access of air. The remaining three pieces were transferred to a drying closet, and allowed to remain until they were thoroughly desiccated, or as near so as the composition of the tissue would permit. They were then put into an air-tight case, and the lid securely luted on with india-rubber. Twenty-four hours after exposure the case containing the two prints that had not been dried was opened and one of the pictures removed, the case being again closed and secured as before. Upon development this print proved to be nearly dark enough, though not quite sufficiently so. Four days after the exposure the second print was removed, and upon development it proved to be very nearly insoluble; but, by dint of long soaking in hot water, a very much *over-printed* picture was obtained. On the seventh day the case containing the prints that had been dried was opened, and a print removed (the case being, of course, secured as at first). This proved, on development, to be quite as soluble as the first piece had been, and the picture not a bit darker. Twenty days after another piece was developed, and this, like the previous one was found to have gained nothing either in exposure or insolubility. Sixty days after the sixth and last print was developed, and it proved to be very nearly insoluble—quite as much so as the third picture, which had been kept four days only, but the gain in exposure did did not seem quite so great.

Mr. Foxlee attributes this gain and insolubility to the tissue having absorbed moisture from the atmosphere when the case was opened (this, he says, it will do with great avidity when it is in such a very dry condition), as the air was very damp at the time. This is borne out by the fact that it was not so crisp as when first sealed up. Mr. Foxlee has shown us a print that was kept for seven weeks after exposure which is not a bit darker than one from the same set of negatives developed immediately after exposure.

These experiments cannot fail to be of much interest to carbon printers, and will greatly tend to remove what has hitherto been considered one of the uncertainties of the carbon process. We hope Mr. Foxlee will continue his experiments, and that he will give our readers the benefit of such tentative experiences.

A REALLY RELIABLE DRY-PLATE PROCESS.

A communication to the Photographic Society of Great Britain.]

Although from time to time an immense number of formulæ for collodio-bromide processes have been published, I am induced to add still one more to the list, and, I believe, not without some satisfactory reasons. I have entitled this paper *A Really Reliable Dry-Plate Process*, as I feel convinced from a multitude of trials, under the most varied circumstances, that plates prepared in the manner I am about to describe fulfil all the requirements of the artistic photographer, whether amateur or professional; and, so far as I can judge, there is only one respect in which they might be improved. A little extra rapidity would add to their value; but even this I hope soon to gain. It must be borne in mind it is of the plates themselves, when ready for the camera, I speak as being all but perfect. In the method of their preparation very many improvements may in time be made.

It will doubtless be within the knowledge of many of my hearers that for many years past I have devoted a great deal of time and labour to experiments on various emulsion processes; that I have, from time to time, at longish intervals, published formulæ for the help of others working in the same direction as myself; and also that I have often shown at the Society's exhibitions pictures produced by the methods I at the time advocated.

We began with a very simple process, and then as we went on from step to step all varieties of complications were introduced with much pride by different individuals. Then came a reaction. We almost returned to our pristine simplicity; and at last the *washed* emulsion process was invented, and ultimately became a practical commercial success. When this stage was reached we most of us imagined the experimentalists might take a well-earned rest, as we had obtained what had so long been desired—a simple and sure process. But soon these delightful dreams were rudely disturbed, and we awoke to the knowledge of difficulties of a new kind, and after much disheartening work I began to think we had, after all, been working in a wrong direction, and I even hinted in print at my melancholy convictions. Spite of the exquisite simplicity of the method, and the very fair quality of the negative given by many of the washed emulsion processes, I was compelled to confess that I, at least, could not prepare plates by the process which, after keeping for some time, give even decent negatives, and hundreds have echoed the same doleful tale.

To those who have taken any interest in the subject, the discussion on the peculiar spots and markings which almost were the defect on these plates must be too familiar for any need of much reference to it now. Suffice it to say my own convictions, based on a multitude of experiments, were at the time quite in accordance with those of most other workers as to the cause of our trouble; and in a short article in both this year's almanacs I recorded my opinion that our enemy was simple organic dust, and at the same time held out hopes of a cure. Doubts have recently been thrown on the correctness of our supposition as to the cause of the spots, and I am anxiously awaiting Captain Abney's promised disclosures on the subject.

However, be the cause what it may, we are all agreed that the use of a "preservative" in the preparation of the plate will entirely prevent the appearance of the pests; and I am much pleased to be able to give formulæ by which films possessing the following most desirable qualities may be produced with certainty and rapidity. First: the *quality* of image is almost perfect, much resembling that given by a really good collodio-albumen plate. Secondly: the films will keep for a lengthy period without deterioration, both before and after exposure. I shall exhibit a negative which was kept five months before exposure, remaining for three months in a dark slide, and carried about on long journeys, being submitted to many variations of temperature and hygroscopic conditions of the atmosphere. After exposure and before development it was kept five weeks. Other plates have been kept three months after exposure. I give these *data* as many folks' ideas of a "lengthy period" are various. I have plates prepared early this year which I am keeping on to test from time to time.

In exposure very great latitude is allowable—an unspeakable boon to the photographer on a tour, with no conveniences for developing a trial plate from time to time. This last summer I took a number of plates away with me on a three months' outing, and exposed some of them from time to time on a variety of subjects, and many times felt quite at sea as to the proper exposure to give, and yet on my return home I developed every plate I had exposed into a decent negative.

Another point of importance is that the development is simple, entirely under control, and the most varied effects may be produced during its course by judicious use of the powers alkaline development give us. Some may think it rather late to bring forward a slow process in these days of extra rapidity; but I for one require plates to give me *pictures*, and I must have materials over which I can exert some influence during the progress of the chemical changes which produce the visible image. I must be able to modify the action of the developer, both generally and locally, and so be able, to a certain extent, to raise the production of a negative from the region of mechanics to that of art. This we cannot do at present with gelatino-bromide plates, and, until the extra-rapid films are as much under control as the slower collodio-bromide, I shall surely keep to the latter for general work, reserving the "rapids" for special and exceptional cases.

Before giving my formulæ and working directions I must (once for all) disclaim any claim at novelty. It has only been by making use of the experiences of many fellow-workers that I am able at last to give a formula with entire confidence, and you will find in it very little indeed that has not been published before, either by myself or others. It would unnecessarily take up your time were I to try and apportion the credit of each point to its proper author; and, besides, it is not needed, as most of you are acquainted with the whole history of emulsion work.

I have lately been asked if a commercial washed emulsion would not answer for the process as well as the one I recommend. Unfortunately I have not succeeded nearly so well with any of the host I have tried as with the one I am now about to describe. However, I have reason to hope the drawback of each one having to prepare his own emulsion will speedily be removed, one house having already requested permission to prepare it strictly according to my instructions, and to vend it under a distinct name.

And now to give the formulæ as briefly as possible:—Prepare first a stock of plain collodion by dissolving 160 grains of ordinary pyroxyline in six ounces of absolute alcohol and ten ounces of ether. Good methylated alcohol will answer for these first solvents, as also ether s.g. 730, purchasable at 1s. 6d. per pound. Also make an alcoholic solution of zinc bromide, eighty grains to the ounce. Even after filtering this solution will throw down a deposit upon keeping, and this must be carefully left undisturbed.

To make ten ounces of washed emulsion, take five ounces of the above collodion and add to it one ounce of the zinc bromide solution and twenty minims of syrupy lactate of ammonia.*

Sensitise with 150 grains of silver nitrate, dissolved first in eighty minims of water and then in three ounces of strong alcohol. Boil together, and add it to the bromised collodion at once. I attach importance to the addition of the boiling solution, so as to raise the

* Some experiments made since this paper was first written go to show that a great gain in sensitiveness may be obtained by reducing the proportion of plain collodion. I have tried three ounces, and even two ounces, instead of the five, with the most encouraging results. I am indebted to leaders in The British Journal of Photography for the suggestion.

temperature of the mixture, and when only a small quantity (such as the above) is made I take the precaution to wrap the bottle in a thick cloth to retain the heat as long as possible. On examining the portions just given it will be seen the silver nitrate is decidedly in excess, and that the alcohol is used in larger proportion than usual.

Lactate of silver has long been a favourite addition of mine to emulsions, and I am more than ever pleased with its action. I must call attention to a curious effect which is produced if the bromised collodion be allowed to stand many minutes after the lactate is added, and before the sensitising. The collodion becomes quite milky, and throws down a crystalline deposit. It is well to add the lactate immediately before the silver, or even to defer putting it in until after the sensitising. I cannot pretend to say what chemical or physical effect occurs in the "lactised" collodion. I merely mention the fact.

The emulsion is ripe in about twenty-four hours; but I am disposed to think it an improvement to keep it for a longer time—up to three days. At the expiration of the ripening period twenty minims of strongest nitric acid are to be added, and the emulsion well shaken. I prefer to add the acid just before the washing instead of at first. I believe a better film is given by so doing.

We are now faced with the question of how best to wash the emulsion. Shall we pour it out and evaporate the solvents, or precipitate it? From a lengthened experience of both methods I cannot recommend precipitation, except in cases where the finished emulsion is to be used up within a month. It is now a generally-acknowledged fact that precipitated emulsions will not keep. But where large batches of plates can be prepared at a time, and no waste occurs, I can speak to the good qualities of the emulsion when precipitated by mixing it with twice its bulk of the following organifier, and when the pellicle has fully separated and set, washing for some time in water containing a little nitric acid (half-an-ounce to one gallon), and finally in several changes of pure water:—The mixture:—Tannin, 500 grains; gallic acid and grape sugar, each 200 grains; strong acetic acid, ten ounces, or a proportionately lesser quantity of glacial is to be dissolved in water and made up to 100 ounces. This method is expeditious. The alternative and, I think, the better plan, is to pour out the emulsion into a sufficiently large dish (one ounce to twenty-five square inches, or say five ounces in a 12×10 dish). Evaporate the solvents more thoroughly than usual; in fact, the pellicle may be allowed to get almost dry, wash first in water containing half-an-ounce of nitric acid in one gallon of water, and then in plain clean water for some considerable time. If the water in use is hard, distilled water should be used at first. And lastly, wash thoroughly. The extra drying of the pellicle, and the large proportion of alcohol it contained, will materially assist in shortening the time. When dry, dissolve the above quantity of pellicle in five ounces of pure absolute alcohol, and a like quantity of extra-purified methylated ether, s.g. 720. An emulsion prepared in this manner with the lactate of ammonia will give excellent negatives without further preparation if the plates are used at once; but its subsequent treatment with alkaline albumen gives the especial qualities for which I so greatly value it. The plates are much quickened by the after treatment. This particular emulsion has its sensitiveness doubled, whilst some others are rendered slower.

A substratum is necessary for all plates above half-plate size, and I know of nothing for the purpose to equal the insoluble gelatine I introduced some little time ago. For convenience sake I repeat here the method of preparing and using it:—Soak sixty grains of Nelson's best sheet gelatine in water, drain, and pour on ten ounces of boiling water. Then add two drachms of a ten-grain solution of chrome alum. Stir vigorously. Filter and use whilst warm. Coat the plates without drying them after cleaning, and after draining place them to dry in a box or cupboard with the lower edge resting on clean filtering paper. They must be completely desiccated before use. A good plan is to heat them singly and to coat as soon as cold. Small plates may have an edging only either of the gelatine or india-rubber; but I prefer to give them the full coating. It is less trouble by far than wiping and polishing the plates. Coat with the emulsion. When well set immerse in water. I use a grooved box, well coated with shellac, and when I have coated and immersed as many plates as I intend to prepare I cover up the box and thoroughly ventilate the room, so as to get rid of all fumes of alcohol and ether before proceeding further. I see no reason why a tin box with removable grooved pieces, similar to the ones sent out by the Autotype Company for developing chromotypes, should not answer. Of course it must be kept for this purpose alone.

The plates are now to be flooded with the alkaline albumen or dipped in a bath of it. In either case the albumen must be in contact with the film for at least a minute. The plate is then to be thoroughly washed, flowed with a preservative, drained, and dried. After backing it is ready for the camera. The albumen may be prepared in bulk either with white of eggs or with the pure dried preparation. Of the latter dissolve sixty grains in three ounces of water and add one drachm of strongest liquor ammonia, 880. If white of egg be used, first pour in a few minims of dilute acetic acid and stir well. In two or three hours strain, and to each ounce add two of water and one drachm of liquor ammonia.

For the "preservative" I have tried a host of substances, and find the simplest of all to be the best, viz., a two-grain solution of gallic acid. For the sake of constant uniformity and certainty I was anxious to discard from my formulæ all compounds of uncertain chemical constitution, such as beer, or even tea and coffee; or else I could, from my own experience, speak strongly in favour of a decoction of tea, made by boiling one ounce of compressed fine black tea in four ounces of alcohol and twelve ounces of water. One ounce of this is diluted with ten ounces of water to form the final coating for the plate. It is of importance that the plates should be thoroughly dried, especially if intended for packing; as, although these plates will stand exposure to a moist atmosphere better than most others, any damp remaining in the films when they are stored away will be a source of future trouble.

I trust I shall not be thought tedious if I devote a very short time to a description of my method of packing dry plates. It is old enough, as Mr. R. M. Gordon and I have used it for years, and I believe both of us have described it more than once. Cut some strips of cardboard a little more than a quarter of an inch wide, and glue them down on a piece of silk, strong muslin, or other flexible material, about one-eighth of an inch apart. When dry, cut with a sharp knife along the centre of each strip of cardboard, thus making a number of strips of flexible material with a strip of card one-eighth of an inch wide glued on each edge. For large plates the card may be wider. The space between the strips should be equal to the thickness of two plates. Cut the strips to the length of one side of the plates. To pack a dozen plates, lay one on the table face upwards, and, taking two others in the hand, place them back to back (without anything between), and put one of the card and linen guards over each end; lay these on the single one, and then on them place two others back to back as before, without any guards, then two others with guards, and so on until enough are thus laid in a heap, when we finish with a single plate, face downwards. It will be seen from this that two guards will suffice for four plates, and although the faces are kept away from one another by the strips of card the backs of the plates have nothing between them. To protect the parcel of plates I wrap it first in very thin sheet gutta-percha, then in tinfoil, and finally in good brown paper. Although perhaps too expensive a method for commercial use, I consider it perfect for amateurs, who can use their cardboard, guards, gutta-percha, &c., over and over again.

Returning to the plates themselves: the next point is the exposure. As I have before said, they are not very rapid, and it is well to give a full time in the camera.

In referring briefly to the development, I may sum up my experiences in the form of a few maxims to be observed:—Beware of strong pyro. Use it very light to begin with—from one-fourth to one grain per ounce—and add carbonate of ammonia and bromide of ammonium as the exigencies of the case may require. For a $7\frac{1}{4} \times 5\frac{1}{2}$ plate I usually begin with an ounce of water with half-a-grain of pyrogallic acid, one drop of a saturated solution of ammonia carbonate, and a like quantity of a ten-grain solution of ammonium bromide. Use patience and do not hurry the development. When all the details are out a little stronger pyro. will give plenty of intensity. Beware of making the image too intense; this is easily done. By pouring the developer repeatedly from the measure upon one spot, especially if a little extra ammonia be used, local detail may be coaxed out, and by employing the same plan with stronger pyro. local intensity is easily obtained. With these plates the developer may be used almost like a painter's brush, and it is only by the intelligent and artistic use of all such means to an end that *pictures*, such as a true artist would value, can be produced by means of the camera.

In conclusion: I must again for a moment refer to the want of novelty in the foregoing. In some quarters I know a certain amount of curiosity has been excited by my new process; and, although I have many times declared I was only working upon old ideas with a slight leavening of new ones, I fear a good many may be disappointed at first when they find there is really so little new after all.

All I can say is I am thoroughly well satisfied with it, and feel amply rewarded for the years of labour I have devoted to emulsion work. I can only trust, if others will strictly follow out the formulæ and directions given, they will be equally pleased with the certainty and simplicity of the process and the excellent quality of its results; and I hope they will then feel as grateful as I do myself to the many experimentalists through whose united labours we are at last in possession of so good a process. H. COOPER, Jun.

A CASE OF THE DESTRUCTION OF THE LATENT IMAGE ON WASHED EMULSION, AND ITS RESTORATION.

[A communication to the Photographic Society of Great Britain.]

WE do not nowadays hear much talk of proselytism, but I must confess I take great pleasure in converting a photographer from the wet process to the dry.

Some time since my friend, Mr. Payne Jennings, and myself discussed the question of wet *versus* dry processes, and I succeeded in getting him to solve it by actual experiment; and, being a great admirer of the high artistic skill of the solver, I endeavoured to do all in my power to make my favourite emulsion process a success in his hands.

Our scene of operations was Bolton Abbey, in Yorkshire, and, to be quite certain of giving proper exposure, I took down a tent and the necessary chemicals in order to develope a plate occasionally. Two days before we started I got my friend's camera, and washed and varnished it, and this, as I expected, proved a perfect protection against spots, which invariably occur when a camera which has been long in use is employed for emulsion work. I took 12 × 10 plates prepared with washed emulsion, and without any substratum or preservatives, the surface of the glass before washing being rubbed with talc or French chalk to prevent the slipping of the film during development. We also had 12 × 10 plates to clean on the spot, and a good quantity of emulsion in bottles, together with sensitive tissue in blocks, and my own apparatus and roller slide. When we arrived at St. Pancras station, and all our luggage was put together on the platform, I confess I felt uneasy, as the amount was not likely to impress my wished-for convert with the reputed portability of the dry process over the wet. After a day's travel we arrived at Bolton Abbey in the evening; but, owing to a want of accommodation in the hotel, we were forced to convert a shed used for picnic parties into a regular laboratory. The next day we began our operations early, exposed a plate, and having erected our tent, developed it, and it proved perfect. So satisfied were we with our success that we proceeded to photograph the abbey and magnificent scenery with which we were surrounded, leaving development for a later period. In the afternoon of this first day we experienced windy weather, and from this time till our departure the weather broke up; but having made such tremendous preparations we decided to remain in Bolton to wait for fine weather, but everything was against us. One of the heaviest thunderstorms of the season caught us when we were away in the woods some half-mile from the hut where we had left our reserve plate boxes in the open. When we arrived, after the storm had somewhat abated, we found everything drenched, and literally drowned in water. The water in the hut covered the tops of some of the bottles, and mixed with the various chemicals used for development, giving them a dark brown tint, and floating in it was a portfolio containing exposed sensitive tissue—our hope and my pride.

During the morning we tried to develope a plate or two, and they came out well, as did some of the drowned sheets of tissue. On our return to London, owing to press of business matters, we did not develope the remainder of the plates till a week had elapsed, and, alas! the first, second, and third plates proved complete failures—an unmistakable indication of the destruction of the latent image. After the ordinary treatment the sky line appeared, then fog, and no variation in the mode of development could save the plate. This was incomprehensible. I have seen a similar occurrence when the plate was kept a long time between development and exposure; but then a fortnight is not a long interval.

Casting about for a reason of this destruction, I could only account for it from the influences of ozone generated during the thunderstorm in Bolton—an opinion conformable to that held by Captain Abney. Whatever the cause, I was greatly annoyed at the failure; but considering that an antidote must exist I looked about for one. I experimented on the tissue in my roller slide, and also in Mr. Skeen's, who accompanied me, and I was rewarded by complete success.

Cases of the sudden and inexplicable disappearance of the latent image on dry plates are recorded by many experimentalists, and hoping that the remedy I shall now describe may be useful in like instances, I have thus minutely entered into details.

After the plate is treated with alcohol and washed with water it is *immersed* in a saturated solution of carbonate of ammonia, where it remains some four or five minutes. It is then drained and developed in the ordinary manner. I do not wish to enter into an explanation of the action of the carbonate of ammonia, because I cannot avoid being empyrical; but I cannot help putting on record that it dissolves away a certain amount of the silver compound (presumably oxide of silver) from the *exposed* plate, which can be detected by the adding of potassium bromide to it. There is every appearance that this salt, formed by atmospheric influence, is the cause of the evil, and that it is soluble in the carbonate of ammonia. When it is removed the plate is just as amenable to development as when in its best condition.

I conclude these observations by stating that all Mr. Payne Jennings' negatives on glass or tissue were successfully developed by this treatment. Some of them are exhibited in this room. I may also mention that some very old tissues, exposed two years ago and not developed, gave me good results when so treated. In my experiments I treated only half the plates with the carbonate. I developed the two portions simultaneously. The difference in result is striking. LEON WARNERKE.

PRACTICAL INSTRUCTIONS IN MODERN PHOTO-MECHANICAL PRINTING METHODS.

PART I.—PHOTOLITHOGRAPHY.

VIII.—FAILURES AND THEIR REMEDIES.—A very frequent source of failure arises from a tendency towards a general insolubility on the part of the bichromated organic matter which forms the sensitive surface of the transfer paper, the result of this being a general adhesion of the printing ink to every part of the surface, notwithstanding a prolonged soaking in water. Now, taking bichromated gelatine as a type of the sensitive surfaces one has to deal with, it must be remembered that insolubility is not only induced by the action of light, but also by other agencies. In actual practice complete insolubility is seldom induced by accidental or unforeseen causes, but it often happens that a sufficient tendency to a general insolubility occurs to seriously interfere with the operations of the photolithographer or to cause entire failure.

The most frequently-occurring causes of insolubility on the part of the sensitive coating of the transfer paper are the following:—Slow drying. Presence of reducing agents in the air, among which may be mentioned sulphuretted hydrogen, effluvia from drains, and sulphurous acid arising from the combustion of coal gas. The continual addition of moisture to the air, which may happen when a paraffine stove is employed for producing the heat and provision is not made for carrying off the water formed by the combustion. Long keeping of the sensitive transfer paper, especially in a damp place.

The injurious tendency of all the above circumstances is considerably lessened by keeping the air slightly charged with ammonia, this being most conveniently done by saturating a tuft of cotton-wool with strong ammonia solution and placing it in the drying-room. In the case of dry paper a few lumps of ammonia carbonate may be placed in the box where it is kept.

Some other causes of insolubility are enumerated below, and in each case the remedy is obvious:—Omission to add ammonia to the bichromate bath. Use of paper containing alum. Inadvertent exposure to light. Over-exposure under a thin negative. Use of a gelatine hardened by the addition of alum.

It sometimes happens that the gelatinous coating of the transfer paper dissolves entirely away during the operation of developing the transfer, and the surface becomes, in consequence, entirely denuded of ink. This generally happens when an exceedingly soluble gelatine has been employed for making the transfer paper, or when the gelatine has been deteriorated by its solution having been kept hot for several hours. This dissolving away of the coating from the paper is more likely to happen when the coating is unduly thick than when the thickness is moderate. Remedies: use of a harder sample of gelatine or increased exposure.

Ink is often removed in patches from the lines of the transfer by the use of a brush which has become matted or clogged up with ink. In developing the soaked transfer with a wet camel's-hair brush no adhesion should be noticeable between them, or the transfer is likely to be damaged.

After insolubility, the most frequent cause of failure in the process of making a half-tone or stipple transfer, as described in the preceding chapter, is damage caused by a slight rubbing action during the use of the inking brush, the consequence of this being the removal of portions of the farinaceous coating, together with some fibres of the paper.

The failures incident to the transference of the fatty image to the lithographic stone arise from a variety of causes, and the principal iculties arising at this stage of the process are as follow:—Puckering up to the transfer when the pressure is applied. Non-penetration of the ink into the stone. 3. Undue adhesion the transfer paper to the stone. 4. Blurring or spreading out of lines. 5. Slipping of the transfer on the stone. 6. The image, a great part of it, remaining on the transfer paper.

The puckering up of a transfer when the pressure is applied may se from the fact of the transfer being too wet, and the mischief y be exaggerated by the tympan being insufficiently stretched or perfectly lubricated. Too much backing material often increases tendency to puckering. In addition to altering the above-ntioned unfavourable conditions, the sheets of French-chalked per, recommended on page 556 of the present volume, may be erposed between the transfer and the tympan. This remedy is nerally useful in any case of the transfer slipping over the stone. non-penetration of the printing ink into the stone generally arises m extreme hardness on the part of the stone or from the presence moisture or mucilaginous matter in its pores. An ink highly rged with pigment has less tendency to penetrate than an ink taining a small proportion; it is, therefore, sometimes advisable add lithographic varnish to the ink employed for coating the nsfer.

One of the most annoying sources of failure is an extreme degree adhesion between the transfer paper and the lithographic stone, d this generally arises from the fact of the stone being made so as to partially melt the gelatinous coating of the transfer paper. a case of this kind rather warm water will have to be employed order to effect the removal of the paper; but it is extremely diffi-t to remove all traces of gelatine, so as to enable the gum to netrate into the pores of the stone. When circumstances render desirable to use transfer paper rather thickly coated with gelatine, d to warm the stone rather more than usual, it is as well to harden transfer by immersion in a ten-per-cent. solution of chrome alum ore putting it down on the stone. Blurring of the transferred age generally occurs if too much ink has been applied to the nsfer in the first instance. When a transfer is observed to be er-inked it is generally advisable to put it down on a stone only a degrees warmer than the air of the room. The fact of the fatty age on a transfer remaining entirely or partly adherent to the per, instead of becoming transferred to the stone, generally arises m insufficient damping of the transfer, from the partial or complete ying of the fatty ink, or from insufficient pressure.

The greater number of the difficulties which are likely to trouble beginner will probably be found to occur during the operation of nting. Let us first devote attention to cases in which the whites the subject become inked, and under this head may be included only a general tinting of the whites but also the presence of dark ots, and a gradual clogging up of the fine portions of the subject.

Some lithographic stones are so porous that the moisture applied the surface is immediately absorbed, leaving the face of the stone dry as to become tinted by the ink. In a case of this kind it is ll to put the stone into a tub of water until it is moistened all ough.

During the operation of printing it frequently happens that old ages, which have been imperfectly removed by grinding, make ir appearance. As soon as a spectral image of this kind is iced a transfer must be printed from the defective stone, and it ould then be put down on a fresh stone. Any trace of the old age which may be transferred with the device may generally be aned off by rubbing with a small slip of snake stone, followed by energetic an acidulation as the subject will bear. Old oil or grease rks on a stone naturally lead to similar difficulties, and require nilar treatment.

Sometimes traces of greasy matter in the gelatine employed for ating the transfer paper give rise to markings on the stone, and if ese markings are not very intense the mischief can often be reme-ed by a strong acidulation, or by erasure with snake stone. When e stone has been made so hot as to melt the gelatine of the trans- paper it often happens that some of this substance penetrates so eply as to prevent the proper action of the gum and the etching id. In a case of this kind a tinting of the whites often occurs er a number of copies have been printed off. Occasional re-idulations will generally prove a remedy, as the gelatine gradually comes eliminated, making way for the action of the acid.

The use of very hard water for the moistening of the stone will casionally cause a slight tinting of the whites, but a re-acidulation ll generally prove a remedy in a case of this kind. A gradual ogging-up of the finer parts of the subject often arises from under-idulation in the first instance. As soon as any indication of this is served it is well to re-acidulate with as strong an etching fluid as can be ventured on, and, at the same time, to see that the ink is not too thin or the roller too highly charged. A little of the etching fluid may also be added to the moistening water. A rise in the temperature of the rooms where the operation of printing is conducted will sometimes soften the ink and cause a tendency towards clogging-up, it being merely necessary, in a case of this kind, to employ a stiffer ink.

Other causes which tend towards a tinting of the whites and a gradual destruction of the device by the undue deposition of ink are as follow:—A very soft roller; over-slow motion and undue pressure in inking; ink which is naturally too thin, or is made so by the presence of oil of turpentine remaining in the roller; the use of paper containing alum; the presence of soap in the cloths employed; or the use of a roller insufficiently prepared. Such a roller requires to be over-charged with ink in order to keep out the moisture, and this over-charging with ink is often quite inadmissible.

When the subject on a stone has become much damaged (run smutty) by the use of too thin ink, or insufficient etching in the first instance, it often happens that re-acidulation will not mend matters. In a case of this kind it is advisable to wash the stone with turpentine in the following manner:—After having well wetted the face of the stone with water, a few drops of oil of turpentine are poured on and rubbed over the device by means of a wet rag. The excess of ink being thus removed the stone is wiped, gummed, inked, and re-acidulated, after which it will generally be found to work satisfactorily. In conducting the above-described operation it is often advisable to employ a mixture of oil of turpentine and printing-ink rather than pure oil of turpentine.

Any well-defined and intense black spots which may make their appearance during the operation of printing are best removed by erasure with a sharp penknife, after which those parts of the stone which have been laid bare should be gummed and acidulated in the usual way.

Having now considered cases in which the whites of the subject become blackened during the operation of printing, we may pass on to a study of those cases in which the black parts of the device become gradually removed or destroyed. Among the causes of this kind of failure may be mentioned over-acidulation, the continual use of moistening water containing acid, an over-hard roller, or the use of an extremely stiff ink. The operation of washing out the image with turpentine will often much deteriorate it, unless care be taken not to employ much turpentine or undue friction.

The remedies for a gradual weakening of the device will naturally be as follow:—The use of a soft roller well charged with ink, accompanied by a slow motion and considerable pressure in its application. The rubbing-in of linseed or palm oil through a layer of mucilage spread on the stone will often prove useful, and in extreme cases friction may be continued until the stone becomes dry, after which it is washed with water, and the printing is resumed.

When the device on the stone is well defined and sufficiently inked, but the impression on the paper is grey or lacking in vigour, a deficient pressure may be suspected; and if the lines on the paper are ragged and a little smeared, while those on the stone are clear and sharp, it is probable that the ink is too thin or the paper is not sufficiently moistened.

The next branch of the subject to be considered will be the production of typographic blocks by photographic means.

T. Bolas, F.C.S.

NOTES ON THE PLATINOTYPE PROCESS.

[A communication to the Photographic Society of Great Britain.]

The process I have the honour of illustrating to you tonight depends upon principles which may not be known to all here. I will, therefore, with your permission, commence by giving a short sketch of them.

Ever since the dawn of photography it has been well known that ferric oxalate is very sensitive to light, and that thereby it is reduced or converted into ferrous oxalate. This piece of paper I have here has been coated with ferric oxalate, and has since been exposed to light under a negative. The image formed by light, which, though rather faint, you can distinctly see, consists of ferrous oxalate. But I discovered some four or five years ago that ferrous oxalate, when dissolved in a hot solution of potassic oxalate, instantly reduces the metal from chlorides and other salts of platinum.

This flask contains some ferrous oxalate. On pouring into it a solution of potassic oxalate and heating the mixture, you see that the ferrous oxalate has mostly dissolved, forming a reddish solution. Now, on dropping some of this platinum salt (K_2 Pt. $Cl._4$) into the flask, you perceive that the latter salt has been decomposed; the black powder which is now subsiding is metallic platinum.

Now, suppose a platinum salt is mixed with the ferric oxalate with which we coat the paper, we shall find upon exposing such paper to light that the ferric salt only is affected, being changed into ferrous salt, as in the first experiment; but the particles of this ferrous salt are now in contact with platinum salt. If, now, this insolated paper be floated on a hot solution of potassic oxalate, its ferrous image will be dissolved by the potassic oxalate; but we shall expect that at the moment of solution it will reduce, *in situ*, some or all of the platinum salt so intimately mixed with it. This is what really occurs, and the result is a picture in pure metallic platinum.

Until very recently I had discovered no means of getting down the platinum in a sufficiently fine state of division without the aid of a preliminary coating of silver salt. Now, however, I have overcome this difficulty. By adding a platinum salt to the developer I find that the metal is reduced in a very fine state of division.

Having given an outline of the principles upon which the process is based, I will now proceed to show how it is at present conducted.

The following materials are used:—Plain paper, or paper having a slight additional sizing of some colloid. A solution of ferric oxalate, containing about 130 grains of the salt to each ounce of water. A solution containing thirty grains of potassic chloro-platinite and five grains of plumbic chloride to each ounce of water. A solution containing in each fluid ounce 120 grains of potassic oxalate and seven grains of potassic chloro-platinite. A sheet of the paper is now suitably fastened on a plane surface. Equal quantities of the ferric oxalate solution and of the potassic chloro-platinite solution are mixed, and two fluid drachms of the mixture are evenly spread over the paper by means of a piece of flannel wound around a glass rod. The paper is now hung up to dry; as soon as all surface moisture has disappeared the drying is finished before a fire or stove. The paper is now ready for exposure under a negative. I may here remark that this sensitised paper has kept perfectly good in a dry atmosphere, both before and after exposure, for more than a month.

The time of exposure may be determined by an actinometer or by simple inspection—preferably by the former method. The length of exposure is about one-third of that required in ordinary silver printing. I have not shown these operations of sensitising and exposing, because they are so exceedingly simple and you are probably familiar with similar ones.

Now here are some papers which have been sensitised and exposed in the manner just described. The visible image is formed in ferrous oxalate; light has produced no effect on the platinum salt lying in contact with it. I will now float this print for a few seconds on this hot solution, which contains potassic oxalate and potassic chloro-platinite. On raising it you will see that the brownish ferrous image has been converted into a black one, an image or picture in metallic platinum. The potassic oxalate dissolved the ferrous image, and the solution thus formed, before or at the moment of leaving the surface of the paper, reduced the platinum salt in the manner I have previously described. The image, as I have just said, is now in metallic platinum—one of the most stable substances known to chemists, perfectly unalterable by any atmospheric influences, not oxidised in the air at any temperature, and not attacked by any single acid or alkali. W. Willis, Jun.

ON THE SUBJECTIVE AND OBJECTIVE OF PICTORIAL PHOTOGRAPHY.

[A communication to the Photographic Society of Great Britain.]

The title of this paper may possibly seem to be too metaphysical, and, therefore, not practical; yet, at the same time, the meaning of the terms used so well express what is desired to be understood that we shall accept them as the further carrying out of another term more frequently used when speaking about photography, viz., art-science.

Now the terms "subjective" and "objective" may be accepted as representing certain conditions which, at first sight, might appear to be almost similar, but which, when closely analysed, are found to be very different. Primarily, the term "subjective" refers to something arising from within the individual self; and the term "objective" to something outside oneself. Thus, anything that bears the impress of my mind upon matter, and which I, myself, create, is subjective; that which already exists, and which others create, is to me objective.

Now, probably, there is scarcely any other subject in which these terms can be so justifiably used as in photography, and just in proportion as one side or the other be cultured and made the serious study of its votaries so will the results tend towards the progress of its dual nature—art and science; but, unfortunately for the subjective, with which is connected the art side of photography, it must be closely united to the objective, with which is associated the science side of photography. And as the one depends upon emotion and feeling for success, it becomes difficult to reconcile or mix this up with the other side, which, being composed of facts, has nothing at all to do with emotion or feeling.

Hence, as it is far easier to imitate a physical model than to follow a mental example, so we find that the objective, or so much of the science of photography as is necessary for its manipulatory practice, can be and has been imitated to a great amount of nearly equal success, and the outcome exists in the general capacity to produce good negatives, so that on this side great progress has been made. On the other hand, the power of using the subjective side of photography, so as to impress an art value upon the work done, has been less cultivated, and therefore much less progress made.

In considering this matter I purpose only to take the subjective side of photography, and, as a matter of fact, it must be self-evident that all that emanates from oneself must be *subjective*; hence it follows that not a single pictorial photograph exists which does not bear an impress of its producer's individuality, whether it be good or whether it be bad.

Now the important question arises—Can photography be made the medium for the visible existence of art conceptions? The reply must be—Most certainly. But as I have hitherto always most carefully endeavoured to formulate in estimating its value, it should never be subjected to the same method, either of appreciation or criticism; that appertains to the products of a fine art. And, in passing, it may be observed that it is owing to the forgetfulness of this guiding principle that so many artists as well as critics of the public press, when speaking of photographic art, seem to entirely put out of thought peculiarities which accompany the production of pictures by the agency of science; and so, whilst it is very easy to condemn work as not approaching to some standards in fine art, it is seldom pointed out what is really praiseworthy and capable of further culture and advancement in an art direction. Why, then, is it that more artistic culture has not been brought to bear upon pictorial photography? One great reason is this: in its manipulative operations so much exists that is purely objective—viz., outside and beyond artistic impress—that hitherto the educated artist has disdained to use it for any other purpose than as a fixed substitute for original positions and detail.

And very naturally this to some extent must always be the case with those who have given time to train the hand not only to imitate what the eyes sees, but also, whilst doing this, to impress upon the work an individuality unmistakably different from the hand work of another artist. Hence what is wanted amongst photographers is not the academical student, but more of the cultivated connoisseur—one who to succeed must use his thinking faculties in training latent art feeling, in cultivating a taste for what is beautiful, and in studying how the masters in art, in producing their pictures, worked upon matter by impressing upon it their own emotions and feelings; and those only who can be touched by such pictures will succeed in finding out the motive power which was the germ of the successful work.

And in considering this matter we must never forget that the subjective in photography is made evident by a totally different mode of working to that necessary in fine art. The photographer can so little impress his work through the agency of the hands that the popular notion has arisen, and consequently the assertion been made, that photography possesses no subjective power, when possibly fifty pictures by fifty different people all show an equality in objective work, but where the subjective has been completely down at zero.

It, therefore, follows that any training of the hands to obey the impulse of artistic culture is unnecessary in photographic study; but at the same time it lays a most difficult task upon the mind, which has to design, carry out, and perceive the entire picture in all its detail—modelled in absolute reality before any pictorial *facsimile* can be produced. It is this fact which makes the thought of producing pictures so almost impossible to those who possessing latent art tendencies try to give an existence to the same through the agency of photography.

Having so far endeavoured to explain what I have in view, it may be asked—Why use complicated terms to express a simple idea? The reply must be that, as the subjective side of photography is almost totally a purely mental operation, it follows that the mind alone needs training; and as one means to that end I cannot but think the constantly having before us some word or phrase which shall serve as the watchword that immediately brings to mind a distinct and leading principle will cause some amount of *thinking* to understand, and thus the commencement is made in the direction of the study required.

At some future opportunity I shall go further into the subject, closing this paper with the words of an eminent living American theologian, recently spoken:—"An artist is a man who has the power of changing an idea into a thing; no man is fit to paint a picture who merely copies. The man that simply makes a portrait of a man is an artisan—he is respectable, but he is only an artisan; whilst the man who has a mind so rich that he sees something that the man suggests as well as that which the literal photographer depicts—the man who moves in a larger atmosphere, and beholds the more suitable relationship of things, and has power so to reproduce them in matter that others can see or feel them, even if they cannot analyse them—that man is an artist." Edwin Cocking.

Our Editorial Table.

York's Lantern Catalogue for 1878-9, and Lantern Readings.
London: Frederick York.

The new catalogue of slides and other appliances for the magic lantern just issued by Mr. York is exceedingly comprehensive. We very well remember the first catalogue issued by this enterprising *entrepreneur*, and it is interesting to compare the goodly *brochure* now before us with its small but stimulating predecessor. When we say that the new catalogue is both comprehensive and suggestive we have said all that is needed. We could not hazard a guess at the number of thousands of subjects for the magic lantern here catalogued; but they are all well classified so as to make reference very easy. Of the merits of the pictures themselves we have only to say that the great skill of Mr. York, who is a practical photographer of the highest eminence, has been thoroughly utilised in the production of slides on a scale of great magnitude. We have carefully examined a series of views taken in Paris by Mr. York himself, which, as regards both artistic and technical merits, cannot be surpassed. What we specially prize in Mr. York's transparencies is their permanence—a point on which we can speak with all confidence. Indeed the sterling qualities in these slides have been recognised by every connoisseur.

The lantern readings form useful hand-books to accompany the respective sets of slides. As a rule they are ably written, and afford the greatest possible amount of information in the most condensed form. Among the subjects of those more recently issued are *The Russo-Turkish War*, *The Human Body*, *Paris and the Recent Exhibition*, *Electricity*, *Central Africa*, and others.

Mr. Talbot Lane's "Economic" Chromotype and Combination Printing-Frame.
London: Maull and Fox.

The opportunity for carefully examining this frame—which, owing to pressure of business, was impossible at the Technical Meeting of the South London Photographic Society—has since been afforded to us, and we are now in a position to speak of it in detail. This, however, we prefer not to do at present, but wait until the specification of the patent is open to our inspection. It is sufficient here to say that the frame, which is very ingeniously constructed, permits of a variety of "effects" being obtained in printing, either in silver or carbon. But from the subjoined remarks, which were submitted at the Technical Exhibition, our readers will, meanwhile, be enabled to form a fair estimate of this printing-frame:—

"It will be seen, from an examination of the "economic" frame, that chromotype and combination printers have a still further choice of means at their command for the production of their specialities, and one that will be found to combine within itself special features which are likely to be fully appreciated by those who use it.

"In the first place, it may be noticed that there is not the trouble of having to use *two* frames for the production of one picture; and, in the next, that every frame carries its own actinometer, thus rendering it perfectly independent and complete in itself. The actinometer is so placed in each frame that the eye may pass along a row and detect the condition of each at a glance.

"There is also a clever arrangement for vignetting, which will enable photographers not only to vignette with ease and certainty, but also to print a tint on the paper, thus doing away with the strong contrast which is often so painful to see.

"Masks and discs are provided with each frame, and they are so made that they can be used alternately, being secured in position by means of a spring. The masks and discs are united to each other at the end or side as the case may require, forming, as it were, a couple of leaves. The discs are mounted upon a transparent medium which receives letterpress, thus printing an address, &c., whilst the tint is being printed.

"The frame and its appliances are used in the following manner:—After placing a negative in it adjust one of the masks over the negative, and secure the end of the mask by the spring. Turn the disc backwards, laying it down out of the way, then place the prepared tissue or sensitive paper, registering it by the corner of the frame most convenient (the frame has a raised ledge for this purpose), and print, adjusting the actinometer as desired (it is an advantage to mark tissue on the back, so as to be able to recognise the registered end). When printed take out the negative, do not alter the spring holding the mask in position, replace the negative with a plate of clear glass, turn the mask underneath and backward, bring the disc over and forward, replace the tissue or silvered paper, and complete the printing.

"It will be seen that this mode of working places in the hands of a printer the means of securing by masks and discs of various shapes numerous combination effects, as backgrounds, clouds, &c., may be added or suppressed at will.

"In using this frame for chromotype work a considerable saving of time can be effected by cutting the tissue twice as long and twice as broad as the negative to be printed and folding it once, or, if there be two negatives on a plate, eight copies can be printed on a single sheet, and, of course, all developed or transferred by a single operation.

"The frame shown will print one $8\frac{1}{2} \times 6\frac{1}{2}$ or two cabinets, or four *cartes de visite* in silver and one $8\frac{1}{2} \times 6\frac{1}{2}$ autotype print, or one cabinet or two *cartes de visite* in chromotype work, the chromotype and combination printing being for the smaller sizes. A frame is being prepared by which larger sizes in combination printing will be executed. Of course the vignetter is available for either carbon or silver printing."

Full details as to its construction will be given on an early occasion after the specification is open to inspection.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
December 26 ..	Oldham	Hare and Hounds, Yorkshire-st.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

As we stated in last week's number that the discussion on the papers read at the meeting held on Tuesday, the 10th inst., would not be sufficiently clear in the absence of the papers, we now give both the papers and the discussion thereon, for which we are indebted to the official organ of the Society.

On the conclusion of Mr. Henry Cooper's paper on *A Really Reliable Dry-Plate Process* [see page 602], and Mr. L. Wanerke's paper, entitled *A Case of the Destruction of the Latent Image on Washed Emulsion, and its Restoration* [see page 604], a discussion took place on both papers.

Captain Abney observed, with reference to spots in emulsion plates, that though they were undoubtedly sometimes caused, as Mr. Cooper observed, by organic dust, he hoped to be able to show at the next meeting that dust was not the only cause, but that they arose from other circumstances within the ordinary experience of every dry-plate worker. Mr. Cooper, he noticed, attached great importance to heating the nitrate of silver and closing up the emulsion to keep the heat in; and further on he referred to the evaporating of the solvents to dry the pellicle. He (Captain Abney) did not see why these two operations should not be combined; that is to say, to evaporate the solvents by means of heat, and thus avoid the necessity of "cosying" up the emulsion. He was in favour of evaporating the solvents by distillation in preference to any other means. With regard to the lactate of ammonia used by Mr. Cooper, he stated that the crystalline deposit was probably lactate of zinc. He would recommend a modification of this part of the process. By the use of lactic acid instead of lactate of zinc, lactate of silver was formed and nitric acid set free, and thus the addition of nitric acid in a separate state was done away with altogether. He had found that by the use of albumen great delicacy was produced, though he had chiefly tried it in combination with albumen, the result being a formation of a double salt of silver. This combination he strongly recommended. The use of gallic acid he thought was not so good as sodium sulphite. Gallic acid was undoubtedly of great excellence, but he preferred always, if possible, using a mineral substance as a preservative rather than an organic one. In recommending albumen it might be thought he was contradicting himself; but it should be remembered that the albumen, in this case, was of a colloidal character, and not crystalline.

Mr. Sebastian Davis said that during the summer he had made some experiments with emulsion in a simple form. Instead of using the bath in the preparation of his dry plates he had used the emulsion, and then had proceeded according to the formula he had laid down in a paper read by him last session. This formula, by a singular coincidence, was very similar to that stated by Mr. Cooper. In using the simple cadmium bromised emulsion he had determined the exact quantity of bromide in solution by using paper impregnated with bichromate of potash in a similar form to litmus paper. This paper was dipped into the emulsion, and showed the presence of an excess of silver by turning red; bromised collodion was then added by degrees until a state of neutrality was reached. He (Mr. Davis) wished to draw attention to a defect in the emulsion process which he believed all workers in it had met with. This defect was a mottling in the higher lights, more apparent when the collodion was poured over the plate than when a bath was used. A reduction in the amount of pyroxyline had been recommended in the emulsion, and he had tried this plan of reducing the quantity from five grains to two grains per ounce. He had found that this reduction materially lessened the mottling; but he had not, owing to the bad weather, been able to test the method definitely, or whether it made any difference in the picture. He believed this tendency to mottling was the greatest difficulty the worker in the emulsion process had to contend with.

Mr. W. Bedford observed that his experience as to mottling was, that it was due to the quality of the pyroxyline. If it were of the proper quality there was no mottling, and by the emulsion process he had been able to obtain results equal to the wet.

Mr. Davis remarked that he had used pyroxyline made according to the formula recommended in the paper read before the Society, and other samples which were generally considered the best for the purpose.

Captain Abney said that it was a common practice with him, for the last two or three years, after emulsion had been standing and had settled down at the bottom, to decant half and add fresh solvents, and so get rid of half the pyroxyline. He was inclined to think, after a good many trials, that the emulsion was better if made with the full amount of pyroxyline and the latter lessened afterwards, although of course this method might be considered a wasteful one. If the pyroxyline were diminished it was necessary to use a preservative of some kind, or the plates would not keep. It should be remembered that the collodion itself was a kind of preservative from atmospheric influences.

Mr. W. Willis, Jun., then read a short communication—*Notes on the Platinotype Process.* [See page 605.]

In reply to the President,

Mr. Willis stated that gold could be used instead of platinum.

Mr. S. Davis inquired what was the composition of the platinum salt. The ordinary composition of the salt was 2KCl., Pt.Cl.4 forming a double salt or bichloride of platinum.

Mr. Willis said the salt he used was quite different, the formula being 2KCl. Pt.Cl.2.

Mr. Davis pointed out that if ferric oxalate were reduced by the action of light to ferrous oxalate, it would also be affected in bulk in a similar way to what it appeared to be in the pictures produced by the process demonstrated that evening.

Mr. Spiller apprehended that Mr. Davis wished to know whether the ferric oxalate was affected by light when in solution.

Mr. Willis: Undoubtedly. The ferric oxalate when in bulk or solution is reduced by sunshine to ferrous oxalate, and carbonic anhydride can be seen making its way to the surface until the ferrous oxalate is thrown down. The action of light on this salt is quite independent of any organic substance whatever.

Mr. Davis: It would be necessary then to prepare the ferric oxalate out of the influence of light?

Mr. Willis: Yes; and to store it in the same way.

Mr. Davis: The ordinary salts as purchased would not answer the purpose?

Mr. Willis: It is of no value whatever.

Mr. England: Do the prints require much washing?

Mr. Willis: About ten minutes after removal from the ferric oxalate, and about three changes afterwards of ten minutes each.

Capt. Abney observed that the ferric oxalate was one of the earliest photometers used. Draper somewhere about 1840 showed that the ferric oxalate in the presence of light was gradually reduced to the ferrous state. The amount of carbonic anhydride given off was measured to find the intensity of the light. He (Capt. Abney) had largely experimented with ferric oxalate, and was very much astonished to hear that the prints would keep between exposure and development. He had noticed that in thundery weather the ferric oxalate was very readily reduced, and he had sometimes been enabled to develope prints within so short a period as an hour after exposure.

Mr. Willis thought this rapid deterioration might be explained by the fact that oxidation only took place when a certain amount of moisture was present. Ferrous oxalate was soluble in an acid solution of ferric oxalate, and when this condition was produced by moisture in the paper the picture was destroyed. If two pieces of paper were prepared, and one kept in a chloride of calcium tube, and the other left in the room (say) where the meeting was then being held, in the course of a week the one in the room would be found to have almost entirely lost its impression. One could imagine that when the salts were lying side by side the slightest alteration would be sufficient to set up decomposition. He had always found that pictures kept for a time in presence of moisture had faded. The prints exhibited that night had been exposed on the previous Friday and had been kept since in a dry atmosphere.

Mr. Jabez Hughes thought that Mr. Willis had scarcely done himself justice in one important particular. When the process was first introduced to the photographic world it was felt there was in it a weak element arising from the use of a secondary action by means of silver, and to get rid of the silver the use of sodium hyposulphite. Now, in the process shown that night this weak element had been eliminated, and it must be admitted that this was a distinctive feature of advancement. He thought that in justice to Mr. Willis this fact should be acknowledged.

Mr. E. Cocking then read a short paper *On the Subjective and Objective of Pictorial Photography.* [See page 606.]

The President remarked that the last photographic exhibition was to his mind a proof that photographers had kept the principles advanced by Mr. Cocking in view. He considered that, from an art standpoint, the last exhibition had been a great advance upon its predecessors.

The meeting was then adjourned to Tuesday, January 14, 1879.

EDINBURGH PHOTOGRAPHIC SOCIETY.

The annual dinner of this Society took place on Tuesday, the 6th instant, at Mrs. Main's, "Peacock" hotel, Newhaven; but owing to the unfavourable state of the weather the company was not as large as it otherwise would have been. Mr. W. H. Davies, one of the originators of the Society, occupied the chair, and Mr. M. G. Dobbie, Honorary Secretary, acted as *croupier*. The dinner was served in Mrs. Main's best style, and ample justice was done to it by the company, whose appetites were sharpened by the strong nor'-easter which was lashing the Firth into fury and rendering the roads almost impassable by snow-drifts. On the removal of the cloth,

The Chairman, in a neat and humorous speech, gave the first toast —"The Queen and Members of the Royal Family." Before doing the honours, however, he remarked that the gentleman who drew up the programme must have been napping here, for was it not a fact that Her Most Gracious Majesty was something more than a Queen—was she not also an *Empress?* Therefore, the toast should be, "The Empress and Members of the Imperial Family." (Cheers.)

The next toast, "The Army, Navy, and Volunteers," with, of course, the Reserves, was responded to by Messrs. Young and Pringle.

The toast of the evening, "The Edinburgh Photographic Society," was given by Mr. Robert Russell, who remarked that, though not a professional photographer, he took a deep interest in their beautiful art-science, and his experience assured him that the Society was one of the most influential in the empire. It did its work right well and thoroughly, and its popularity and great success were ample proof of his statement.

The Chairman, in responding, alluded to the work which had been done by the Society during the nineteen years it had been in existence, and trusted that the honourable name already acquired would be sustained in the future.

Mr. Alexander Mathison, in replying to the toast of "The Office Bearers and Members of the Council," said that he was gratified to find that it had been determined to give another presentation print this year, as he believed it to be a great stimulus to subscriptions, the picture alone being worth the whole subscription. By thus acting liberally he was certain the membership would still increase, whilst the funds in his hands would not suffer.

The next toast was proposed by Mr. F. P. Moffat—"Photographic Literature."

The Chairman, in replying, said there was a vast number of volumes of what was considered to be photographic literature—quite a library, in fact—dating from the time of Sir Humphrey Davy to the present day. He was afraid that during the last three or four years this class of literature had been distinguished more by a multiplication of words than ideas; still there was a demand for literature relating to photographic art, and publishers and printers found a ready market for their publications, who, after all, were simply carrying out the law of supply and demand. One work he would like to see reprinted—and he was sure it would have a successful run—and that was Cuthbert Bede's *Contributions to the Comic Literature of Photography.*

The Croupier, in a flowing and characteristic speech, gave the toast—"Kindred Societies"—which was responded to with all honours.

During the evening Messrs. Pringle, Howie, Moffat, Young, Hannah, and Reid entertained the company with some capital vocal and instrumental music.

Mr. Howie proposed the health of the Chairman, and the meeting separated, satisfied that the evening had been agreeably and profitably spent.

GLASGOW PHOTOGRAPHIC ASSOCIATION.

A meeting of the above Association was held in their Rooms, 172, Buchanan-street, on Thursday, the 12th inst., there being a fair attendance of members,—Mr. Urie, in the absence of the President, occupying the chair.

The minutes of the previous meeting having been read and approved of,

Mr. Paton, of Greenock, was asked to practically demonstrate the carbon process and chromotype printing *à la* Lambert. For this purpose Mr. Paton had brought all the necessary materials, and from sensitising the tissue to stripping the finished prints from off the glass went through all the manipulations. The meeting took a conversational turn, Mr. Paton inviting inquiries as he went along.

At the close of his demonstrations some of the members remarked upon the beauty and simplicity of the process, and complimented Mr. Paton on his unvarying success in obtaining beautiful results.

The Chairman expressed the opinion that, perhaps, not a little of the demonstrator's expertness lay in his being a successful enamel worker previous to adopting carbon. He (the Chairman) also thought that if carbon enlargements could be produced *directly* from small transparencies by means of a strong light a great advance would be made. He had heard they had been so produced by the electric light, but fancied it possible by sunlight also.

A hearty vote of thanks having been awarded to him,

Mr. Paton replied by saying he felt more than repaid for any little trouble he had been at by the kindly and attentive manner in which the members had received him. In answer to the Chairman he said he had tried enlarging direct on to carbon from a small transparency, but his success had not been such as to tempt him to repeat the endeavour. He thought it a great mistake and pity that some Lambert licensees had not persevered a little more, and ultimately adopted carbon printing, as the process was simplicity itself.

Some specimen prints of cattle, taken by Newton's dry-plate emulsion process, were shown by Mr. George Mason, of Sauchiehall-street. It was quite evident the pictures had been taken instantaneously, and showed clearly that extreme rapidity was obtainable by this emulsion.

A vote of thanks to the Chairman brought the proceedings to a close.

Correspondence.

MEETING OF THE PHOTOGRAPHIC SOCIETY OF FRANCE.

THE usual monthly meeting of the Photographic Society of France was held on Friday last, the chair being occupied by M. Davanne, President of the Committee of Administration. M. Peligot expressed by letter his regrets at being unable to preside. [The latter gentleman has since received a distinguished decoration from the King of Italy in testimony of the high appreciation in which his scientific services rendered at the exhibition are held in Italy.]

M. Marres, painter, and Captain Jolly were unanimously elected members, and MM. Raoult, Stebbing, Thoroulde, and Vandesmet were proposed for a like honour at the following meeting.

M. C. Fabre, Hon. Secretary of the Photographic Society of Toulouse, wrote to "reclaim" the priority of publication of the employment of nitro-glucose in collodion emulsions, in consequence of an article by M. de Pitteurs, published lately in THE BRITISH JOURNAL OF PHOTOGRAPHY and the *Bulletin*. The following remarks, so unusual under like circumstances, were received with applause:—Although M. Fabre was an unsuccessful competitor in the *concours* of the Society for the best dry process, he had the rare candour to acknowledge, and begged loudly to proclaim his opinion that the commission had done justice in the award it had made; and he complimented, in well-chosen terms, M. Alfred Chardon, the successful competitor, stating that he thought the theory of the emulsion process, put forward by that gentleman, was the best published, and consequently experimentalists need only occupy their attention in endeavouring with M. Fabre to improve the manipulations of the process. He begged the Society to publish in the following number of its *Bulletin* the description of the process sent by him to the *concours* in December, 1876, so as to establish his rights, seeing that every month claims were made and published of principles and details submitted by him at that date.—This request was referred to the Commission on Emulsions and to the Committee of Redaction.

M. Pector, in the unavoidable absence of M. Perrot de Chaumeux, secretary for foreign correspondence, read the extracts from the foreign journals, amongst which was the formula supplied by Mr. Morgan as that of M. Boissonnas, and first published in THE BRITISH JOURNAL OF PHOTOGRAPHY a short time ago. This was followed by the not uncommon experience related by Mr. F. A. Bridge, and taken from the same source.

Mr. Gutekunst, of Philadelphia, sent for the inspection of the Society a series of *cartes*, album portraits *en buste*, vignetted upon a tinted background, the high lights strongly defined, and very well executed; this artist was awarded a silver medal, for, amongst other productions, the accessories and backgrounds of his negatives, which were engraved with the needle in the manner of etchings, and which by contrast gave a remarkable degree of softness and harmony to the face and other parts produced by pure untouched photography.

M'dlle Assis, of Bordeaux, forwarded to the Society a stereoscopic proof made under the following circumstances:—She exposed a dry plate for an hour in dull, cloudy weather, the sun shining for an instant only in an interstice between two clouds, and, notwithstanding its extremely short appearance comparatively to the long exposure given, it was most curious to observe that the shadows projected by the sun upon the landscape were really well rendered in their proper value; but the sun was not sharply defined, the focus having been made on the nearest objects, and it was, therefore, altogether out of focus.

The *concours* established by the Society for the best substitute for glass as a support for the sensitive films of emulsion or dry processes suitable for amateurs, and to be used in travelling in foreign parts, will close on the 31st of December, 1878, and for which the grand medal of the Society will be given. There is at present but one competitor, namely, M. C. Fabre. The members of the Commission on Emulsions were charged with the decision.

M. Castellano exhibited some charming views, about 12 × 10, of the borders of the River Marne, which he had taken by the emulsion process of M. Alfred Chardon, and the fine, artistic feeling of M. Castellano was much admired.

M. Pinard, professor and photographer of the National School of Medicine at Nantes, sent for inspection a marvellously-fine album containing a great number of coloured anatomical and medical studies taken in the laboratory of the college, which showed most decidedly the great advantages of the truth and fineness to be obtained by photography when directed by a master in the art, and which the hand of the designer could not rival or even approach. Thanks were voted unanimously for this important application of photography to medical science.

M. Vidal, suffering from indisposition, begged the Chairman to present for him several specimens of his process of phototypy in two tones after the designs of Giacomelli, forming a new publication called *Ailes et Fleurs*, the cost, including the mounting on Bristol board, the text, and the profit comprised, was 3½d. per plate of about 12 × 9 inches. The work of M. Vidal, which reproduced so well the individuality of the artist, merited the approval it received; but *la couronne du bouquet* was the first ten numbers of the *Tresor Artistique de la France*—a magnificent undertaking, absolutely unique in its style, comprising the principal rich works of the national museums and the most remarkable private collections, reproduced by the photochromic process of M. Vidal, with the special authorisation and patronage of the minister of Public Instruction and of Fine Arts, and under the direction of M. Paul Dalloz. The proofs are in colour, in silver, steel, bronze, and in all the materials of the objects of art gracing the Gallery of Apollo in the palace of the Louvre. To show the facility at which the inventor has arrived in the execution of his patent, he said that for a proof of about ten inches, with an impression of a thousand, at the same time varying the colours and metals employed, the price is not more than 6½d. to 10d., the mounting on Bristol board excepted. It is the industrial arts especially which should profit from the publications made by the aid of this unique method of reproduction.

Many specimens of Mr. W. B. Woodbury's recent improvements in his photographic films were laid upon the table and excited the interest of the members to such an extent that nearly all of them were "appropriated," and the looks of Mr. Woodbury's representative at the close of the meeting was as "small" as the remainder of the proofs found upon the table. M. Davanne, who had exhibited some pellicular proofs several years ago, said that Mr. Woodbury had made such progress with his process as to render it a commercial success.

M. Ferrier, one of the oldest, if not the oldest, of the workers in stereoscopic photography, exhibited a number of slides produced upon plates prepared by the Taupenôt process in 1863, which had been kept for fifteen years without more than usual care but in a dry place. These had been lately exposed in the stereoscopic camera, seven days after being immersed in an aceto-nitrate of silver bath followed by washing in water, and the negatives were of rare excellence, showing the value and rapidity of the old process. Several negatives were exposed, quasi-instantaneously, in the Champ de Mars and the Trocadero, with clouds and natural skies. The fine definition of objects in the different planes of perspective, so necessary for the stereoscope and sometimes lost in other processes, is a well-known quality in the old Taupenôt process. It is to be observed, in connection with the development of these instantaneous negatives, that after the ammoniacal application warm pyrogallic is flowed over them, which brings out the image and strengthens it. The positive slides on glass, by the albumen process, with beautifully-rich colours, were in the best style of the veteran artist, and the whole bore conclusive testimony that his hand had not lost its cunning.

M. E. Lamy presented a little instrument which he called an "actinometer," intended to measure the action of the light during the exposure and printing of carbon paper, and made some remarks upon its application, which will be reproduced in next number.

Asnières (Seine), Paris, December 17, 1878. W. HARRISON.

A RELIABLE DRY PROCESS.

To the EDITORS.

GENTLEMEN,—My health not allowing of my being in London at this season, my paper on *A Reliable Dry Process* was read for me by my brother, and I was thus prevented from hearing and replying to Captain Abney's remarks at the late meeting of the Photographic Society of Great Britain.

Captain Abney agrees with me as to the importance of using heat during the preparation of the emulsion, and suggests distilling off the solvents. This is a plan I have not yet tried; but I invariably use heat in evaporating the solvents by standing the dish containing the emulsion on a large hot-water tin. This has for so long been a part of my ordinary practice that I rather stupidly forgot to mention it in my paper. As to the substitution of lactic acid for the ammonia salt, I have purposely used the latter, so as to avoid the presence of free nitric acid to any perceptible amount in the emulsion during the progress of its ripening, and I should not care to add the lactic acid as a final dose, wishing to have the lactate of silver in contact with the bromide from the first.

I rather regret that a rule of the Society necessitated the cutting out of the name of the maker of the pyroxyline I recommend. There are many sorts in the market, and each maker's has some very distinctive features. The one I use in my process is retailed at one shilling per ounce, and is, therefore, a low temperature cotton It is perfectly soluble to the extent of ten grains to the ounce, and gives rather a tough film, being very suitable for enamelling, but not for some other purposes. I really cannot see any harm in my mentioning that Messrs. Hopkin and Williams are the makers.—I am, yours, &c., HENRY COOPER.

Homehurst, Torquay, December 14, 1878.

P.S.—I hope soon to have something more to communicate on the effects produced by the reduction of the proportion of pyroxyline. This weather is sadly against comparative work in the camera—the only kind I really trust; but I may say my experiments are so far very satisfactory.—H. C.

CAMERA FRONTS.

To the EDITORS.

GENTLEMEN,—Will you permit me to add my testimony to the efficiency and convenience of the camera front as suggested by Mr. Baynham Jones last week? I have used one made on that principle during the last two years, and nothing can be better or simpler. I was indebted to Mr. Jones for the idea, and Mr. Lancaster, of Birmingham, carried it out very satisfactorily. In addition to its other good qualities the cost is small.—I am, yours, &c., G. SMITH.

The Castle Hill, Dudley, December 14, 1878.

EFFECT OF PETROLEUM ON CARBON TISSUE.

To the Editors.

Gentlemen,—As a sequel to a communication on the effect of petroleum stoves on carbon tissue I wish to communicate the following:—A short time ago the tissue which had been sensitised during the evening was, through the carelessness of an assistant, submitted to the effect of gas during the whole night. The gas was turned off and turned on again while the tissue was wet, and it dried in that atmosphere. Of course I expected that it had become insoluble, but it worked as well and developed as easily as ever. The tissue was so well impregnated with it that it exhaled the odour of gas an hour after it had been removed from the room.

Some of the tissue intended for the solar camera had been sensitised with five per cent. of bichromate; and in such tissue the tendency to insolubility is much greater than in that prepared with one or two per cent. of bichromate. It would be interesting to know what would have been the effect if the gas had been kept burning all night, instead of escaping. I have, however, had gas burning for two or three hours in the room where the tissue was drying without observing any ill results.

I cannot avoid thinking that the effects of gas on sensitised tissue have been somewhat exaggerated. The great causes of insolubility are, I believe, heat and moisture, and they generally exist together in this region.—I am, yours, &c., Charles Waldack.

Cincinnati, December 3, 1878.

RECENT MEDAL AWARDS.

To the Editors.

Gentlemen,—I know nothing of the details of Mr. Jennings' busiuess management. I sent my friend's order to an agency firm to execute, and heard no more till informed of the unsatisfactory result. As some people in India have also wanted prints, apparently two people have been victimised.—I am, yours, &c., H. Stuart Wortley.

Rosslyn House, Grove End-road, London, N. W., December 16, 1878.

THE LUXOGRAPH TESTIMONIAL.

To the Editors.

Gentlemen,—It has ever been my policy as well as my endeavour to avoid entering the arena of controversy, which I am now most reluctantly compelled to do, owing to the extraordinary statements in your last issue of Mr. Robert Faulkner, the eminent photographer, and a gentleman whom, until now, I had held in high esteem. If he consider that he has suffered in status by my having stated that he was in my company when we both visited the office where we saw the pleasing iliustrations of the nowadays indispensable luxograph, will he permit me to apologise very humbly for having wounded his susceptibilities?

But to come to the facts. Unless I have entirely lost my knowledge and appreciation of the English language, Mr. Faulkner really did express his admiration in terms so very unmistakable that I myself, further fortified by the fact of Mr. Gregson ordering an apparatus there and then, was induced thereby to intensify the decision at which I had arrived respecting the desirableness of ordering three of these instruments—one for each of my studios. Nor was Mr. Faulkner's enthusiasm very short lived; for I am assured that his assistant, Mr. Ross, who was also present at the demonstration on the evening in question, was sent by Mr. Faulkner, and actually waited subsequently upon the patentees of the luxograph, offering one-half the ordinary price in cash, one dozen of his cabinet portraits as specimens, and a *splendid testimonial*, if they would give him an apparatus.

It appears, however, that Messrs. Alder and Clarke did not place such a high value upon the professed "splendid testimonial" as did Mr. Faulkner himself, for they did not accede to his terms. *Hinc illæ lacrimæ dolorosæ.*

That the luxograph is a great success is plainly evinced by the evening demonstrations to an ever-increasing number of delighted photographers who, from all parts of the country, come to see, to approve, and to order.

I think it is a great boon to us all, and, without expatiating upon the superiority of the luxograph over any existing apparatus to photograph by artificial light, let me advise my brother artists to go and see it and judge for themselves.—I am, yours, &c., Lombardi.

13 *and* 14, *Pall Mall East, London, December* 18, 1878.

EXCHANGE COLUMN.

Wanted to exchange, Sarony's head and body rest for a Harrison's head-rest.—Address, Forshaw and Coles, photographers, Oxford.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

PHOTO-MECHANICAL CORRESPONDENCE.

S. Smith.—A suitable press will cost about £5.

E. Lake.—You will find the process easier than you appear to consider it. Use a rather thick and close-grained paper.

Carbon.—The reversal of a lithographic image, so as to make the whites black and the blacks white, is not very easy in practice. It would be better to make a transfer from a photographic transparency of the subject.

GENERAL CORRESPONDENCE.

W. W.—Let the reflector be of a spherical form. The parabolic form is quite worthless for the purpose named.

W. J. Gates.—The ignition of phosphorus as described will prove an excellent means for effecting your purpose.

B. O. T.—See an article on the subject in our Almanac for the present year. To this we have nothing at present to add.

Photo.—Thanks for your flattering remarks; but it is not intended to have such a series as you mention in the Journal.

B. S. P.—No other medals were awarded than those published by us. On the other matter we must decline to enter.

John Hancock.—We cannot suggest any fault in the pictures save the presence of a degree of contrast seldom to be found in nature.

Argus.—The work about which you inquire was published in 1865, in the form of an appendix to the principal work. Both are now out of print.

Enamelled Paper Prints.—Messrs. H. and E. Schonewald, of Liverpool, have sent for our inspection samples of their work in this style, which is quite equal to the best that we have seen.

S. P. P.—Dissolve the salt in the smallest quantity of water in which this can conveniently be done. Then add the albumen, and churn the whole up until it assumes the appearance of a frothy mass.

Thos. M'George.—Do not waste your time at present in trying to restore the old bath, but make a new one for immediate use, and then employ your spare time in putting the other into good working order.

E. S.—It will be advisable for you to strip the films from off (say) one hundred of the negatives, and by fusing the silver contained therein and carefully weighing it a tolerably accurate estimate of the whole may be formed.

H. Barlow.—Thanks for enclosure. In reply to your queries:—1. The prints mentioned do, unfortunately, fade—2. The transparencies enclosed are well adapted for enlarging; but it would be better not to carry the intensification quite so far.

Michael Riley (Belfast).—To dye your client's hair of a black colour apply first a solution of nitrate of silver and afterwards diluted sulphide of ammonium. This latter application will necessitate a further purchase of some strong aromatic preparation.

J. Wilson.—The focus of the lens is too long by three-quarters of an inch. This may seem to be very little to you, but if you refer to the table of enlargements in our Almanacs it will be seen that it renders necessary the further extension of the camera to something within a fraction of two feet.

E. H. A.—Having obtained a new sample of paper from the firm mentioned we tried it thoroughly and found it to work quite as well as a supply we had from the same firm last summer. It is probable that there must be something in the conditions under which you work that militates against your success. We have never experienced a failure with it.

F. S. Smith.—The difficulty may easily be surmounted. Pour upon the black varnish a little benzole to soften the asphaltum, lay a plate of glass over it for a few minutes to prevent the escape of the benzole while it is acting the part of a solvent, and then apply more until the whole of the black varnish has been removed. No fear need be entertained that the picture will suffer, for collodion is unaffected by benzole. When the image has been cleaned in this manner a transparency should be taken from it, and from this transparency must be obtained a printing negative which may be either larger or smaller than, or the same size as, the original.

Pont-y-pais.—Mr. Hadow's method of recovering silver from old baths consisted in adding to the negative baths an excess of chloride of sodium, old hypo. baths being treated in like manner with sulphide of potassium. The resulting precipitates, after having been washed and dried, were mixed with two or three times their weight of nitre (nitrate of potash), and a portion of this mixture was placed in a hollow formed in a block of wood and set on fire by thrusting in the end of a red-hot stick of wood. When deflagration had fairly commenced the remainder of the mixture was added by small quantities at a time. The whole is then scooped out and hot water employed to remove the soluble salts, leaving the silver in a spongy condition. To reduce this into a compact mass mix six parts of nitre, two parts of fine sawdust, and one part of powdered sulphur, and place a small quantity of this in an iron ladle with alternating layers of the insoluble silver. Upon applying heat the mixture burns with an intensity so great as to reduce the silver almost immediately to a compact button at the bottom of the ladle.

Royal Appreciation of Photo-Enamels.—We understand that, on Wednesday last, Mr. A. L. Henderson attended at Marlborough House, on a special summons, to receive the commands of H.R.H. the Princess of Wales, relative to the immediate production in enamel of a photograph of one of the members of the royal family. It is gratifying thus to find that the undoubted value of photographic enamels is much appreciated in high quarters.

CONTENTS.

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 973. Vol. XXV.—DECEMBER 27, 1878.

THE PAST YEAR.

The time has once more come round when the duty devolves upon us of reviewing the noteworthy occurrences of the past twelve months, and though, as in previous years, we have nothing of a more than ordinarily interesting character to record, still in some respects the year 1878 has witnessed changes which, if not productive of much immediate progress, afford the prospect of future improvements in our art-science.

Though not directly connected with photography, the subject of electric lighting may be mentioned as one of the more prominently distinguishing scientific features of the year, and from its possible bearings upon photography we cannot but feel deeply interested in its future. Without venturing an opinion as to whether it will ever supersede gas, there cannot be a doubt as to the advantages, in portraiture at least, which are likely to accrue to photographers from its introduction in a really practical and convenient form. Its capabilities in that direction have been already clearly established, and all that now remains to be done is to simplify the apparatus required for its production, and to reduce the cost sufficiently to permit its general use. Meanwhile a simpler means of arriving at the same end—namely, the production of portraits by artificial light—has been placed within the reach of all by Messrs. Alder and Clarke, whose "luxograph" has been recently fully described in our columns.

Another feature of a more purely scientific character, to which we have had occasion to allude in our present volume, is the liquefaction of oxygen, hydrogen, and nitrogen, which have hitherto defied all the efforts of chemists to compress them into the liquid form. Whilst all other substances usually existing in the gaseous form had succumbed to suitable treatment, the three gases mentioned had remained refractory, until MM Pictet and Cailletet succeeded in solving the problem of their liquefaction. As an example of the triumph of science over apparently insurmountable difficulties, the successful results which have crowned the persevering efforts of MM. Pictet and Cailletet cannot fail in fixing the attention of all interested in chemical pursuits, while they further encourage us in the hope that some of the knotty points more immediately connected with photochemistry may in like manner succumb to the persevering efforts of our scientists.

Turning to practical photography, the department in which the largest amount of energy has been exhibited is in connection with carbon printing. This is, perhaps, mainly owing to the fact that, in February of the present year, some of the patents connected with the carbon process were thrown open to the public. Opinion may be divided on the subject of the general working of patent rights; but we think that in the case in question the existence of such rights has proved of real benefit, not only to the process itself but also to photographers. Had the carbon process been entirely free from restrictions (restrictions which existed only in name, as it happened) it would scarcely have been worth the while of any individual or company to enter into it as a commercial speculation, and we imagine no one would have taken it up with the philanthropic intention of demonstrating its capabilities without an adequate *quid pro quo*. Be this as it may, under the fostering care of the Autotype Company carbon printing has been raised to a firmly-established position, and it was only to be expected that the lapse of the patents would give a further impetus to its general adoption.

Early in the year Mr. J. R. Johnson—whose name is identified with many improvements in carbon printing—obtained a patent for further modifications, chiefly in connection with the mechanical phases of the process. The principal feature in the patent, however, was the substitution of alizarine for the fugitive colours formerly employed in the production of tissue of certain favourite "tones;" and the discussion which followed the introduction of this new substance elicited much valuable information on the subject of the permanence of carbon prints. Dr. van Monckhoven also made a communication to the Photographic Society of Great Britain, in which he recommended the employment of certain compounds of iron as the basis of the colouring matter of the tissue. Later we were able to lay before our readers, on the suggestion of Mr. J. G. Tunny, a hitherto unsuspected cause of the deterioration of carbon prints, traceable to the discolouration of the paper itself; and, thanks to the publicity thus given to a possible cause of danger, there is every likelihood that increased care in the manufacture of the paper will add to the permanency of this class of picture. While on the subject of printing we must not forget to mention Mr. W. Willis's further improvements in his platinotype process. By the removal of all necessity for the use of silver in the formation of the image, the last doubt as to the permanence of the results disappears, while their beauty as well as the extreme simplicity of the manipulations were fully demonstrated at the last meeting of the "Parent" Society.

In dry-plate photography, though we have nothing of a strikingly novel character to record, there has been more than the usual amount of attention given both to its theoretical and practical phases. In the former branch we again find Captain Abney in the front rank amongst our experimentalists. His contributions to our knowledge of the physical and chemical branches of the science have, as usual, been marked by sound practical sense, and bear evidence of an amount of patient research such as few are capable or willing to devote to a pursuit which must be considered in the light of a recreation. His communications to the Photographic Society of Great Britain, and in our columns, have thrown light on several hitherto obscure questions; and in the discussions which they have elicited the name of Mr. H. B. Berkeley must be honourably mentioned.

In the practical applications of dry plates the wonderful results obtained with gelatine plates are chiefly noticeable. The process formulated by Mr. Charles Bennett, while bringing in nothing of a specially novel nature, combines so completely all the best qualities of gelatine as to place his process far ahead of all others—not even excepting the wet process—in all cases where extreme rapidity, in conjunction with the highest class of results, is desirable. The degree of rapidity attainable is such that it has been found possible to produce photographs by means of the actinically-feeble light of gas or paraffine, as demonstrated by Mr. Bennett himself, and by Mr. W. Brooks, under circumstances already reported in our columns.

Mr. Henry Cooper—already well-known in connection with collodion emulsions—has also contributed his quota in the shape of a "reliable" emulsion process; and, though we have not yet had an opportunity of testing his new method, we have not the slightest doubt from our knowledge of Mr. Cooper's judgment and capability as an experimentalist, that it will be found to come up to all he claims for it.

In the practice of washed emulsions nothing of great moment has transpired. A discussion as to the comparative merits of washing and precipitation in the preparation of such emulsions has led to the enunciation of the opinion in various quarters that, though extremely convenient, and capable of giving results of a high quality within a short period of preparation, precipitated emulsions do not possess keeping qualities equal to those exhibited in the case of washed ones.

The greatest "fillip" which has been given to the practice of dry plates generally is, undoubtedly, the introduction of the ferrous oxalate developer, which, so far as present experience goes, promises to be the developer of the future. Its advantages are not so much in the direction of a better quality of negative, as in the production of equal results with a saving of trouble as compared with alkaline pyro.; and the substitution of this new developer will go far to reconcile professional photographers to the adoption of emulsion plates in studio work.

In wet-plate work the most noticeable novelty is Herr Obernetter's reversed negative process, which consists in a reversal of the usual conditions of the collodion and bath—the former of which carries the silver and the latter the haloid salts. This does not seem to have come into very general use, though we have heard it favourably mentioned in connection with enlargements. The instantaneous or "lightning" process of M. Boissonnas also has secured a footing, though there exists a diversity of opinion as to its advantages, and as it is a "secret" process it is beyond our function to criticise it.

In the way of apparatus and appliances we may notice a new portable camera by Messrs. Rouch and Co.; the pneumatic shutter of M. Cadett, and similar appliances by Messrs. Cowan and Weaver; Mr. Woodbury's arrangements for applying photography to military purposes by the aid of a captive balloon; and, lastly, Mr. W. J. Chadwick's new safety oxygen retort. In connection with the last-named it is to be regretted that such accidents as that by which Mr. Wrench lost his life still continue, and the fact only proves the want of some such appliances as those which have emanated from our Manchester friends.

The various societies still continue their good work—the "parent" one being decidedly on the road to improvement. Whereas but a short time ago the papers read were "few and far between," now a plurality at each meeting is the rule, and at the last meeting there were no fewer than four such communications. This is encouraging, and shows that a wider interest is being evinced in photography. A further incentive will be found in the recently-instituted "progress medal" of the society, the first of which was very properly awarded to Captain Abney; while, as an encouragement to the younger followers of photography the prizes offered out of the society's funds in connection with the technological examinations of the Society of Arts must eventually be productive of important benefits. The South London Photographic Society keeps up its "technical" meetings, which have proved so useful as well as interesting in their special line. If *all* exhibitors at these meetings be not fully satisfied with the results, it should be borne in mind that the very nature of the experiment precludes the possibility of concentrating general attention upon any one exhibit; the object is merely to pass in rapid review before the assembly any inventions or appliances of a novel character, leaving it to those interested to take subsequent means of becoming more closely acquainted with anything which may particularly strike them. It savours somewhat of selfishness, then, for any individual to claim a larger share of notice than his neighbours, or to feel aggrieved at not obtaining it.

Death has, as usual, been rife amongst the followers of photography, and many well-known names have disappeared from amongst us. In France, MM. Antoine Becquerel and Regnault, whose contributions to chemistry and the higher branches of the science have been many and varied, have been removed. Voïgtlander, the world-renowned optician, and in practical photography Braun, of Dornach, have paid the last debt. America supplies two names in Messrs. J. L. Gihon and W. H. Rulofson; while nearer home the list is swelled by the loss of Messrs. J. A. Spencer, Alfred Hughes, Thomas Lampray, and while preparing for press we are informed of the death of Mr. William Carrick of St. Petersburg.

In conclusion: let us express a hope that the year about to commence may witness an improvement in the present depressed state of business—not only in photography, but in all branches of commerce—and that 1879 may prove to all our readers a prosperous and

A Happy New Year.

THE LESSON OF THE FROST.

We make no doubt that, long ere this, the severe weather that is accompanying the dying days of the Old Year will have taught many a lesson on the effects of low temperature upon saline solutions; and, far and near, we hear of such disaster and trouble through the failure of water supply, and the stoppage of light by the thick blankets of snow which lie on roof after roof, that we think a slight rehearsal of some of the precautions adopted by "old hands" may not be amiss to our readers.

What to be done with the snow on the glass causes anxiety in the minds of many despairing photographers at the time we write, we feel sure, seeing that none will venture upon the roof in such slippery weather, the fate of poor Rulofson being fresh in their minds. The lesson to be learnt is to build the skylight with as steep a slope as possible, and to do as one far-seeing photographer we know of has done against this and other contingencies—laid down a firm footway all round the eaves of his roof protected by a light iron fencing, so that the most timid could walk without fear, whether for repairing the roof or, as at the present time, removing snow or other obstructions. The glass roof along the footway is also guarded by a narrow strip of wood to keep careless toes clear of the glass. In the particular case we allude to, the gentleman states that if he were constructing another similar arrangement he would cause the footway to project about six inches from the glass to enable the snow the better to slide away during a thaw.

Few there are who have not had burst water pipes this winter. It may be well again to remind our readers that it is not the *thaw*, but the frost, that bursts them; though until the frozen contents are rendered liquid by the flight of the frost the damage is not observed. So long as the water pipes are exposed to the action of frost it is not possible to take perfect precautions against its effects, though the well-known device of covering them with hay bands is a very good preventive; and, if combined with the ingenious expedient of letting in to the more exposed portions of the water pipe, at intervals, tubes of lead closed at one end, so as to form a cushion of air to relieve the expansion of the water caused by freezing, the danger of a burst is reduced to a minimum.

To pass into the dark room. What trouble is in store there if no means of artificial heat are in constant use! Chemicals frozen, bottles broken, and general difficulty of working at all! A paraffine lamp constantly burning is an excellent source of heat, care being taken to keep it from dangerous proximity to collodion or ether, and when it is used it is generally approved of.

A very important matter is the keeping the bath warm; and the suggestion, recently made in a letter in our pages, of using an india-rubber hot-water bottle for the purpose we know to be excellent, one photographer whom we could name having, to our knowledge, had the plan in use with great benefit for some years. It will be found that in cold weather, when the bath is at a lower temperature than about 45° F., a very considerable increase in the strength of the bath is necessary to obtain clean plates, and that with baths well used considerable time is required before they are fit to be put in the slide without fear of streaks being produced in development. With a temperature at all approaching 32° a strength of sixty grains will not be more than equivalent to the ordinary summer thirty-five grains, and an iron developer of forty will be almost equal under the same circumstances to twenty-five grains.

We may conclude these brief hints by a reference to a very peculiar case of failure that once occurred through a severe frost. A Winchester of bath was frozen in its containing vessel almost solid, and, being required for use, was placed in a warm place to thaw. As soon as it was melted it was poured into the bottle—all but a few ounces at the bottom, to avoid chance of sediment. It behaved most singularly. The plate would not "cream" in it, little beyond a faint milkiness being produced even after prolonged immersion. It was, therefore, set aside and a new one made. The cause of the failure—which was not discovered for some time—was very simple, and was owing to a peculiar and interesting property of freezing solutions, by virtue of which a salt which is held in solution remains dissolved while the water continues to freeze, and will always be found either in a residue of fluid or in that portion which is last frozen.

In the case of the bath the silver was contained in the few ounces of unfrozen liquid, which would be of considerable specific gravity; and as the mass of ice in the bottle (which would contain scarcely a trace of silver) melted the solution of silver would fall to the bottom of the bottle, and not mix without a considerable amount of agitation—the very point which was carefully avoided. With this singular experience we leave the subject in the hands of our readers, trusting that neither bursting of waterpipes nor other *contretemps* may have marred a Merry Christmas!

A SIMPLE and ready means of testing for free silver in emulsions has long been a *desideratum;* and though there are several methods in general use, none answer thoroughly to the requirements as regards ease of application. At the last meeting of the Photographic Society of Great Britain Mr. T. Sebastian Davis mentioned a most simple method adopted by himself which seems likely to answer its purpose in every respect, without adding anything to the already numerous troubles of the emulsion photographer; indeed, the only wonder is that the idea has not found an earlier exponent. We imagine there are few of our chemical readers who are unacquainted with Gay Lussac's bichromate test for soluble salts of silver—a method based upon the reactions of bichromate of potash (or other similar salt) in the presence of free silver. This has already, to a certain extent, been utilised for the purpose of detecting the presence of excess of silver in emulsions or dry-plate films; but it has never, to our knowledge at least, been reduced to so simple a form as that in which Mr. Davis places it before us. Briefly stated, the method we speak of consists in the employment of a "test" paper, prepared by merely immersing a sheet of any ordinary paper in a solution of bichromate of potash; this, when dipped into a solution containing an excess of soluble silver salt, at once strikes the well-known red-brown colour of silver chromate; and, while the colouration is so marked and characteristic as to leave no ambiguity in the result of the test, it is also more than sufficiently sensitive for all the purposes to which it is likely to be applied in connection with emulsion work. A word or two may be said, however, in qualification of what has recently passed, in order to avoid any misunderstanding with regard to the working of this test. It is quite possible that the bichromated paper may, upon dipping it into an emulsion *soon after sensitising*, show the brown discolouration denoting an excess of silver, while at the same time no such excess really exists. It is generally understood that the nitrate of silver added to the collodion in sensitising requires a certain length of time to enter into combination with the soluble bromide; and, if the test be applied before this combination is complete, the discolouration of the test paper may possibly lead to an erroneous judgment. It is, therefore, desirable to make sure that a sufficient time has elapsed for the thorough decomposition of the salts in the emulsion before applying the test. The presence of free acid also militates against the accuracy of readings obtained with the bichromate test; but whether the comparatively small proportion of acid likely to be present in an emulsion, under ordinary circumstances, will interfere with the estimation of the relative proportions of bromide and silver we cannot say; but at least we can put forward Mr. Davis's test as an improvement upon those already in vogue.

NEGATIVES AND ARTISTIC PHOTOGRAPHY.

[A communication to the Manchester Photographic Society.]

IT has not hitherto been the custom in this Society for the President to deliver what is called an address. I am not aware of any reason why it should not become so; but I think, for reasons which may be passed over, that it should remain a matter of option. There might be some advantages in such a custom, but no disadvantages. Every man has a train of thought peculiar to himself. Almost every one of us may take notice of something that others overlook, and may possibly be able to pick up a grain of gold where many would see only sand. This in itself would be a sufficient reason for the formation and continuance of photographic societies, and also a presidential address is a good introduction for a new President. I have no wish to adopt the functions of a teacher; I desire only to direct your attention to a few matters that have forced themselves on my notice during my rambles among the pleasant ways of photography, and in doing so I may, perhaps, seem more dogmatic than I wish to be.

Some good things have recently been said about negatives. The Editors of THE BRITISH JOURNAL OF PHOTOGRAPHY, for instance, have been discoursing *On the Qualities Desirable in a Negative*, and gave some valuable hints. I have also something to say about negatives—perhaps not new to many of you, but possibly so to some.

It has often occurred to me that many people, particularly young photographers, have an incorrect idea of what a good negative should be; and, in order to arrive at a fair perception of what it should be, I will first say what it should not be. It should, then, be neither black nor opaque. I have many times heard it said by gentlemen, when describing a pet process, that any amount of density could be obtained, even to blackness; and I have had negatives submitted for my admiration that were capable of producing only the extremes of light and shade in a print, yet they were said to be everything that could be desired. That is a favourite expression, but, for all that, a very misleading one. Whenever I find a photographer using it I have a desire to examine his results, so as to ascertain from them what his standard of excellence is.

Some people have a fancy for thin, pretty negatives, full of detail but without force, and quite unsuitable for the production of good paper prints although they would do very well for making lantern slides. Such negatives appear to me as if they were produced in films too thin to carry a sufficient weight of deposit to bring up the high lights. If any member will make a powder picture such as is used for enamels, and try to pick it up with a film of thin collodion, he will get at my meaning in a practical way. He will find that a thin collodion will take up a portion only of the powder, and leave the remainder.

A good negative should not be over-full of clear glass portions; there should be a deposit, however small, almost everywhere. Clear glass is in place just under the edge of a roof, or any similar part where a narrow cast shadow is met with, but not in any portion which is only in the shade. I like a negative fully exposed and fully developed, and, if taken by the wet process, on a collodion with a good body. A Woodbury transparency is a capital guide to the kind of transparency that is required in a negative, and slow development on a fully-exposed plate seems to me the proper way to obtain it.

Before I leave this subject I will ask you to take a walk about town and compare the best portrait work with the worst, and ask yourselves why the best is the best. Consider the subject quite apart from the question of arranging the sitter. I more than suspect that short exposures and over-intensification are the causes of the worst, and the contrary of the best. No after-treatment, as you know, can fully compensate for under-exposure. Intensification I look upon as an unmitigated evil; a correctly-exposed and developed negative does not need it. The best printing portrait negative I have was fully exposed, slowly developed with iron solution, and not intensified at all. It was intended for enamel work.

Now, when you know what a good negative is, and know how to produce one, it would be useful to you to study the rules of art a little, and if more than a little all the better. You may obtain a good photograph without any such knowledge. You might now and then get a good picture; but without some acquaintance with art rules you cannot reasonably expect uniform success pictorially. After the rules of art, a careful study of the best works in a black and white exhibition would be found immensely instructive. In works of that kind there is no colour to take the eye—all depends upon light, shade, and shadow, and their disposition. Shade and shadow are different things. Shade is that portion which is illuminated by diffused light, or that side of an object which is not in the direct light of the sun; while shadow is a place that would be in the full glare of the sun's rays but for the interposition of some object. Shades always carry detail, and shadows do so in a less forcible degree. High lights often possess less detail than shades. Light, shade, and shadow are absolutely essential to the production of a successful picture; therefore, never expose in the expectation of entire success unless these three requisites be present. Observe that the light and shade of a good picture are about equal in the surface they cover. When you set up your camera do your best to ensure similar conditions, and, if you have a choice of situation, walk round about your subject in search of this equal division of light and shade and of something else that I shall come to presently.

I once saw a number of gentlemen rush at a subject, and in great haste plant their apparatus and go to work. There were one or two cameras not far away, but it never seemed to occur to any of those who came with such eager desires to ascertain if there were any advantages to be secured by looking round. At one time I noticed four cameras all in a line before and behind each other, with the object in front of all. I think that was a mistake; but, perhaps, some people like to see cameras in their pictures! I do not, as I don't consider them picturesque objects, especially when the operator is under his black hood!

I have always found it best to spend some time in getting a knowledge of the locality in which I intended to work, and, if necessary, to spend a whole day in doing so. Of course if you are out for an odd day only you must do the best you can. It is very pleasant to have a companion when away for a week's work, but I have always done best when I have had no company but my apparatus and my pipe.

The rules of art that a photographer should observe are not very numerous, and for the benefit of those who do not know them, I will state them in my own way:—Avoid all lines that run parallel with the horizontal and perpendicular margins of your plate, such as a long wall or a railing. Avoid parallel lines in any direction whatever, either curved or straight. Never admit an object either immediately behind or above another; the effect is very bad. I once saw a picture, by an artist so called, in which he had placed the figure of a woman exactly before the trunk of a huge tree. I think I never saw anything so painfully out of place as the figure of that woman. Parallel lines were there. One object before another and one object above another were present, the impression conveyed being that some poor woman had been placed there and rolled in flat. You will find something of the kind in this group, taken at Hawarden, only the figure against the turret is both round and square, and these features, combined with the surroundings, tend to mitigate the otherwise bad effect.

In photographing long distances endeavour to get a bold object in the foreground, so as to send your distance back; and I would suggest something better than part of a tree, which generally turns out a black patch. If you have occasion to take a street or road scene, place your camera so as to include more of one side than of the other, and do not allow the distant centre of the street to be in the exact middle of your intended picture. Never permit a road to run out from your view; such an arrangement carries the eye out of the picture and away from that which is intended to be seen. Rather let the road steal quietly away at some distance from the margin of your picture.

Every picture should have a principal object, and that should be more or less distant from the centre. Do not attempt to include *too many* objects. A few bold, well-lighted, and well-balanced ones are more effective; for where too many are introduced the eye is embarrassed in consequence, and there is no rest for it. I have a drawing which includes a road on one side and a pretty tumbling stream on the other, and the eye wanders from one to the other without satisfaction. One principal object in a picture, like one theme in a musical composition, is more agreeable than two. Light, shade, and shadow are common to both, and parallels are objectionable in either; contrary motion is most satisfactory in both.

All these things have been said and written before, in different ways and by various people; but they somehow get overlooked. It is profitable, however, to turn them out for an occasional airing, especially as there are plenty of recruits constantly entering the photographic army.

Alluding once more to light, shade, and shadow: an artist friend of mine says:—"Mr. Black never lives next door to Mr. White; Mr. Grey always dwells between." In other words, severe contrast is to be avoided. By attention to the laws I have endeavoured to place before you a great deal more would be gained than some of you may imagine, and systematic attention to them for a time would speedily become habitual. I know they are sometimes disregarded for special purposes by experienced artists; but the results, like Gainsborough's *Blue Boy*, are pictures in spite of the violation, not in consequence of it. There some other things that landscape painters observe, and which landscape photographers might, perhaps, study with benefit either in the production of their negatives or during the process of printing. Atmosphere, for instance, is deplorably absent from most photographs. I have found a hot, still day most favourable to success in this direction; but it is necessary not to overstep the capability of the camera as regards distance. What is known in art *parlance* as "keeping"—that is, the preservation of relative distances—is another point that might claim some consideration from us. As far as I can see this cannot be obtained in photographs without a constant light. Shifting clouds that sometimes cast shadows on foreground and distance alternately are fatal to it.

Contrast both in form, line, delicacy of middle tint and depth of tone should be sought after. Variety is essential to ultimate satisfaction; to say nothing of perfection. There may be, to all appearance, an abundance of variety in a mass of shingle; but in a photograph it often looks like a stone wall. The eye is captivated with the colour of vegetation that occasionally shows itself more or less in such masses, or with the various colours of the stones themselves; and unless the ambitious photographer is careful to recognise light and shade without reference to colour he is doomed to disappointment. Colour is the most difficult thing we have to contend with; it is the syren that leads us on to failure if we trust it. Bright reds and yellows that are lights to the eye are black in photography. I sometimes think it would be profitable to arrange a number of different colours and shades and photograph them, noting carefully the result—not in the negative, but in the ultimate print. I never saw, to the best of my recollection, a photograph of a red-haired person, but I should scarcely think it would be at all flattering to the original.

I think I have said sufficient to lead you into a new train of thought as regards these matters in their connection with photography. It appears to me that we trouble ourselves too much about apparatus; we have too many mechanical contrivances to take our attention, like people who have heaps of books and don't read them. The frame is so rich that we miss seeing the picture in it. I do not mean to insinuate that efficient and sufficient apparatus are undesirable; but we could all do very well with a smaller stock than we have. Such things do not see and think, and seeing and thinking are what we should cultivate. We must remember that Galileo did wondrous work with a telescope that was a mere toy in comparison with what we have now. We should make the best use of the apparatus we have, and not defer the acquirement of art principles and artistic feeling until we can obtain better. By following this course we should be the better able to make an intelligent use of the "better" when we could get them. CHAS. ADIN.

CHADWICK'S NEW DUPLEX GAS LAMP.

[A communication to the Manchester Photographic Society.]

IN fulfilment of the promise I made at our last meeting I send you the following particulars.

On "taking stock" of Mr. W. J. Chadwick's new naphthalised coal gas lamp the two burners seemed to me to be too wide apart. As it was probable some alterations would be made in the lamp I deferred putting any porous material into the naphthalising box, as it would be worse to get out than in. As a substitute I placed the lamp on a hot iron when trying an experiment. To partly fill up the space between the two burners a small wedge-shaped tin box was made, having two rows of small holes near the thin end of the wedge, a piece of lead gas pipe being soldered into one side at the thick end. Upon trying how the thing would answer I got a very smoky flame from the two gas burners. A very gentle stream of oxygen being then allowed to issue against the inner side of each gas flame a very brilliant light was the result. The flames were ragged, and not sufficiently compact to put before a condenser. Instead of oxygen, coal gas or atmospheric air might be tried, just for information, before any alteration is decided upon.

The alteration I would make would be the addition of an intermediate naphtha flame fed by a cotton wick, getting its supply from the naphthalising box below. The capillary attraction of the wick would bring up a large supply of the volatile liquid, part of which would be burnt in the usual way, while another part would be vaporised by the heat, and help to still further increase the two gas flames. There should be a narrow passage on each side of the centre burner to admit air; this being done, I have no doubt you would have a very large, smoky flame, giving off any quantity of smuts.

As the lamp cannot be allowed to smoke, or any stimulant in the shape of oxygen permitted, when at work, in the interior of a lantern or sciopticon a powerful and well-arranged draught of air must be provided, so as to produce the best light and a clean flame. The centre wick-holder might be so arranged that when the wick is away a brass cap containing the same number of holes as either of the other burners have could be put on, so that there would be three gas flames all alike. If the pressure of the gas causes the naphtha to over-feed the wick and flow over the pressure would have to be reduced; if that reduced the efficiency of the two outside flames the holes might be "rimered" out larger to suit. Experiment alone can point out what is best.

To "break the lamp in" properly a gallery should be formed to carry a plain glass gas globe. On the top of this globe there should be a long chimney. Through the gallery, or bottom plate, suitable openings must be made. By having a gas globe you will be able to see all around the effect of the various inlets of air to the three flames before fitting the lamp into the place where it is to work permanently. The coal gas might be made hot before entering the box. M. Noton.

M. LAMY'S SYSTEM OF PHOTOMETRY.

The following is an abstract of the remarks made by M. E. Lamy at the last meeting of the Photographic Society of France, in explanation of the system of actinometry to which allusion was made in our last number by Mr. W. Harrison, our Paris correspondent:—

My system of photometry is used in connection with the method I employ of estimating in minutes of a good light at noon in the shade the printing force of a negative. The regularity of its indications depends upon the mode of preparation of the sensitive measuring paper; consequently I shall, in the first place, explain how I estimate the printing force of the negative, and afterwards how I prepare the sensitive paper.

In order to judge the printing force of a negative in minutes of a good light I choose three good negatives—one feeble, the second of good average force, and the third slightly over-strong. I print these three negatives separately, using my carbon paper No. 10, which is the most rapid for positives developed by the double transfer method, the tissue being sensitised on a bath at three per cent. Exposed *in the shade towards noon*, the most feeble portrait negative will generally require an exposure varying from six to nine minutes, those of average force from ten to thirteen minutes, and the stronger ones from fourteen to seventeen minutes. The three negatives are, therefore, exposed respectively for (say) eight, twelve, and sixteen minutes. After exposure and development the proofs are examined, when, if they be either too strong or too feeble, the operation is repeated, diminishing or augmenting the exposure by one or two minutes. When, after development, the right time has been hit with each of the three proofs, the number of minutes required to produce the result is marked upon each negative respectively.

Thus I have three types or models numbered for comparison, which can be framed and placed permanently at a window of the printing-room for inspection. This is the only trouble of any consequence which is necessary, for when it is once done the table of comparison is always ready to hand, and is capable of measuring easily, rapidly, and with exactitude the time for the printing of all negatives. Photographers who have to print from negatives, some of which have been obtained by wet collodion, others by the dry process, or even enlarged negatives, may, in order to render their determinations more accurate, establish tables of comparison with negatives by each of these processes.

To form a correct estimate of the value of a negative requiring numbering, it is compared with each of the types by transmitted light, and it is judged and identified as to strength with one of them. If there be a perfect assimilation with one of the types, a corner of the negative is marked with a label bearing the number of minutes corresponding to the type with which it accords. If there be not an exact assimilation it is readily seen whether it can be placed either in advance of the first or after the last, or between any two of the types, and an intermediate number of minutes marked accordingly on the label. The valuation having been made, and the negatives marked accordingly, they are then delivered to the printer, who, guided by the numbers and the actinometer regulated and numbered to correspond, can produce *at once*, and *without any previous trial*, proofs properly exposed and printed to a nicety.

The method of preparing the sensitive paper consists in immersing for ten minutes a sample of Rives' eight kilo. paper in the following bath:—Distilled water, 100 c.c.; chlorhydrate of ammonium, two grammes.

This plain salted paper (the back of which is first marked) is dried and then floated for four minutes upon the following silver bath:—Distilled water, 100 c.c.; nitrate of silver, twelve grammes; citric acid, six grammes. The citric acid gives to the paper the property of keeping white, and, however old it may be, its colouration under the influence of light is always *alike and equally rapid.* The specimen shown to the Society has been prepared three months, and is now as white as it was on the day of preparation.

The actinometer differs almost entirely from those in use up to the present time. Its comparative tint is a rosy grey, and it is by the aid of this one tint, concurrently with one or more glasses of varying depths of colour, that I obtain the necessary effect.

It is very important that the comparative tint be *unalterable*, inasmuch as it is composed of enamel colour applied upon a support of paper, which is pasted upon a coloured glass fixed in the opening of the cover to form the comparative table of the instrument, and pierced with an aperture, under and across which slips the silvered paper. A band of sensitive paper is rolled round an axle contained in the interior of the instrument, and is held in its place by a small spring; a short length is unrolled so that the end projects a little beyond the exterior, the cover is shut, and the instrument is ready for use. The reading of the tint is easy, and is made from the exterior, upon the table of the cover, without its being necessary to touch the instrument; the renewal of the paper which has been used is brought about by pulling out the end which projects, so as to bring a fresh portion under the aperture.

With the simple slip of wood which I hold in my hand I can explain more easily how I arrive by this system at an indication of widely-varying times of exposure. Upon it you see a piece of enamel-coloured paper, similar to the tint of comparison placed in the actinometer. Under this paper, which is pierced with a round hole, slides the band of silvered paper. If, in a good light, I expose the whole thus fitted up the silver paper, visible through the aperture, tints and assimilates to the colour of the test paper in ten seconds; but if I take a slip of glass of a light green colour, and place it over the opening through which the chloride of silver paper is seen, the latter no longer tints in ten seconds but requires fifteen. If I replace the light green glass by another of a shade a little darker, and I expose again in the same light, I find that the silver paper requires thirty seconds; and by trying in the same way all the coloured glasses of the green scale and those of yellow that I have in my hands, either one by one or combined two and two or three and three, you will see that I am in possession of a system with which I can indicate the different quantities of the action of a good light successively from fifteen seconds up to twenty-five minutes. For the indication of quantities above twenty-five minutes it is necessary to have a combination of coloured glasses of such intensity that the light cannot penetrate easily, so that to measure exposures above twenty-five minutes I am obliged to use successively two different actinometers, the sum of the indications of which would give me in minutes the total sought for, though there are very few negatives, especially of portraits, which require such long exposures. Each of my actinometers is thus regulated in *shade towards noon*, and the readings are based upon the retarding power which coloured glasses, singly or combined, exercise upon the darkening of the chloride of silver paper.

I have here a series of eight actinometers. The first assimilates with the comparative tint in six minutes and passes it in seven. The last of these actinometers takes the tint wished for in twenty minutes and passes it in twenty-five. Each instrument thus indicates two quantities of the action of a good light.

The Working of the Actinometer and some Observations Thereon.—For printing, the printing-frames of negatives marked with similar numbers—say seven—are exposed altogether, accompanied with an actinometer indicating the same number. Those negatives marked "ten" are also exposed simultaneously along with the actinometer of the same number, and so on with each series of negatives. The exposure of each class of negativs is stopped the instant the tint of the corresponding actinometer is accomplished. With this system, whatever may be the light, the impression is always perfectly exact.

If the exposure of the last batch of printing-frames for the day has not been sufficiently long before work ceases, or the light has departed, each series of printing-frames is taken to the work-room with its corresponding actinometer, and the exposure is continued the following day, when the operator will find that the prints have been done to a nicety.

The supposition that the impression of the image continues afterwards in the dark is, in my opinion, a great error. The gelatine impregnated with bichromate becomes so much harder in proportion as the keeping has been more or less protracted and the air more or less humid, or the opposite.

The carbon paper after being bichromatised for several days, whether it has been impressed under a negative for some time or has only just been exposed, necessitates, for the development, water heated to a relatively higher degree of temperature than the carbon paper has been kept at, according as the atmosphere is more or less humid, dry, or warm. In thus raising the temperature of the water to the degree which best accords with the circumstances one can always ensure that the image will be of the desired vigour and strength.

But if a carbon paper bichromatised and kept several days after it has been used be developed with water heated to the degree which suits paper freshly sensitised and exposed, the development takes place very slowly, and it is believed to be terminated when it is only partly so, and the washing being stopped too soon, the image thus obtained will appear to be too much printed.

With my instrument it is better not to print in the sun, otherwise its indications would be incorrect, and in consequence a stronger light should not be used than that which has served to regulate the actinometers. The scale of colouration of chloride of silver paper exposed directly to the rays of the sun is very different from that obtained by the exposure in the shade.

I have very recently observed, after the experience of several consecutive days during a temperature below freezing-point, that carbon paper exposed under a negative in the open air in a garden, and consequently subjected to the effects of cold, was a little slower in printing. To meet this special case I made use of an actinometer marked with a number one-fifth higher than that on the negative. This is an exceptional experience, which, I believe, may very usefully be made known.

Amongst carbon papers there are some which, in consequence of their density of colour in proportion to the quantity of gelatine, or from the presence of particular colours—such as blue and certain iron reds—do not print with the same rapidity; nevertheless, for these papers the base of the printing depends always upon the numbers on the negatives, such as I have indicated above. In this case, to be able to print exactly right, here is what is necessary:—Open, for instance, a roll of carbon paper containing blue (which is the slowest colour, and mixed with gelatine forms the best medium for obtaining harmonious images); take a piece and sensitise it upon the bichromate bath at three per cent.; when dry expose it under a negative along with the same numbered actinometer, then develope, and by examining the image it can be judged, by the experience gained in our profession, that to be properly exposed it would have required either one-fifth, a fourth, a half, two-thirds, three-fourths, or even double more. If it seem from this one trial that the printer cannot judge with sufficient precision he can repeat the experiment with an actinometer which he supposes will approach nearest to the impression required for the paper under trial. This done upon the outside of this and similar blue carbon paper we mark, the difference. If, for example, we have recognised that the image obtained is too feeble by half we inscribe on the roll "one exposure and a-half;" when, with the blue carbon paper thus marked, we wish to print a negative numbered "ten" we expose the printing-frame along with an actinometer marked "15," and in this manner up to the end of the sample of blue carbon paper we obtain the same perfect exactitude in the printing.

THE REACTIONS OF CHROMIC ACID AND CHROMATES UPON SUBSTANCES OF ORGANIC ORIGIN, CONSIDERED WITH REFERENCE TO THEIR USES IN PHOTOGRAPHY.*

The Behaviour of Gelatine with Reagents.

The behaviour of gelatine and chrome gelatine with reagents has already been partly described where it appeared to be necessary in order to preserve the connection of the subject, and by this proceeding the difficult-to-review-subject material has been divided.

In considering the action of chrome alum upon gelatine we find that chondrine is at once precipitated by heat, while gluten is not. I followed closely the somewhat developed phenomena of the reaction, because they throw a new light upon the process of photography with the chromates. A certain proportionate concentration must be maintained during the reactions, for gelatine solutions containing from twenty to thirty per cent. of gelatine, of whichever kind its origin may be, will be rendered very thick by chrome alum and will stiffen quickly. A five or ten per cent. solution of gelatine rich in gluten will not be precipitated from its solution by an excess of chrome-alum solution. It will not be visibly changed, nor will the solution gelatinise more rapidly than pure gelatine. Occasionally this addition will delay the gelatinising, but not for long. When the solution has stiffened it is still soluble in boiling water, but only slowly. After one hour, or even after twelve hours, the jelly gives off no chrome alum to the water, if the former was not added in excess, and it will now have become insoluble even in boiling water.

If the chrome alum added to the gelatine solution be equal in quantity to half the quantity of dry gelatine used, then when once the jelly has stiffened it will have become so well able to resist the action of boiling water that even boiling for several hours produces no solution. It is only after boiling from six to ten hours that the chrome-alum gelatine dissolves into a green fluid which no longer possesses, or scarcely possesses, the property of jellying. The shrunken, stiffened chrome-alum gelatine gives off, after digesting for days in cold water, some chrome oxide and a great deal of potassic sulphate, of which only a very small quantity is retained. If the water in which it is digested be now made slightly ammoniacal a great proportion of the sulphuric acid will be redissolved while the chromic oxyhydrate remains combined with the gelatine. The compounds of gelatine with the chrome oxide salts are insoluble in hot water, as well as that with chromic oxyhydrate.

A relatively smaller addition of chrome alum suffices to make the gelatine insoluble. Some ten per cent. of chrome alum to the weight of dry gelatine renders the jelly insoluble in boiling water, but does not produce that lasting resistance to its action induced by the addition of an equal weight of chrome alum. An addition of five or even two per cent. of chrome alum to the gelatine produces temporary insolubility, but in from a quarter to half-an-hour boiling water dissolves such gelatine. If a stiffened jelly of pure glue be digested with a solution of chrome alum it will become insoluble, and so will air-dried sheets of glue, when allowed to soak in a cold solution of chrome alum, become insoluble in hot water.

* Continued from page 583.

When gelatine, to which chrome alum has been added, once becomes dry it resists the boiling water much more obstinately than the jelly. If from ten to fifty per cent. of chrome alum be mixed with gelatine, and the dissolved mixture be allowed to dry up, the longest soaking in cold water will no longer cause it to swell, though boiling water still slowly produces a slight swelling. From one to three per cent. of chrome alum does not prevent the swelling caused by long soaking in cold water, though it is very slow, taking place faster the warmer the water is.

This insoluble mixture does not resist the continuous boiling with water for a whole day, but dissolves. Increase of the chrome-oxide contents also renders the same gelatine insensitive to water.

The behaviour of gelatine rich in chondrine is still more pronounced. It stiffens with chrome alum, even in a hot solution, and is then insoluble in boiling water. The boiling must be continued for a whole day before the once-stiffened mass begins to dissolve, otherwise both sorts of gelatine behave alike. If acetic acid be added to the gelatine solution before the chrome alum then the solution will not stiffen when cold; but when once the fluid dries up it will have lost its solubility in hot water.

Dilute hot muriatic acid, sulphuric acid, or nitric acid accelerate considerably the solution of stiffened gelatine and chrome alum. Acetic acid, even when boiling, has but little effect upon it. Hot potassic ley dissolves it very rapidly, even when very dilute; a solution of soda acts in a similar manner, though weaker. Strongly chlorine water, even boiling, has little or no effect; and calcic chloride has a moderate action. Potassic permanganate accelerates greatly the solvent action of boiling water by precipitating manganic peroxide. This solvent action is, however, but a secondary consequence of the decomposition of the potassic permanganate which separates into manganic peroxide and potassium, the latter of which acts energetically as a solvent. A permanganate solution, to which acetic acid has been added so as to combine with the potassium set free, dissolves chrome-alum gelatine very slowly; indeed, a jelly treated with it is even more insoluble than before. Potassic permanganate was first used by Swan[1] to intensify carbon pictures, and is now extensively used for that purpose.

The property possessed by chrome alum of rendering glue particularly insoluble has been generally known for a long time, but Swan[2] called special attention to it. He utilised the insolubility of chrome alum for waterproofing textile fabrics[3]; and he also proposed to use chrome alum for the production of an insoluble, gluey film upon the transfer paper used in the carbon process[4]; for which purpose Liesegang,[5] Vogel,[6] Monckhoven,[7] Phipps,[8] and others use it. Chrome-alum gelatine is also used in the preparation of photolithographic paper.[9] The addition of a small percentage of glacial acetate to the chrome-alum gelatine prevents its too rapid stiffening, and makes it more fluid without affecting its insolubility after drying.[10] Chrome-alum is also recommended for staining and hardening photogalvanographic gelatine reliefs[11] and carbon pictures.[12]

Though, for many reasons, the addition of chrome alum to photographic chrome gelatine is recommended, still, as it always lessens the solubility and renders impossible the development of the picture by dissolving out the unlighted gelatine, it is only necessary to consider its use in relation to lichtdruck plates. A moderate addition of chrome alum gives the gelatine more consistency and greater power of resisting mechanical pressure and friction. I proved that this really occurs with almost all sorts of gelatine, though in a greater degree in the case of some than with others, and I calculated the degree of hardness induced in a large number of varieties of gelatine (this point will be taken up again further on). A small addition of chrome alum makes the chromated gelatine very difficult of solution in boiling water, without wholly depriving it of its power of absorbing water.

Chrome alum presents many advantages for the lichtdruck process, since the films do not lose their sensitiveness to light, but, as some think, rather gain,[13] while the difference in insolubility and in respect to the power of absorbing water still remains sufficiently great, between the exposed and unexposed chrome gelatine, to furnish fine lichtdruck plates, and plates able to furnish a greater number of impressions. Thus the attempt to introduce chrome alum into lichtdruck is not without justification. Amongst those who recommend the addition of chrome alum to chromated gelatine is Edwards,[1] who mentions that lichtdruck plates to which it has been added do not show such a high

relief after washing. Abney[1] and the Heliotype Company,[2] at Kilburn, have also used chrome alum for this purpose. Waterhouse[3] found that lichtdruck films containing chrome alum, though pretty hard, were apt to spring off the glass if the quantity of chrome alum contained was great. He prefers to add, for hardening purposes, chromate of mercury and lacs. It was apparently the effort to harden liehtdruck gelatine which induced Geymet[4] to boil the chromated gelatine for three minutes before spreading it upon the glass plate, as he lays stress upon this proceeding as adding to the firmness of the film.

When lichdruck plates have a solution of chrome alum carried over them the parts so treated take on black. In this way printing plates can, according to Waterhouse[5] and Voight,[6] be retouched.

(To be continued.)

NOTES FROM THE NORTH.

One by one the ancient landmarks are being removed. This is true of photography, as well as of most other things; and we have an instance of it in a notice which appeared in a recent number of the official *Edinburgh Gazette*, which deserves more than a mere passing notice. There are few of those who have been privileged to watch the progress of photography, from its earliest dawn as a profession down to its present state as an institution in every civilised quarter of the globe, that are not more or less acquainted with the names of "Ross and Thompson," and more recently "Ross and Pringle." Mr. Ross, who had the advantage of being trained as an artist, was one of the fortunate few who, having taken up the new art enthusiastically, soon adopted it as a profession, and he is one of the still fewer whose career as a professional photographer has been in every way an unqualified and unbroken success. Those who had a personal acquaintance with Mr. Ross have no difficulty in finding the cause of his great success both artistically and pecuniarily. He had a high appreciation of, and an intense love for, art; and in his daily work seemed ever striving after an ideal perfection. Instead of trying merely to satisfy the tastes of his numerous patrons, who, though drawn mainly from the more cultivated classes, were in many cases somewhat deficient in art culture, he, by his suavity of manner and genial *bonhomie* which so peculiarly characterised him, easily led them on to do, and let him do, that which generally resulted in work of artistic as well as technical excellence.

Mr. Ross rarely, if ever, complained of dull times, and was as rarely to be found idle, delighting in experimenting with varied methods of lighting and posing, as if he had been a student fresh from the academy. In this way, and as the result of much well-spent leisure, he produced many exquisitely-beautiful gems that found their way all over the world, and many of which were from time to time reproduced as engravings in various illustrated periodicals. His suavity of manner, intensity of friendship, and open-handed liberality secured for him the affection and esteem of all who knew him; and, as he retires from business in what may still be said to be the prime of life, he carries with him their heartfelt wishes that he may long enjoy the repose that has by a well-spent life been so faithfully earned.

By an ever-active interest in all that concerned the welfare of his *employés* Mr. Ross gathered round him those who were both able and willing to do all in their power to aid in carrying ont his designs, and as each had the interest of all at heart, the changes in the *personnel* were comparatively few, and the work of the large establishment went on with an admirable smoothness. It will, no doubt, be satisfactory to all interested in good work and the continuation of time-honoured institutions, to know that in the hands of Mr. Pringle, who has been so long associated with Mr. Ross, the establishment is likely to retain its high character; for now, in a time of depression such as has rarely, if ever, been experienced in Scotland he is still able to find plenty of work for his willing hands.

I hope dry-plate workers iu general, and the less experienced of that now large body in particular, will "mark, learn, and inwardly digest" the remarks on development by Mr. Henry Cooper in his recent communication to the Photographic Society of Great Britain, as I think he sounds the keynote of success when he says—"Beware of strong pyro.; use it very light to begin with. * * * Use patience, and do not hurry. * * * The developer may be used almost like a painter's brush; and it is only by the intelligent and artistic use of all such means to an end that *pictures* such as a true artist would value can be produced by means of the camera." A few days ago I met with an amusing corroboration of Mr. Cooper's opinion of the benefit to be derived from the use of a very weak developer at the commencement of development. I called on a friend who had been fairly successful with collodio-bromide, and had recently taken to gelatine, but complained bitterly of being able to get nothing but "tame, flat, useless negatives." He was in his dark room, and as I entered exclaimed—"Eh! man! yer just in time! I've fairly mastered the billie noo, and ean gar him come oot wi' as muckle birr and beauty as a wet negative!" He was working 10 x 8 plates, and proceeded by making about two ounces of a three- or four-grain solution of pyro. with the addition of sufficient ammonia and bromide. After well moistening the plate under the tap he poured about two drachms of the solution into a four-ounce developing cup, and nearly filled it with water. With this he flooded the plate and watched the effect, commenting the while pretty much as follows; but, as under the least excitement he runs off into the vernacular, it is not easy in these degenerate days to carefully follow him:—"There! the billie come noo! Ye see he disna like to be driven; but just gie him his ain time and ye can make him onything ye like! He's rather weak i' the head, and canna stand strong drink to begin wi' without getting muddled all over. The fach is gelatine is a kittle billie, and canna stand muckle licht, and so ye'r aye gie'nt our muckle or our little, an' there's naething like a weak drink o' pyro. to begin wi' to gaur it tell its ain story." Holding the negative so that it might be examined by transmitted light, he continued—"Is'nt that grand? no' a trace o' muddling there!—as clear as clean glass, an' fou o' detail as the image on the focussing screen; an' it only wants a bit shirt here and bit great-coat there, to make it a perfect negative!" The "bit shirt" and "bit great-coat" were various degrees of additional intensity on the higher lights of the picture, and these were readily obtained by the partially local application of the undiluted solution wherever they were required. In this way, and with a consumption of not more than ten minutes of time, a negative was developed that not only gave a print full of delicate detail and charming contrast, but one that was itself beautiful to look at, and rich in the *bloom* so characteristic of the olden time when wet collodion and pyrogallic development were in vogue.

Of course I am aware that we have high authority for the use of very strong developers; and, in certain cases where the proper exposure has been accurately hit, I know that exquisite results may be obtained by its use. But even then an equally good negative may be got by the more patient method of slow action, and the intelligent operator who wishes to stamp his work with what Mr. Edwin Cocking has so well called the "subjective" of pictorial photography will find the method advocated by Mr. Cooper—accidentally hit upon by my friend already mentioned, and practised by some of the most successful dry-plate workers for many years—a most valuable means to that end.

It has been often observed that photographers are of a "conservative" turn of mind, apt to prefer something that has the flavour of age to such novelties as may be brought under their notice, and for such the method of slow development ought to have a charm. Some of my readers will remember that nearly twenty years ago a series of exquisite instantaneous seascapes, with vessels in full sail, were produced in Glasgow by (I think) Mr. Kibble. They were known to have been obtained on dry plates; but, so far as I understand, the process has never been published, the only information regarding them being that the development occupied a period of several days and nights. Another notable example of a believer in slow development was the late Mr. W. D. Clark, of Edinburgh, whose dry-plate work at the time of its production was far ahead of that of most of his contemporaries, and some of his pictures that lie before me while I write are still equal to anything that is being done at the present time. His method—which I published in this Journal more than a dozen years ago—was to use a developer so weak that a dozen hours or more were required to bring out the detail of the image, and sometimes three or four times as much to produce sufficient density. During that time the plate was frequently removed from the solution, washed, and dried, and such parts as were sufficiently intense varnished to protect them from further action and again returned, till the whole was completed to his satisfaction.

Notes of progress from the North are at present difficult to obtain. The commercial crisis consequent on the failure of the ill-fated City of Glasgow Bank has cast a gloom over society generally, and photographers, amongst others who minister to the luxuries rather than to the necessities of the public, are the first to suffer. The complaints regarding dull trade are both loud and deep, and, so far as I can judge, were never made with so much cause. During a few calls made one day last week amongst a class who are usually tolerably full of work at all seasons, and who have hitherto regarded the Christmas and New Year holiday times as periods of "haymaking," I found one photographer had gone to London to spend Christmas and try to pick up something novel with which on his return he might bring back his *clientèle*; another had laid in a stock of chlorate of potass and manganese, with the intention of earning a few guineas from lantern exhibitions; while a third had looked out the negatives of a few of the most likely of his patrons, and was filling up his time by making enlarged collodion transfers, which he intended to send to the owners in the hope that he would sell sufficient to pay for the cost of production of all, and leave a small margin of profit for himself. He complained, however—and I understand the complaint is general—of the difficulty of getting other than a bluish-black tone, and was very anxious to have it warmed up a little. On reaching home I made a few experiments, and happening to have on hand

some old "fixing and toning bath"—hyposulphite of soda and gold—it was used to fix the image instead of the usual simple solution of hypo., and the result was just what he required. "Such a tone will not be permanent," some of my readers may say, and it is just possible that the statement may be true; but I have before me now stereoscopic transparencies toned in that way fifteen years ago. They were then a fine warm brown, hardly to be distinguished from the French slides then so popular, and they are now exactly as they were at that period; and if the collodion transfers now being made by my friend retain their beauty for fifteen years he need not bother himself about their after-history.

John Nicol, Ph.D.

ON PROCESSES OF MAP PRODUCTION BY PHOTOGRAPHY.*

Daguerreotype Etching.—Many attempts have been made to engrave the beautiful and delicate photographic image formed on the daguerreotype plate. Thus, Donné simply etched the image with dilute nitric acid, which attacked the silver forming the shadows, leaving the whites protected by the mercury untouched. Grove etched the plates with the aid of the galvanic battery. Fizeau first etched as deeply as possible with dilute muriatic acid, and then, having filled up the hollows with drying oil, deposited gold upon the lights; the oil having then been removed, the plate was bitten with dilute nitric acid. In order to render the silver plate more capable of standing the wear and tear of printing it was covered with a thin film of copper, which could easily be removed and renewed when required.

Other processes were also put forward, but they all failed from the difficulty of biting the image to a sufficient depth and of obtaining the requisite "grain" to enable a large number of impressions to be pulled off. None of them seem to have ever come into practical use, and, like the daguerreotype, they have almost fallen into oblivion.

Though they have the advantage of rapidity, all these processes, in which the image is obtained by etching or biting in with acids or other etching fluids, are open to the objection that for all subjects containing fine and delicate lines the etching and stopping out require almost the same manipulative skill and care as in ordinary engraving, and the processes consequently become expensive to work. There is also a tendency for the lines to become coarse and heavy. In those gelatine processes in which the etching fluid acts through the gelatine it gradually loosens the latter from its support and attacks the parts which should not be bitten at all. These defects are to a great extent obviated in the processes we are now about to consider, in which the printing plates are produced by the electro-deposition of copper on the photographic image.

Electrotyping Methods.—In nearly all the electrotyping methods the printing plate is obtained by depositing copper on a gelatine relief obtained by the agency of light, or on a cast in plaster, gutta-percha, &c., taken from such a gelatine relief.

If a dry film of chromated gelatine on a suitable support be exposed to light under a photographic *cliché*, and then plunged into hot water, the parts acted on by light, being insoluble, will remain on the support in different degrees of relief according to the intensity of the light, while the unexposed parts will be washed away. An image in high relief formed of hard and insoluble gelatine will thus be obtained, from which a cast or electrotype in intaglio may be made.

If, however, instead of using hot water the plate be plunged into cold water, the gelatine will be found to absorb water and swell up in the parts protected from the light, while in the parts acted on by the light it will only slightly absorb the water, and these parts will thus form hollows. The power of absorbing water will also be found to be in exact proportion to the degree of protection from light. In this case an image in low relief is obtained which may also be moulded from, or electrotyped.

Upon these two principles several processes of producing printing plates both for copperplate and letterpress printing have been founded with more or less success.

The first process of the kind was Paul Pretsch's "photogalvanography," invented in 1854. He appears at first to have obtained his plates by coating a glass with gelatine and bichromate, exposing to light, and then washing away the soluble gelatine and taking a mould of the resulting relief, in gutta-percha, from which an electrotype was made in the usual manner.†

This process gave fair results both in line and half-tone, but, owing to the washing away of the soluble gelatine being effected on the side of the film exposed to light, the plates were defective and required a good deal of touching up by skilled engravers, which vastly increased the expense of their production. The process failed as a commercial speculation.

Almost immediately afterwards, in 1855, Poitevin published methods of obtaining plates from the gelatine reliefs obtained by swelling the sensitive films in cold water. Plaster casts were either made from them or the gelatine surface itself was metallised and electrotyped in the usual way.‡

This method produced tolerable results, though the prints were always somewhat coarse, owing to the fact that swollen gelatine will not give the same sharpness as when dry.

* Continued from page 592.
† See *Photographic Journal*, vol. iii., p. 85.
‡ See *Traité de l'Impression Photographique sans sel d'Argent*, p. 49.

Both these processes were more or less unsuitable for reproducing subjects in half-tone—Pretsch's because in the process of washing away the soluble gelatine the lighter half-tones were liable to be lost, and Poitevin's because of the difficulty of keeping the swelling in relative proportion owing to more absorbent parts of the film lying under less absorbent parts. Both processes also failed to give the necessary "grain," without which the proper inking of the engraved plates could not be effected.

Various attempts were made to improve on these processes, but unsuccessfully, until M. Placet showed that it was necessary to adopt in them the same principle of exposing on one side of the gelatine film and developing on the other which, as we have seen, had previously been shown to be necessary for the preservation of the half-tones in the pigment-printing process, and for a similar reason.

M. Placet indicated several ingenious ways of obtaining his results.* They may, however, be briefly summed up as follows:—

A film of chromated gelatine is exposed under a transmitted positive *cliché*, so that the light acts on the under-side of the film; this is done either by covering the collodion side of the *cliché* itself with the sensitive coating, or by using a thin transparent sheet of transfer collodion or mica as a support for it. After exposure to the light the film is soaked in water, whereupon those parts which have been protected from the light swell up in proportion to the amount of the action of light upon them. By treating the mould in relief thus obtained with metallic solutions an electrotype copy in copper may be produced, which can be printed from in the copperplate press.

If a negative *cliché* be used the unaltered gelatine must be dissolved, or a second electrotype must be used.

M. Placet also suggested the employment of a sensitive surface which would become soluble under the influence of light, such as a mixture of gelatine or other colloid with perchloride of iron and tartaric acid, as recommended by Poitevin for pigment printing. In this case the solvent acting on the exposed side hollows out the image, in the same way as an etching fluid does on copper, but with the advantage that each line has only the exact strength given to it by the intensity of the *cliché*. Or the altered parts of the gelatine film may simply be swollen with cold water, producing an image in relief. In either case a mould is taken from the gelatine and electrotyped, or copper may be deposited on the gelatine itself.

By his process M. Placet was able to obtain very perfect gradation of shade in the half-tones of his pictures, with a fine natural grain produced by some means which he did not divulge. He has lately, however, described a method of producing the grain, which consists in plunging the gelatine plate into a solution of bichromate of potash and then treating it with a solution of protosulphate of iron containing acetic acid.† The principle he lays down is first to treat the gelatine with a solvent and then with a solution of some substance that will tan or contract it.

MM. Fontaine, Avet, and Drivet have also proposed similar processes, in which they have partially overcome the difficulty of obtaining a proper "grain" by interposing between the *cliché* and the gelatine film a fine network or an impression of an engraved or *roulette* tint; but these artificial grains have a disagreeable effect, and the methods seem to have fallen into disuse, except for line work and phototypography, which will be described further on. Avet's process is, however, I believe, still in use for producing the maps of the Italian surveys.

Geymet's Method.—The fourth method—that of electrotyping from a gelatine relief obtained by the pigment-printing process—is somewhat similar in principle to Placet's process; but as there are important differences, and the process appears likely to prove of some utility, it may well be treated separately.

According to M. Geymet, who has very fully described the process and all the manipulations of preparing and electrotyping the reliefs in his *Gravure Heliographique*, it was the invention of M. Audra, a French amateur.

Pigmented gelatine tissue is sensitised and exposed to light exactly in the manner previously described for the autotype process. It is transferred to a smooth glass or a polished copperplate, developed in warm water, and when dry is metallised and electrotyped. If the subject is one in line or dot only the above operations are sufficient; but if the subject is a photograph from nature, or any other with gradation of shade, it is necessary to obtain a "grain," and this M. Geymet does by taking a copperplate with its surface grained or engraved with a ruled or *roulette* tint, inking it up in the ordinary way and then covering it with a coating of transfer collodion. When dry, the film of collodion is stripped off the plate and carries with it the impression of the grain. This film is then placed between the *cliché* and the sensitive gelatine film, and serves to break up the shadows in the more transparent parts of the *cliché*.

A similar process has been used at the Depôt de la Guerre, in Belgium, for the reproduction of maps.‡

ON THINGS IN GENERAL.

Surely this is a "black letter day" in the Publisher's annals! He and we are going to lose the genial spirit who has so long presided over the destinies of this Journal. With a broad and powerful grasp of all subjects connected with our art-science, he has, with the aid of many contributors, upheld the dignity and increased the usefulness of an important technical journal, and for many years has enabled The British Journal of Photography to retain the position of the leading representative of photography in position and circulation. Whether for the troubles of the tyro or the more intricate difficulties of the "old hand," he has ever been ready with aid and advice, as the thousands of replies in the "Answers to Correspondents" so abundantly testify, without ever losing patience, though it must often have been sorely tried. He will have the heartiest good wishes of many thousands of readers for his success in his new sphere, and, for myself, I wish him—God speed!

I do not want to finish the Old Year in a mournful strain of mind, and hence I turn my Pegasus towards the coming man, whose abilities are well known to us all. I offer him my most knightly salutations, assuring him of the goodwill of a multitude of readers. *Le Roi est mort! Vive le Roi!* He knows all the ins and outs of emulsion, quick and slow, and if he had a file of the last year's Journals to ride or tilt at he would not know where to begin.

One of the most striking statements I have read amongst many is that Mr. Warnerke's emulsion is forty times as slow as wet collodion—a fact of Herr Seligman's after which I take the liberty of placing a note of interrogation. In Berlin, however, they seem to know how to "place" the various processes of the day. After noticing that Herr C. Ficke offered to the society his new instantaneous process for the sum of 300 marks, I read that "no wish was expressed to acquire the process for the present at anyrate." Had the ardour of the members been damped by Herr Duby, who, like a true man of science, accompanied his explanations with the remarks that the examples he showed were not to be considered as by any special process, but merely by ordinary processes carefully worked out? What a contrast is continental journalism to English! I presume we have to wait for the foreign journals to "come out" before their report of their societies' meetings can be given here; and in consequence I find that the report of the Berlin society from which I have extracted these facts is just two months' old! What would the readers of the "British" say if they were given news of their own country's societies seven or eight weeks' old?

There are often some good things to be read from the "Edinburgh Society"—a tone of culture generally running through their discussions very pleasant to note; but I was rather surprised that no one traversed the statement of Dr. Hunter that artists "did not pay sufficient attention to the shade of the picture." He also thought photographers should look pre-eminently upon the general form of their subjects, leaving the details to take care of themselves, by which means, he judged, pictures of high practical value would be obtained. Is not "practical" a misprint for "poetical?"

The new artificial light apparatus seems likely to give the Journal a lively time among its testimonial-giving correspondents. Testimonials are mysterious things. I used many years ago to think that persons got their living by giving them. I believe at the present day you can buy them at per quire. I have a recollection of the great rubbing-in process—chalk and pumice—where less than three figures would not be looked at as an exclusive licence price; and there were names appended to enthusiastic testimonials in its advertisements—great names the owners of which, rumour said, had not paid a penny for patent rights, their name being their fortune. "What's in a name?" indeed! A great deal, forsooth!

We are closing the year well. Mr. H. Cooper's "reliable" process and Mr. Willis's platinum process appeal to practical men as real successes. The latter was well served by Mr. Jabez Hughes pointing out the great advance in the process, the withdrawal of the only possible source of suspicion—a companion metal along with the platinum. No one can now suggest a shadow of suspicion that the platinum image could give way. It is like Cæsar's wife; and I predict a great future for it. It is an undoubted fact that the carbon process leaves something still to be desired, even in the best of prints, while a good platinum print has such a velvety transparency of shadow and such purity of colour, while delicate in the whites, that it appeals strongly to the artistic taste. If the new year be only as fertile in real advancement we should do well, I trust it may be a Happy New Year to my readers.

Free Lance.

Our Editorial Table.

The Magic Lantern Manual. By W. J. Chadwick.
London: Warne and Co.

Mr. Chadwick's name is familiar to our readers as that of a gentleman fully conversant with the requirements of the magic lantern, and this in itself will cause his *Manual* to be received with no small degree of confidence. The author is by no means averse to speaking pretty freely as to the places where specialties may be obtained and the firms by whom such matters are manufactured or sold. This course will necessarily give offence to some, but it is very useful to the reader. In the historical part we observe that the sixteenth century-work, "*Ars Magna Lucis et Umbræ*," is attributed to Kerchler. In some historical observations on the same subject made in this Journal about fourteen or fifteen years ago, we attributed, on undoubted authority, the authorship of this work to "Kircher." If, upon subsequent investigation, the name of the author given in Mr. Chadwick's work be found incorrect, it will be well that it be rectified in subsequent editions. While on this subject we may observe that the proof reader has taken a liberty with the name of an esteemed *savant* in spelling it "Doclberner," and that he has mixed up his plain "Mr's." and "Esqr's.," as applied to exhibitors and opticians, in a manner that we know cannot have met with the approval of the author. These notwithstanding, the book is a thoroughly readable one, and contains much interesting matter relating to the magic lantern. In the description of cheap forms of objectives for the lantern, we find one described as composed of "two plano-convex lenses, mounted with the *concave* sides together," the word we have italicised being evidently a misprint for *convex*. Our object in mentioning this is not to point out an error, but to state that if two such lenses be mounted so as to have their convex surfaces nearest to the picture to be magnified they will form a good monochromatic objective; but that if, instead of plain lenses, achromatic ones be made use of, the image will be free from colour, well defined, and sharp to the edge. This description of objective is now extensively employed, although for architectural subjects it is inferior to the portrait combination on account of its giving a slight amount of outward curvature to the marginal perpendiculars of such pictures. The most modern appliances for producing oxygen are here to be found, together with a description of the more recent forms of lanterns.

Men of Mark. Edited by Geo. C. Whitfield.
London: Sampson Low and Co.

In the present (the third) series of his *Men of Mark* Mr. Whitfield has clustered together thirty-six portraits of men of eminence and position, including the Archbishop of York, Anthony Trollope, Lord John Manners, the Bishop of Manchester, Frederick Max Müller, C. R. Darwin, and others of similar renown. We have on former occasions spoken of the excellence of the photographs produced by Messrs. Lock and Whitfield for the *Men of Mark*. Those to be found in the present volume are in every respect quite up to the high standard these eminent artists have set up. The descriptive matter is written with good taste and discrimination.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
January 1......	Edinburgh	Hall, 5, St. Andrew-square.
,, 1......	Bristol and W. of Eng. Amateur	Museum, Queen's-road.
,, 1......	Photo. Benev. Asso. (Ann. Meet)	160a, Aldersgate-street.
,, 2......	South London	John-street, Adelphi.

MANCHESTER PHOTOGRAPHIC SOCIETY.

The usual monthly meeting of this Society was held at the Memorial Hall, Albert-square, on Thursday, the 12th instant,—Mr. Charles Adin, President, in the chair.

The minutes of the last meeting having been read and passed, Mr. John E. Macdonald, of Cheetham, was duly elected a member of the Society.

The President read an address elaborating upon the subject of *Negatives and Artistic Photography* [see page 613], prefacing the same by some remarks in reference to the altered positions of officers in the Society. In a very flattering manner he spoke of the long friendship and esteem he had always entertained for the new Secretary, Mr. W. J. Chadwick, and hoped that their unanimous working would be felt and appreciated by the Society.

Mr. John Holding said (as he also belonged to that body of artists whose pictures were produced by aid of the pencil and brush) he felt bound to disagree in some measure with a few points in the President's communication. The opinion *artists* entertained of photographers was that they were mere "mechanical operators," and often too stupid to listen to the advice of an "artist like himself." Even on the occasion of the last excursion of the Society he tried to persuade some of the members to take their pictures from a point of view he thought superior to that which they had chosen, but they would not. They were too clever, and would go on in their own stupid way in spite of his advice; and, although many of their photographs were fair copies of the subjects they were to represent, they wanted "his eye" and "his ideas" to make *pictures*. He could not agree with the President's remark that art was to be classed with rules. "Art was a natural gift, and could not be learned by rules."

The CHAIRMAN said he thought many artists would do well to take a few lessons which photography could easily teach in the study of nature.

The SECRETARY then read a short communication from Mr. M. Noton on *Chadwick's Duplex Gas Lamp* [see page 614], which, it will be remembered, was before the members at the previous meeting.

Mr. Robert Knott, who was unable to attend, sent two silver prints from *carte de visite* negatives which he had printed by the electric light—one printed at twelve inches' distance from the light in fifteen minutes, and the other at twenty-four inches' distance in thirty minutes. The latter was by far the better, and was fully exposed.

Mr. Harrison Gartside also exhibited a print by the electric light exposed under similar conditions.

Mr. GEORGE GREGORY then exhibited a number of excellent portraits, some of which had very pretty effects introduced. He also exhibited the negatives from which the prints were taken. He called attention to the method he had adopted, and, although he claimed no credit for the originality of the "dodge," he thought it might be new to some and interesting to others. At the back of the negatives were gummed in some instances as many as three or four layers of thin tissue paper, portions of which were torn away in places where force in the picture was desired and for introducing high lights, &c., &c. He had found the tissue paper an excellent medium for "touching" upon. He (Mr. Gregory) also exhibited a landscape—a monochrome in oil—which was the subject of some little discussion.

The SECRETARY said that, at the request of several of the members, he had written to Mr. L. Warnerke; but as that gentleman was at present in Russia, Mr. Payne Jennings had kindly sent two 12 × 10 transparencies printed on Warnerke's tissue. These were handed round and examined by the whole of the members with deep interest and admiration. He (the Secretary) briefly explained the development and manipulation of these tissues. Many of the members were so interested as to promise to give the process a fair trial. He then exhibited in action the original oxycalcium lamp, invented by Canon Beechey thirty years ago, for illuminating two or three optical systems of a magic lantern at one time by one light, consisting of a fountain oil lamp with circular wick, in which olive oil is burned with a gentle stream of oxygen gas passed through the centre of the flame. A small ball of lime is suspended over the flame, the lower portion of which, being rendered wholly incandescent, produces a light of great brilliancy.

Mr. W. Watts introduced a very novel and convenient little electric battery of great power for use with the sciopticon, and constructed to fit into the hollow space in the front portion of the base of that instrument, for displaying many beautiful electrical phenomena on the screen, such as the decomposition of water, &c. It was highly appreciated. He also exhibited some other apparatus in connection with electricity and lantern appliances; but as the evening was far advanced he promised to enter more fully into the details on a future occasion.

The Secretary then called attention to three magic lanterns of the oil-burning family sent, by invitation, by their respective makers for inspection and trial. These were carried into the lantern room and lighted; but, in consequence of the late hour of the evening, the trial was postponed till Saturday, December 14, and twelve gentlemen were nominated to attend and act as judges. A short time sufficed to satisfy those present that one of French manufacture, although burning two two-and-a-half-inch wicks, was inferior to the other two—a Newton's lantern fitted with a triple wick refulgent lamp and an improved sciopticon. The latter instrument had a recently-introduced addition by which the picture could, by means of a movable stage and rack and end pinion, be moved from the condenser, thus permitting it to be placed in the more concentrated portion of the converging rays, so that the whole (or nearly so) of the light was allowed to pass through the aperture of the slide.

ON Saturday evening, December 14th, the appointed time for trial, the President and those gentlemen most interested in the lantern gave judgment unanimously in favour of the sciopticon for intensity of illumination, whiteness of light, and better definition.

The trial was conducted in the following manner:—The triple-wick refulgent lantern and the improved sciopticon were placed on an elevated platform, and as the objectives of the two lanterns were not quite of equal foci the lanterns were arranged at such distances that each projected a disc of eight feet diameter with pictures having the same-sized aperture (two and seven-eighth inches). Three slides were procured from Mr. Frank M. Good's negative of the *Lattice Windows of Cairo*, printed in carbon and of equal density and colour, and so nearly alike that experienced photographers were unable to distinguish any difference. The judges, after seeing the lights in each lantern burning satisfactorily, took their seats beneath the lantern platform, so that they were unable to tell by which lantern the picture on the screen was shown; and as each was exhibited alternately they gave judgment, and in every case decided in favour of the sciopticon. The two pictures were next partly covered with a piece of opaque card, so that from each, separately, only one half of the picture was shown (the same side of the slide in each case); but when the two lanterns were allowed to project their semicircular pictures upon the screen at the same time a complete disc was formed. The sciopticon half was again pronounced the brightest and best definition. The pictures were changed about and reversed, with the same results.

PHOTOGRAPHIC SOCIETY OF VIENNA.

THIS Society met on the 15th October,—Herr von Melingo in the chair, in the absence of Dr. Hornig.

The Chairman announced the death of two members of the Society, and then welcomed the guest of the evening, Captain Waterhouse.

On the motion of Herr Luckhardt, M. A. Poitevin was elected an honorary member of the Society.

A letter was then read from Herr Schwier, of Weimar, in which he invited the Society to take part in the proposed German Photographic Conference at Dresden next August.

The rapid processes of Dr. Richard and MM. Boissonnas and Klary came upon the *tapis*, but nothing new respecting either transpired.

Herr LUCKHARDT said he had been astonished by the rapidity of a process worked at Paris by M. Chambay. About five o'clock in the afternoon he had, along with Herr Lewitzky, of St. Petersburg, visited the *atelier* in the Grand Hôtel, which is principally used for taking little children, and there M. Chambay took a portrait of him which by the process Herr Luckhardt himself works would, under the then existing conditions of light, have required an exposure of twenty seconds.

The Secretary intimated that Herr Kroh, of Vienna, had sent samples of the negatives produced by his rapid process, and, though unable to be present at the meeting himself, he had asked the Secretary to invite any members of the Society interested in the subject to visit his studio.

Herr Luckhardt gave some particulars as to his visit to the photographic section of the Paris exhibition.

A number of articles were then laid upon the table for examination, and the meeting was shortly afterwards adjourned.

Correspondence.

THE RECENT MEDAL AWARDS.

To the EDITORS.

GENTLEMEN,—I should be pleased to know what is the object of Colonel Wortley's letters. It appears to me that the correspondence may be summed up in the maxim—*Ex nihilo nihil fit.*

If I correctly understand the Colonel's epistles, he wishes your readers to understand that he did not get prints to his liking. To me, however, it seems that this is exactly what he did do. He evidently wished for prints in haste that he might condemn at leisure, or he would not have summoned to his aid the imaginary gentleman going in such a terrible hurry to India or Afghanistan. The demand, I am told, was so urgent that one might have thought the capture of Shere Ali himself in his capital at Cabul depended upon the delivery of the order.

Only *one* set of prints was ordered by the agency firm, and these are the identical copies in question.—I am, yours, &c., PAYNE JENNINGS.

[The foregoing letter was received too late for insertion in our last number. On the assumption that as it had appeared in another journal last week it would occupy a place in our columns this week, Colonel Wortley has forwarded the following rejoinder, with the publication of which, in abstract, the correspondence must now cease.—EDS.]

To the EDITORS.

GENTLEMEN,—I cannot undertake to follow Mr. Jennings into his attempts at excuse. My knowledge of the matter is limited to my handing my friend's order to a trading firm, and that the order was not correctly executed. * * *—I am, yours, &c.,

Rosslyn House, Grove End-road, N. W., H. STUART WORTLEY.
December 23, 1878.

THE PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

To the EDITORS.

GENTLEMEN,—In your number for December 20th you quote the report of the last meeting of the Photographic Society of Great Britain from the Society's own journal, and a printers' error in the original report has unfortunately been reproduced in your pages.

In Captain Abney's interesting remarks he is made to say—"He had found by the use of *albumen* great delicacy was produced, though he had chiefly tried it in combination with *albumen*, the result being the formation of a double salt of silver."

I shall be glad to know what word is to be put in the place of one of the "albumens."—I am, yours, &c., HENRY COOPER.

Homehurst, Torquay, December 21, 1878.

THE LUXOGRAPH TESTIMONIAL.

To the EDITORS.

GENTLEMEN,—Permit me to state the facts relating to the luxograph testimonial—so distorted and exggerated by Signor Lombardi in his letter published in your issue last week. Accompanied by my friend and operator, Mr. Ross, I witnessed a demonstration of the luxograph light. Pleased and amused I yet declined to give Messrs. Alder and Clarke a testimonial as to the value of the light, or to purchase the apparatus until it was improved. Two days afterwards, talking over the affair with Mr. Ross, I thought I saw a means to fitting up the luxograph apparatus in an improved manner; and, at my request, Mr. Ross called on Messrs. Alder and Clarke to inform them of my plan, and to request them to supply a *portion* of the apparatus, for which I was willing to pay £15 15s.—a very liberal price for what I wanted. He was also to promise a good—not a "splendid"—testimonial as soon as I had tried the light and personally proved its value; also to supply them with copies of the pictures produced by the aid of the light. This offer was declined with the very significant remark—"As to Mr. Faulkner's testimonial we can get *that*," the meaning of which became evident the following Friday. When the luxograph testimonial written by Signor Lombardi was published I then saw, to my surprise and annoyance, that my name had been put forward without my knowledge, as endorsing Signor Lombardi's enthusiastic and eulogistic opinion of the luxograph.

In consequence of a letter writen to Messrs. Alder and Clarke, one of these gentlemen called on me. I requested him to withdraw my name from the advertisement, and to state that it had been added without my knowledge or approval. This he declined to do for the following reasons:—That he considered Signor Lombardi was my friend, and therefore must have known my sentiments on the subject, and that I had promised to give them a testimonial (when confronted with Mr. Ross he was compelled to admit that this was to have been given conditionally). I explained to him that if the practice of using a man's name without his consent were tolerated there would be an end to all candid expression of opinion, and a system of mistrust would be engendered.

So far from Signor Lombardi being a friend of mine, I had only met him four times, and I knew nothing whatever of him except what he had told me of his ideas and mode of conducting his business; and, judging him from his own words, I should have a very strong objection to having my name associated with him in any affair whatever. The publication of my name, for the purpose of puffing the luxograph, was a piece of gross impertinence on his part, and of sharp practice on the part of Messrs. Alder and Clarke.

During the demonstration I heard Signor Lombardi ask to be taken into partnership, and from the fact that the offices of the Luxograph Apparatus Company are now at his studio it is only reasonable to conclude that an arrangement has been entered into between Messrs. Alder and Clarke and Signor Lombardi; hence his enthusiastic advocacy of the luxograph scheme, and his abuse of me is a mere vehicle for that purpose.

I regret exceedingly to have occupied so much of your space.—I am, yours, &c., ROBERT FAULKNER.

21, *Baker Street, W., December* 24, 1878.

To the EDITORS.

GENTLEMEN,—I note the correspondence which has been addressed to the photographic press by Signor Lombardi and Mr. Robert Faulkner. As my name has been incidentally mentioned therein I feel compelled to trouble you with a few words of explanation.

I was present, in company with the above-named gentlemen, at a demonstration of the new luxograph light, at Messrs. Alder and Clarke's, and was so gratified with the *results* I witnessed that I at once ordered an apparatus. Signor Lombardi's assertion that Mr. Robert Faulkner expressed his admiration of the new light—and that in no unmistakable terms either—is perfectly truthful; and I am somewhat surprised that the latter gentleman should now disavow that which I plainly heard in common with Signor Lombardi.—I am, yours, &c.,

Talbot-road, Blackpool, December 23, 1878. EDWARD GREGSON.

[In addition to the above letters we have also received one from Messrs. Alder and Clarke, in which, among other matter, they say that the fifteen pounds, the testimonial, and the dozen of cabinet portraits offered by Mr. Faulkner for the apparatus was not to include the table or cupboard on which the apparatus stands. But quite enough has now been said about this matter, in which neither our readers nor ourselves can be expected to feel any deep interest. On the general subject of "testimonials" given, or intended to be employed, for advertising purposes, we think it extremely desirable that no names should be introduced in such documents without the persons so employing them having first obtained the sanction of those whose names are introduced. Such step would only be fair and courteous.—EDS.]

Miscellanea.

PLATT'S UNIVERSAL FILTER.—I take pleasure in sending you a cut of my universal filter. I use it as follows:—For varnish or albumen I use an ordinary tin funnel. I first solder a tin band one inch wide on the top, then make the adjustable top of tin to fit in loosely; this consists of another band two inches deep. Spread a piece of cotton flannel over the narrow band on the top of the funnel, with nap side up, then crowd in the wide band, which will draw the flannel snug. The filter is then ready. For varnish, wet the flannel with alcohol; for albumen, use a piece of muslin if the flannel does not filter fast enough. You will at once see it will do all kinds of straining or filtering, as anything, from the coarsest of wire sieving to the finest muslin, can be used. I have used it for collodion, varnish, cream, milk, fat, paint, albumen, honey, and a host of other things I will not mention.—*Phil. Phot.*

PRINTING.—It was but a few years ago that printing was considered to be the most mechanical part of photographic work, and that any boy was capable of doing it after a few weeks' instructions; but, today, what a difference! It is thought now to be one of the most difficult parts of photography. The printer now studies the quality of the negative. He prepares his paper to correspond with the varying conditions of the negative, he masks one part of the background and prints in deeper on another part, as may be required to give the best effect, and in various ways controls the work as it progresses, so as to produce the best possible result. Printing in this way is as much an art as that of negative-making, and requires as much study and skill to do justice to the work. What encouragement does the operator have when he looks at some prints, from a nice, brilliant negative, over-toned, with no brilliancy to them, or some other carelessness on the part of the printer? I do not mean to say that it is the printer's fault that the majority of photographers do not do better work, for in most cases it is that man's fault who makes the negative. He does not study enough; he is getting behind the times. Photography today is not what it was long years ago. It needs as much study and skill as it does to become a lawyer or a doctor.—*Ibid.*

BLACK'S HOMESPUN LIGHTNING PROCESS.—*Nitrate Bath.*—First put the amount of silver to be used into an evaporating dish, and allow it to melt. Then (while it is in a molten state) add to each ounce of silver about three grains of the following salts:—

"*Bromo-iodide.*"

Iodide of lithium	10 grains.
Iodide of ammonium	30 ,,
Iodide of cadmium	2 ,,
Bromide of ammonium	20 ,,
Bromide of cadmium	10 ,,
Bromide of potassium	10 ,,

Put the above into distilled water in a clean evaporating dish, and evaporate to dryness; then let cool. Dissolve the silver in distilled water, forty grains to the ounce, and sun well. To a bath of one gallon, add half a drop of C. P. nitric acid.—*Collodion:* The amount of bromo-iodide mentioned is sufficient for twelve ounces of collodion. Dissolve in alcohol and ether, equal in parts in winter, but in summer there should be a little more of ether used. Cotton to suit your taste—say five grains to the ounce.—*Developer:* Dissolve in sixty ounces of water four ounces of protosulphate of iron. When all is dissolved filter clear into a clean bottle. To use, pour out sixteen ounces; add one and a-quarter ounce of acetic acid and a-quarter ounce of alcohol. Anyone trying the above formula, if they are at all careful, will find it will give good results. Should negatives lack intensity they can be strengthened after fixing, and *washing well* with the following:—Pyrogallic acid one and a-half grain, citric acid one grain, water one ounce. The collodion should be filtered after adding the bromo-iodide through filtered paper, and also after adding the cotton. Use a collodion filter.—*Ibid.*

OBITUARY.—We have received from Mr. V. Sreznievsky, Secretary of the new Photographic Society of St. Petersburg, the following obituary of Mr. W. Carrick, whose pictures attracted so much attention at the late exhibition of the Photographic Society of Great Britain:—Our Society has sustained a severe loss in the death, on the 23rd of November, of our fellow-member, Mr. William Carrick. Of athletic build and stature, and remarkably handsome and expressive in countenance, he also possessed an exceptionally kind heart, a generous nature, and an honesty positively ideal. The hard school of life had not shaken his faith in truth, in virtue, or in the high mission of man. Whenever he confessed his ignorance of any subject there was no false ring, no humility that apeth pride in his confession, and this endeared him still more to those acquainted with his other high qualities. Mr. Carrick was a hard worker all his life, and just managed to make a living. He loved his art for its own sake, and regarded it not as a means, but as an object, of life; and where another of his profession would have made a fortune, this unceasing labourer barely succeeded in making both ends meet. A Scotchman by birth, he received his education at St. Petersburg, where his parents had settled. In accordance with their wish he entered, at the age of seventeen, the Imperial Academy of Arts, in order to study architecture. But he never cared for the profession, although he received his diploma as architect in 1852. He then proceeded to Rome, where he resided three years, applying himself exclusively to painting in water-colours. On his return to St. Petersburg in 1856 he discovered that it was impossible to make a living by water-colour portraits, which have no chance of competing with photography. Accordingly in 1857 he proceeded to Edinburgh, where he studied photography with Mr. Tunny, and there made the acquaintance of Mr. John Macgregor, who joined him in St. Petersburg in 1859, and became his partner. The friendship that arose between them terminated only with Mr. Macgregor's death in 1872. It is questionable whether any photographer has taken as many copies of paintings by Russian artists as Carrick had done, and possibly no one as faithfully represented the originals. He attained these admirable results by being extremely exacting regarding himself, and, if displeased with his work, would take copy after copy until he procured one in all respects satisfactory; in fact, Carrick was an artist-photographer. Photography with him was a means of reproducing and imparting the beautiful. Each one of his photographs proves it. How admirably the standpoint has been chosen! What life there is in his landscapes! And how the Russian peasant, whose likeness he delighted to impress, stands naturally and easily before his lens, and not as though posed for the purpose! Carrick photographed neither views nor types, but reproduced the outer life of the Russian labourer. He never strove for effect; but effect seemed to insinuate itself, as it were, into his pictures. Look at his photographs, and observe what a fulness of life there is in them! Now you have a view of a number of log cottages with their courtyards full of rural implements; here is a picture of a ferry-boat, with carts and peasants, crossing the river—there a number of horses drinking from a trough; here a crowd of urchins and girls, half naked, half wild—there a gathering of peasants. All these are faithfully reflected in Carrick's works as in a mirror. A friend of Carrick, Mr. M. Lokovnin, on whose estate he had done some of his best photographs, writes of him thus:—"Few people know with what love Carrick, though a Scotchman, took pictures of Russian life, and what a priceless addition he has made to Russian ethnography! For several years he had been making a collection (which reached to upwards of three hundred) of types in the county of St. Petersburg, but something drew him to the interior of Russia, to the banks of the Volga, and in 1871, in company with Mr. Macgregor, his partner—as genial and noble a fellow as himself—he paid us a visit in the government of Limbirsk. They worked from morning till night, and enriched their collection not only by taking photographs of Volga scenery in some of the virgin woods of Limbirsk, but also by a number of types of the local races. In 1875 Carrick again paid us a visit, bu alone on this occasion, and added several hundred negatives to his already rich stock. Altogether the number of views and types done by him (cabinet size) reaches seven hundred, representing an enormous expenditure of labour." Many of his pictures taken from nature have been reproduced in the paintings of various artists. Of course Carrick's name was never mentioned. A well-known London illustrated paper also borrowed many of his Russian types without acknowledgment, and had them engraved for its pages, without even alluding to Carrick. His photographs from an ethnographical point of view have not been appreciated in Russia as they deserve to be, probably because his rich collection was never exhibited as a whole, and it is only by viewing it collectively that its merits can be fully valued. It is only then that one observes how complete it is, and how admirably it depicts what Carrick always sought after—the simple and honest side of human nature. He found it in our Russian peasant, and devoted himself to its portrayal. The English were more fortunate than ourselves, for the whole of Carrick's rich collection belonging to Mr. L. Warnerke was shown at the last exhibition of the Photographic Society of Great Britain, and was praised alike by the public and the severest of critics. Carrick died of heart disease, on the night of the 23rd November, in his fiftieth year.

EXCHANGE COLUMN.

No charge is made for inserting these announcements; but in no case do we insert any article merely *offered for sale*, that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a *nom de plume* be thought desirable), otherwise the notice will not appear.

Bath and stand, glass, size 18 × 14½, whole-plate gutta-percha do., half-glass, water-tight, whole-plate bellows camera, and stove for studio, will be given in exchange for half-plate camera and anything useful.—Address, Ward, 54, Brixton-road, S.W.

A patent geyser will be given in exchange for a tourist camera with two double dark slides and lens, in good condition, for plates no smaller than cabinet size, and a glass bath for plates 18 × 14, with dipper.—Address, Harrison, photographer, Falmouth, Cornwall.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

T. C. A.—Yes, you are quite right; but you are, perhaps, not aware that your "quotation" is made from a catalogue which has had three successors.

R. Perry.—We regret our inability to offer any hint at present that would be worth much. We shall make a few experiments soon and record the result.

F. R. S.—See that the camera is capable of being extended forty-three inches. If it fall short in this respect, even to the extent of one inch, another lens will have to be procured.

P. J. F. L.—1. Dissolve the cotton first, and then add the colouring matter.—2. The orange dye is more effective than any of the others mentioned. Make an alcoholic rather than an aqueous solution.

P. L. T. A.—1. Obtain a cylindrical precipitating glass capable of containing about sixteen ounces.—2. See that a temperature of 80° Fahr. is maintained evenly during the whole time the mass is digesting.

Spes.—1. Notwithstanding the excellence of the Kinnear camera it is now being rapidly supplanted by cameras of other forms.—2. We do not consider it would be expedient for us to offer such an opinion as you wish.—3. Both possess an equal degree of rapidity.

J. Bastie.—Your query—"What is a photographic clock?" puzzled us a good deal at first, and might have been doing so still had we not, when turning over the advertising pages of an American journal, come "right across" the name. It is simply an ordinary clock, having a large seconds' hand.

Vero.—In answer to your first query, we have not the specification at hand for reference; but, in reply to the second question, the difference between the two is so little that it can only be discovered by an expert. Of the more recent production we are quite unable to speak from personal acquaintance. One word—avoid density in the materials.

R. M.—The hydrometer (or argentometer) is a very effective and tolerably accurate means by which to ascertain the strength of a silver bath to which no other salts have been added; but it will scarcely answer for such a delicate analytical purpose as that mentioned. In this case recourse must be had to the volumetric method of making the quantitative test.

W. F. R.—For the purpose intended the collodion must be very old and red, otherwise the transparencies will be wanting in force and purity. It may, however, be well to try the effect of the addition of tincture of iodine to the collodion, this addition being carried to such an extent as to render it of a port wine colour. Bromine may also be used with advantage.

Old Subscriber.—1. The *easiest* method for obtaining a warm brown tone is the application of bichloride of mercury followed by sulphide of ammonium; but, unfortunately, it is so far from being the *best* that we always sound a note of warning against its use. Try acetic acid and albumen in the developer.—2. Carbon tissue can be used in the solar camera.—3. Mr. Solomon, of Red Lion-square, publishes a manual on enamel photography, price five shillings.

W. L. R.—Your queries had been mislaid, hence the delay in replying:—1. Try the effect of nailing the cover to the inside of the box with small tacks, and to the erect back, also to the diagonal strut behind as far up as the upright rod shown in the picture. This will allow of the cover being thrown back for packing.—2. Any albumen on the back of the plate will be liable to injure the bath. If kept dry the plates will keep indefinitely.—3. Everything depends upon the method by which the plate has been prepared.

M. Boissonas (Geneva).—Received. In our next.

South London Photographic Society.—The first meeting for the session 1879 will take place on Thursday next, January 2nd, in the Rooms of the Society of Arts, Adelphi, at eight o'clock, when the evening will be devoted to a lantern exhibition—principally views of the Paris Exhibition, by Mr. F. York. Further information can be obtained of the Hon. Sec., H. Garrett Cocking, High-road, Lee, S.E.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician,
For the two Weeks ending December 24, 1878.
