Dr. Higgins said: Mr. Newton, at our last meeting, exhibited a certain negative, in taking which he placed in opposition with the print copied a piece of glass, one half of which was tinted slightly with blue (aniline, I believe). The negative showed no distinction; the two halves seemed exactly alike. Mr. Chapman thought, at the time, that the intensity of the blue was not sufficient to make it an *experimentum crucis*. Since that meeting I have tried the same experiment in a somewhat different manner, and in a manner that, I think, will be considered pretty conclusive, from the intensity of the blue glass I used—an intensity far greater than probably ever would be made use of—the ordinary blue glass which has been the mania for a long time, pure cobalt, and of very great intensity—that is, as far as photographic use would go. In that shield (exhibiting) I placed two pieces of glass, of the same thickness by careful microscopic measurement—one white and the other blue. I then placed in the shield a sensitised plate, and exposed to the gaslight. The result is here shown. The upper half has one-half the exposure of the lower. The right hand is the clear glass; the left the other. They are marked. It will be seen that with that intensity of blue the injury, or, rather, decrease in sensitiveness, is about one-half, especially if the two corners, which are marked with a jog, taken out are compared, as the exposure of one is exactly double that of the other. The right hand is the white glass, the same as in the shield, half exposure—ten seconds on that, twenty seconds on this (the blue). When exposed an obscuring medium was placed over the glass in that way (illustrating). I pursued the experiment in the same way with a negative in copying by gaslight, thinking that, possibly, and very probably, the yellowness of the gaslight flame mixed with the blue glass in the shield would, as it naturally would do, give a green character to the light passing through. I then exposed a plate in the camera by daylight, and the result is here shown (exhibiting). The square in the centre of that plate is simply a piece of card, to see that my emulsion was working clearly. That was directed to simply a white sheet hung up in the room; it does not show quite so much difference by daylight as by gaslight. That plate also shows the loss of power which results when a portrait lens, as that was, is used upon a plate that was focussed upon a white sheet. A curious result occurred in the taking of a further picture. I separated the two pieces of glass in this shield, leaving a half-inch or thereabouts between them, so that there should be no glass interposed between the object taken with the camera in the daytime and the negative. The result is very marked, showing the loss of intensity when the light passes through a glass. It is often said that portraiture, or work inside the room, is much slower than outside work; may it not be that the light has to come through the glass with which the room is roofed, and that if those roofs were sliding we should have the same quickness as we would have outside? I think, also, that that last plate shows how much the thickness of the glass in lenses has to do with their responding quickly to the action of light. I think that would satisfy Mr. Chapman.

The President: He would argue that there would be a difference; that the ratios would diminish with the depth of colour. My experiments were made mainly to see if Mr. Chisholm's conclusions were correct, as he was strongly impressed with the idea that he got quicker results with blue glass, but it was a very delicate light blue that he procured in this city; so that in making my glass I only aimed to get just sufficient blue to change definitely the colours under the blue, making the yellows green, the reds purple, and the browns a deeper or colder brown. That was all that I aimed at. I felt very confident that blue of that depth would be a very serious impediment in the force of actinism in the solar ray. I think that Dr. Higgins' experiment is conclusive as to the retarding influence of the blue of that degree of intensity.

Dr. Higgins: And, to follow it up, there can be no such thing as acceleration by blueing the light.

The President: That is the ground that I have always taken. I stated that, unless it could be shown that there existed in the solar ray a retarding influence which was filtered out by the use of a blue medium, there was no foundation in theory even that acceleration was possible in the use of blue light, for all the actinism in the solar ray is contained in white light.

Dr. Higgins: In taking these negatives I had to make a special emulsion, to work exceedingly slow. In using my ordinary emulsion (I do not know whether it is slow or rapid; usually an exposure of two seconds is a full exposure with it) I found it very difficult to not over-expose it, and then the difference was not so marked by any means. Therefore, I made a very slow emulsion, with which I could expose ten up to twenty seconds without over-exposing; then the difference between the two was easily discerned, but with a sensitive emulsion it was not so conspicuous.

The Secretary (Mr. O. G. Mason): For several reasons I do not consider the experiment so critical a test as the one the President made. One reason is, here are two pieces of glass not identical—one blue, the other clear; it may have a greenish tint or a yellowish tint, if examined critically. If you could take the blue out of this blue glass we do not know what we would have left. There may be a green or yellow tint mixed with the blue, but the blue preponderating to such an extent that it obscures the other colour. In experiments requiring such delicacy in order to arrive at a certain and satisfactory conclusion I think it is necessary that all those points should be carefully considered. Ten or twelve years ago I put in my studio a window glass similar to this; and then I changed it for a much lighter blue, and found the difference very marked. These experiments led me to the conclusion that properly-constructed blue glass, having the proper amount of blue on or in a proper body of otherwise colourless glass, was really an advantage. I actually believe that it does not retard the actinic force at all; and I yet believe that if Dr. Higgins will go into such a series of experiments as he is capable of carrying out, he will find the blue glass has some virtue in it.

The President: The glass that I used was a sheet of 8 × 10 inches, very thin—I do not believe it was a thirty-second part of an inch in thickness—and that would account, probably, for there being no perceptible difference between the part covered with the glass and the part that was not. In my experiments I am inclined to think that where the glass is immediately in contact, pressed upon the object being copied, that the difference would not be as perceptible as if placed in this position.

Dr. Higgins: There is no doubt that the thickness of the glass would have to do with the result. In my case it is quite a heavy glass—a thick piece of ordinary negative. In the President's case he used very thin glass, and the result would not be as perceptible. Again: the light going through the lens, all the rays of light that struck the picture perpendicularly to itself would not suffer refraction, only those striking it obliquely. Light, in striking perpendicularly upon a medium, passes through without refraction; but if it strikes it in the least obliquely then it will become refracted. In my case the absence of glass here in the central part of the plate is seen, so that the presence or absence of it would have no effect, so far as refraction of the rays would go. In the President's case it would have great effect, by reason of its object being inclined at an angle.

The Secretary: I had in my possession, and still have, a series of French lenses which, if you remove from the cells and look through the edge, you will find the glass has quite a blue tinge, instead of yellow or green. These lenses worked a very great deal quicker than any others I ever used. They are also somewhat thinner than our American lenses, and that may have had something to do with their action. I found that the lenses made by that firm invariably had this tinge of blue. Another fact was brought out by the complaint of a brother photographer that his lenses which he had been using some eight or nine years, he was confident, worked a great deal slower than at first. The question naturally arose, why they should work slower? He had been through experiments which convinced him it was not retardation resulting from the use of chemicals less sensitive to light, but it was really the lens. It had been used for outdoor work, and he had allowed the light to strike on it (probably been in the full blaze of sunlight for a great many hours), and it is possible that the tinge of the glass may have changed somewhat.

The President: The colouring of glass by long exposure to light depends something upon the flux used in its manufacture. One of the proprietors (Mr. Gaffield) of the Lennox Glass Works, in Mass., was at one of our meetings several years ago with a large quantity of samples, specimens of glass that were very old, some being obtained from windows in buildings at Bowling Green, that had been in the windows fifty, sixty, seventy or more years, and had turned a very deep, dark brown. He stated that this result was found mainly in glass where magnesium salts were used as flux.

The Secretary: I might differ a little with both the President and Dr. Higgins in that which perhaps appears to them an axiom—that a part is not, for many purposes, equal to a whole. Now we will suppose a case. We have a ray of what we call white light, which we know is composed of primary colours, or that it can be decomposed, showing that it contains blue, yellow, and red, which have very slow actinic force, possibly retarding also the other rays. Suppose that we can take from that white light the red and yellow, is it not fair to suppose we gain instead of lose? Another case: we all know that certain acids will act as corrosive agents upon certain metals; that these acids are made of exactly the same elements in different proportions. Now, if the whole will accomplish a certain thing, why do we vary those elements and leave a part of one element out and put in a greater proportion of another? If these proportions are not fixed pretty nicely the action is very materially modified; and I believe there are parts or portions in a ray of what we term "white light" which have a retarding instead of an accelerating influence in photographic work. A series of experiments, concluded many years ago, plainly indicated to me that such was the fact.

The President: This matter was pretty thoroughly investigated by a committee of this Section several years since. It was brought to the immediate notice of the Section through the introduction of a paper by a scientific gentleman, Mr. Gutzlaf, residing in Bahia, S. A., and brought here by Mr. Gaensli. This gentleman had gone through a very elaborate series of experiments with different-coloured pigments—red, orange, and yellow—to ascertain the correctness of the theory of Edmond Becquerel, which up to that time had been received by scientific men in the main as correct. That part of it with which we have to do proceeds in this way: that the orange, red, and yellow have no actinic property or force, but contain properties peculiar to themselves, which are manifested in this wise—they have no power to educe a photographic image on a sensitive film, but when that image has been once impinged by the more actinic rays they have the power of carrying on the action which has been set up. Now this gentleman had prepared a very peculiarly-coloured glass (I have it at my house now; Prof. Tilman, Mr. Chapman, and myself were on the committee). He gave the details of the manner in which it was prepared, and claimed that it was perfectly non-actinic. He had utilised it in this way:—He would take a negative with half the ordinary exposure in the gallery, place it under this coloured glass, and expose it to direct sunlight under this coloured glass for a definite period of time, which could be determined with a little experience, and the action would continue, so that if one made a picture in half the time and allowed it to be acted on by this light and then developed it he would get a fully-exposed negative as the result. This was his claim; and, when it was brought here, there were negatives brought with it to illustrate the fact. Upon investigation we found that the whole theory was a fallacy—that the light acting through that very non-actinic glass was actinic; and to demonstrate this fact I prepared a sensitive plate and covered one-half of it and exposed it under that glass to the direct rays of sunlight for five minutes, and then developed it. The part that had been exposed developed very quickly. His experiments had evidently been superficial. We took that same glass to Mr. Rutherfurd's observatory, and under a powerful condenser submitted it to sunlight for half an hour, and through it photographed the spectrum quite down to the red. I was then satisfied, and promulgated this theory that actinism is a property of light resident in all the rays, and manifesting its force in the ratio of the vibratory motion or wave length, but not in an unbroken scale; and I believe that this is correct. I have never seen a piece of coloured glass yet that by its mere colour would not admit actinic light. It was a matter of time and quality, not quantity. Expose a sensitive film under it long enough and you will get actinism. The statement that actinism is in the ratio of the wave length requires some qualification. It was discovered that were the different-coloured rays mingled in some instances the action was peculiar. This may be best illustrated, perhaps, in the excitation of the auricular nerve by the action of the atmospheric waves. When atmospheric wave lengths of different rapidity excite this nerve a peculiar sensation is the result, which is defined as harmony or discord. This effect is never induced by a single wave length, whether slow or rapid. In the solar spectrum, where the different wave lengths mingle, there seemed to be an analogy with that of the atmospheric waves. Actinism at such points seemed to be retarded or accelerated according to the conditions of harmony or inharmony. Therefore we concluded that the theory of M. Edmond Becquerel was not founded upon fact; and that has been one of the reasons why I have always maintained the position previously stated.

Dr. Higgins: The fallacy that acceleration and not retardation is produced by blue glass is equal, in my mind, to the fallacy that emulsion—dry-plate photography—is not as quick as the bath process. I see it stated in books, and universally in print, that for dry plates you must give an exposure, some say of three, and some run up as high as ten, times that of bath plates. I would ask the Secretary, who is a bath plate worker, what is the usual time of exposure with him in his studio?

The Secretary: The time varies from one second to half-an-hour.

Dr. Higgins: I would ask further whether on that exposure of one second he has the development of all the intensity that he can desire?

The Secretary: Yes; and, in some cases, a good deal more.

Dr. Higgins: Do we understand that the majority of cases of exposure are on the one second or half-hour side?

The Secretary: I should say that the majority of my cases—not portrait work, of course—require an exposure of about fifteen minutes.

Dr. Higgins: On inquiring among the portrait workers I found the usual time is about thirty seconds. With emulsion photography the usual exposure in my room is never over three to five seconds. I present for view to the Section a plate taken this morning in a well-lighted room, but where there is no skylight, in which the exposure was less than one second; the cap was simply removed and replaced as quickly as possible. The developer was our President's, weakened with water sixteen times.

The President: There is intensity enough. I would say that to obtain such a result with a developer one-sixteenth the strength I ordinarily use would require sixteen times the exposure.

Dr. Higgins: That is to show the action of the light, not as a picture. It was held a foot from the window—a diffused light; not sunlight. A similar plate made by gaslight a foot from the flame was placed in a printing-frame. It was covered two-thirds, and exposed by counted time, thus—one, two, three. Here are the three exposures, just as quick as you could move them along; the whole three counts would not make a second of time. (Plate shown.)

The President: In reference to the new developer with the neutral oxalate of potash: I gave the formula to Mr. William Hudson, an amateur photographer, residing near Boston, Mass., to try on dry plates. In my experiments I had only used it on wet emulsion plates. I received a letter from him a few days since, stating that he had tried it on dry plates with the most satisfactory results; he had produced with it the finest negatives that he had ever made on dry plates, and had exhibited them to some experienced photographers in the vicinity, who had expressed themselves in the same way. In this connection I would say that I advised at the last meeting the use of acetic acid to acidify it. I tried tartaric acid and found that I got a stronger negative. The negatives I had made needed strength. They were very delicate, but were not up to the strength necessary for printing; but with tartaric acid I got greatly-increased strength, and all the other good properties at the same time.

The proceedings then terminated.

Correspondence.

WARM BLACK.

To the Editors.

Gentlemen,—Mr. Sórensen, a photographer in a little town here in Denmark, knowing somewhat of Mawson and Swan's endeavours in England, applied in the course of 1866 or in the beginning of 1867 to our Government for a patent for a certain kind of carbon tissue which he had invented. I subjected myself to his instruction, employing partly his tissue, partly tissue of my own production, quite comprehending that only a *black* material of carbon would be permanent. The refusal of the Government to grant Mr. Sórensen a patent for a branch of industry now well known by every Danish photographer, the difficulties in connection with a new method of printing, a total lack of materials and implements, and the care of my regular daily business, prevented my proceeding with the otherwise very agreeable undertaking.

Afterwards, when the improved carbon process was published by the Autotype Company in London I obtained from them an excellent sample of a carbon print in black—a portrait 24 × 18 inches—accompanied with a copy in purple, and the following remarks:—"We have sent you by post two specimens of an enlargement—one printed in black, as requested, and one in a photographic colour which is generally preferred." It is probable that this preference by photographers and their customers has from the beginning driven the new art into that dismal field where it now is.

I think it best to solve the question by turning back exclusively to the use of (warm) black tissue. All other pigments, we know, are untrustworthy, except, perhaps, ochre, which is vulgar and without lustre.

The characteristic tone of a carbon print should be a warm black, and it is a pity that photographers should have aped the fading colours of silver prints. All prints from engravings in steel, copper, wood, and stone are black (carbon), and nobody would prefer pictures of that kind in other pigments. We should no longer allow the art of carbon printing to be degraded as a slavish imitation of the "ghostly vanishing" of silver products.—I am, yours, &c., Peter Chr. Koch.

Copenhagen, April 27, 1878.

PRECIPITATING RESIDUES.

To the Editors.

Gentlemen,—The subject of collecting residues has appeared in your columns several times recently without any of the writers noticing the difficulty I have experienced in the slowness with which the precipitation takes place under some circumstances, the only place in which I have seen this difficulty recognised being in your "Answers to Correspondents," on page 106, where you recommend the addition of nitric acid to facilitate the precipitation.

I have observed a very simple way of producing this effect which I think may be useful to some of your readers:—I was on the point of throwing away a rather large collection of wastes which I had been putting aside in a dark cupboard for some months, and the chloride showed scarcely any signs of subsiding. At last I set the vessels containing it in a strong light, waiting to be thrown out when the precipitate settled down in a very few hours. I have since tried the effect of exposing to light chloride under precipitation, with the invariable result of the deposition being complete in an hour or two, when I pour off the clear liquid after trying if there be any further opalescence on the addition of more sodic chloride, and turn the deposit into a bottle large enough to hold all the moist silver chloride I am likely to collect in a reasonable time, and this, in its turn, has the clear part poured off occasionally. These two vessels are sufficient for the storing of a very large amount of waste.—I am, yours, &c., A. S. Elgood.

April 29, 1878.

Miscellanea.

Crookes's Radiometer.—In the *Photographisches Wochenblatt* Herr Fritz Haugk has an article on Crookes's radiometer regarded as an actinometer, in which, after giving an account of the instrument, he relates the following experiments made by himself:—It is, of course, known that under the influence of heat the radiometer revolves in a bell glass from which the air has been exhausted as much as possible by an air-pump; but Herr Haugk was unwilling to admit that this movement could not also be produced by the influence of light, and in such a manner that a certain number of revolutions of the radiometer should represent a certain definite quantity of light. Accordingly one day, when the light was very changeable, he took a sheet of freshly-silvered albumenised paper and placed it in a printing-frame, covering half of it with orange-coloured paper, and upon this covered half he placed his radiometer. As soon as the sky became quite clear he exposed the whole to the light until the radiometer had performed a hundred revolutions, the time required for the hundred varying from six minutes in the first experiment to ten minutes in the last of the three experiments. He then went into the dark room and placed the yellow paper over the half of the sheet of paper already printed, placed the radiometer upon it, and uncovered the other half. Then when the sky became overcast he gave three other exposures lasting each a hundred revolutions, and found in this case that the time required varied from twenty to forty minutes. The sheet of paper was then completely uncovered, removed from the frame, and examined, when it was evident that the piece of paper longest exposed had printed to a much greater depth than that which had been exposed only for a short time, while in each case the radiometer had made but three hundred revolutions. Thus the position that a revolution of the radiometer bears a definite relation to a certain quantity of actinic light becomes untenable. Herr Haugk does not go the length of saying that light has no influence upon the rapidity with which the radiometer revolves, but is convinced that it has but little, and that as an actinometer it is untrustworthy. He also thinks that it is not even very reliable as a thermometer. In these conclusions he is supported by the experiments which have been made by various British photographers, and Mr. Crookes himself is perfectly aware that the radiometer is more affected by heat than by light; but there still remains the difficulty of producing a really perfect vacuum in which to place the instrument. Lastly: Herr Haugk thinks that the radiometer loses its sensibility by degrees, and that in time it would almost lose it altogether.

The Chemical Actions of Light and their Electrical Relations.—Professor Dewar began his discourse at the evening meeting of the Royal Institution on the 29th March with experiments showing the action of a beam of the electric light upon two plates of silver, and the formation of an iodide of silver when they are subjected to the vapour of iodine—the first principle of photography. He then noticed the evidence of electric action, during the process, recorded by the galvanometer, in relation to which he alluded to the remarkable experiments of Becquerel and Grove. He next explained and illustrated the researches of Dr. McKendrick and himself on the electro-motive force generated in the human eye and the eyes of various animals, as observed by a very sensitive galvanometer, every source of heat being carefully excluded. There was a sudden increase of the force by the impact of light; during its continuance it fell to a minimum, and suddenly increased on the withdrawal of the light. The complexity of this physiological action induced Professor Dewar to undertake a series of delicate experiments, his object being to produce such a form of cell as would give large electric curves when filled with fluid substances sensitive to the action of light. He described different forms of the apparatus, and showed that an instrument exposing a fine wire no greater in diameter than a hair was as active as a large surface in true actinometry. Some of these effects were rendered visible to the audience by the movements of a small mirror attached to the needles of the galvanometer, which cast a spot of light on the screen. One of the compounds specially selected was the peroxide of chlorine—a most unstable gas, which, when subjected to light, decomposed into chlorine and oxygen with a slight explosion; and, by the Professor's placing it in connection with differential thermometers, it was shown that this gas might be used to form a very delicate photometer. Among other interesting experiments the Professor demonstrated the opacity of chlorine for all coloured rays of light higher in refrangibility than the blue, such as indigo and lavender, by showing the sudden increase of the volume of the gas when exposed to blue as compared with red and yellow light, which, in ordinary cases, produce expansion through the evolution of heat. In conclusion, Professor Dewar commented on a series of tables giving the minute results of a series of laborious and delicate experiments, made with recording apparatus exhibiting the varying results of the electric action of light on certain fluids of different opacity, and on the solution of various salts alone, or mixed with other substances. Future researches in the Institution will be prosecuted by means of a very fine galvanometer recently presented by Dr. Warren De la Rue, F.R.S., the chairman of the evening.—*Illustrated London News.*

On the Light Admissible for Preparing and Developing Plates.—The quantity and kind of light that is allowable in the preparation and development of dry plates is a subject which is of the greatest importance, and yet regarding which but very little care is usually taken. For wet-plate photography, or when silver bromo-iodide or iodide is employed, the requirements are not difficult though often neglected. In some dark rooms the ordinary flashed yellow glass is employed, and for certain work this is all very well, as it gives a subsequent and preliminary access to actinic light, which, as has been shown, is valuable in diminishing exposure in the camera. For plates prepared with these salts in which the exposure to this coloured light is likely to be at all prolonged, this kind of glass is objectionable and conducive to fog. In this case is to be recommended a deep orange glass, which is called "stained red." The light passing through it is of an orange tint, and not so deceptive to the eye as that which passes through flashed ruby. Paper dyed with aurine may be pasted over the ordinary yellow glass before mentioned, or the dye may be dissolved in varnish and applied, and this will be equally as effective as the stained red glass. For silver bromide emulsion much greater care is required in selection, since it is sensitive to a greater or less degree to the red rays. In this case the quantity of light is as important as the quality, more particularly when compounds are present which are sensitive to the ultra red, as is the case in some of the new emulsions. In this case if the dark room is to be lighted from the sky the glass must be of flashed ruby, and even this must be carefully selected. In examining most of this kind of glass by the spectroscope with a wide slit, it will be found that though the yellow is absorbed, yet a portion of the green light will be transmitted, and this is absolutely fatal to freedom from fog where a very sensitive emulsion is being manipulated. The ruby glass selected should show an absolute absorption of all rays but the red, and the amount of light admitted should be but small—in fact, only just sufficient to see the image. Perhaps the best light for these plates is artificial light—either a candle or gaslight, screened from the plate by a coloured globe or stained paper. For a covering of a globe there is nothing better than aurine and varnish, and aniline scarlet and varnish. One surface is covered with the one and the other with the other. The light penetrating through the two will be strongly coloured. If such a light be placed six feet away from the operator all danger of fog will be eliminated. For suppose that to get a transparency half a second is required at six inches distance from the naked flame, then we should require 144 half-seconds, or 72 seconds, at six feet to get the same result. When the most intense part of the rays are cut off we may say that it would require at least twenty times that exposure to get a perfect positive, or, roughly speaking, half-an-hour's exposure. It will be manifest that exposure to such a light for the short time required for the preparation or development of the plate will practically have no effect on the film, since when moistened with the developer it becomes much more insensitive than in its dry state.—*Photo. Journal.*

EXCHANGE COLUMN.

Wanted, in exchange for a Jamin whole-plate lens, a microscope with mechanical stage. Value adjusted.—Address, F. W. Evans, 246, Old Kent-road, S.E.

I will exchange a whole-plate portrait combination lens by Fleming, of London (Waterhouse diaphragm), for something more useful to an amateur photographer.—Address, A. Marchant, 3, Unity-street, College-green, Bristol.

I will give a Dallmeyer's No. 2 triplet, 10 inches focus, and a Dallmeyer's wide angle rectilinear, 3½ inches focus, for a portrait lens of from 6 to 8½ inches back focus, and half-plate camera.—Address, H. Paton, 59, Landressy-street, Bridgeton, Glasgow.

Dark tent of deal, size outside 3 ft. 6 in. × 4 ft. × 1 ft. 7 in., having two yellow glass windows, and two oxyhydrogen burners for mixed gases, will be exchanged for lantern slides—three-inch picture nursery tales, or designs for interchangeable chromotype frame preferred.—Address, C. J. Clark, 27, Maitland Park Villas, Haverstock Hill, London.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

F. Gutekunst.—Received. Thanks.

P. (Helensburgh).—The subject shall receive our most careful consideration. Thanks for making the suggestion.

T. O. B.—There is nothing for it but the making use of a stout paper having a smoother surface than cartridge paper.

J. M. Danks.—We are about to try your plates against others that have been prepared by the same formula, and shall let you know the result.

W. P. (Dartmouth).—We have spoken to two or three makers, but they do not exhibit any enthusiasm in connection with the manufacture of the article.

Microphoto (Bristol).—The number to which you refer has been out of print for several years. Another having an article on the same subject will be selected and forwarded.

Quercus.—1. There are several photolithographers in London; at present, however, we do not know of the addresses of any.—2. See the articles on photolithography published in our Almanac for 1876.—3. Yes.

Clericus.—1. The book is not yet published.—2. Nothing but changing the sample of collodion, or adding an unusually large proportion of alcohol to the developer, will overcome the repelling action.—3. Thanks for kind expressions.

R. Price.—A little chloride of lime, together with the use of pumice-stone, will remove the stains. Few have a correct idea of the great value of pumice-stone as an agent in the removal of silver stains. We use it very much for this purpose.

T. Riley.—The matter is one altogether beyond our province; but we presume that you have received the expected reply before this. There is every excuse to be found for those who have of late been depending upon unbroken sunlight.

Semper Vigilans.—During the months of July and August last year we published a few chapters on *Single Transfer*, from a perusal of which you will obtain very full information respecting that phase of carbon printing upon which you write.

Norman May.—We think it probable that the album shown at the meeting in question is one for which a patent was obtained about two years since, and which is described at page 422 of our volume for last year, under the name of *Prince's Patent Kaleidoscope Album.*

J. Latham.—See our answer to "T. O. B." in our issue of April 19, coupled with that to "L. D." in the number for April 26, and on a cognate subject to "chromotype" in that of April 12. All these have reference to the presence of minute air-bubbles imprisoned between collodion and gelatine films.

A. B. G.—One of the simplest hygrometers, as it is certainly the best, consists in that arrangement of two thermometers known as the wet and dry bulb thermometers. The one that is covered by muslin, which is kept moist by capillary attraction from a water-bottle, is always a few degrees lower than the dry bulb thermometer, and the difference between their readings indicates the degree of moisture in the atmosphere.

Rev Geo. White.—We cannot advise you to produce your binocular views for the *reflecting* stereoscope, because the *refracting* instrument is so much more convenient and satisfactory in every way. We quite admit that in a reflecting stereoscope pictures of even two feet square may be examined. But what then? They will not subtend a greater angle when examined by reflectors than will a three-inch picture when scrutinised through a lens having a focus of five or six inches; and, as the sensation of magnitude is dependent upon the angle anything subtends to the eye, where would be the gain? Always remember that a binocular picture when examined in a refracting stereoscope is *magnified.*

F. S. K.—A somewhat singular kind of phenomenon in connection with the preparation of a gelatino-iodide of silver has been experienced by a correspondent, who describes the occurrence as follows:—"Having been in the habit of using in gelatine emulsions a little iodide for landscape work to prevent blurring, and wishing to make a stock of pellicle which should be available for either portraits or landscapes, I made some with bromide and iodide separately, intending to use the former *alone* for portraits, and a combination of the two in certain proportions for landscapes. I found the bromide pellicle dissolved easily. The iodide pellicle also *swelled* easily, but refused to dissolve—long continued heat only causing a slight solution. Can you tell me the cause of this? How am I to rectify it?"——Not having experienced such an occurrence we submit it to our readers.

J. L. B.—Our meaning is not that an instantaneous negative from other than a portrait lens will not bear enlarging from in any degree, but that, owing to the greater amount of light admitted by a portrait lens when working with full aperture, an instantaneous picture can be better taken by such a lens than by any other. We are unable to express any opinion as to the rapidity of the lens you have obtained; but this point can be easily tested by taking a street view in which there are a number of moving figures, and comparing the length of the foot (of any passer by) which is above the ground and moving forward with that which rests upon the ground. If there be *much* fuzziness about the moving foot, reduce the exposure by increasing the strength of the spring by which the trigger-movement-shutter is impelled. You quite correctly apprehend what was said about the radius of the plano-concave lens; but this curvature also depends upon the kind of lens to which the corrector is to be applied.

Received.—*The Magazine of Art*, Part I. (Cassell, Petter, and Galpin); Thornthwaite's *Hints on Reflecting and Refracting Telescopes; The Annual Report* of the Royal Cornwall Polytechnic Exhibition; *The University Magazine* for May; Samples of "Swan," "Bennett," and other dry plates. Notices of these in our next.

W. L. R.—On the subject of cleaning old glass plates our correspondent writes:—"I should be glad if you would inform me whether you think there is any 'best' process of cleaning old glasses which are intended to be used again. I will detail my own method, and if you can suggest any more thorough process than my own you would oblige me, as I find unless I albumenise my plates (after the usual cleaning) that in an under-exposed picture the shadows are often 'smeared' and dirty, and sometimes I can even trace the direction in which the cleaning cloth has traversed the plate:—I soak the plates in a strong, cold solution of washing soda until, on lifting them out, the film is so loose as almost to be left behind. I then rub each plate with my hands on both sides, wash the batch, each separately, three or four times under the house-tap, and then wipe with linen cloths which have been boiled to extract soap or soda. I now leave them on a shelf till required either for use or coating with albumen, when I proceed as follows, using one of the three following—tripoli, old collodion, or ammonia. Lately I have used the collodion most:—Place the plate in a holder, and rub thoroughly with cotton wool containing the cleaning medium, traversing the plate all over twice. Rub well with a clean linen cloth, and polish with wash leather—each kept for the purpose. But after all this I cannot depend on the shadows being clear; instead of detail in an under-timed one I get smears. Albumen gives clean shadows, but I do not want to be dependent on this. Any information would oblige."——In reply: our correspondent has proceeded in a very thorough and excellent manner to clean his old plates; but there is a still better method—one, indeed, which, in reply to his first query, we do not hesitate to designate as the "best" process. It is one that was introduced by Mr. M. Carey Lea a number of years ago, and which is extensively used throughout the world. The following account of it is given by Mr. Lea himself, in his valuable *Manual*:—"Provide a large glass pan, in which make a mixture in the following proportions:—

Bichromate of potash	2 ounces.
Sulphuric acid	3 fluid ounces.
Water	25 ,,

Place the plates of glass in the pan alternately, one at each end, so that their ends shall overlap a little, and allow the free passage of fluid between them. For new glass half-a-day will be sufficient to destroy the greasiness. Old glass that has been used before should have a day, and, if it has been varnished, even longer, or a mixture containing only half the above proportion of water. So long as this bath is yellowish-brown it is active. When it acquires a violet colour it is spent, and will want renewing. After a suitable immersion in the cleaning bath place the glasses one by one in a water faucet, and as fast as the water fills the pan lift one end and empty it. Repeat this half-a-dozen times at least. Then take up the first plate, let the stream of water run some seconds—first on one side, then on the other—until every possible trace of the cleaning bath is removed, and then rub dry with soft blotting-paper—*not* with cotton rags, as so universally directed." We have given Mr. Lea's remarks at length in the belief that they will be appreciated by those who have not seen the excellent *Manual* from which they are extracted, copies of which may be obtained at our Publishing Office.

Improvement in Lanterns.—When we described, in our number for November 30, 1877, the new "refulgent lamp" for the magic lantern, for which Messrs. Newton and Co., of Fleet-street, had obtained a patent, we did not specifically allude to one of its features—one, indeed, which it shared in common with all lamps of the same *genus*—namely, that of possessing *two* wicks. Since that description was written—indeed within a very recent period—Messrs. Newton and Co. have added a third wick, with the gratifying result of an important increase in the luminousness of the disc—a result of which we are able to speak in a decided manner, as we have subjected the disc to a careful examination. Owing to the fact of the wick-surface being small, the heat arising from the flame is by no means great, while the combustion is perfect.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician.

REVERSING THE NEGATIVE PROCESS.

Once more we find the wheel of time bringing round to us an old, old process which, though long since tried and relinquished, now makes its reappearance as a novelty. We allude to Herr Obernetter's "reversed negative process" described in our last number. As old as the collodion process itself, the idea of sensitising a collodion containing a soluble silver salt by immersion in a bath of soluble haloid has long since given place to the method now generally followed, in which the conditions are reversed; but, though for various reasons the former plan was found in years gone by to be inferior to the one which replaced it, there is no reason why, at least for special purposes, it may not be found to possess at the present day advantages which may render it convenient.

Numerous instances may be found in the history of our art-science of processes or formulæ which have been tried and set on one side, if not as impracticable, at least as offering no advantages over alternative methods already in vogue; but as years go on and our knowledge increases, or as our requirements become changed, these rejected processes crop up again as novelties and are received into general use. Such may possibly be the case with the one under notice; for, although we are not prepared to accept it in the light in which its author places it before us—namely, as a substitute for emulsions—we can readily believe that under the special circumstances for which he recommends its use, and in view of the advantages he claims for it, it may find a place amongst our established processes.

At the same time, as regards the mere facility it affords for the colouration of the collodion film in the manner suggested by Herr Obernetter, we fail to see that it offers any advantage over an emulsion, or that the difficulties involved in the preparation of the latter are sufficient to justify us, even for the special purposes mentioned, in relinquishing its use. For general work, landscape or otherwise, the practice of staining the film has now, we believe, fallen into disuse, as any slight benefit which may accrue from such treatment is found to be more than counterbalanced in other directions. But in the particular branch of photography to which allusion is made in Herr Obernetter's article—the production of negatives for colour printing—we believe we are correct in stating that both MM. Leon Vidal and Ducos du Hauron largely employ stained emulsion films.

But, turning to another phase of the question, we think a considerable modification of the formula will be necessary before the highest class of results can be obtained. It will be noticed that Herr Obernetter recommends the same collodion—that is to say, a collodion containing the same amount of silver nitrate—to be used independently of the action of the "sensitiser," whether it be iodide, bromide, or a mixture of the two. Now we know that in the ordinary bath process the conditions necessary to be observed in iodising or bromising the collodion are respectively very different; we may, for instance, bromise the collodion to an extent which would be quite inadmissible in the case of iodide, as the physical character of the silver iodide and the greater rapidity of its formation cause it to "burst" out of the film, or to form loosely on its surface, much sooner than is the case with bromide. And, again: it is possible to work a purely iodised collodion with a bath of silver nitrate containing only thirty or twenty-five grains to the ounce, whereas a bromised collodion requires at least double that strength in order to give a satisfactory result.

Such being the facts in the ordinary method, it is but reasonable to suppose that in reversing the process the same rules will, to a great extent, hold good; that, in fact, if a collodion containing a given quantity of silver gives the best possible results when converted into an iodide film, the proportion will require to be largely increased in order to render it workable to the best advantage when bromised. If we analyse Herr Obernetter's formula we find that his collodion contains, roughly, five and a-half grains of silver nitrate and six and a-half of pyroxyline to the ounce. Now, if we suppose the whole of the silver contained in the film to be converted by the haloid bath, we shall find that the treatment with iodide produces a film as nearly as possible equivalent to one obtained in the ordinary way from a purely iodised collodion containing a little more than four and a-half grains of iodide of ammonium to the ounce; while, if bromide be used, the result would be equivalent to an emulsion prepared with a fraction over *three grains* of ammonium bromide. If we compare these figures with the formulæ in vogue for iodised and bromised collodion we find a great disparity; for, whereas the iodide is about the usual mark, the bromide might, with advantage, be increased to double or even treble the quantity.

We direct attention to these points, not with a view of showing that Herr Obernetter's method is impracticable, but rather to demonstrate in what manner it may be made to satisfy ordinary requirements. That gentleman, in fact, closes his article by recognising the possibility of improving the process by varying the formulæ, and having had some experience with silvered collodion we may be allowed to say a few words on its capabilities.

First, as regards the quantity of silver it is possible to introduce into the collodion in a state of solution. Contrary to pretty general opinion silver nitrate is very soluble in alcohol of ordinary strength, especially when heat is employed to assist the solution; even in absolute alcohol at boiling point it is stated to be soluble to the extent of twenty-five per cent. by one authority. The admixture of ether, as in collodion, limits the solubility considerably, but still leaves it, when proper precautions are observed, fully sufficient for any purpose, emulsion or otherwise. There is not the slightest difficulty in introducing twenty grains of silver to the ounce of collodion, and at that strength it will, with most samples we have tried, remain in solution without crystallising on cooling.

The way we proceed is as follows:—The collodion is prepared in the first instance from solvents as free from water as possible, as this admits of the use of more of the latter in getting the silver into solution. Ether and alcohol of ·725 and ·805 respectively are quite good enough. The silver is soluble *theoretically* in half its weight of boiling water, but practically even a less quantity of water suffices. If it be dissolved, then, in as small a quantity as will suffice, and three or four times the quantity of alcohol *previously raised to the point of ebullition* be gradually added, the solution may be transferred to the collodion without the slightest risk of precipitation, even when working, as we have said, to the proportion of twenty grains to the ounce. With some samples of pyroxyline it will be found that after standing an hour or two the collodion becomes opalescent or decidedly opaque, presumably from the formation of minute crystals of silver nitrate, but the precipitation takes place in so fine a state that the mixture partakes of the character of a perfectly smooth emulsion. If methylated solvents be employed a faint discolouration of the silvered collodion takes place after a short time, but this disappears entirely upon the addition of a soluble haloid; it is safer, therefore, or we may say necessary, to add one minim of nitric acid to each ounce of the collodion, in which state we have kept it satisfactorily for several weeks.

We have for some time practised this method of sensitising our ordinary bromide emulsions, for which purpose it seems eminently adapted, as a larger body of silver bromide can be thus introduced into the emulsion without fear of precipitation than when the opposite course is pursued. It is equally suited to Herr Obernetter's process, all that is necessary being the arrangement of the proportion of silver to suit the altered requirements. In thus preparing a bromide emulsion there is, however, one precaution to be observed, namely, not to add the bromide too rapidly, *especially when approaching the point of neutralisation*. So long as there is a considerable excess of silver the bromide forms rapidly and in a state of extremely fine division; but as the point of saturation is reached, if extreme care be not observed, it will separate in "flocks," leaving the collodion perfectly clear. But should this occur it is only necessary to add a fresh portion of silvered collodion and shake vigorously, when all will come right again; then proceed to neutralise more carefully.

We have, however, derived the greatest use from this reversed method in the preparation of emulsions containing a trace of iodide As all our readers who have gone through the preparation of bromo-iodised emulsion will be aware, the presence of free silver appears to be necessary to prevent the precipitation of the iodide, and, in spite of every precaution, the behaviour of the emulsion is sometimes most refractory. In such cases we have allowed the emulsion to "ripen" in the presence of an excess of silver, and have then poured it out, and, after allowing it to set, treated it with a weak solution of soluble haloid, preferably bromide, as the desensitising action is then less than if iodide be employed.

In conclusion: we can only say that Herr Obernetter's paper comes as a valuable suggestion of what may be possible in the direction of silvered collodion. Not having yet tried his process in its entirety we are unable to speak of its capabilities; but we are of opinion that while for reproductions and for other purposes where extreme rapidity is not sought for it will form a ready means of securing the object without the necessity for any very delicate manipulations. When, however, rapidity is a desideratum it will, we think, be necessary to resort to a second sensitising—a condition which deprives the process of much, if not all, of its simplicity.

RECENT IMPROVEMENTS IN CARBON PRINTING.

It is still fresh in the recollection of our readers that Mr. J. R. Johnson recently obtained a patent for certain improvements in carbon printing which, with the exception of one, or possibly two, points that were to have been disclaimed are now being brought into practical if not commercial existence. As the outcome of these inventions we have received from Mr. Johnson a variety of pictures which bear the imprint of Mr. Sarony, of Scarborough, with whom, we understand, Mr. Johnson has been engaged for several months in carrying out the details of his inventions.

In Johnson's patent special attention is directed to the fact that when a large proportion of the permanent alizarine is added to carbon tissue the staining of the paper (single transfer being presumed) upon which the print is to be developed introduces an element replete with serious annoyance to the photographer. From what cause this arises we know not, but we are very well aware that the staining alluded to really does take place, and we have frequently been asked by correspondents if we could account, and provide a remedy, for such an element of disturbance. A remedy is well known, namely, the addition of such a quantity of freshly-precipitated alumina as will render the alizarine completely insoluble—in other words, which will produce one of the alizarine or madder lakes so well known to artists, some of them since the time of Rubens. But, unfortunately, the remedy is as bad as the disease; for the aluminous base of the lake renders the gelatine as completely insoluble as does the oxide of carbon formed by the action of light upon the bichromate in the carbon tissue. Mr. Johnson claims, after a series of experiments extending over a long period, to have succeeded in forming an alizarine lake free from these defects, while it yields a rich and brilliant pigment by which all the photographic tints can be produced. Into the mode of effecting this we do not enter, preferring to refer the reader to the specification of the patent, which we published in our issue of November 9th, 1877. The specimens now before us fully bear out what has been claimed, the whites being singularly pure and the general tone very rich.

The perfection of single transfer printing is to be found in its application to opal glass. In purity and beauty such pictures quite rival the finest vitro-enamels. Compared with similar pictures on paper the latter are coarse and granular, arising from the fibrous texture of the paper being seen below. We have already called attention to the advantages that would arise from the employment of a fine, highly-glazed paper; and in Mr. Johnson's patent this has been carried a step farther by the employment of a paper prepared with an enamel surface that has special properties, namely, that unlike the paper referred to by Dr. Monckhoven, and which, owing to the presence of bartya, took a permanent stain, this is free from that defect, being prepared with materials which do not combine with chromic acid, details of which are to be found in the specification to which we have already referred. The prints forwarded to us in illustration of this feature are certainly very fine, possessing a freedom from texture peculiar to a vitro-enamel, with the purity of whites already spoken of in connection with the previous portion of the patent.

The eburneum process at one time (now several years since) evoked a large amount of sensation among photographers. It was the invention of the late Mr. Burgess, of Norwich, but, owing to the heavy smudginess of the tones and the silver basis, few cared to adopt this process in everyday practice. Mr. Johnson and Mr. Sarony have taken it up and worked it by the light of modern knowledge, and especially by that of carbon printing as described in Mr. Johnson's patent. The appearance presented by the modern specimens, compared with those by Mr. Burgess, is very marked in the contrasts. The latter are hard and possess an inky-black tone (we speak of those sent to us by Mr. Burgess, and which we noticed at the time), while those by Mr. Sarony and Mr. Johnson are delicate and transparent, the tone being warm and the permanence undoubted. We are informed that the chief advantage claimed in connection with these "ivorytypes"—as Mr. Sarony prefers to designate them—consists in preparing the artificial ivory in large sheets and in advance, so that these beautiful prints can be produced as easily and as expeditiously as an ordinary double transfer print. Further: these pictures, although possessing a highly-glazed surface that can neither be scratched by the nail or injured by a wet sponge are, nevertheless, produced without coating with collodion the glass upon which they are developed. The impression we receive from this is that a considerable saving of time and money must result from the working of this new eburneum or "ivorytype" process.

In working out these practical details, Messrs. Johnson and Sarony are said to have discovered the source of the great variations in the manufacture of carbon tissue which has hitherto rendered it a matter of difficulty to obtain two samples equal as regards colour, solubility, and other qualities. This we are very glad to learn. Carbon tissue makers have hitherto been troubled by every passing thunderstorm. Ajax-like, these experimentalists may now defy it.

RETOUCHING SUBSTITUTES.

It is perhaps rather a contradiction to speak of a substitute for retouching, considering that before retouching existed "substitutes" were in vogue; but we wish to examine the question thoroughly, treating of methods which have been invented or theorised upon, since the advent of the pencil has revolutionised the practice of portrait photography. Indeed, it is not too much to say that the practice of protraiture has been revolutionised by the process of freckle extermination, for which is so frequently substituted likeness and character extermination.

We tread on dangerous ground, we are aware; but we do not intend, in what we are about to say, to speak in a partisan spirit of any part of the practice of "*la retouche*," which is at present a great and recognised power. Still we may allude to its abuse while treating of its use, for scarcely a day comes but we see some examples; and hence we are not surprised to notice the various nostrums brought forward as substitutes—efficient, and economical of time. Retouching properly employed has its artistic aspects, and here is the old story—art by machinery or process.

Retouching is found so costly in many a studio that the salary of the *employês* engaged only upon it has made all the difference between a profit and a loss, and this is another reason for attempting to find out something to replace it at a lower cost. Consequently we find that modification of the light occupies a prominent position in the recommendation of the substitute advocates, and very remarkable are their statements.

There is at present a heated discussion going on in the American societies about the merits of blue glass as bearing upon this question, and one side confidently avers that by its use the need for retouching is reduced to a minimum, that freckles and wrinkles show less, and that the whole face comes up with greater roundness and modelling. We cannot admit that anything of the sort would happen by the substitution of glass of any colour in the studio for the time-honoured "colourless" sheets that are used in almost every studio in this country. We consider it to be impossible that any colour modification of the light can alter the relative intensity with which a patch of red or a freckle, for instance, is represented, compared with the surrounding flesh tints.

We are, however, of opinion that as it is rare that there is smoke without fire, the conflicting testimonies may be explained in a rational manner, without imputing either ignorance or wilful perversion of facts to their originators; and quite recently a case was brought under our own notice which gave us, as we thought, the key to the whole matter. Having been invited to see a newly-constructed studio, in which already active work was going on, we were struck by the absence of blinds overhead, and we asked the photographer whether he did not find it to work with too heavy shadows. He pointed out to us a portable screen which we had not before observed and showed how it could be made to cast a shadow or diminish an undue preponderance of light in any direction. It was made after the fashion described in these pages some months ago, and we were assured was found a valuable adjunct. But what most struck us was the gentleman's remark that the yellow calico it was covered with had such a modifying effect upon the light that it did away with a good deal of retouching. Here was a personal example o the very argument we have condemned, and an able photographerf the exponent. It was, we confess, rather staggering; for of the ability of the photographer, both as a retoucher and a manipulator, there cannot be two opinions; we, however, soon got to the bottom of the matter, and saw the little bit of fire from whence came all the smoke.

When a portrait is taken with no blind and no reflector it is evident that there would be such great preponderance of top light that the lower shadows of the face would be very obtrusive, and that a large part of the face would be in half-shadow. Further: without the screen the exposure would be timed for the higher lights, and if correctly done there would be a large part of the face in the very condition which would give prominence to colour inequalities, such as freckles; for we need not draw attention to the fact that they always show most on the under-exposed portions of the face, and are scarcely seen at all in an over-exposed picture. And, again, the shadows would be lightened by the use of the reflector—and so, in truth, less retouching would be required, the work expected of, or performed by, retouchers in some establishments in the direction of modifying over-heavy shadows alone being most considerable. We think we have here offered a completely satisfactory solution of the puzzling problem of the contradictory effects ascribed to coloured lighting. In the majority of cases the coloured glass would be put in the very position where it would prevent the casting of heavy shadows, and so would tend to the production of such harmonious negatives as would consequently need less work with the pencil.

In one of the continental cities there is a celebrated lady photographer who is noted for the delicacy of her portraits, and we have been positively assured by more than one of our friends who have visited her studio that before photographing the sitter she thoroughly well *paints* the face, the eyebrows, &c. Here is an example of the oft-named plan of "powdering" the sitter before photographing to eliminate all imperfections in the texture of the skin. We, however, unfortunately have not been informed of the extent of the *modus operandi* of the fair operator's exploits with the palette and brush upon her sitter's face; and we are strongly of opinion that it is not the face generally which is treated, but special portions, such as the eyebrows, the parting of the hair, and many little special excrescences, or too great amount of local colour, which are heightened or reduced in effect, as the case may be, by a hand trained by long practice.

We allude to this because of the very persistent manner in which the face-powdering process has been recommended. We have in many cases experimented with it, but with most decided failures. No matter how carefully and delicately we attempted to cover the whole face with violet or other powder we found the result in the camera was that the face had a disagreeable, uneven, chalked appearance that was most unsatisfactory, though when a coloured powder was used the results were much better, but still practical failures.

One professional photographer to whom we mentioned our trials and their results entirely coincided with us, and said that his own attempts in a similar direction enabled him to find out the cause of some failures that had often puzzled him in the course of his practice. He had occasionally found a face to come out wanting in harmony in a peculiar way, and no rearrangement of blinds would make any difference. After his trials with the face-powdering process he discovered that these failures arose from his sitters having powdered their faces in such a skilful manner as to prevent his noticing it, with the annoying result alluded to.

It has been suggested that as the minute, downy covering with which the face, in common with almost every part of the human skin, is protected was repulsive to dust, it would be better to lay the colouring or covering matter by means of a liquid. Of course there are some sitters whose vanity would lead them to suffer any amount of inconvenience for the sake of appearing "beautiful for ever" in their pictures, but we must say that we cannot recommend any such process. To say nothing of the impractibility of painting subjects like this with a reception room full of impatient sitters, it must be ever borne in mind that the dexterous retoucher can take out everything necessary, and even produce any amount of flat, objectionable "finish' desired. In the case of a stray sitter such experiments might be tried by the *dilettante* photographer, but for all professional and practical purposes we are strongly inclined to advise that they be left alone.

Recent attempts to find a convenient and suitable substitute for glass in outdoor operations have not only demonstrated the possibility of success, but have also tended to stimulate the popular desire for some modification in this direction. The chief requirement, of course, is that, while saving the great weight of glass and freeing us from the dangers which arise from its fragile nature, the results obtained shall be in no respect inferior. This condition is undoubtedly fulfilled by Mr. Warnerke's tissue, but, especially amongst amateurs, there exists a large class who are not satisfied with any process which they cannot carry out themselves in its entirety; and, though the fullest details of the preparation of the tissue have been freely made public, it must be owned that the process is not one which can be conveniently worked upon an "amateur" scale. We have recently read a description of a simple method which appears likely to meet the wants of the class we speak of. It is due to M. Laoureux, a member of the Liege section of the Belgian Photographic Association, who describes it as a process "without anything new in its details, but constituting collectively a real novelty." The substitute consists of paper or cardboard waxed in the ordinary manner and then rubbed with powdered talc, as frequently recommended in connection with glass. To collodionise it it is laid, by means of the squeegee, upon a sheet of glass, a little larger than itself, previously moistened with alcohol. The preparation of the "plate" is completed in the usual manner, when the flexible tissue detaches itself from the glass support and may be stored away in a book or case. If paper be used it will be necessary to expose through a sheet of glass, but a tolerably stiff cardboard does not require this. The latter must not, however, be too thick, or it will not dry flat. The development is performed in a dish or on a glass plate, as may be most convenient. When completed the negative is accurately levelled and coated with a solution of twenty parts of gelatine and two to four of glycerine in one hundred of water, and allowed to dry. It may then be detached with the greatest ease from the paper or cardboard support—an operation which offers not the slightest risk of failure. The process appears to be of the utmost simplicity, and if the cardboard support can be prepared in such a manner as to resist the action of the developing solutions, so as to render its re-employment possible (*à la* Sawyer's flexible support), it promises to go a long way in driving glass out of the field.

ON THE CALOTYPE PROCESS.

[A communication to the Bristol and West of England Amateur Photographic Association.]

The calotype process of taking negative photographs on paper has become quite obsolete and a thing of the past; but it is a question whether its being so readily abandoned for the collodion process was not a great mistake. A very considerable experience in both processes in this country and in India warrants my giving a decided opinion that the paper process has some advantages over the collodion for a certain set of subjects.

The superiority of the collodion process for portraiture and for stereoscopic and microscopic subjects is unquestionable; but for landscapes of a large size, for foliage, for architecture where the carving or tracing is not very minute, and particularly for copying sculpture and inscriptions, I consider the paper process capable of giving all that can be desired. The definition, though not quite equal to that on glass, is sharp enough, and the absence of extreme sharpness in many subjects is desirable in an artistic point of view.

It has been urged that paper will not give objects at a distance with any distinctness; but my experience goes to prove that distant objects are, as a rule, rendered better on paper than on glass, from their not being liable to obscurity through solarisation so much as is the case with collodion negatives. I have paper negatives, taken in India twenty years ago, giving objects very clearly at distances from four to twenty miles, so that this objection is groundless. To show that prints from paper negatives are not very far below those from collodion I may mention that on my return from India, in 1863, I sent a number of prints from paper negatives to an exhibition in London, where they were mistaken for prints from collodion plates, and pronounced very beautiful, but not quite equal to the ordinary collodion pictures. When it was represented that the prints were from paper a prize was awarded. Moreover, a collection of prints from my paper negatives sent by Government to the Paris exhibition gained a medal.

The rage for portraiture, the little appreciation shown for landscape photography, and the collodion process presenting fewer difficulties, I believe, constitute the principal reasons for the paper process having been so soon abandoned for the collodion process. With the latter the iodised surface was obtained ready prepared and was easily applied; whereas good paper was difficult to be obtained, and when obtained the process of iodising the surface was one of great nicety, neatness, and delicacy of manipulation.

The one great drawback to the paper process is the long exposure required; but even this has its advantages in allowing more detail in the shadows to be brought out than can be done with short exposure. In this country and on the western coast of India the average exposure with a four-inch landscape lens was three minutes; but away from the coast of India, in hot and sandy districts where the radiation from the ground was great, the thermometer varying from 80° to 85° between nine and ten a.m., the exposure was as high as twenty minutes. Against this, however, the portability, freedom from risk of breakage, scratches, &c., are advantages which are of great weight, particularly with negatives of a large size. I found what was called the waxed-paper process—viz., waxing the paper before iodising—a decided failure. The negatives produced were always woolly and indistinct—the result, I think, of the texture of the paper having been disturbed by the removal of the size and the application of the wax. I have never seen any really good negatives produced by the process. The process I found to answer best was the following, which I got from Mr. Buckle, of Leamington, from whom I had one hour's instruction, and I have never seen any photographs superior to those taken by Mr. Buckle:—

Having procured suitable paper—in which the size should be hard, the surface smooth, the texture close and even, and the body free from metallic particles—I cut it up into pieces fitting exactly the negative frames, marking the smooth side of each in one corner with a cross in pencil. I had several boards made of deal one inch larger every way than the negative paper, the front of each board covered with fine flannel over a thin coating of cotton wadding, and at the back a loop of broad elastic large enough to admit the hand to hold and manipulate the board easily. Over the flannel I laid a sheet of clean, white blotting-paper the size of the board, and then pinned a piece of paper, to be prepared, on the blotting-paper, to the flannel with silver pins made for the purpose, and one and a-half inch long, the pins lying almost flat on the board. Then with a Buckle's brush (which consists of a glass tube four inches long and half-an-inch in diameter, and a silver wire hook which draws a tuft of clean cotton wool partially into the tube, leaving a ball of wool outside, which with a little care can be made into a perfect shape by pulling the superfluous cotton away) I applied the following solution to the surface of the paper evenly and gently, without disturbing the surface of the paper, but working it over several times lengthways and crossways, namely—

Nitrate of silver	33 grains.
Distilled water	1 ounce.

This sheet was then left on a table or flat surface while a second piece was similarly treated. The pins were then removed from No. 1, and the paper taken up by two corners and placed on a table covered with a clean sheet of blotting-paper, face uppermost. Then No. 3 was prepared, and the pins removed from No. 2, &c., and No. 4 prepared. When six or eight had been thus treated No. 1 would have become surface dry, or like a newspaper just out of the press, and would be ready for the next process—that is, of immersing in a bath composed of—

Iodide of potassium	20 grains,
Distilled water	1 ounce,

turning it over and removing air-bubbles on the iodised surface and back with a soft camel's-hair brush. After a minute and a-half or two minutes the sheet would be ready to be removed into a bath of rain water, the water being changed every half-hour for three hours, and so on till the six or eight sheets were completed, and then another batch proceeded with.

After three hours the papers were removed carefully (being very tender) and thrown over a piece of broad tape suspended across the room, and covered with strips of white blotting-paper, the papers being face upwards on the blotting-paper, and placed cornerwise so as to drip from two corners. When dry they were taken down and pressed flat, care being taken not to finger the surface, and if kept in a dry place they would keep good for an indefinite time.

When required for use the iodised surface was rendered sensitive thus:—The paper was pinned, as before, on to the board over blotting-paper, and parts of the following solutions A and B applied to the iodised surface with the Buckle's brush plentifully, evenly, and quickly in the dark:—

Solution A.

Nitrate of silver	50 grains.
Distilled water	1 ounce.
Glacial acetic acid	10 drops.

Solution B.

Saturated solution of gallic acid.

Take of solution A	6 drops.
,, ,, B	6 ,,
Distilled water	120 ,,

(In very warm weather 180 drops of water.)

After exciting one piece, the pins were removed from the corners, and the board with the paper still on it allowed to remain on a flat surface while a second piece was excited. Then all the superfluous liquid was blotted off the first piece with a piece of clean, white blotting-paper, and the sheet placed in the negative frame. The second piece was then blotted off and placed also in the frame, and the frame screwed up tightly. The double frames used were not hinged, but the inner surface of one half grooved, the other carrying a corresponding projecting ridge, and fastening together with four screws. The glasses were not cemented as usual, but lying on beds of sheet india-rubber. There was thus no fear of breaking the glasses in screwing the frames together, and the papers were kept flat and airtight. Paper excited at nine or ten o'clock at night was generally exposed and developed before twelve o'clock the next day.

The development was as follows:—The negative was pinned on the board over clean blotting-paper, and equal quantities of solutions A and B were applied with a clean Buckle's brush quickly and evenly over the surface, which was kept till wetted in every part. When the detail of the picture was well out, but wanting depth, some of solution B alone was poured on to the picture, and quickly distributed all over the surface with the brush, and the same was repeated until no more would develope. Then the negative was removed and plunged *quickly* (or stains were likely to appear) into clean rain water, and left in this till it was convenient to fix it and remove the iodide of silver in a bath of strong hyposulphite of soda, the negative being kept in this bath till all yellow colour was quite removed. It was then placed in rain water and well washed for several hours. After this it was placed in a bath of hot water, as hot as the hand could bear, for half an hour, to remove the size and render it capable of taking the wax properly. It was then hung up to dry.

When dry the negative was placed, face downwards, on several thicknesses of white blotting-paper, and a hot box iron run over the back. The iron was held in the left hand, and its course followed by a cake of pure white wax held in the right hand, and the wax rubbed on to the negative, which was hot enough to melt the wax. When the wax had been applied as far as required the negative was turned over, and the iron run quickly over the face to draw the wax through the paper. The negative was then placed between two pieces of blotting-paper, and all superfluous wax taken off by passing the iron over the blotting-paper. The negative was thus finished and ready for printing from. Thos. Biggs, *Colonel R.A.*

REPRODUCTION AND ENLARGEMENT OF NEGATIVES BY THE COLLODIO-EMULSION PROCESS.

[A communication to the South London Photographic Society.]

Reproduction of Negatives.—Photographers, at times, are at their wits' end to know how to get off prints in large numbers from a single negative, and failing to do so a great deal of business is entirely lost. Sometimes it may be a portrait of some celebrated person, at other times a landscape; and we all know that, if in dull weather a publishing order be given by one of the wholesale houses, unless we have some means of reproducing the negative it is quite impossible to execute a large order when pressed for time. I have seen many attempts made, and have made many myself, with the bath process, but I have never seen a result produced that would compare with a proof print from the original negative.

Some few months since a well-known firm had an order to execute, and I was asked if I could reproduce some negatives so as to get the number of prints completed by a given time. I set to work and reproduced several, which gave great satisfaction, and thereby the firm were enabled to execute their order. I now submit for your inspection a proof from the original negative, and also a proof from the reproduced one. The method I adopt is by no means a difficult one, which I here give in detail.

The first thing to do is to produce a transparency as perfect as possible. I always find it best to use patent plate, and after this is well cleaned it is edged with india-rubber solution for about one-eighth of an inch all round; it is then coated with washed emulsion and allowed to dry. I use an ordinary oak printing-frame with a thick plate-glass bed plate, similar to that I have here. I then get a piece of six-sheet card or mounting board large enough to fit in the printing-frame, and then lay the original negative down on it, marking round it with a mount cutting knife. After removing the negative I cut out the centre, which is the size of the negative; when that is removed the negative will fit in tightly. If this mask be not used the transparency will have a halo all round the edge for about a quarter of an inch, and sometimes half an inch, according to the subject. When the negative is in the mask I very carefully dust it with a stiff brush, a flat hog's-hair varnish brush being best. I then, with great care, bring the two edges of both the negative and the prepared plate together and lower it down in contact. The utmost care must be taken not to allow the plate to grate, or the film of emulsion will be injured and cut. The putting in of the back of the printing-frame requires notice. In putting it in always place the side in first nearest where the bars are hinged, thus always keeping it pressed as tightly as possible in that direction; for, if it be not, when the bars are brought down the springs will give it (the back end) a sliding motion and cut and injure the film. The bars having been fastened the frame is now turned over and exposed to light for a length of time depending on the density of the negative, and also on the rapidity of the emulsion and quality of the light. The frame is then taken into the dark room, the back board carefully removed, still keeping it pressed towards where the bars are hinged, when the plate may be removed by a pneumatic holder. While attaching it press on the plate with the thumb and forefinger of the left hand. In my own case I place my left hand on one edge of the plate and lift the plate by one corner with the nail of the fore-finger of my right hand, and by adhering to these rules I seldom damage or injure a plate in the slightest degree.

The development is effected by alkaline pyro. in the usual way, and the proper intensity must be obtained by the alkaline developer alone. The plate is then fixed with hypo. I find it best to add a drop or two of acid to the hypo., as this prevents the film from becoming baggy. The plate is next well washed; not only well washed, but allowed to soak in a tray containing plenty of clean water, as it seems almost impossible to wash out the last traces of hypo. from the film, owing to its being so porous. If not washed properly, after a few days the transparency becomes stained all over in patches, which ruin it completely. About half-an-hour is sufficient time to allow it to soak; it is then well washed under the tap and set up on end to dry spontaneously, and varnished with a pale-coloured, thin spirit varnish.

Having produced the transparency possessing the requisite density—namely, the shadows deep and the high lights transparent, with the intermediate gradations—the next step is to produce the negative. The negative is replaced in the frame by the transparency and another plate placed in contact with it in a similar manner as before when making the transparency, and is developed with alkaline pyro. The intensity must in this instance be also brought up with the alkaline pyro. to avoid any texture, and with ordinary care results can be produced that will satisfy the most fastidious.

Enlargement of Negatives.—The transparency is produced in the same way as already described, only care must be taken not to have the shadows too intense. It is better to make the transparency on a plate somewhat larger than the original negative, for if the plate be the same size the edges of the holder which holds the transparency reflects light, and the edges of the enlarged negative is imperfectly rendered. I use an ordinary room, the window of which is fitted with a shutter in two halves. The bottom half carries the camera, which is fitted to it with focussing arrangement; and about two inches on the further side of the transparency I have a piece of ground glass to diffuse the light. In the upper part of the shutter I have a sliding sash glazed with non-actinic glass, and over that an opaque sliding shutter. In front of the camera I have an upright easel on castors, and on the floor, at right angles with the camera, I have a piece of wood, about 3×2 inches, screwed; and by keeping the side of the foot of the easel close up to it I am always sure of having my subject square. I focus on a piece of glass covered with white paper, the lens open when focussing, and then stopped down. I only require in my practice to work up to 24×18. I do not find the slightest difficulty in coating the plate with emulsion, providing I pour plenty of it on in the first instance; the plate neither requires an edging or substratum of any kind. I always use a washed emulsion, and there is not the slightest fear of the film slipping, for it sticks like wax. When the plate is coated and set, the same as with ordinary collodion, I put it to soak in water (common water), making use for this purpose of a wooden tray lined with sheet zinc, which answers admirably. It is allowed to soak for about ten minutes or a quarter of an hour, or even longer; there is no fear of it spoiling. When the water runs freely over the surface it is taken out, slightly drained, and the exposure made. The plate will keep in good condition for an hour or two. I find about the same time as for wet collodion quite sufficient. When the plate has been exposed, and before applying the developer, it is flushed with water. I find it best to apply the alkali and bromide first. It is immaterial whether ammonia or washing soda is used. After it has been on the plate, and well worked about to ensure even action, a drop or two of a ninety-six-grain alcoholic solution of pyro. is added. If a thin, delicate negative be required use very little pyro.; if an intense negative be necessary use plenty of pyro. I have developed a 24 × 18 plate with only one grain of pyro. By regulating the quantity of pyro. any class of negative can be produced as desired.

I consider enlargements made by the collodio-emulsion far superior to those made by the bath process. I submit for your inspection some prints from negatives produced by this method, and you will find there is not the slightest texture. The foregoing remarks I have made are relative to the way in which I am in the habit of working; others may work in a different way, according to circumstances. WILLIAM BROOKS.

NOTES ON PASSING EVENTS.*

By a Peripatetic Photographer.

We all know well enough that photographic prints fade; and, knowing this, some of us have put ourselves to a good deal of trouble to discover and adopt a process the principle of which enables us to say that all doubt as to the possibility of fading is removed. Not so, apparently, does a certain "F.C.S." think; for if we are to believe a statement in a newspaper published within a radius of (let us say) a hundred miles of Liverpool, that "fellow," in announcing his discovery of a new printing process, says that he has "hitherto always adopted the most permanent method known, but the very principle of the present process removes all doubt as to the impossibility of fading." Hitherto photographers have been too much addicted to making assertions as to the durable character of their prints; commend me to the plain out-spoken honesty of the artist who thus claims for his process the absolute certainty of fading. (Do not two negatives equal one positive?) With strange inconsistency, however, he has tacked the former statement on to an announcement that "after many years of experimenting he is now able to publicly state that the photographic basis of all his best paintings is produced by a method which enables him to guarantee its permanency." Now, which of these two assertions am I, as a member of the body public, to accept—that in which permanence is guaranteed, or that in which all doubt as to the *im*possibility of fading is removed? By the way, are only his *best* paintings produced on a permanent basis? If so, on what sort of a basis does he produce his "second best" works of art?

In an excellent letter in The British Journal of Photography, by Mr. James Stothert, on *Horizontal Lines*, that gentleman, after some preliminary reasoning involving no small acquaintance with arithmetic, deduces a conclusion that certainly is in accordance with the editorial teachings of this Journal, and which must approve itself to the common sense of everyone. It is this—that in order to secure a proper balance of lines, and a freedom from abrupt or violent perspective, the point of delineation ought to be as far as possible removed from the subject of delineation, especially when the subject is an architectural one. O, yes! but what about dwarfing the image in such a case, making molehills of the distant mountains, and a mere porter's lodge of my lord's great castle? Mr. Stothert shows that this illustrates the value of long-focus lenses, when practicable, for such views. They compensate, he says, for the apparent loss of size, while preserving the favourable proportion among the lines of the picture secured by the greater distance of the standpoint from the subject. To such doctrines the "Peripatetic Photographer" says "amen" with all his heart.

A good, sound rule, or, at anyrate, an understanding, prevails in the press that no observations should be made upon cases still pending in our law courts; but in the interest of the accused in one such case—a certain artist whose name is far from being unknown to photographers, and who is "in trouble" on account of a charge of bigamy—I must crave permission for a remark. The inspector in charge of the case is reported to have boldly stated to the judge at the Hammersmith Police Court that "he had been informed that the prisoner had married six or seven wives." A bold man, this artist, if such were true; but in the interests of truth I am compelled to say that I have since seen statements in other papers to the effect that he had only three, or at most four, wives living. But even with this reduced number such courage must surely deserve admiration.

Mr. Samuel Fry, who a short time ago was by some persons looked upon as the very apostle of carbon printing, now resolves, after travelling hundreds of miles to obtain data, that he will issue his prints in silver and not in carbon; at the same time he firmly believes that the general use of carbon, when that process of printing is perfected, is but a question of time. It will, perhaps, be in the recollection of most of my readers that it was Mr. Fry who inaugurated the discussion on carbon printing which took place at a meeting of the Photographic Society of Great Britain about sixteen months ago, in the course of which discussion statements were made and specimens exhibited calculated to induce any one to imagine that the photographic millenium had at last arrived. Yet little more than a year elapses ere Mr. Fry speaks patronisingly of it as something that in course of time will come up to the surface when it is "perfected." May not poor carbon well exclaim—*Et tu Brute?*

The term "sal soda" has greatly "exercised" me of late. It is an American term, but as it is sufficiently expressive I see no reason why it should not be acclimatised in this country. From all that I can see it bids fair to be much used, inasmuch as the thing signified is likely to form a component part of the alkaline pyro. developer. The name is far from being all that might be wished, but it is greatly preferable to "washing soda." To designate it as "carbonate of soda" would mislead, as this term is already claimed by the bicarbonate or "baking soda." Then the simple "soda" might also mislead, owing to the bad habit into which photographers have got of using this terse term in connection with the hyposulphite. Many foolish words have been imported into photography, and it may be sometimes expedient to employ terms that do not quite partake of scientific accuracy; hence, if we can swallow "squeegee," there does not appear any strong reason why we should strain at "sal soda." So much for the name; now for the thing itself—of course as an element in the composition of the alkaline developer. I have used it very much of late, and prefer it greatly to carbonate of ammonia, over which it possesses this great advantage—that being stable while in solution a large quantity may be prepared at a time, and it may be left uncorked and uncared-for on the shelf of the laboratory without becoming deteriorated or losing its activity. This cannot be said of the solution of the ammonia salt.

* Concluded from page 208.

THE PRACTICAL WORKING OF THE COLLODIO-BROMIDE EMULSION PROCESS.

[A communication to the Edinburgh Photographic Society.]

I have been asked to give—not certainly a paper on the collodio-bromide emulsion process, but to show my mode of working it. I do so with the greatest reluctance, as the subject has been discussed so often that anything I can say will be just a repetition of what has been said before. It has now been before the photographic world for nearly fourteen years, and during that time has been brought out in many different forms. I refrain from touching on these, as it is sometimes in connection with photographic processes no easy matter to give honour to whom honour is due.

It is now two years since my friend, Mr. Aird, gave me the formula which I at present work. At that time nobody here thought of working anything but Mr. W. H. Davies's beer and albumen process, with which fine work was done; and when I discovered that I had to make the collodion and, what appeared worse, to test the emulsion, I believe I would never have tried to get over it had not Mr. Aird showed me the whole process.

Well, with his assistance, I am just going to do the same thing here; and from the many inquiries which have been made since I showed the work I had done last season, I know that a few more of my amateur friends, when they see the simplicity of making the plates, the beauty of development, and the certainty of results, will give it a trial. A process which has these advantages has certainly a great deal to recommend it, especially when you read a confession like that which appeared in last week's number of The British Journal of Photography, from one of our ablest experimentalists; I refer to Mr. Henry Cooper, who says that with washed emulsions he has, after hundreds of experiments, never been able to depend on plates that have been prepared for more than a few days. Now with this you can keep the plates for a year at all events, and, contrary to the opinion of many, this emulsion will, if properly prepared, keep good for many months. A friend of mine used some that had been kept for a year, and could see no difference in the results from the plates he made and used when the emulsion was new. Now I think this is an advantage that will amply recompense you for the little extra trouble in preparing it.

Professional photographers will, I also hope, be induced to turn their attention to it; for, with a few plates prepared at some time when other business is quiet, they would be ready to do any outdoor work that was wanted—a thing which many of them at present decline to undertake on account of the trouble in taking all the paraphernalia requisite for the usual wet process. I further think the process would be well suited for enlargements. Transparencies, both by contact and in the camera, can be very easily produced by it, and if you have got a good transparency I think any one could with little expense have the means of doing enlargements up to (say) 24 × 18 inches.

I may say I have found these plates no more sensitive in their wet state than when used dry; and lately, when trying them wet, I could not by any possibility keep the film on the plate, but when allowed to dry they would stand any amount of washing.

I will now give you a practical illustration, and will begin with the collodion, a stock of which should be kept on hand, as it improves greatly with age, and it is just as easy to make a large as a small quantity. Our manufacture in the present case, however, will be on a small scale—for the sake of convenience say two ounces. For this quantity I will take four drachms of alchohol. We will now have to weigh our bromides; but, unfortunately, the cadmium salt generally sold is not anhydrous, and we therefore take a small quantity into this small evaporating basin and apply heat, which will soon drive off the moisture. Take twelve grains of this and six grains of bromide of ammonium; mix them together, which seems to make them more easily dissolved. Add this to the alchohol, and then put in twelve grains of pyroxyline, which does not require to be any special kind. This will readily dissolve. Then add twelve drachms of ether, and this is your collodion.

We will now emulsify it; and for the two ounces take twenty-four grains of nitrate of silver, put it into a test tube, dissolve in the smallest quantity of water with the aid of heat, and then add four drachms of alcohol. Boil over a spirit lamp; then add this to (say) one and a-half ounce of your collodion, shake well, and in a few minutes add the other half ounce of collodion. This method of emulsifying seems to give a more sensitive film and finer deposit than if you had added the silver to the full quantity of collodion.

Now for the testing, which frightens so many. Could not some of you give the experiment a better name? I think if it were just said "we will see if the emulsion is right," it would be better. Take a little of it in a measure glass, run it round the glass till a thick film forms, then add a little distilled water; break the film well up, and decant a small quantity into two test tubes. To one add two or three drops of a twenty-grain solution of silver; to the other add the same quantity of bromide of potassium. Should either of them be the least milky there is an excess of the opposite material to that with which it was tested; that is, if the tube be milky to which the silver was added there would be excess of bromide, for which the remedy is to add a little more silver. If the tube to which the bromide was added be milky then you have excess of silver, and require to add a little more collodion. Should the tubes remain clear then you may consider you have your emulsion in its most sensitive state. It should now stand for twenty-four hours at least, during which time you can give the bottle an occasional shaking. Filter through linen, and you are now ready for preparing a batch of plates.

Keep always a supply of clean plates in your box. I prepare mine by soaking them in very dilute sulphuric acid. If they have been varnished put them in a solution of warm water and washing soda, which will soon take the film off; then rinse in cold water, and put them into the acid. When wanted I take them into the washing-house, put the plate on the bottom of a tub, give it a good scrub with a hard brush, rinse with water, drip, and then flow it over with albumen. When dry they are ready for use.

You can now coat the plate with the emulsion. This must be done slowly, as if you tilt the plate suddenly, the same as you might do with wet collodion, there would be a mark made at the top of the plate. Allow it to set well; then plunge it into a dish of water. Take as large a vessel as you can get, and you can then go on coating the plates till your vessel is full; but they should remain in this till greasiness disappears. Take your first coated plate out, drain, and flow over with preservative. Almost any of the usual preservatives will do, but I use bitter beer. It needs no alcohol to moisten the plate before development, and works nice and clean without any restrainer in the developer. You have only to flow it over once or twice, and put it aside to dry.

Like most dry plates these require a backing of some colouring matter to prevent blurring—say a little burnt sienna, to which has been added a little gum to make it adhere, as also a small quantity of alcohol, which allows it to dry quickly as well as helps it to keep.

The plate is now ready for exposure; and although these are, perhaps, not the most sensitive plates you can get, yet my impression is that as you increase the rapidity you also increase the uncertainty. I have two plates with me to develope that were exposed yesterday with Dallmeyer's $8\frac{1}{2} \times 6\frac{1}{2}$ rapid rectilinear, stop $\frac{1}{18}$ focal length, for one and a-quarter minute, and I am quite sure they will be fully exposed.

The development of these plates is, you will see, so simple and beautiful that I do not think any of you will envy those who go in for some of the new processes, where they have almost to work in darkness, and turn up the back of their plates with the expectation of seeing a "ghost." In most cases you only require two solutions in developing—one a saturated solution of carbonate of ammonia, and the other a sixty-grain solution of pyro. in alcohol.

I will now try and develope this plate. First wipe off the backing with a wet sponge; moisten the film with water, or rather wash it till all greasiness disappears. Now take a quantity of the ammonia solution, to which add a few drops from the pyro. bottle; and then flow it with a good sweep over the plate. The image will soon appear, and will rapidly gain in intensity as well as in detail. If the plate be properly exposed it will require nothing further; but should all detail come out without sufficient density, owing to the plate being over-exposed, you had better wash and apply the usual acid pyro. and silver intensifier, not forgetting to swill the plate with weak acetic acid, to neutralise the ammonia that may be left in the plate, before applying the intensifier. You can fix with hypo. or cyanide, but I prefer hypo. ALEXANDER MATHISON.

A PHYSIOLOGICAL HINT TO PHOTOGRAPHERS.

DISCOMFORT, amounting in many persons to actual distress, is experienced in sitting for a photographic portrait. The eye is fixed on a certain spot, and, whilst staring at this, vision becomes indistinct, surrounding objects especially being lost in a thickening mist. A feeling of giddiness, and even of faintness, is apt to follow if the sitting is at all prolonged. Whilst undergoing an ordeal of this kind a few days ago, in Mr. Fradelle's studio, the idea came across me that this strain was unnecessary, and could be avoided by a simple contrivance. Having begged a piece of paper, and drawn upon it a circle of about four inches in diameter, I converted this into a sort of clock face by adding the usual Roman figures in their accustomed places. The paper was then nailed to a post about eight feet distant, and when the sitting began I first fixed my eyes upon the figure XII, then upon I, II, III, and so on, "all round the clock," the gaze shifting leisurely from one figure to another. As I had anticipated, the sitting ended without any sense of strain, mist, or giddiness having been felt; and in place of the eager longing for release usually experienced it seemed to me that I could have sat on without effort.

As Helmholtz clearly puts it, "to *look* at anything means to place the eye in such a position that the image of the object falls on the small region of perfectly clear vision. This we may call *direct* vision, applying the term *indirect* to that exercised with the lateral parts of the retina—indeed, with all except the yellow spot." The mistiness which occurs when the gaze is long fixed in one direction appears to come up from the periphery of the field of vision. This means, probably, that the fatigue of the nervous element is shown first in those portions of the retina which are least highly developed, and where vision is indirect. These parts in the ordinary method of procedure are subjected to a constant strain for a period which frequently amounts to sixty or seventy seconds. By the plan which I adopted, each movement of the eye which brought a new clock figure upon the yellow spot, necessarily shifted also the position of all surrounding objects in relation to the rest of the retina, fresh points of the nervous layer being thus presented to the action of luminous rays every three or four seconds. Hence, fatigue of the nervous element never had time to occur. On the other hand, the rotatory movement of the eyeball in adapting itself, step by step, to the figures upon so small a circle at such a distance was so excessively fine as to cause no interference with the photographic process. Mr. Fradelle, who has since applied the suggestion in many other cases, writes me that "the eyes are excellently well defined, even to the iris; not alone yours, but all the pictures I have taken since have a marked superiority over those I had previously taken in the manner in which the details of the eyes are reproduced. In my opinion, the success of your idea is unqualified. I have questioned my sitters after the operation, and they express themselves as not having had any strain upon their eyes."

It is evident that the plan described is likely, incidentally, to prevent to a great extent the staring expression which the face assumes when the gaze is longed fixed upon an object; for it combines a certain amount of free play of the eyes with accuracy of photographic definition. A somewhat larger circle, I have no doubt, may be employed with even greater advantage; and printed words, pictures, or other objects may replace the figures. For children, and others who do not easily follow directions, a disc with a single aperture towards its edge might be made to revolve in the direction of the hands of a clock before another disc prepared with pictured objects of some kind or other, so that one would appear at a time at short intervals of space and attract the eye. Various other modifications, indeed, at once suggest themselves as feasible, so long always as the figure towards which the gaze is directed presents a *succession* of objects arranged in a circular form.

—*Lancet*. THOMAS BUZZARD, M.D.

ASTRONOMICAL PHOTOGRAPHY.

An interesting course of lectures upon astronomical photography has just been delivered in the Theatre of Gresham College, Basinghall-street, London, by the Rev. E. Ledger, M.A., F.R.A.S., Gresham Professor of Astronomy. The following is the complete syllabus of each lecture of the course.

Lecture I., April 30.—The importance of photography in connection with astronomy. Various photographic processes. The first photograph of the moon taken by the daguerreotype process. The collodion process now chiefly used. Description and practical illustration of the *wet* collodion process. Its special advantages in certain astronomical observations. Explanation of the production of an invisible photographic image by the action of light on molecules. Also of its subsequent development and intensification or building-up. False effects may thus be easily produced in astronomical photographs. *Dry-plate* processes. Their advantages. Illustration of the process used in the recent English transit of Venus expeditions.

Lecture II., May 1.—The nature of light. The actinic or photographic effects of different parts of the spectrum or of differently coloured lights. Importance of such effects in the construction of telescopes for celestial photography. The action of prisms and lenses upon light. Achromatism. Reflecting and refracting telescopes. Necessary difference in refracting telescopes made for eye-observation or for photography. The actinic or photographic focus of an ordinary telescope. Equatorial mountings, heliostats, and other apparatus required. Special arrangements for photographing the moon, the sun, and the spectrum of the solar light respectively,

Lecture III., May 2.—First successes in celestial photography. Records of sun-spots by means of photography and otherwise. Their periodicity. Discussion of their possible causes, and their relation to planetary action, terrestrial magnetism, auroras, meteorology, famines. The recent extraordinary success of Janssen in photographing the sun. Exhibition of some of his results. The probability that the condition of the general surface of the sun as thus shown is of more importance to us than the number or size of the spots upon it.

Lecture IV., May 3.—Photography as applied to the observation of solar eclipses. Exhibition and discussion of the results obtained in 1860 and since. Photographs of the solar prominences. Increasing success in photographing the corona. Exhibition of a photograph of the transit of Venus, and of a Janssen plate of photographs in successive seconds taken by the English expeditions. Discussion of the difficulties involved in such photography. The effects of diffraction, of the atmosphere of Venus, and of the atmosphere of the earth. The coming transit of Mercury. Photographs of the moon taken at Melbourne, and by Rutherfurd and others. Stellar and planetary photography. Recent advances in spectrum photography. Oxygen in the sun.

The lectures were free to the public, and were illustrated by means of the lime-light.

Of the first lecture the *City Press* says:—The lecturer, after a lucid explanation of the importance of photography in astronomical observations, described the various photographic processes which had been found applicable, and showed with a powerful lens on a proper disc the first photograph taken of the moon by the daguerreotype process. He also, by the same means (taking certain observations of the planet Saturn and its ring), exhibited and described the "wet" collodion process. He also explained the advantages of the "dry" process, in which, by means of white of egg and washes of beer, plates could be prepared beforehand and used, without loss of time, in succession, in such a lengthened observation as that by which the transit of Venus was lately recorded. The cleverness of the illustrations and the value of the explanations were testified to by repeated applause.

On Friday last the concluding lecture was delivered to an attentive audience. The illustrations by lime light were numerous and interesting; indeed it was evident that the Rev. Professor had gone into the subject with great energy. He paid a graceful tribute to the men of philosophical position who had made photography so useful, such as Secchi, Janssen, Abney, and others. He exhibited the photographs he had received from Rutherfurd, Draper, &c., of America; from Professor Piazzi Smyth, Astronomer-Royal of Scotland; Professor Airey, Astronomer-Royal of England; and concluded with Mr. Browning's photographs of Mars. The lecturer stated his desire to make the course one of clear exposition of the way the sciences accorded with each other to develope to our minds the connection of the laws of the universe; and, while he acknowledged the attention of his hearers, he hoped his reward would be to have awakened enthusiasm in some of his audience who would appreciate the progress of science. The enthusiastic Professor was rewarded with hearty applause at the conclusion of the lecture.

Our Editorial Table.

A Manual of the Carbon Process. By Dr. Paul E. Liesegang.
London: Sampson Low, Marston and Co.

In this admirable work will be found an immense store of information relating to the important subject of carbon printing. The treatment is such that the work forms an excellent history of the art, an invaluable manual for the carbon student, and a useful work of reference for the advanced printer.

Its appearance in an English form is owing to the fact of the translator, Mr. R. B. Marston, having had some of his negatives printed in carbon, he was so much struck with their beauty that, when afterwards meeting with a copy of Dr. Liesegang's *Der Kohle-Druck*, then in its fifth edition, he formed the determination of translating and publishing it in England. This, from his connection with the eminent firm by whom the work is published, Mr. Marston was easily enabled to do. The work is "got up" in an admirable form, is well printed on toned paper, and contains numerous useful illustrations.

Having completed the historical portion of the work, Dr. Liesegang describes in what manner work-rooms should be fitted up, passes on to the various preparations required in carbon printing, devotes a chapter to the making of carbon tissue in various colours, describes in what manner single and double transfer papers are prepared, and, after remarks upon the best methods of reversing, multiplying, and detaching negatives, enters upon the details of printing in its various ramifications. In this department of the work such subjects as photometers and printing and tinting-frames receive due consideration. Transparencies next claim the attention of the author; and having treated on enlargements, he closes with a useful chapter on *Failures and Remedies.*

In the above manner have we epitomised the contents of a work containing upwards of a hundred and forty pages. The author endorses the opinions we expressed some years ago when we spoke of the value of white "alba plates," or enamel tablets, as a base upon which to develope carbon pictures. Here is what he says respecting this:—

"Instead of on to transfer paper, the carbon print adhering to the flexible support may be transferred to any other surface which has been coated with gelatine.

"A fine carbon print on an alba plate has an extremely charming appearance. These plates are ferrotype plates coated with a delicate white lustreless enamel. They can be coated with collodion like glass and a carbon print developed thereon, only the picture will then be reversed. To obtain a correct picture the print must be developed on the flexible support and, after drying, transferred to the enamel plate, which must in this case have been previously coated with gelatine. The gelatine should be used in a two-per-cent. solution, and just before use a little chrome alum* solution added whilst the mixture is stirred. It should be put, while still warm, on the enamel with a broad brush, and allowed to dry. The flexible support with the adhering tissue and the gelatinised enamel plate are placed in cold water, and, under water, the two prepared surfaces are brought together. Both are then taken out and allowed to dry; the flexible support can then be taken off and leaves the print on the enamel.

"In the same way any carbon print can be transferred *from the flexible support* to canvas, opal glass, porcelain, and other surfaces, provided they are previously coated with the gelatine solution."

On the subject of toning and intensifying carbon prints Dr. Liesegang says:—

"A carbon print on clean (plain) or collodionised glass can be intensified in various ways; in proportion to its thickness the damp gelatine will absorb both fluid colouring matters as well as solutions, which by double decomposition yield coloured deposits.

"The object of the colouring may be both to give the print another tone and strengthen or make it more vigorous.

"A solution of permanganate of potash poured on to the damp carbon print changes its colour to olive green. This shade, though unpleasant to the eye, is yet of great value in multiplying negatives, as it imparts photographic, though not visible, vigour to the print.

"A fine purple is obtained by employing solutions of purpurine or of artificial alizarine diluted with water. Many aniline colours yield extremely pretty shades; but the want of permanency renders their employment unadvisable, especially in prints which are much exposed to light.

"Laurent recommends dipping the picture into an old iron solution (developer), and, after washing, pouring gallic acid over it. This plan has been improved upon by Monckhoven, who steeps the print for five minutes in a solution of four parts of persulphate of iron (not to be confounded with the usual protosulphate of iron) in 100 parts of water, rinses for an instant in cold water, then steeps it for ten minutes in a two-per-cent. solution of carbonate of soda, again rinses in water, then places it in a one-per-cent. gallic acid solution until it assumes the desired dark violet tone. The print is then washed and dried.

"Pictures on glass to be intensified in this way should not be printed too dark.

"A very beautiful blue-black colour is obtained as follows:—Logwood extract is dissolved in warm water and allowed to get cold. This solution is poured on to the damp print; after a short time it is rinsed with water and a solution of bichromate of potassium poured on. This treatment may be repeated several times, but not *too* often, or a deposit will form on the gelatine film. Prints so treated gain in vigour wonderfully.

"As before mentioned, the damp picture can also be intensified with pyrogallic acid and silver, like a collodion negative." †

* Three hundred grains of gelatine in twelve ounces of water, to which is added a solution of fifteen grains of chrome alum in half-an-ounce of water,

† Herr von Stefanowski has described a large number of different methods of intensifying carbon prints.

From the brief extracts given may be formed some idea of the value of this very practical manual of carbon printing, which is published at a very opportune period.

Hints on Reflecting and Refracting Telescopes.
By W. H. Thornthwaite, F.R.A.S.
London: Horne and Thornthwaite.

It is somewhat difficult to imagine the existence of a telescope unrepresented in this treatise, which bristles throughout its hundred pages with useful information in connection with reflecting and refracting telescopes of every kind and equatorial stands, accompanied by explanatory diagrams. It forms the most pleasant and not the least profitable reading on the subject of telescopes that we have ever met with, besides being highly suggestive. The work embraces various formulæ for silvering glass mirrors, for we need scarcely observe that silvered glass mirrors have now superseded the time-honoured metallic specula in reflecting telescopes. It also contains, in tabulated form, a list of those stars that are used as tests for separation, definition, and illumination, together with numerous hints on the treatment of telescopes. The present edition is the third, and it has been much enlarged and improved.

The "Bennett" and "Swan" Dry Plates.

When the gelatine process was commercially introduced a few years ago we well remember Mr. Kennett complaining, with no small degree of bitterness, that he could not induce photographers to expose their plates for a sufficiently brief time. In every instance, he said, in which a failure occurred it arose from over-exposure. He met this "sin of unbelief" by introducing plates which would bear a protracted exposure—an exposure equal to, if not exceeding, that required for wet collodion. Even this, it must be admitted, is very rapid for *dry* plates, which have hitherto been associated with the idea of very prolonged exposures.

When in our issue for March 22 (page 134) we noticed certain pictures that had been exhibited at the South London Photographic Society by Mr. Bennett, who subsequently presented to the readers of this Journal the details of his *modus operandi*, a revolutionary step seemed to have been taken; for pictures on dry plates of interiors by gaslight, and of river scenes taken by the action of a drop shutter, transcended the popular idea of the capabilities of dry plates. Following close upon this we have the announcements—made in connection with the commercial aspect of photography—that the Liverpool Dry Plate Company on the one hand, and Messrs. Mawson and Swan on the other, are issuing dry plates of exquisite sensitiveness, and it is our privilege at the present time to speak of trials made with the dry plates of these firms which have been sent to us for "review."

Mr. Mawdsley's plates, we are informed, are prepared on the basis of the directions given by Mr. Bennett in an article in our number for March 29th. These plates, it is said, "will prove invaluable to professional portrait photographers, who are many times called upon to take the portraits of nervous or paralytic persons, or of fractious children, in the photographing of whom the ordinary wet collodion, sensitive though it be, proves too slow." This certainly is a very strong statement, and indicates in unmistakable terms a decided advance upon the rapidity of wet collodion.

"Swan's plates" (manufactured and sold by Messrs. Mawson and Swan) are also introduced to us in very strong terms of commendation. In brilliant noonday light, we are told, and using a quick-acting lens, views of the sea with shipping, and street views with moving figures, may be secured; a fraction of a second will suffice for the duration of the exposure in the camera.

We have tried, very carefully, both the "Bennett plates" and "Swan's plates." We have given to both of them exposures which have been *exceedingly* rapid, and in both cases we obtained most excellent negatives. The "Bennett plates" have a glassy surface; in "Swan's plates" the surface partakes of a slightly mat appearance. When using some excellent ferrous-oxalate developer sent by Messrs. Mawson and Swan with the "Swan's plates" we found that the image appeared very soon after it was applied, and that this image, which was on the surface, took some little time to reach the back of the film. To ensure the perfect development of a picture Messrs. Mawson and Swan recommend that a bath be employed, and that an immersion of from five to fifteen minutes be given. The "Bennett plates," owing to a difference in the permeability of the film, are acted on throughout the thickness of the pellicle with great rapidity. Our experiments with these plates have not been quite so complete and exhaustive as we should have liked them to be, owing to the inclemency of the weather at the time we had set apart for trying them on landscape subjects; but we have seen enough to enable us to speak with certainty concerning their merits, and by the time we have used up the samples with which we have been furnished we shall be enabled to speak more positively with respect to them.

In using such sensitive plates it is of the utmost importance that the light in the dark room be very much subdued; if professional wet-plate portrait photographers fail with them it will be owing to the amount of light usually present in their dark rooms. We shall return to this subject.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
May 14	Photographic Society of Great Britain	5a, Pall Mall East.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

The usual monthly meeting of this Society was held on the 2nd inst.,—the Rev. F. F. Statham, President, in the chair.

After the transaction of private business Mr. William Brooks read a paper on the *Reproduction and Enlargement of Negatives by the Collodio-Emulsion Process.* [See page 219.] During the reading of the paper specimens were handed round for examination.

The Chairman thought that they could not have better or more perfect specimens than those exhibited, and thanked Mr. Brooks for his paper.

Mr. Bridge had worked very successfully by artificial light in the way suggested by Mr. Brooks.

Mr. Foxlee up to the present time had imagined that nothing could equal carbon as a process by which to obtain a good enlargement, but it was evident that the emulsion process was quite as good. He inquired by what process—whether by wet collodion or emulsion—the negatives were obtained from which were produced the enlargements then exhibited.

Mr. Brooks said they were by the wet collodion process; but if he were taking negatives with the view to their being enlarged he would certainly employ an emulsion process. Mr. Foxlee, he was aware, had by the wet collodion process obtained negatives in which the deposit was a mere stain.

Mr. Foxlee said that in doing so he had employed a purely iodised collodion and pyrogallic acid development, the resulting pictures being composed of silver in a state of division so minute that Mr. J. T. Taylor had pronounced it to be a stain.

Mr. J. T. Taylor considered that the term "stain" was applicable to Mr. Foxlee's negatives only when examined by a low power under the microscope. But when a high power was employed the atoms composing the image were plainly visible, hence the term "stain" was inadmissible either in this or in the albumen process, in which the atoms were equally diminutive.

Mr. W. M. Ayres spoke of the great advantage of using only a very small quantity of pyrogallic acid when developing emulsion plates.

Mr. F. Wratten confirmed this statement. A weak solution of pyrogallic acid possessed great power in developing a feebly-impressed image.

Mr. Brooks advocated the system of duplicating negatives before sending them to be printed from. There was no trouble in taking a transparency, from which negatives could be made whenever required. He much liked the use of moist emulsion plates. They were treated, after collodionising, with a mixture of one part of glycerine and five parts of water. He used cheap glycerine at tenpence per pound.

Mr. Harrison exhibited a simple yet effective double dark slide for the camera; after which the proceedings terminated.

EDINBURGH PHOTOGRAPHIC SOCIETY.

A meeting of this Society was held in 5, St. Andrew-square, on the evening of Wednesday. the first instant,—Mr. Muir in the chair.

The following gentlemen were unanimously elected members of the Society:—Messrs. W. Gibson, C. N. Byrne, John Anderson, Alex. Craig Christie, Alex. Mitchell, Robert Wallace, James S. Sutherland, John Masterton, John Ancrum, H. S. Pillans, Wm. Jenkinson, P. Canning, J. R. Cooper, J. T. Gerard, — Ross, and Henry White.

The whole evening was devoted to an interesting demonstrative lecture by Mr. Alex. Mathison, who entered fully into the most minute details of the collodio-bromide emulsion process as practised by himself, illustrating practically the manufacture of the plain collodion, the salting and sensitising of it, the testing of it when made, and so on in all its stages to the final development and finishing of the negative. From the great interest manifested and the eager attention with which every detail was followed by the large number of amateurs present, it may be anticipated that this process will receive even more attention than it has hitherto done, although for some time past it has been the established favourite of the Society. For Mr. Mathison's paper see page 220.

Mr. T. Pringle said that all present must have been greatly benefited by the most explicit demonstration just witnessed. He had always found Mr. Mathison very anxious to give all the information in his power, and on one occasion he (Mr. Mathison) had supplied him with a batch of plates. He had found them so very simple to manipulate, and so certain in results, that he was quite enamoured with the process. While allowing that it might not be the most rapid process known, he thought there was not one process that was so certain to produce perfect results by such simple means and with such little trouble.

Mr. M. G. Dobbie considered the Society was under a deep sense of gratitude to Mr. Mathison for the very graphic manner in which he had experimentally illustrated all the minutiæ of the process. It was another valuable communication of an intensely practical nature, enabling those present to carry away with them something tangible, to be utilised in the future daily experience of all interested in their fascinating art-science.

Mr. Aird acknowledged the kindness with which Mr. Mathison had so courteously associated his name with the process, but he considered that gentleman was too modest in his estimation of the part he himself had played in advancing the merits of the process so persistently, as it was greatly due to his (Mr. Mathison's) personal exertions that the Edinburgh Photographic Society had so largely adopted it. He, however, thought that Mr. Mathison had scarcely done justice to its capabilities when he described it as "slow." He believed it was not only the most reliable process known, but he had practically proved it more sensitive than some of the most celebrated gelatine processes; and he considered that if the exposure of the plates developed before the Society had been very greatly reduced, equally good negatives would have resulted by somewhat prolonging the action of the developer.

Mr. W. T. Bashford (Corresponding Secretary) congratulated Mr. Mathison on his very successful demonstrations. He had often before borne testimony to the remarkable simplicity of the operations and the beauty of the results. He was glad to find that the process was at last taking the position it deserved. A gentleman at a distance, knowing the great interest the Society had taken in the emulsion processes, had forwarded a very fine twenty-four-inch enlarged negative, which he submitted to the criticism of the Society, and bore testimony, similar to the large negatives exhibited by Mr. Mathison, that very large plates could be coated by collodio-emulsion without any defect whatever. The emulsion used in that particular instance was Mr. Brooks's emulsion, and possessed the very remarkable property of needing no substratum or edging. His correspondent wrote as follows with regard to enlarged negatives by wet emulsion:—

"The transparency is made by contact on an emulsion plate (dry) in an ordinary printing-frame, and developed with alkaline pyro. (carbonate of ammonia being the alkali used). The enlarged negative is made with ordinary apparatus. I used a room with the camera and focussing arrangement fitted to a shutter that is fitted to the window. An upright easel on castors runs the whole length of the room. This system has been described many times, and needs no further comment. The glass plate neither requires a substratum or edging with india-rubber, and there is no fear of the film slipping, as it sticks to the glass like wax. The plate is coated with collodio-bromide emulsion, and as soon as set it is placed in a large dish or tray of water. I use a wooden tank lined with zinc. The plate is allowed to remain for about a quarter of an hour; it is then moved about, and when all greasiness has disappeared it is taken out, drained, placed on the easel, and the exposure made. An emulsion used in this way requires only a short exposure. It is then developed with alkaline pyro. (carbonate of ammonia and common washing soda being used), and then fixed with hypo."

Mr. J. R. Crighton exhibited four very choice views taken at the recent outdoor meeting held at Rosyth Castle, the property of the Earl of Rosebery. This was the first of the season. The pictures were greatly admired for their composition and feeling, and it was remarked that in general effect they had more of the picturesque than is ordinarily obtainable.

With the usual votes of thanks the proceedings were concluded.

BRISTOL AND WEST OF ENGLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

The ordinary monthly meeting of this Society was held at the Museum, Queen's Road, Bristol, on Wednesday, the 1st inst.,—Colonel Biggs in the chair.

The minutes having been read and confirmed the Rev. C. Harg, of near Frome, was elected an ordinary member, and Mr. L. Miles, of Cardiff, a corresponding member of the Society.

Colonel Biggs then read a paper entitled *On the Calotype Process* [see page 218], which explained in a most clear and practical manner the whole formulæ and details of the process, and which was a most interesting communication. The enjoyment of the paper was also greatly heightened by the presence of a large number of exquisite productions of Colonel Biggs, taken while in India, the majority of the pictures being of large size. It was remarked by many that it seemed a great pity that a process yielding such beautifully-harmonious pictures should have fallen almost entirely into disuse.

Mr. Holt suggested an attempt at finding some suitable flexible substance, instead of glass, between which to expose the sensitive paper, as then it might be used with a roller dark slide.

Colonel Biggs feared that could not be effected, as the paper must be kept damp, therefore considerable compression was required.

Mr. H. A. H. Daniel remarked upon the great delicacy of detail and beautiful atmospheric effect obtained in the negatives placed before the meeting, and said that everyone must have noticed the great absence of granularity in the appearance of the pictures. He considered that for large work the results could be considered very little, if at all, inferior to those of glass negatives.

Colonel Biggs pointed out the great advantage of the extreme lightness of the sensitised surfaces as compared with a box of (say) 15 × 12 dry plates.

Mr. E. Brightman said that since he had seen one or two of the very fine results exhibited by Colonel Biggs at a previous meeting he had many times felt very anxious to make a trial of the process which Colonel Biggs's valuable paper had now rendered not only possible but most clear.

A vote of thanks was accorded to Colonel Biggs for his most interesting and instructive paper.

The Secretary then reminded the members that was the last indoor meeting of the session, and that after a Council meeting had been held the first outdoor meeting would probably take place in the first week of June.

Correspondence.

THE FRENCH EXHIBITION.—MEETING OF THE PHOTOGRAPHIC SOCIETY OF FRANCE.

On the 28th ult. I paid a visit to the *Exposition Universelle* in the palace of the Champs de Mars, and in the British section there were no photographic prints visible—the screens to which they were to be suspended not being then finished; in fact, French workmen were engaged nailing on rough canvas and papering. This last is of a warmish, flat colour to relieve the tone of the proofs. The screens—fourteen in number, and open at the bottom—are about seven and a-half feet high and about nine feet long, surmounted by a black moulding. They are movable, being supported upon scrolled feet, both sides of the screens being available as hanging surfaces, and therefore balancing each other. They will occupy the floor space between the court of the noble display of drawings for the *Graphic* and the upright window forming part of the Street of the Foreign Nations. The screens are to be placed at right angles thereto, and therefore having, like a portrait studio, a very high northern side light very suitable for the uniform lighting of the photographic specimens which will be exposed for our admiration.

The old saying that "one volunteer is worth a dozen pressed men" will again be verified, for a distinguished photographer having offered his services to hang the pictures sent in by British photographers, and which having been accepted by Mr. Cunliffe Owen, I am sure that what man can do in the very limited time left, whether his tastes be of the school of Young England or of Old England, will be ably and efficiently done to the best of his talent. I think I have sufficiently named Mr. William England, who will be aided by his *confrères*, Messrs. Payne Jennings, Warnerke, and other English exhibitors.

During the same visit, and likewise on a previous occasion, I had the pleasure to see completed with its noble contents the exhibition of Mr. J. H. Dallmeyer, and which, amidst the astonishing chaos around it, is seen to great advantage. For the early completion of this show-case great credit is due to the exhibitor's son, Mr. Andrew Dallmeyer, whose activity under trying circumstances is very praiseworthy, and who was well seconded by one of the *chefs d'atelier*, Mr. Ford. The automatic equatorial appears to be of marvellous construction, having the seal which also stamps the production of this celebrated optician, including his photographic lenses, telescopes, microscopes, view searcher, &c. I also remarked the show-case of Mr. Dolland, with its thermometers, field glasses, levels, burners, &c., but which were, like a lady's hair on the eve of some grand display, still in paper.

Mr. T. J. Middleton has a well-got-up triple lantern, designed by Malden, consisting of French polished mahogany body and brass fittings. The back of the show-case being a large mirror enables the visitor to see the back of the lantern, with its electric gas tubing and stopcocks, without changing his position. It is accompanied by numerous examples of lantern slides.

The colony of Victoria has already arranged a large collection of photographs of her public buildings, country houses, and scenery. There are views in Melbourne equal in artistic merit to anything in the old country. I was pleased with a photograph of Sargood, Son and Co.'s stores, Melbourne, which possesses a fine Italian palatial front of great architectural beauty. This picture, and also that of the classical elevation of the Mint and the town residence of Dr. Beanay, are by Mr. C. Nettleton, photgrapher, and are worthy of praise. The city of Sandhurst and the borough of St. Kilda have sent frames of interesting prints, among which are the great Yen Year reservoir and the residence of Mr. Twentyman, which display great taste. There is a frame from the borough of Echuca connected with the united shire of Metcalfe, the shire of Colac, and other subjects. This Victoria collection occupies a wall space of about twenty-four yards long, and was the first I saw completed, which is highly creditable to the representative of a country one of the farthest from the place of exhibition.

Sydney, New South Wales, is largely illustrated. Owing to its great size the eye is at once attracted to the panoramic view of Sydney harbour and suburbs, photographed by Mr. Charles Baylis. The work is about eleven yards long and in twenty-three pieces. This print, which is attached to a flat wall, would have had its importance and value increased had it been exposed upon a circular surface like a diorama, which would admit at the same time of arrangements to increase the appearance of reality. The work of the photographer is meritorious, but he should have reduced the darker parts of the margins of the several pieces to conform with the tone of the central parts. There is a copy from a negative five feet by three feet two inches in one piece—a view taken from the same residence and by the same photographer—which in its immensity and excellence I have not seen surpassed in Europe, and here the defects I have alluded to in the panorama do not appear. Mr. Greenfield's name is on several frames of enlarged portraits, and Mr. Hubert Newman, photographer, of Sydney, exposes some really excellent large portraits direct from life, and which display fine artistic qualities, the sizes being about 20 × 15 inches.

In the section of the United States the only display of photographic prints I saw during my recent visit was some that were utilised above the cornice, and forming part of the glass show-case of Mr. Mohr, of Philadelphia, which contained their manufactures, and the photographs showed the different *employés* of the establishment in which their goods were manufactured. The idea is excellent.

In the Spanish department I only saw the photographs of Ortega, Otera, and the good work of Alviach.

In the Hungarian section were already placed the show of Kozic, of Pressburgh, and Zansboni, of Fiume.

The Austrian photographic display is in an outer building, and is under the able direction of Dr. Hornig, who, I find, has been promoted to the rank of Colonel.

In the Russian department will be found the name of Count Lewitsky, whose name is highly esteemed in France, and who will represent his country here as juror—the same office he so well filled at Vienna, where he gained universal approbation by his knowledge and great courtesy to his colleagues. M. Lewitsky first introduced negative pencil retouching in Paris, having learnt it, when he was an able and rich amateur and Grand Seigneur, from a young English lady who practised photography professionally at Naples, and whose talent was so highly appreciated that an appointment for a sitting could not be secured under three weeks. This lady's name, if I recollect rightly, was Young, but she was best known under a French translation as Mademoiselle Lejeune.

In the French portion of the photographic display very little progress has been made, owing, in a great measure, to the delay of the administration in the construction of a staircase up to the top of the roof for repairing and cleaning purposes, and which prevented the court being finished, and at the same time occasioned great quantities of dust.

I again made a tour of the palace on the 30th of April, the day and evening before the opening day, and found my expectations as to the English section gratified, for Mr. England and his associates had in two days made considerable progress, and it was my privilege to see, among other contributions, those of Mr. William Bedford, who makes a goodly show. Amongst the exhibits of the London Stereoscopic Company are portraits of the Beaconsfield Cabinet. Mr. A. L. Henderson exhibits enamels; M. Bardoux, of Jersey, shows chromotypes; Mr. Carl Norman agricultural specimens; and Mr. Faulkner a large collection of portraits of children and fine enlargements. The Autotype Company contribute collotypes and an enlargement of the Princess of Wales. Mr. Samuel Fry shows three *genre* pictures, and Mr. England a collection of views and sculpture. At the time of my visit the pictures of Mr. Payne Jennings and some others had not been hung. Mr. Slingsby exhibits his picture entitled *Alone*, which appears to me to greater advantage lighted up as it now is from the north than it did when shown in the London Photographic Society's top-lighted gallery in Pall Mall. Mr. Slingsby also exhibits two portraits.

Mr. Robinson has contributed his two well-known pictures, *When the Day's Work is Done* and *Preparing Spring Flowers for Market*. Last, though not least, in the show Messrs. Elliott and Fry exhibit several large and effective heads and busts, relieved by colour, and also a full-length, naked sleeping child, on seeing which some of my American cousins exclaimed—"What a sweet little darling!"—"What a shame it should be naked!"—"Pray cover it up!" whilst one kind soul tried to catch with her hand a fly resting and sucking the left arm, and on finding out how she had been tricked by the artist said—"Well, really, it is too wicked of the painter to attempt to play upon our feelings by representing the sweet love of a child likely to be disturbed by such a blood-sucking monster!"

Altogether, if the English contributors do not startle the Parisians by the large number of works exhibited, they will, at all events, do so by the quality of their exhibits.

In the French Court the dirt has been got rid of and progress made. A splendidly rich collection of frames and portraits in various sizes by M. Frank de Villecholles is displayed. M. Pierre Petit contributes portraits, some on porcelain in blue, sepia, and purple, which I was told by one of the committee were burnt in the fire, but which I imagine are not vitrified pictures at all, being probably in carbon and warm dried varnish; in fact, some of the portraits have the lightest half-tones washed away, as is well known by carbon workers when the development is commenced with too hot water.

I recommend English visitors to examine the richly-bound and gilt-edged portfolios of MM. Provost, Pere and Fils, of Toulouse, containing some fine pellicular films, which are very thin but perfectly flat. They smell of caoutchouc, and are accompanied by a positive placed in juxtaposition. They are only attached by a slip at the upper edge, and so rest suspended while the pages of the portfolio are turned over and examined. The negatives are pure and without spots, stains, or other defects. M. Manoury, of Angers, comes out strongly. MM. L. Loup Fils, of Rodez, has some very creditable and clean photolithographs from negatives after nature. M. Ernest Ravet, notary, shows diatoms and other microphotographs of great excellence. The exhibits of M. Baldus, helio-engraver, do not show much advance; and the same may be said of the productions of M. Henri Garnier, the inventor of the method of coating engraved copper plates with iron. The proofs of M. Jeanrenaud (from negatives on bromide of silver, partly emulsions and partly bath plates) are in carbon prepared by himself. Two of his prints are perfect pictures. He has a partiality for sepia or black tones like engravings. M. Walery exhibits silver and carbon prints—*cartes*, cabinets, whole size, and enlargements; also enamels of great dimensions executed in his own studio. His carved frames and fittings up cost over £300. M. Gumet exhibits some most excellent views in silver with a sepia tone. M. Vidal has a goodly show of his varied works, in printing ink, Woodburytype, and photochromy, which, I need not say, are unrivalled. M. Vidal is entitled to great praise for the progress he has made, and his present work may be regarded as only the *avant courier* of what he will yet do. M. Liebert makes a good display, and his frames are most luxurious—in no way behind his competitors for public favour. A special feature is his carbon printing. Every day will now largely add to the attractions of the photographic court.

I must return on a future occasion to the admirable photographs displayed in the Canada section, where some of Mr. Notman's frames were only brought out for the inspection of the Prince of Wales during the general review he made before the opening, and which were then closed in consequence of the dust.

May 1, 1878.—It would be out of place in this Journal to say more than this grand day for France is past, and all her friends who, like myself, remained upon her soil and laboured hard for her during her days of misfortune and suffering may well rejoice at the grandiose aspect of the *Exposition Universelle* opened with such ceremony, and in the presence of such an illustrious company, scarcely a few years after her days of disaster and grief. It was truly a solemn moment, and the patriotic emotion of the spectators can well be appreciated and acknowledged by one of her old and steadfast friends.

At the same time my native loyalty was not extinct, for I became for the moment fugleman and gave the measure of time with my "hip, hip, hurrah!" as the old Marshal came gingerly along upright, slightly like a dashing young cavalry officer, picking his way along the newly-made roads freshly gravelled, which from the almost unprecedented fall of a thunder shower a short time before was like a sponge and retained, in chemical phraseology, an unknown quantity of water, until he reached the terrace in front of the Palace of the Champ de Mars, having on his left the Prince of Wales. The ringing cheers produced by the measure I adopted quite took by surprise my French friends around me, and they actually, in the heat of the moment, neglected to give (except in the case of one solitary patriot) the counter cry of "*Vive la Republic!*"

I noticed a French photographer at work on the balcony over the central entrance, giving numerous but long exposures of from five to ten seconds with a large single lens of patristic shape—that is, of French manufacture—and which would embrace the lines of soldiers, the park, the bridge, the fountains on the slope of the hill side crowned with the palace of the Trocadero and its hemicycle of galleries, arcades, and columns—a view and decoration truly French in character and unequalled in the world,

I looked around for Messrs. England, Payne Jennings, and York, and their *instantaneous* exposures of the ceremony, having understood they had made applications for the necessary official permission to photograph generally the Exhibition.

The whole world now photographs, and from every clime are contributions which I must examine and see if national peculiarities have any bearing upon our art; for even Japan uses photography to illustrate her works, and I saw prints of the silk-weaving establishment of Oshmia Shosha, showing an excess of most minute details. I had almost written that you could count the blades of grass in the foregrounds, and this quaintlike minuteness is to be found in many of the Japanese productions.

At the last monthly meeting of the Photographic Society of France there was a very poor programme, consisting mostly of presentations of examples of proofs in printing ink and of M. Vidal's new publication—*General History of Tapestry*—a work admirably adapted to display the marvels of photochromie. The Honorary President (M. Peligot) and the Honorary Secretary were unavoidably prevented from attending,

I had the honour, as representative of The British Journal of Photography, to introduce to M. Davanne, who so well occupied the chair, three English gentlemen whom I had invited to be present.

First there was Mr. William England, whose labours, M. Davanne said, for many years in several quarters of the world, in heat and in cold, had brought him universal renown. Secondly, to Mr. Payne Jennings, M. Davanne said, on regarding an album of his landscapes, that in offering to him his compliments he must add that France, after a display of such great beauty, had still to learn how to produce landscapes. Thirdly, to Mr. Warnerke he (M. Davanne) remarked that his reputation as an emulsion worker commanded his respect. To the three gentlemen the Chairman gave a warm welcome, and said the Society was honoured by their presence on that occasion. The reception by the members of Mr. Payne Jennings' proofs was the event of the evening.

I must, from the length of this communication, reserve further remarks until next week, simply adding that I shall forward to the Editors one of M. Michaud's photo-engravings, presented by him to the Society. Mr. Warnerke had the kindness to make an interesting experiment on blurring; but he wishes the details to be reserved until he can present them, together with a paper, to the Photographic Society of Great Britain on his return to England.

Asnières (Seine), Paris. W. Harrison.

THE FERROUS OXALATE DEVELOPER.

To the Editors.

Gentlemen,—I have two slight remarks to make about the using of ferrous oxalate developer:—

1. Opalescent streaks sometimes occur when this developer is used. These are probably due to the formation of oxalate of lime in conjunction with the use of water containing lime for washing the plates subsequent to development. These streaks (which, however, are not very detrimental to the printing qualities of the negative) will be avoided if rain or distilled water be used for washing the plates instead of tap water.

2. I find that ferrous oxalate solution advantageously replaces the nitrate of silver, Schlippe's salt, or other of the chemicals now commonly used for blackening the image after treatment with bromide of copper. —I am, yours, &c., Joseph W. Swan.

11 *and* 15, *Mosley-street, Newcastle-on-Tyne, May* 3, 1878.

BRISTOL AND WEST OF ENGLAND INTERNATIONAL PHOTOGRAPHIC EXHIBITION.

To the Editors.

Gentlemen,—As the intention to hold this exhibition at the end of this year has got considerably abroad, I write to you just to state that, looking at the unsettled state of things at home and abroad, it has been decided to postpone the exhibition till December, 1879, all things being then favourable.—I am, yours &c., H. A. H. Daniel, *Hon. Sec.*

Bristol, May 7, 1878.

EXCHANGE COLUMN.

A Voigtlander rapid B *carte* lens, also 1B long Dallmeyer with rackwork camera for two *cartes.* Wanted, in exchange, No. 3 and 4 Steinheil or 6 × 5 and 8½ × 6½ rapid rectilinear.—Address, R. H. D., care of Mr. Starkey, 2, Lower Notting Hill-terrace, W.

Wanted to exchange, a 10 × 8 rapid rectilinear lens, 13 inches focus, with stops (quite new), for a No. 5 wide-angle landscape lens, 15 inches focus, or a No. 3 wide-angle rectilinear, 13 inches focus—all of Dallmeyer. Difference in money to be adjusted.—Address, W. Harding Warner, Duffield, near Derby.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

Albert E. Fradelle.—Thanks.

W. L. R.—1. Several months.—2. We have now discontinued (at least for a time) the use of carbonate of ammonia.

Photographer (Oxford).—Mr. M. Carey Lea's *Manual* is probably the best book on the special phase you mention.

W. H. Wells.—A solution of Canadian balsam is much employed for this purpose. Let it be dissolved in spirits of turpentine.

S. A. S.—Write to the various makers of and dealers in lenses and obtain their catalogues, and then devote an hour to studying the prices. You will in this manner be enabled to decide as to the probable advantages of buying a new or second-hand article.

T. B.—There is nothing specially the matter with the negative. Had it been a little longer exposed it would print softer; but even as it is it will produce a good print. Of course the paper must be sensitised so as to suit the negative. Let it be printed in a weak light, not in the sun.

H. W.—So long as the air-bubble is allowed to remain in the cement of the lens it will be quite impossible to obtain good definition on one particular portion of the picture when using the lens with its smallest diaphragm. It will be much better for you to have the lens re-balsamed, by which operation it will be restored to its pristine excellence. In reply to your second question: we are not in a position to offer any opinion, the data for forming such being insufficient.

R. H. D.—1. Grind the glass with flour emery and water, making use of a small, flat piece of glass for the purpose.—2. Clean the brass and apply a solution of chloride of platinum.

Geo. Adams.—Make some glazier's putty, but instead of employing whiting in doing so make use of brown ochre. When this putty has become tolerably hard make it into a roller and move it all over the glass of your window, by which a uniform brown colour will be imparted, coupled with that agreeable matt peculiar to such an application of putty.

C. O. O. S.—It is somewhat surprising to learn that anyone who has given the process of photolithography a fair trial has failed to succeed with it, because, like the wet collodion process, anyone who bestows a little care and attention upon it is certain to succeed. To give you the few hints craved for in this column would be quite out of the question; it is for you to give us a detailed description of your manner of proceeding, by which we shall readily discover the special point where you fail.

G. H. R. (Leeds).—Pour the whole of the albumen on a plate of tin, taking care that it does not run over the edges. The tin plate must, of course, be placed quite level. Now arrange for a current of air to pass over the surface so as to dry the albumen rapidly. Heat must on no account be applied, or the albumen will be coagulated, not desiccated. When quite dry it may be removed from the tin plate and broken up in small pieces, in which state it will remain good for many years if kept in a bottle.

J. B. R.—For a lens that has a long focus a swing back is almost indespensable in taking a landscape; for without this adjunct it will be difficult, if not impossible, to get the grass, flowers, and objects in the immediate foreground as sharp as is desirable. Owing to the law of "conjugate foci" the particular portion of the lens by which the objects in the *foreground* are delineated is of longer posterior focus than the part by which distant objects in the same picture are formed; hence the importance of being able to swing the upper part of the ground glass farther away from the lens.

Medicus.—Seeing that the distance between the visual and chemical focus of a lens increases in proportion as the object upon which it is focussed is approached to the camera, it is quite impossible to adopt, with any degree of success, the plan you propose for the purpose of effecting the focussing. Much better is the system, which has been frequently recommended before now, of having a simple convex or concave lens (a spectacle lens will answer) interposed—*à la* Waterhouse diaphragms—between the lenses, the focus of this lens being equal to the difference of the two foci. After focussing with such a glass the dark slide is inserted, the supplementary testing lens is removed, and the picture is taken.

Geo. Wilson.—Our correspondent, in writing to thank us for publishing the new patents relating to photography in the systematised manner that we adopt, is of the opinion that it would still further conduce to the interest attached to photographic patents if we would periodically publish a list of the lapsed patents—those on the one hand which have lapsed at the termination of the six months of provisional protection, and on the other those which go out of existence at the termination of the three, seven, or fourteen years of their more extended existence. We have often thought of doing so, and may still carry it into effect; but usually when describing a patented invention we make use of such terms as indicate the fact of any one such invention being only provisionally protected. In all cases of this kind the invention is open to the public at the expiration of six months from the date of application.

Photographic Society of Great Britain.—The next meeting of this Society will take place at 5, Pall Mall East (when the summer exhibition of the Water Colour Society will be on view), on Tuesday next, the 14th inst., when papers will be read on *Dry Plate Processes* by Mr. W. England, and on *Photography at the Least Refrangible End of the Spectrum,* by Captain Abney, R.E., F.R.S.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician.

For the Week ending May 8, 1878.

These Observations are Taken at 8.30 a.m.

May.	Bar.	Wind.	Wet Bulb.	Dry Bulb.	Max. Tem.	Min. Tem.	Remarks

No. 941. Vol. XXV.—MAY 17, 1878.

BROMIDE OR BROMO-IODIDE?

As an example of the manner in which photographic fashions change with time it is noticeable that, though for many years pure bromide of silver plates have almost entirely superseded bromo-iodide in dry-plate work, there is at the present day a tendency in many quarters to return to the old style. Many of those who have quietly settled down to the employment of the simple bromide plates still retain a lingering fondness for at least a trace of iodide in the film, but have been, no doubt, prevented from indulging their fancy in that direction by the difficulties which formerly accompanied the preparation of a bromo-iodised emulsion, except under certain conditions.

The process introduced by Mr. M. Carey Lea, three years ago, in which a small proportion of iodide in conjunction with the bromide is employed, reduces these difficulties to a minimum, provided the conditions laid down by the author are pretty closely adhered to; but if any considerable departure be made from those conditions the results obtained, if not always inferior, are at least uncertain in character. There are other methods, however, at the present day by which a bromo-iodised or even a purely iodised emulsion may be prepared with the greatest ease; hence, if the advantages supposed to be derived from iodide prove to be real, there need be no longer any difficulty in securing them.

It is somewhat difficult to define the exact nature of the claims made in favour of the admixture of iodide; but we believe they lie chiefly in the direction of a more vigorous development, and, as some writers state, greater rapidity. On theoretical grounds, if we consider that iodide of silver alone is *practically* inert to alkaline development, the first claim appears difficult of explanation, while, similarly, the fact that in the dry state, and in the absence of free silver, the bromide is generally believed to surpass the iodide in sensitiveness, the statement that a small proportion of the latter tends to greater rapidity appears somewhat paradoxical.

Though appearances rather incline to favour the latter supposition, we have previously expressed an opinion that the effect produced is not really due to increased rapidity, but rather to the fact that the fainter details develope more vigorously upon a bromo-iodide plate with a given exposure than upon one simply bromised. This throws us back upon the first claim, and we must confess that, as far as alkaline pyro. is concerned, we are entirely at a loss to explain the undoubted fact that the presence of a small trace of iodide does add strength to the development. With any form of silver development (or intensification) the case is different, and we can readily understand that under such circumstances a much stronger image would be secured.

In comparing the results obtained upon the two descriptions of films with a given exposure in the camera, considerable difficulty is experienced in arriving at a decision as to whether the difference is one of sensitiveness or of development. Looking at the question from one point of view it may be argued that, if with a given exposure one form of plate gives printable detail in the most feebly-lighted portions of the picture, while with the other the darker parts have no printing value, the result in the first case is practically equivalent to an increase of sensitiveness. But if we cut down the exposure to such a point that the bromide plate just—and only just—falls short of rendering such detail, and we find that with a similar exposure the bromo-iodide plate also loses in the same manner, it must be evident that the iodide produces no real accelerating effect.

In applying a practical test to the question we have utilised the graduated scale described some weeks ago in our article on actinometers. It is not necessary for this purpose that the instrument be graduated with extreme delicacy, as a wide range of tints is not required. Six or eight tints composed of thin waxed paper will be found to satisfy all requirements should any of our readers desire to perform the experiments for themselves; in fact, the results so obtained will, perhaps, be more conclusive than if a more delicate scale were employed. The only preliminary preparation required is to ascertain by actual trial the exposure necessary to impress some intermediate tint on the scale. By exposing the plates in pairs for the length of time fixed by the experiment the most accurate and interesting information is obtained.

In our first experiment a bromide and a bromo-iodide plate received similar exposures at a measured distance from a gas flame; after moistening with alcohol and washing, they were plunged simultaneously into the developing solution contained in a dish and allowed to remain until the required tint was produced on the bromide plate, when the solution was poured off and rapidly replaced by clean water. It was then found that the faintest tint was rendered with about equal intensity upon each plate, though the deposit differed in colour, being of a colder, almost black, colour upon the bromo-iodide. A second pair of plates were then exposed and treated in a similar manner, but allowed to remain in the developing solution for a very much longer time. In this case, though very little difference could be detected in the appearance of the bromide image when compared with the previous one, the faintest tint on the bromo-iodide plate was much more distinctly marked, appearing by reflected light stronger than the darkest portion of the bromide scale. By transmitted light the different tints were more clearly defined and presented a series of greater contrasts than those on the bromide.

The difference in the behaviour of the two plates under the action of the developer was very noticeable, the best-lighted portion of the bromo-iodide scale appeared first, the action spreading gradually to the lighter tints. The bromide image was slower in starting, but the different tints followed one another with greater rapidity.

In the next experiment the two plates received similar exposures, but were developed separately with the view of pushing the development to its fullest extent in either case. This was repeated several times with variations in the strength and proportions of the developers; but in no case could we detect any advantage on either side in point of sensitiveness. In one or two instances the bromo-iodide showed a faint trace of the next higher tint, while it was indistinguishable on the corresponding bromide plate; upon fixing and drying the latter image and pressing it in contact with a sheet of white paper the extra tint, however, became faintly visible.

Other experiments were made, but the results were in all cases in accordance with those we have detailed; and we are, therefore, we think, confirmed in the opinion we have before expressed—that the addition of iodide confers no increase of sensitiveness upon the emulsion. Its action, however, appears to be beneficial where a more vigorous development is desired, and this is especially the case when silver intensification is employed. For this reason it would seem to be valuable for purposes of reproduction, or for subjects where the natural contrasts are feeble. The colour of the image and its vigorous appearance by reflected light add much to the comfort of development in the feebly-illuminated laboratories, so requisite to success with very rapid dry plates.

DRY PROCESSES—ANCIENT AND MODERN.

V.—ENGLAND'S MODIFIED BEER AND PYRO. PROCESS.—SEBASTIAN DAVIS'S "TOURIST" COLLODIO-ALBUMEN PROCESS.

The process to be first described is fairly entitled to be designated the most modern of all—at least with regard to the time of its publication—inasmuch as it dates back only so far as Tuesday evening last, when Mr. William England read a brief paper on *Dry-Plate Processes* before the members of the Photographic Society of Great Britain.

Let us premise that the process in question is not a *new* one in the ordinary sense of the term—it would place Mr. England in a false position were such a designation claimed for it; still, the fact that a photographer possessing the artistic and manipulative ability of this gentleman finds very decided advantages resulting from the modifications of another process he has adopted is sufficient to warrant us in presenting it as a process entitled to great consideration.

In a recent number of this Journal (April 26), and in the third chapter of the present series of articles on *Dry Processes*, we described the beer and albumen process, which, after modification by Captain Abney, had been adopted by the latter and his friends with a marked degree of success. Among those included in this category was Mr. England, who was accidentally led to make a departure from the routine of the process as previously adopted. About two years ago, during a photographic visit to Switzerland, he was working Captain Abney's process, and while engaged in developing some plates he found that one of them refused to produce an image. This, he soon discovered, arose from its not having been exposed. Having removed the pyrogallic solution by washing he dried the plate, and some time afterwards exposed it, not a little curious to know what would be the result. It turned out to be a negative somewhat superior to those obtained on plates of the same kind when treated in the usual manner. This resulted in his adopting a reconstruction of the process, which may be summed up as follows:—

Allowing it to be borne in mind that Captain Abney applies a mixture of beer and albumen to the sensitised and washed plate, and after washing this off gives it a final coating of beer containing one grain of pyrogallic acid to each ounce—the drying taking place after this treatment—the nature of the departure from this will be understood when we say that the collodionising and sensitising are conducted by Mr. England in the usual way, the plate being then washed, followed by an application of beer without anything else. We are unaware whether or not it was a *lapsus* of Mr. England's, but he appeared to assume that up to this stage he was describing Abney's method, whereas there was no mention whatever of *albumen*, which forms an essential feature of Captain Abney's process. Mr. England next dries his plates, and afterwards gives them a final wash of pyrogallic acid, followed by slight rinsing and drying.

Now, both in the paper and in the course of the few words of further explanation which followed, it appeared to us as if there were something descriptive still further required than that which was given. It may be that Mr. England does not feel justified in speaking of the process in terms more definite than he has employed; but, from his having made the statement that the pictures for which he was awarded a medal at the last exhibition were all taken by this process, he will readily understand the prevalence of a desire to "know all about it." Every one who has had much experience in dry-plate experimental work knows that very frequently a great deal depends upon a very little. At first sight the process does not recognise the employment of albumen at all, and yet if the plates made use of by Mr. England were prepared by Abney's formula this substance must have been present, although in the subsequent modification by Mr. England it is discontinued. It would appear that a preservative or, in this case more particularly, an *organifier* of beer and pyrogallic acid alone is employed, and that these are used separately. The plain beer is applied to the film after it has been washed, and the plate is next dried. This, apparently, is an important element in the routine of preparation, if we rightly understood Mr. England's remarks in reply to a question put after the reading of the paper. After having been dried a one-grain-per-ounce aqueous solution of pyrogallic acid is applied, followed by washing and drying.

This may be thought analogous to the "final wash of gallic acid" which is given with such excellent effect to plates prepared by the collodio-albumen process; but in the latter case the plates are dried with the preparation left on, whereas in the former it is washed off. This particular part of the operation is more in harmony with the method employed by Major Russell, who, after giving the plate a thorough washing, applied a solution of tannin which he afterwards washed off. But whether Mr. England, on the one hand, makes use of pyrogallic acid along with the beer that is first applied, or uses beer alone—or whether, on the other hand, he uses beer along with the pyrogallic acid that is afterwards applied, or prefers an aqueous solution—are matters which each experimentalist may easily determine for himself as to which would be best in his individual experience.

We are here reminded that mixtures of beer and tannin, as well as of simple malt-infusion and tannin, have hitherto been employed with excellent effect in the production of dry plates. The negatives obtained by the aid of these preservatives possess a marked resemblance to the fine example exhibited on Tuesday evening by Mr. England, although the tones are somewhat darker, assimilating in a greater degree to those obtained by wet collodion.

We now pass to a second process, which was also described on Tuesday evening by Mr. T. Sebastian Davis, and by means of which we had before seen most charming negatives produced.

Like that of Mr. England's just described this is likewise a bath process, which, in its original form, was known as the "tourist collodio-albumen process," and is certainly a most trustworthy one. The plate is coated with collodion salted (speaking somewhat roughly) with one part of a chloride, four of bromide, and twelve of iodide, the basis of these being cadmium and ammonium. After the plates are excited in the silver bath they are washed and coated with a preservative composed as follows:—

Albumen	1 ounce.
Solution of extract of raisins (one to five)	1 „
Water	1 „
Ammonia	30 minims.
Ammonium chloride	15 grains.

This is poured on and off several times over the surface and allowed to act upon every part, after which the plate is washed thoroughly. The application of water containing a trace of acetic acid, followed by pure water, will neutralise the alkalinity of the film and thus save prolonged washing. A final application of a three-grain solution of gallic acid completes the preparation of the plates, which keep well both previous and subsequent to exposure.

The solution of extract of raisins alluded to in the above formula requires a few words of explanatory comment. To prepare it let the fruit be torn open or crushed so as to allow the water to have free access to the sugar contained inside. The water added to the raisins must be hot; but it is imperative that it be allowed to stand until it is quite cold before the extract is decanted for use. One part of this extract to five parts of water forms the "solution" mentioned in the formula.

THE FRENCH EXHIBITION.

From a glance at a catalogue of the British Section of the Paris Universal Exhibition, forwarded to us by the Commissioners, we ascertain the position occupied by British photography at this exhibition, so far as that can be deduced from a knowledge of the exhibitors and their subjects. Photographs are to be found under "Class 12—Photographic Proofs and Apparatus"—in which are included "Photographs on paper, glass, wood, stuffs, and enamel; heliographic engravings, lithographic proofs, photolithographic proofs; photographic stereotypes, stereoscopic proofs, and stereoscopes; enlarged photographs; colour photographs; instruments, apparatus, and chemicals necessary for photography; materials and appliances used in photographic studios." Only thirty-five exhibitors rank in the list.

The English display of photographic enlargements appears to be confined to Mr. Vernon Heath, whose fine collection was on view at a recent meeting of the Photographic Society of Great Britain. The Autotype Company also exhibit largely.

Messrs. F. Baum, A. Boucher, Elliott and Fry, R. Faulkner and Co., the London Stereoscopic Company, A. Beau, W. F. Maltby, C. Baudoux, Godbold and Basebe, R. Slingsby, and Herbert Watkins exhibit portraits.

Landscape photography is represented by Messrs. Beauford and Bruce, W. Bedford, T. M. Brownrigg, W. England, B. Lemere, Payne Jennings, P. Mawdsley, Carl Norman and Co., W. Sherlock, W. H. Wheeler, and Matthew Whiting.

"Animal" photography has for its representatives Messrs. A. S. Fisk, D. Hedges, and F. York, whose exhibits are confined to transparencies prepared for the magic lantern.

Genre or composition pictures have for their exponents Messrs. S. Fry and H. P. Robinson, the latter exhibiting the picture for which he obtained the medal at the last London exhibition.

Vitrified enamel photography has its sole representative in Mr. A. L. Henderson. Mr. D. C. Dallas exhibits prints produced from plates and surface blocks; while Mr. L. Warnerke contributes a collection illustrative of the applications of his sensitive negative tissue, with apparatus specially designed for its use. Mr. W. A. Brice exhibits his "photographon." Mr. J. H. Dallmeyer has sent a large collection of lenses of different kinds, and Mr. George Hare cameras, graphoscopes, albums, and other apparatus. Although not mentioned in Class 12, we find in Class 15 ("Philosophical Instruments") that Messrs. Ross and Co. also exhibit a variety of cameras and lenses.

LENS SCREENS.

Any of our readers who are in possession of an old lens will see how in the earlier days it was considered necessary to adopt some sort of shield against the entrance of useless rays of light into the camera, or, at least, against their striking the glass, the result being the time-honoured hood. Latterly, however, many photographers have seemed to think the use of this appendage was "more honoured in the breach than in the observance," and, so far from endeavouring to prevent the access of adventitious rays, they have invited their presence by recommending that even the lens or the inside of the camera should be painted or papered white, or some one of the colours of the rainbow. This fancy was part of the "free" and "after" exposure mania which seized on so many when it was at its height, but which now has probably found its own level—its actual value, we think, having been pointed out years ago in these pages by our esteemed correspondent, Mr. M. Carey Lea.

Putting aside, however, any discussion on the actual merits of such extra exposures, we believe we are right in stating that by no artist of note in the kingdom were they made use of under all circumstances, and hence we may assume that there are at anyrate disadvantages attending their use; and, further, that the old principle of excluding the unused light was perfectly correct in practice. No doubt there are times when the extra exposure may be useful, but the arrangements for obtaining it must be special and separate, and not permanent additions to camera or lens.

Beyond the lens hood supplied by the opticians it was at an early date recommended to adopt an extra screen, and it was the practice of many photographers to do so, one of the earliest we remember being made from one of those familiar, useful wood packing-boxes with the tinfoil bands. The lid was rejected, a hole cut out of the bottom so as just to fit the lens, and the whole of the inside covered with black velvet. This was superior to many of later date, which have been constructed on the principle of a cone. A cylinder may answer well, but a cone has a very objectionable feature, inasmuch as it reflects, even though covered with black velvet, an appreciable amount of white light—far more than with an arrangement having sides parallel to the camera; and, when its pile has become a little flattened by time and use, the cone presents a reflecting surface of considerable power, actually placed in such a position as to send into the camera more light than would enter if no screen whatever were employed.

We are quite of the opinion that the use of a screen of a very complete description should be adopted under all circumstances for portraiture, but for landscape work one of slighter make. For the latter the well-known sky-shade answers nearly every purpose, its ready adjustability to any angle making it of great value. For example: in a case which arose quite recently in our own experience we had promised to take a group of friends, and we found the camera could not be placed in the shade, there being only one spot available for the group. The sun shone immediately into the lens, and it was only by depressing the shade to the utmost that a picture could be obtained. In one way the sun, notwithstanding all our precautions, did just catch one portion of the lens, and the result was, of course, complete fog. The actual rays of the sun possess no special property of fogging beyond their superior intensity, and for the reason that with objects all round throwing into the lens light, white and coloured, their aggregate power has similar effects to that of direct sunlight.

The shape often recommended for these screens is one possessing a circular aperture, but it is obvious that this more expensive mode of construction is not by any means necessary, and, indeed, we prefer one square or oblong as being more useful.

It is worth while here to point out that in designing a shade the longer it can be made the more efficient it is in blocking out all extraneous light, and that a shorter shade with a proportionately smaller section is not equivalent to a long one of a certain aperture. This is a matter of some importance.

We recently inspected a shade made to be used in a studio forty feet long. It was designed so that at that distance from the sitter a series of lines drawn from the outside of the lens, cutting the aperture of the screen and continued to the background, would include only just as much of the end of the studio as could possibly be included in any picture. Hence it will be seen that no light from the windows or skylight could enter the lens, and every source of fog from external causes was removed, this being a matter of vital importance in producing brilliant negatives, when, as at the present time, negatives are made as thin as is compatible with the production of a good print.

If, however, this screen we have described had been made half the length, with an aperture of the size that would be indicated by cutting a cone of rays having the centre of the lens as apex and the screen aperture as base, it is evident that a good portion of the direct light from the sky would enter the lens, unless the windows were constructed on the corrugated principle patented by Mr. Vanderweyde.

We may note a further point of this model screen: it had a hanging velvet flap in front to modify the height of the aperture for different lenses (the *width* was not under control, therefore to this extent it was not the realisation of a perfect ideal), and it was attached to the camera stand by a projecting board fitting in grooves, which allowed its distance from the lens to be under control. It was covered with black velvet, and its owner informed us that it was very essential to keep the lower face free from dust and the pile not pressed down.

As, however, the floors of a studio do not often reflect much light, it is obvious that this lower side of the endless box, as we may term it, is of least importance, and that a very good substitute may be made by simply suspending a piece of velvet over canvas projecting from the camera front to a suitable distance, the chief objection being that where constant work is going on frail contrivances of this nature are apt to get knocked about and injured.

We have also seen cameras constructed in which the sides were continued to an abnormal extent so as to form a screen; but, as they were under disadvantages as regards working the rack and pinion and uncapping the lens, we do not recommend them.

In conclusion: we would strongly advise all who do not use a screen to hasten to supply themselves with one of some kind and to give it a fair trial. We think they would find an improvement in their negatives. A slight veil in the shadows is not of much consequence with a dense negative, but it is ruinous to a weak one.

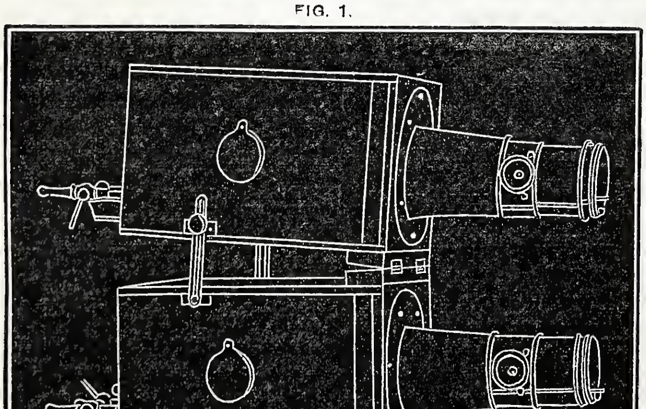
THE iron developer, though almost exclusively employed in wet-plate operations, has as yet found but little application to dry plates, as, for some reason or other, its action appears to lack energy as well as uniformity. An additional obstacle to its employment for this purpose is found in the fact that the solution becomes muddy and exhausted from precipitation of the silver long before the somewhat protracted operation of developing a dry plate is complete, and repeated applications of fresh solution are both inconvenient and inefficient. Many attempts have been made to overcome the latter difficulty by the addition of a variety of restraining agents; but none, so far, have proved practically successful or sufficiently promising to afford a prospect of iron supplanting pyro. for dry as it has done for wet plates. The last expedient we had occasion to notice in this connection was the employment of salicylic acid, as suggested by Herr Richter; but, as we pointed out at the time, in our hands at least, it produced no further effect than to strike a characteristic purple colour when added to the iron. M. Damry, a member of the Belgian Photographic Association, has added to the list another acid which, though by no means new as an adjunct of the developer, has never, so far as we are aware, been recommended for the special purpose. Nitric acid is the agent employed, and, so far as one or two rough experiments go, it seems to act efficiently in preventing the too rapid deposition of the silver. We cannot, however, hold out a hope that it will enable the iron solution to replace pyro.—at least for simply bromised plates—as our experience leads us to believe that no form of silver development succeeds as well as alkaline pyro. in the entire absence of iodide. M. Damry's plates, it may be noticed, are bromo-iodised; hence, probably, the explanation of his success.

A NOVEL MAGIC LANTERN.

ON Thursday evening, the 9th inst., I had the pleasure of exhibiting the above to the members of the Manchester Photographic Society, and by desire of many and for the benefit of others I now request space for a description of the same.

My object in designing this style was to combine simplicity, cheapness, and efficiency. It will be seen from the accompanying

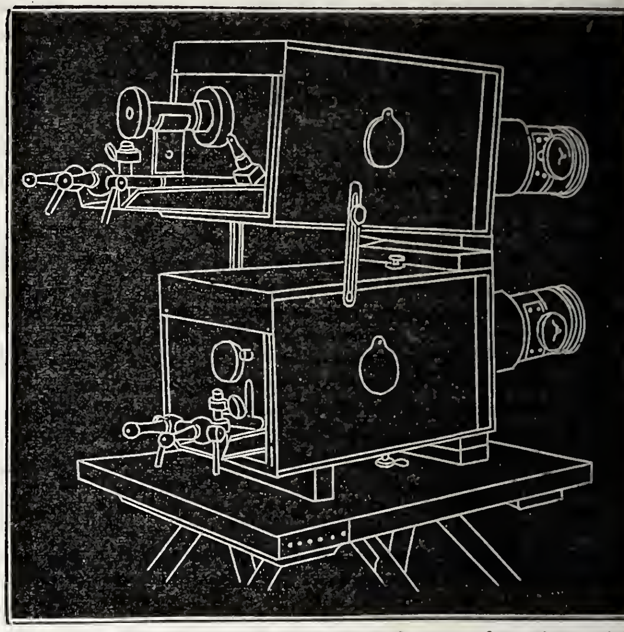
FIG. 1.



drawing, *fig.* 1, which is a perspective, and showing the front and one side of the apparatus, that the lanterns can be separated and used singly if required, and that, if necessary, a third lantern on the same principle may be placed on the top. It will be observed that I have dispensed with chimneys, having found them quite unnecessary. The bodies are made of thin baywood not much larger than cigar boxes, the interiors lined with tin, and perforated in such a manner as to prevent the emission of light while securing the most perfect ventilation.

The discs are brought concentric on the screen by a hinged piece securely attached to the bottom of each lantern, which forms a means of coupling the two, and also of securing them to a table, stand, or tripod-top, as shown in *fig.* 2 (which is a perspective view,

FIG. 2.



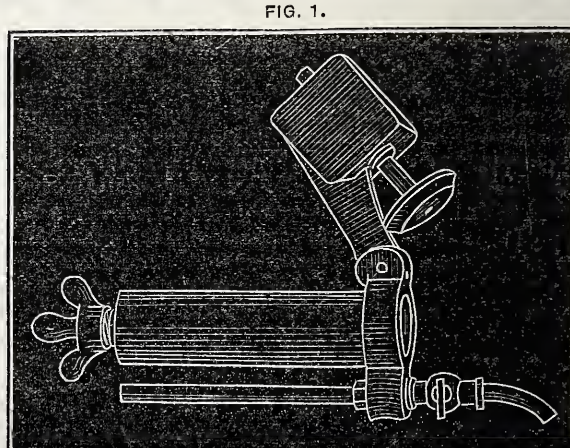
showing the back end). When adjusted they are kept in position by means of a screw in a slotted bar at each side, as shown in the drawings. The tin conical fronts holding the objectives are fixed by screws to the bodies, the flanges of the same having the holes slotted, so that the fronts can be detached instantly, and, if required, can be packed in the bodies of the lanterns. The apertures for the pictures are made the usual width, in which I place my well-known registering carriers. The shutters at the sides cover small blue glass windows through which the light may be viewed. The burners I have adopted are on the "blow-through" principle, the nozzles of which can be removed for cleaning when required. I use the disc form of lime, the holders of same being perfectly adjustable, easily removed, and are manipulated by wood discs placed at their outer ends.

I have found these lanterns to realise my best expectations, and as a good, serviceable, and portable apparatus I have great pleasure in bringing the same under your notice. W. J. CHADWICK.

ANOTHER SAFETY OXYGEN RETORT.

HAD it not been for the interest displayed by the members of the Manchester Photographic Society in magic lantern appliances I

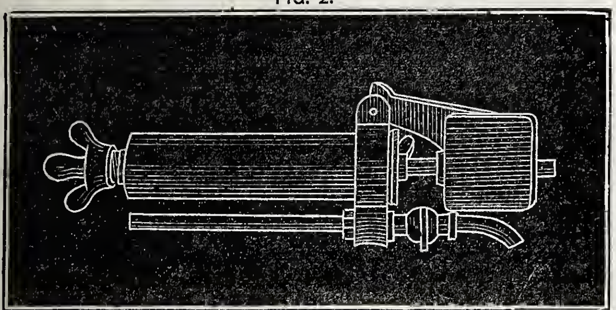
FIG. 1.



should have been reluctant to bring before them another oxygen retort, they having previously seen so many. The accompanying drawings, from photographs, illustrate an oxygen retort adapted for the use of plugs, to which is applied my now well-known safety-valve arrangement, in this instance using a weight instead of springs (both methods of which I have already published).

The principle is clearly shown in the drawings—*fig.* 1 showing the retort open, and *fig.* 2 showing it closed. If the pressure should from any cause rise in excess of that to which it is weighted, the gas would be liberated at the front end by virtue of the weight which is hinged to the retort, and has attached to it the cap-lid in such a manner that it is not quite rigid, but is free to move a little so as to find its proper position. On the cap-lid is a small projection, shown in *fig.* 2, for the purpose of removing any substance which might

FIG. 2.



interfere with the joint, and also permits of the lid being ground into its proper place. The method of opening and closing the retort is simple:—Turn up the weight and the retort is open, or turn down the weight and it is closed.

Plugs of chlorate of potash and manganese may be made and used in thin sheet iron cases if preferred, or a method I have adopted is to make the plugs on a wire, with a sheet iron disc at the bottom end and a small loop at the other (just resembling a sugar crusher). As soon as the plugs dry—which they do much sooner than when bottled-up in a tin case—I dip them in plain manganese and water; this, when dry, prevents any sticking to the retort. Should the plug break, or any part become detached, the disc at the end of the plug, and attached to the wire, on being extracted brings all with it. I must apologise for having trespassed upon so much of your valuable space. W. J. Chadwick.

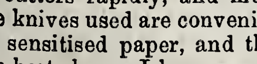
OUR APPARATUS.

No. VI.

Arrangements for drying silver prints after toning, fixing, and washing are not much varied. For small quantities of work nothing is better than two flat boards with six or eight sheets of stout blotting-paper between them. A sheet of the paper is laid on one of the boards and the wet prints laid evenly upon that. Another sheet is laid upon the latter, and the process is repeated until the sheets are all full. Lastly the other board is laid on, and the whole left to dry. The great advantage of this plan is that small prints—*cartes de visite* for example—do not curl or become inconveniently dry previous to mounting. If there are many small proofs, a frame something like those used in printing-offices for cases of type will hold a series of these boards and sheets of blotting-paper, and is a very convenient plan. For larger work each proof, or number of proofs on one piece of paper, can be suspended by the corner to an American clip attached to a frame. An ordinary clothes horse, set open squarely, with rods (upon which clips have been fastened a few inches apart) laid across from side to side, makes a compact drying-frame. With highly-albumenised paper, and a very dry, warm room this method causes the prints to curl in a very troublesame manner; care must therefore be taken to keep the room at a moderate temperature, and not let the atmosphere be too dry.

Cutting-boards may be made of any hard, close-grained wood. Lime, oak, or box are generally preferred, and, as Mr. Ayres pointed out at a meeting of the South London Photographic Society, by having the end grain up the necessity of frequent planing, as is the case if longitudinal sections of the tree are used, is done away with. Glass plates used for this purpose, although they ensure clean edges, spoil the cutters rapidly, and much time is wasted in sharpening them. The knives used are convenient if made of two forms—one for cutting the sensitised paper, and the other for trimming the prints singly. The best shapes I have seen are these—

NO. 1.



NO. 2.

No. 1 is chisel-shaped, and only sharp on the chisel end; the other edges are nicely rounded. The advantage of this form is that when wooden rules, or T squares, are used the danger of cutting the ruler or chasing off particles of metal to form metal spots on the prints afterwards is reduced to a minimum. No. 2 is more lancet-shaped, and is more convenient to use when only one thickness of paper has to be cut through; it is also adapted for trimming the finished prints.

There is much difference of opinion as to the best kind of block to be used for the purpose of cutting-shapes. Some advocate glass, and others heavy opaque material, such as stone or metal. Much depends on the preparation of the print in deciding this matter. If the negatives are painted round, leaving the subject a trifle larger than it is intended to remain, or if, by aid of a gauge, lines have been ruled on the print, then nothing can be better than a well-shaped metal block; it is less likely to shift or get the edges rough and uneven. If, however, the print has no guiding lines upon it a glass cutting-shape is very useful. The objection to glass shapes is the difficulty of keeping them free from chips; the corners will get broken, which interferes with rapid and accurate cutting. Metal shapes, I believe, are generally adopted when much work has to be got through well.

With regard to plate-cleaners nothing can be better than a flat board with a raised edge and covered with felt, and a lever to retain the plate in position. The screw contrivance that has been so long a favourite with photographers is also a good one; but there is great danger of breaking very thin glass polished upon it by a little too much pressure, which is entirely obviated by the first-mentioned plan. Albumenising has in many establishments superseded this kind of polishing; but, as very dirty plates will require more than a wash and a coat of albumen to make them serviceable, the polishing-board will in all probability yet remain part of the photographer's apparatus for many years to come.

Retouching desks must, to be useful, possess two essential qualities, which are—first, the eyes must be protected from any light except that which passes through the negative to be manipulated; second, that this light must be strong and uniform in quality. In practising retouching with various kinds of light nothing, take it altogether, is more convenient or better than a good gas burner with the light filtered through ground glass. Daylight is too fluctuating, and a paraffine light throws out a large amount of heat and the eyes soon get fatigued and the operator uncomfortable. Evenness and regularity of light is very important. Variations in this respect lead the judgment astray in the matter of intensity. This is particularly the case in repairing a damaged negative, where clear glass has to be stippled to match the surrounding film, so that the patch will print neither darker nor lighter than the film originally did. At the same time I believe that sufficient skill is acquired by those who confine themselves to this work, so that their judgment of density will be pretty accurate in any light. To those, however, whose occupations are more varied an uniform light will be a great assistance. The magnifier attached to the apparatus should be sufficiently large to allow both eyes to be used simultaneously and also be of good quality. An imperfect magnifier injures the sight and induces headaches if used, as is frequently the case, for hours together.

Printing-frames are best with spring backs of the form usually made at the present time. If pressure be applied by means of screws through bars there is much more probability that the negatives or glass of the frame will get broken, especially if left screwed up tightly during the night. They are a dangerous kind of press to use when the negatives are on other glass than patent plate. The least curvature of the glass will be almost certain to induce a fracture. The spring backs are, consequently, much to be preferred, not only on account of the greater ease and rapidity with which the paper can be changed, but for the much less probability of breakage in their use. Woollen or felt pads are best to use in them, as they do not absorb moisture so rapidly in damp weather as many other materials. These should be very thick and close in texture. If thin, the paper is much more liable to cockle. A pad composed of several layers of *thin* material will allow the paper to cockle much more easily than one of thick, no matter how much pressure is applied. The backs of the presses should be perfectly true and level, and the boards of which they are constructed clamped, for the slightest warping is fatal to good and perfect prints. Especial care must be taken, when examining a pressure-frame as to its fitness for work, to ascertain that it is perfect in this respect; also that the springs are sufficiently strong to retain the back in its proper position when partially opened to examine the progress of the printing. Many printing presses fail in this respect, and give rise to much trouble. The plate glass must be free from scratches and markings. In the course of time, with constant use, the glass will be scratched more or less. Slight scratches are of little consequence, but deep ones will retain dust and dirt, making a white mark on the print, or by reflecting the light from their rough edges make a dark one. In placing the glass in the frame the most defective side should be placed outwards, so that the thickness of the glass may interpose and soften the markings, or render them of slight consequence, which would, if placed close to the negative, spoil the proof. It is also necessary to ascertain that the rebate on which the glass rests is of the same height all round, and that no nails or other hard substances interfere with the level, as either may lead to a fracture of the glass. E. Dunmore.

THE PHOTOGRAPHIC PRINTING PROCESS USED IN THE PORTUGUESE STATE PRINTING ESTABLISHMENT.*

IV.—Photolithography, with the Employment of Tinfoil.

The exposure of prepared stones under the negative seldom gives good results, because it is very difficult to produce an intimate contact between two such rigid substances. The transfer with paper is also not very exact, because the paper, especially when in a moist condition, is too flexible and becomes warped. I have, therefore, sought for another substratum, and have found it in tinfoil. The sheet of tinfoil is first flattened upon a well-polished lithographic stone with a very fine grain. Too great a pressure destroys the flexibility of the metal and makes it easily torn; too smooth a stone does not allow the tinfoil to adhere to it; too rough a stone interferes with the fineness of the upper surface and causes spots to develope on it when rolled.

The flattened tinfoil sheets are made perfectly clean, and then laid flat, without creases, upon a zinc plate moistened with water and levelled as if for engraving upon. If in spite of care creases are formed the tinfoil sheet should be lifted up and the creases allowed to spread out when laying it down again; or the tinfoil should be pressed out as smooth as possible and then made perfectly equal by rubbing with a damp and very soft and flexible ball. The sheet is then cleaned by rubbing it lightly with a linen rag dipped in a ten-per-cent. solution of caustic soda or caustic potash. If that be not sufficient add a little whiting. Then wash the caustic lye completely off and put on the sensitive fluid with a soft, flat pencil. In order to spread the latter dissolve in the water bath—

1.

Good gelatine	40 grammes.
Water	500 ,,

Then dissolve in another vessel—

2

Bichromate of ammonium	20 grammes.
Water	500 ,,

These two solutions are mixed in a lukewarm condition and filtered through double flannel or sponge. The best gelatine is that which is still firm at a temperature of 35° C. but is not difficult of solution. The film should be equalised as much as possible, so as to show neither streaks nor inequalities; also, there should be no free places (or holes in the film) caused by the tinfoil being imperfectly washed. As long as the chromated gelatine is wet one may work by daylight, because when wet it is not sensitive to light; in the stiffened or dry condition it should only be displayed to yellow light.

The sheet of zinc upon which the leaf of tinfoil lies must be placed in a horizontal position and warmed by gas or in a drying-box. When the gelatine film is quite dry the sheet of tinfoil is stripped off the zinc plate, and one may then proceed to expose, which can best be done on a clear day. The gelatinised sheet of tinfoil is laid upon the negative, and a roller covered with flannel is passed over it in order to bring it into absolute contact with the glass. The negative is then placed in the printing-frame. The exposure lasts, in the sun, from five to twelve minutes; in the shade three times as long. If the ground of the negative be perfectly opaque a longer exposure may be given without doing any harm; but if the ground be rather transparent it is better to expose in diffused light than in the sun. The rolling of pictures can be most successfully done the same day as the foregoing, but may be postponed until next day.

The sheets of tinfoil should now be dipped, picture side uppermost, in cold water; then they are laid, wet as they are, upon a perfectly level stone. A wooden roller covered with flannel is used to press them flat upon the stone and to remove the water from their upper surface.

The inking is done with a lithographic roller, furnished with a mixture of two parts of transferring ink to one of printing ink. The composition of the foregoing may be varied to a certain degree, which is dependent on the temperature. It should, however, contain no varnish, as that would make the ink too fluid.

The attainment of the desired result depends here solely upon the skill of the worker. The roller must be very good, somewhat slippery, and should not hold too much ink. The inking is difficult when too much water remains upon the plate, and when the lighting is too short. In that case a more fatty or fluid ink is taken; or, better still, one begins again at the beginning of that process.

If the tinfoil become smeared between the lines, spread over it a very thin layer of starch paste or a still thinner film of gum arabic, and rub out the spots with a very soft sponge. If that do no good rub it with gum and flannel. In this way the affinity of the ink for the surface is diminished, but it may also happen that the drawing may be rendered too weak. If the exposure be too long, so that the tinfoil takes on the colour too readily and becomes smeared, moisten the surface with turpentine and clean it off; then roll anew so that the metal may receive a thin coating of gum water. With care good results may be got in this way.

A thick film of chrome gelatine is easily raised up and torn during the rolling; too thin a film is easily smeared with ink.

When the picture has been well inked the tinfoil is washed with water and left two or three hours to dry. It is now rolled again with ink. It is then washed once more. The sheet of foil is now taken from off the stone and hung up to dry. The picture is then transferred in the usual way to the stone.

V.—Photozincography.

For this a reversed or drawn-off negative is necessary. A thin, well-planed zinc plate gets a fine granulation by the application of pumice stone, is cleaned with potassic or sodic lye, and coated with the following film:—

Gelatine	3 grammes.
Bichromate of ammonia	1 gramme.
Water	100 grammes.

The dry film is exposed under the negative, in the sun, for two or five minutes; in diffused light three times as long. It is rolled by means of a leather or caoutchouc roller with a mixture of printing ink and transferring ink, and then allowed to lie for two or three hours in cold water. At the end of that time, if a good lithographic roller be passed over the film, the picture developes and the superfluous colour is carried off. The picture is then laid in warm water in order to dissolve the unlighted parts; it is now allowed to drip, and the following mixture poured over it:—

Water	1 litre.
Gum arabic	40 grammes.
Cupric sulphate	2 ,,
Gallic acid	5 ,,
Nitric acid	0·5 of a gramme.

This is allowed to dry. Print with a typolithographic press. The lithographic press is not very available, because the rubber injures the drawing. The latter may be replaced with advantage by a roller covered with felt. The ink is carried over the slightly-moistened plate by a lithographic roller. José Julio Rodrigues.

(To be continued.)

TRANSATLANTIC NOTES.

In continuation of the jottings connected with my visit to the establishment of Mr. Gutekunst, I would direct attention to the beautiful effects secured by the etching in of designs as background and accessories, so as to entirely alter the nature of the picture.

There lies before me while I write a charming specimen of this kind of work. The subject is a picturesque porch, some fine trees, a series of ancient-looking steps, and sundry other things required to make up an artistic composition. Inside the porch, and looking out of a window, is a lady holding a baby seated on the window sill. A little in front, and to the right of the window, there is seated, amongst a cluster of flowers and shrubs, a boy, the whole forming about as perfect a picture as one could wish to see. The original from which this beautiful composition was produced was an interior with a pillar in the centre; the child was held on the pillar by the lady, and the boy seated at the base. This was, as all Mr. Gutekunst's pictures seem to be, a fine composition; but, of course, there is a limit to the demand for a family group from even the most perfect negative. A new interest, however, is given, and consequently a new demand arises, from a new combination, when it is really artistically beautiful.

To produce this Mr. Gutekunst stops out the background of the original, and prints the figures only on a plate with a plain opaque background. This is handed over to an artist cunning in this kind of work, who with a sharp-pointed instrument scratches in whatever design his fancy may suggest, and with a little opaque colour puts in such high lights as he may think necessary. Of course this is not

* Continued from page 196.

photography pure and simple; but it is a combination of photography and art which produces exquisitely beautiful results, and which will undoubtedly "bring grist to the mill." I hope Mr. Gutekunst will persevere in his determination to cultivate this branch of combined art, and that some of our artists at home will follow the excellent example, and equal, if not surpass, their *confrères* of the west in the production of the almost unlimited effects thus easily obtained.

The flavour of last year's Centennial Exhibition is still strongly felt in Philadelphia, and in a less degree all over the States. Photography seems really to have had a "good time" of it during the run of the exhibition, and in the hands of Mr. Wilson, publisher and editor of the *Philadelphia Photographer*, who was the enterprising contractor for the privilege of photographing in the exhibition and its surroundings, it has brought both fame and profit to himself and those associated with him. The speculation was undoubtedly a bold one, as the outlay was very great, and the result very problematical. The mere building in which the operations were carried on cost £3,000. It was to be brought to the hammer the day after I had the pleasure of "interviewing" Mr. Wilson, and would not likely bring more than a tithe of that sum. The fittings and apparatus were being brought to his office from the exhibition grounds, and included more than a lorry load of printing-frames alone. Amongst the pile of apparatus which was lying about in all directions in the various apartments of which his establishment consists was one piece which will serve as a proof that no expense was spared in making everything as perfect as possible. It was a burnisher similar to the kind so generally in use for small work in England and Scotland, but with a roller, and, of course, corresponding burnisher, thirty inches in length. This had to be made to order, and must have been an expensive tool; but then, as I have already said, America is a country of big things. I had the pleasure of looking over a set of prints from every negative taken during the exhibition, and while many of them were, from the nature of the subjects and the conditions under which they were photographed, scarcely as good as could be desired, they were, on the whole, very high-class work indeed.

The stereoscope, I am glad to see, is still a popular instrument with Americans, and while in Mr. Wilson's warehouse I had ample evidence that the stereoscopic pictures of the Centennial Exhibition are very much in demand. Such enterprise deserves to be well rewarded, and I hope that the very excellent series of pictures, or rather the negatives from which they were printed, will be "a dripping roast" for a long time to come.

A visit to Philadelphia would hardly be complete without a call on Mr. Marcy, of sciopticon fame. I found him in a comfortable first-floor, at 1340, Chestnut-street, surrounded by several members of his family, each apparently as enthusiastic in the lantern business as himself. I have said a "*comfortable* first floor," but must in some degree modify the adjective, as, like almost all American houses, it was heated to an almost unbearable temperature by a large stove, although the day was as hot as most English or Scotch summer days. Mr. Marcy seems to have been a school teacher with a *penchant* for physical science, more especially for that of optics as applied to the lantern. I was, as usual, very heartily received; and as a part of one of the walls of a large room is painted a pure opaque white, oxygen and hydrogen always laid on, and each window furnished with an outside *jalousé*, whereby it can be made quite dark, we had a sciopticon exhibition in a few minutes. Mr. Marcy has evidently a large business both in apparatus and slides. I saw some very fine specimens of the latter of both continental and American manufacture, but, curiously enough, not one of either English or Scotch production. This will, no doubt, be remedied soon; but there is one absurd drawback to the importation of foreign slides, in the shape of a stupid excise duty of, I think, forty per cent. on manufactured glass, while the no less stupid heads of the customs department insist on the vitreous character of the slides, and insist on that duty being paid on all that are imported. While speaking of lantern pictures, I may say that I saw in the hands of several of the amateur members of the Philadelphia Photographic Society a large number of those productions, both from emulsion plates and wet collodion, quite equal to anything that can be shown at home.

So far as the sciopticon is concerned Mr. Marcy had no improvement to show that has not found its way to Europe during the last year, except what was not inaptly called, by the ex-President of the Philadelphia Photographic Society, "a winker." It is an automatic means of entirely shutting off the light at the instant of changing the pictures, and so preventing the line caused by the two strips of mounting paper and the not infrequent streak of light which passes between them being seen. It consists of a small blacked plate of sheet brass or tinned iron fixed to a wire lever which passes out through the side of the lantern, and so arranged that the passing of the slide along the adapter brings it right in front and close up to the source of light, keeping it in that position till the new picture is in position, when it immediately descends and allows the light again to fall on the condenser. I have no doubt the arrangement of this simple apparatus will be obvious to all who use lanterns; and as the cost need not be more than a few pence, and it is a great improvement, I hope to hear that by next season it will be largely adopted by our photographers at home.

I was sorry to leave Philadelphia without seeing Mr. M. Carey Lea, whose writings have so long interested the readers of The British Journal of Photography and the photographers of Europe and the world generally, but he only comes into the city occasionally, and was not to be in Philadelphia till after the day I was obliged to leave. I called to say "good-bye" to Mr. Gutekunst, who made me almost ashamed by presenting me with a large number of the finest specimens of his best work, including two magnificent panoramas printed from a number of negatives in such a way as to elicit the admiration of all who have seen them, and which I shall have much pleasure in showing to all who desire to see them on my return to Edinburgh.

On leaving Philadelphia matters unconnected with photography required my presence on the banks of the beautiful Susquehannah river, and I had a nine-hours' ride in an express train through the grand and delightfully-photographic "Lehigh Valley," halting for a few hours at "Waverley," in New York State, tempted as much by the associations of the name as by the beauty of the village.

But as this communication is probably sufficiently long, and as kind friends are waiting to give me occupation in a way more congenial than even letter-writing, I shall reserve what I have to say of photography in this and some other villages for a future "note."

John Nicol, Ph.D.

FOREIGN NOTES AND NEWS.

Braun et Cie.'s Reproductions of the Italian Masters.—The Berlin Exhibition of 1879.—Death of Freidrich Voigtlander.—To Sensitise Tissue without a Chromium Bath.—Dr. Adolf Ott on White Carbon Tissue.—New Rapid Dry Process.

The agents of the firm of Braun et Cie., Dornach, are at present in Italy photographing the masterpieces of Raphael, Michel Angelo, Da Vinci, &c. The task is likely to be difficult, and to occupy several years in its execution, as the works to be copied range from the fourteenth to the sixteenth century. The results will, most probably, be published from time to time.

There is a notice in the current number of the *Mittheilungen* to the effect that at the Berlin exhibition, which is to be held next year, none but Berlin firms will be permitted to exhibit. The photographic exhibition at Brussels, in connection with the annual general meeting of the Belgian Photographic Society, was opened on the 12th inst., at the *Musée Royal de l'Industrie.*

The same journal announces the death of the celebrated optician, Herr Friedrich von Voigtländer, which took place in Brunswick on the 7th ult. The deceased was born in Vienna in 1812. He was educated with the intention of succeeding to his father's business. It was not until, along with Herr Petzval, he brought out the first photographic portrait lens—that associated with his name—that he became known. What it was before impossible to do without an exposure lasting several minutes was accomplished by means of the Petzval-Voigtländer lens in as many seconds, and the new instrument soon became the photographer's greatest treasure, carrying the name of Voigtländer all over the world. Some time later Voigtländer made, from Petzval's calculations, the orthoscopic lens, which was in turn superseded by the triplet and the aplanatic. In 1848 Herr Voigtländer removed to Brunswick, where his establishment is now carried on by his son Friedrich.

In the *Archiv* Dr. Monckhoven gives the following directions for sensitising carbon tissue without a chromium bath:—"Dip some common carbon tissue into an aqueous solution (20%) of citrate of iron oxide and ammonia, dry it in the dark, expose in a printing-frame, damp it, and place it, as usual, on a glass plate. On developing with warm water no picture will be visible; but if, after exposing the paper instead of dipping it into water, it be dipped into a solution of bichromate of potassium, and immediately afterwards be laid on the glass plate and developed in warm water, a picture will be got, owing to the actinic action being transferred from the iron to the chromium salt. Instead of the bichromate of potassium, mercuric chloride or other salts, which I shall name at a future time, may be used. If tannin be used the action of the light is reversed, and a negative is produced in place of a positive. Instead of the iron salt other metallic salts may be used whose bases are oxidised in various degrees. What gave me the most trouble in this process was the preservation of the half-tones."

In the course of a long letter from Dr. Adolf Ott, in the *Wochenblatt*, the writer says that of late his firm (Braun et Cie.) have had numerous inquiries for white carbon paper, but that, owing to a pressure of other business, they have not yet been able to supply it. He also says that he does not clearly see what are the advantages to be obtained by its employment, as, though perhaps few carbon printers may have observed the fact, the contour of the image is slightly visible even on dark carbon tissue. If a piece of dark tissue which has been fully exposed under a negative be taken into a dark room, and a pencil of light be allowed to fall on it, a weak impression of the negative may be recognised without difficulty. The cause of this is that the action of the light has caused a slight change of colour, by changing the yellow potassic chromate into brown oxide of chromium. To distinguish the picture only requires a little practice, and MM. Braun et Cie.'s printers seldom make a mistake as to the length of exposure. Dr. Ott thinks this method of determining the length of exposure preferable to the use of a photometer, as the action of the light on the edges of the picture, where the photometer is always exposed, is much weaker than in the centre.

M. Albert Damry communicates to a recent meeting of the Liege section of the Belgian Photographic Association the details of a rapid dry process which he has for some time worked with considerable success, and specimens of which were exhibited. It is based upon the employment of an ordinary bromo-iodised collodion in conjunction with the silver bath, and presents in itself but little novelty, the preservative consisting of a mixture of dextrine, tannin, and gallic acid. The development, however, introduces a novel feature; the principal solution consists of the ordinary mixture of ferrous sulphate, acetic acid, and water, from twenty to twenty-five grains to the ounce. In conjunction with this are employed a five-per-cent. solution of nitrate of silver, acidified with nitric acid in the same proportion as the silver, and an infusion of linseed prepared by boiling for a short time—one ounce of linseed with ten ounces of water—and filtering. Equal parts of the iron solution and the infusion of linseed are mixed and a few drops of the acid silver added; this forms the developing solution, and an additional quantity of silver is added for intensification. It is not stated what *rôle* the linseed plays, but the process is said to be extremely rapid, requiring no more than twice the exposure of a wet plate.

Contemporary Press.

PHOTOGRAPHS OF OFFENDERS.

[Standard.]

The chief of the Berlin police has, according to the *Russian World*, presented to the chief of the St. Petersburg police a richly-bound album, containing photographic portraits of the various criminals who have passed through his hands; and this valuable gift is said to have been accompanied by a request from Herr von Madai that his eminent colleague in the suppression and punishment of crime would forward him a similar collection of Russian offenders. The Berlin police-master has, it further appears, sent copies of his album of suspected and convicted malefactors to all the great capitals of Europe and to several cities usually deemed of minor importance, but which apparently rank high in the statistics of crime. That the album of Prussian wrongdoers should be sent to such populous centres as London and Paris is intelligible enough; but what have Hamburg and Bremen done that they should be made the object of such marked compliment, involving, as it does, a similar attention in return? These seaports are probably looked upon as last resting-places for the absconder about to quit Germany for a voyage across the Atlantic, and it has probably not been forgotten that it was from Bremen that a few years ago the explosive apparatus was to have been shipped which burst prematurely on the Bremen quay. Hamburg, again, besides being an important seaport, is a great commercial city, and wherever business is carried on a certain proportion of business frauds must, of course, be expected.

Frankfort, as the head-quarters of German finance, was not likely to be forgotten, and Frankfort has received its black book, and will, doubtless, in due time, send its own black book in exchange. Where capitalists assemble thither will those whose aim it is to prey upon capitalists be naturally attracted; and though Frankfort is by no means a large city, its inhabitants need not feel hurt at being classed with the places in whose midst Herr von Madai believes that a large number of criminals habitually lurk. Those who know Baden-Baden in its new aspect, since the abolition of the gaming-tables, the partial suppression of the races, and the desertion of the place by the fashionable world and half-world of Paris, will find it difficult to believe that this most delightful of all inland watering places can be a favourite sojourn for breakers of the criminal law. But heavenly bosoms sometimes harbour rage; a glittering halo may hover round fury; and Baden-Baden, with all its beauty and all its calm, is no better than it should be, and has been esteemed worthy of that somewhat compromising gift, the photographic album edited, strictly for private circulation, by the chief of the Berlin police.

* * * * * * * * * * * *

Photography has done so much for criminals that it may be doubted whether, on the whole, this, like many other modern inventions, has not benefited them quite as much as it has injured them. In many of the large prisons the inmates are photographed, so that, in case of their returning after their liberation to evil ways, there may be no mistake as to their identity; and in some French prisons the photograph of the criminal is accompanied by a succinct and impartially-written memoir, that the police may be able to master at the same time the features of the convict and the leading incidents in his life. This seems hard upon the convict; but how often has he not brought himself beneath the action of the criminal law by a too ingenious use of photography, and especially of photolithography, in connection with the production of bank notes!

It would be interesting to know which first turned photography to effective account—the thief-taker or the thief. Probably the latter. For the police, as soon as they hit upon the notable expedient of photographing criminals, proclaimed the fact to the whole world, that the whole world might admire their cleverness. The criminals did not, of course, do anything of the kind. They behaved with modesty, or, at least, with discretion, executing their photographic reproductions as quietly as possible, and never once boasting of the ingenuity they had shown in turning the new process to a use which had probably not been contemplated by its inventors.

Who, again, is to say whether railways and the electric telegraph have, on the whole, been favourable or unfavourable to the practice of thieving? The thief can be followed quickly enough by train; but by the same means he can get away quickly. In railways, too, he found a new scene of action. How many robberies have been committed at railway stations and in railway carriages, from robbery accompanied by murder to simple card-sharping. In England the "road" had already lost its ancient glories when railways were first introduced. But in Spain and Italy, where brigandage still flourished, highway robbery was varied in form so as to suit the new conditions of travelling, and in both these countries banditti learned to stop trains either by placing obstacles on the line and signalling that they had done so, or by the simpler means of letting what they had done produce its natural effect.

The electric telegraph, again, though it has helped to facilitate the capture of criminals, has also enabled them in many cases to avoid being taken. It has been the means, moreover, of putting money in their pockets. There have been numerous instances of thieves telegraphing in false names for remittances to be forwarded immediately to some foreign hotel, where the supposed sender of the telegram might be, but, as a matter of fact, is not staying. A house of business—a bank, for instance—would pay no attention to such a message, except to request that it might be repeated by letter. But numbers of private persons receiving such a demand, as if from a friend, would do what was desired, and, regarding the case as one of urgency, would reply at once without a thought, and indeed without any possibility of making inquiries on the subject.

Among the class of men whose photographs Herr von Madai places in his album are many who are ingenious enough to work telegraphy, photography, and every kind of new invention in various ways, and always to their own immediate advantage. It is right that the tables should sometimes be turned upon them, and the new international exhibition of criminals which the Prussian police-master is endeavouring to organise will probably be found a valuable aid to the effective working of the beneficent principle of extradition.

Our Editorial Table.

Sensitive Plates. By R. Kennett.

We have received and tested a sample of sensitive plates prepared by the gelatino-bromide process. These reveal the fact that Mr. Kennett's hand is not losing its cunning as regards the preparation of gelatine plates, which, to his credit be it recorded, he was the first to introduce commercially to the public.

We have already alluded to the fact that when Mr. Kennett first introduced these plates he prepared them possessing such a degree of sensitiveness that he had great difficulty in inducing photographers to give them a sufficiently rapid exposure. Except under very exceptional circumstances dry plates having a degree of rapidity equalling that of wet collodion had not been met with previously, and there was thus a certain excuse to be pleaded for those who failed at once to realise the altered condition of things. To meet this difficulty Mr. Kennett, at the suggestion of ourselves and others, very wisely issued plates of a lower grade of sensitiveness, or about that of wet collodion—a step which, so far as we have been able to ascertain, has given universal satisfaction. While they are still sufficiently rapid for nearly every purpose, permitting "instantaneous" views to be obtained in a good light, there does not exist the necessity for developing them in a room from which light has been excluded almost altogether—a task extremely difficult and irksome to persons having eyes of only average quality.

The plates we now bring under notice are technically perfect, possessing, as they do, freedom from any mechanical imperfection. They are also very tensile as regards the exposure they may receive. Having given one of these plates an exposure six times longer than that given to another, the subject and lens being the same in both cases, we have obtained good negatives on both. The whole secret consisted in treating the intentionally over-exposed picture to a weak bath of bromide of potassium previous to applying the pyrogallic acid. We are not aware what has been Mr. Kennett's experience in connection with the "frilling" of the gelatine film of his plates; but we have never experienced such a mishap since we adopted the very simple expedient recommended by some writer of whom we have no recollection at present, which consisted in dissolving a pinch of Epsom salts in the water used in the washing, and developing the plates. Soft water sometimes produces frilling; any method by which the water becomes hardened provides, however, an effectual remedy for the evil.

Catalogue of Photographic Apparatus.

London: Wratten and Wainwright.

We have received from Messrs. Wratten and Wainwright, of Great Queen-street, their new *Illustrated and Descriptive Catalogue of Photographic Apparatus and Materials.* In addition to the comprehensive matter it contains as a catalogue, and in which are comprised cameras, lenses, stands, rolling-presses, and the variety of chemicals and preparations employed in photography, there are appended "Notes on Processes," in which we find epitomised much useful information. We present, by way of specimen of this department of the catalogue, what is said concerning one of the processes of the day, namely, *Gelatino-Bromide Emulsion*:—

"Inasmuch as some of our clients who are sufficiently advanced in the routine of wet-plate and dry-plate photography have manifested a desire to make their own dry plates, but have not been well acquainted with the best manner of setting about it, we give the following practical details of the gelatino-bromide dry plates, and we hope so simply and lucidly that their meaning may be easily comprehended.

"To make five ounces of gelatino-bromide emulsion:—

Formula.

Gelatine (Nelson's No. 1)	90	grains.
Ammonium bromide	45	,,
Silver nitrate	75	,,
Water (distilled)	5	ounces.

Select a twenty-ounce bottle with a securely-fitting stopper. First pour in four ounces of the water, dissolve therein the bromide of ammonium, then add the gelatine, and leave to soak for one hour. The advantage of a well-fitting stopper will be obvious; for if, in shaking up, any of the liquid were lost, some of the bromide salt would go therewith, and the balance would be disturbed. There is a manifest advantage in first dissolving the bromide salt in the water, for we thus succeed in evenly and equally distributing it throughout the whole body of the gelatine; and, if precaution be taken in regard to the stopper of the bottle, there need be no loss of bromide. Next, dissolve in a separate bottle seventy-five grains of nitrate of silver in the remaining ounce of water. Place the two bottles in a jar or jug of water of 100° temperature, and solution of the gelatine will quickly take place. Now carefully unite (in the dark room, of course) the contents of the two bottles. The nitrate of silver solution may be slowly stirred into the bromised gelatine, or it may be added in small quantities with a thorough shaking between each. Either method, if *well* done, is efficient. We have now a gelatino-bromide emulsion containing a slight excess of bromide, and this slight excess, while not in any marked degree detracting from its sensitiveness, will be found of eminent service when we arrive at the developing stage. By the addition of the nitrate of silver to the bromised gelatine an action termed 'double decomposition' is originated; in other words, an interchange of elements takes place between the two salts. If nitrate of silver were added to water containing bromide of ammonium in solution an interchange of elements would instantly take place; insoluble bromide of silver would subside, and nitrate of ammonium would remain in solution. But gelatine, being a viscid medium, retards this chemical interchange, and therefore time must be given to bring it completely about. In order, therefore, to keep the gelatine in a liquid condition we place the bottle in water of 100° temperature, and it is found in practice that a period of from four to six hours will complete the double decomposition.

"If water of a higher temperature than 100° be employed the interchange will be completed in a shorter space of time, as the gelatine, being thereby rendered more limpid, presents less obstacle. But we must bear in mind that 100° is a safe temperature, and that a higher temperature can only be employed at the risk of decomposing the gelatine, the results of which would be inconvenient at the final stage of development, these results being blisters and frilling.

"A period of six hours having been given for digestion, take out the bottle of gelatino-bromide emulsion, and pour the emulsion into a flat dish to *set*, and when so *set* the final operation may be performed. It will be seen from the foregoing remarks that the gelatine holds in suspension two compounds—bromide of silver and nitrate of ammonium. The former is the sensitive salt; the latter is matter in the wrong place, and must be removed, or it will crystallise on the plates and spoil them. In order to remove the nitrate salt in the most effective manner we have found the following method all we could desire:—

"*Apparatus Required.*—1. A bag made of that "napless" canvas which ladies employ as the basis for Berlin wool work.—2. A trough, say twelve by ten inches, and ten inches deep, and fitted with tap to draw off the water, with a ledge around the inside, about two inches from the top to support.—3. A tray with wood sides and *calico* bottom.

"Scrape the gelatine up with a strip of glass, and transfer it to the canvas bag; close the aperture of the bag, and, by the pressure of the thumb and fingers, force the gelatine through the meshes of the canvas into a basin of water. We now have the gelatine in extremely fine division; but it is also mixed with a vast excess of water. Now we pour the whole on to the tray with the calico bottom, and the water will pass off, leaving the gelatine high and dry. In order that we may be sure that the proper amount of work is done, it is well to fill up the trough with a fresh supply of water, and let the tray float upon it for ten minutes.

"When the water has been finally drained off we transfer the gelatine to a bottle, stand it in hot water, and when dissolved and filtered it is ready for coating the plates. This latter operation is difficult for a beginner, and inasmuch as the plates require a long time to dry—from twelve to twenty-four hours—he must have a room or a drying-box fitted up expressly to keep out light during drying. When the plates are coated they must be laid on a *levelled* surface to become set, and so soon as set they may be stood up or placed in the box to dry."

The foregoing extract conveys a fair idea of the manner in which these "Notes on Processes" have been prepared.

The Forty-Fifth Annual Report of The Royal Cornwall Polytechnic Society.

We are placed at a slight disadvantage in noticing this comprehensive *Report* on account of the fact that, although it was only presented at the forty-fifth annual meeting of the Society which was held during the present year, the exhibition, with which the *Report* mainly has to deal, was held in September last year, and in our issue of the 7th of that month we were enabled to publish *in extenso* that portion which possesses the chief interest for photographers. From the catalogue we find that the number of professional photographers who exhibited on that occasion was twelve, there being only six amateur exhibitors. Nine medals in all were awarded to these exhibitors.

The following is the list of prizes offered for the next exhibition:—

Sec. I.—Professional Photographers.

1.—For the best landscape, size not less than 14 in. × 11 in.—a silver medal.
2.—For the best landscape, size not less than 11 in. × 9 in.—a bronze medal.
3.—For the best landscape by the collodion emulsion process, size not less than 9 in. × 7 in.—a silver medal.
4.—For the best landscape by the gelatine emulsion process, size not less than 8 in. × 6 in.—a silver medal.
5.—For the best interior by any process, size not less than 11 in. × 9 in.—a silver medal.
6.—For the best portrait, taken direct, size not less than 14 in × 11 in.—a silver medal.
7.—For the best portrait, size not less than 10 in. × 8 in.—a bronze medal.
8.—For the best group, composition or otherwise, size not less than 14 in. × 11 in.—a silver medal.
9.—For the best enlargement landscape (in carbon), size not less than 20 in. × 16 in.—a silver medal.

The judges may decline to make any award in any of the above classes where there are less than three competitors in that class.

All work that has been elaborately touched, either on the negative or print, will be excluded from competition. Slight spotting only allowed.

(*Carte-de-visite* portraits are excluded from exhibition.)

Sec. II.—Amateurs.

Medals are offered for productions in this department.

The University Magazine.

London; Hurst and Blackett.

The May number of the *University Magazine* contains as the subject of its series of "Contemporary Portraits" that of the Right Hon. W. H. Smith, M.P., First Lord of the Admiralty. It is printed by the Woodbury mechanical process from a negative by Lombardi and Co., the likeness being most striking and characteristic. The general articles, of which this excellent number of the *University Magazine* is composed, is of the usual advanced and attractive character.

Burlington House.

London: 15, Russell Street, Covent Garden.

This is the first issue of a new quarterly devoted, critically, to the Royal Academy, Museums, Universities, learned Societies, and Burlington Debating Association, its editor being Mr. C. O. Groom Napier—a gentleman whose name is well known to the members of the British Association. The general contents are not calculated to interest photographers as such, although photography has been employed as a medium by which to illustrate one article—*Ancient Knowledge of Precious Stones*—which it does in an effective manner.

Meetings of Societies.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

The usual meeting of this Society was held on Tuesday last, the 14th inst.,—Mr. James Glaisher, F.R.S., President, in the chair.

The minutes of the preceding meeting having been read, the President alluded in feeling terms to the death of Mr. J. A. Spencer, and expressed sympathy with Mrs. Spencer.

Messrs. J. L. Montifiore and John L. Güger were elected members; after which the President presented to Mr. Henry White, a former treasurer, the medal which had been awarded to him in recognition of the services he had rendered to the Society.

Captain ABNEY then read a paper on *Photography at the Least Refrangible End of the Spectrum, and on Some Photographic Phenomena.* In the course of his communication Captain Abney exhibited a variety of negatives of spectra. Some of these were obtained by diffraction gratings ruled on speculum metal by Mr. J. M. Rutherfurd, of New York, two of which gratings were exhibited to the members—one containing 17·280 and the other 8·620 lines to the inch. The others were obtained by prisms. The second part of Captain Abney's subject was that which will possess the highest interest for practical photographers, as it formed a sequel to his paper of last year *On the Destruction of the Photographic Image by Means of Various Oxidising Agencies.* This paper will appear in our next.

The CHAIRMAN, in tendering the thanks of the Society to Captain Abney, said that the experiments described were quite unique. He had never before seen solar spectra of such perfection, and they must have been the result of protracted experiments.

Mr. WILLIAM ENGLAND then read a paper *On Dry Plate Processes.* This communication also will appear in our next number.

Mr. SPILLER, alluding to one process recommended in the paper, inquired what end was served by drying the plate after the application of the beer and previous to that of the solution of pyrogallic acid.

Mr. ENGLAND replied that it gave the film greater hardness. It was also better to apply the pyrogallic acid solution by itself after the drying of the film, as greater sensitiveness, with more detail, was obtained. With respect to sensitiveness, the process gave plates which were about one-fifth slower than wet collodion.

Mr. WILLIAM WAINWRIGHT, Jun., exhibited a negative taken on a gelatino-bromide plate with an exposure of six seconds, a small stop being employed in the lens.

Mr. T. SEBASTIAN DAVIS, after a few remarks, read a paper in which he gave full details of a dry process that was highly successful.

For this paper and that of Mr. England the Chairman returned thanks to the respective authors.

The CHAIRMAN then announced that there would be an annual exhibition as usual; it would be opened in the beginning of October and closed on the 12th of November. The Council had decided that medals would be awarded for the best productions. Full particulars regarding this would appear in due time. He (the Chairman) also announced that at the next meeting, to be held on June 11th, important communications would be made by Mr. J. R. Johnson *(On Alizarine)*, Mr. Bolas *(On Gelatine)*, Mr. Warnerke *(On the Phenomenon of Blurring)*, and by Mr. Sarony *(On Pigment Printing)*.

The proceedings then terminated.

MANCHESTER PHOTOGRAPHIC SOCIETY.

THE last meeting before the usual summer recess was held at the Memorial Hall, on Thursday evening, the 9th inst.,—Mr. A. Brothers, F.R.A.S., President, in the chair.

The minutes having been disposed of,

The PRESIDENT said it was in contemplation to have an exhibition of photographs in conjunction with the coming exhibition of paintings, &c., at Peel Park, in August next, and requested contributions from the members of the Society.

The Secretary laid the *Bulletins* of the Belgian Photographic Society on the table.

Mr. Lund showed some prints on Durand's paper, printed by himself (Mr. Lund) in December last, and toned on the 5th May. The tones were satisfactory.

Mr. W. J. Chadwick exhibited a pair of lanterns of new design, one feature of which was that they had no chimney. He (Mr. Chadwick) also exhibited a new oxygen retort. [Mr. Chadwick has forwarded to us two short communications on these subjects, which will be found on another page.]

The meeting, which was well attended for the season, was then adjourned.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

AN ordinary meeting of this Society was held on the 15th March,—Dr. Vogel presiding as usual.

Herr Schmidt, of Kiel, sent a carbon print, the greater part of which was covered with white lustrous flecks, which appeared to be particles of paper that had dissolved off from the transfer paper in the course of the second transfer.

Herr SCHAARWÄCHTER said he had observed the same fault, though not very often, and had remarked that it occurred when too long a time was allowed to elapse between the sensitising of the paper and its development.

The CHAIRMAN observed that he experimented with the paper Herr Schmidt had sent along with the pictures, and had got faultless results.

A letter was then read from Herr Siegson, of Ribinsk, Russia, on reversing negatives. The contents of this letter rather surprised those who heard it read, as they were not accustomed to think of varnished negatives being so easily drawn off, and had, consequently, confined their experiments to the drawing off of unvarnished plates.

The CHAIRMAN remarked that he had had difficulty sometimes in drawing off even unvarnished negatives, with leather collodion and caoutchouc, as the negative would not always come off quite free. He then added a little sulphuric acid to the water in which the plates were laid, after which all went well. Unfortunately plates intensified with lead and potassic chromate could not be treated with sulphuric acid, as the lead and chromium compound would thereby be decomposed.

Herr HARNECKER, of Wriezen, showed some of his excellent enlargements, and remarked that he supposed those present were all aware that such enlargements were produced by development. They were obtained by artificial lights, the most powerful of which was the electric light. But, in common with Dr. Vogel, he had experimented with electric light, and found that its chemical action was not so great as would have been expected from its great intensity; still, with a little care, one could regulate the length of the exposure. He was just having a rotating electric machine, driven by a steam engine, fitted up, and he hoped by its means to produce pictures measuring six metres by five metres. He had already produced one print, life size, from a portrait of the Emperor of Austria on horseback. This picture was taken upon shirting, and was intended to be painted over in oils. He (Herr Harnecker) then showed a half-length portrait on shirting, which was but little behind a similar picture on paper.

Herr Obernetter had sent some coloured lichtdrucks of a large size produced by his new process, and made a communication to the effect that fog could be removed from his new reversed negative dry plates by slightly acidulating the iodide and bromide baths.

The CHAIRMAN said he had prepared some good dry plates in the way described by Herr Obernetter. It did not seem to be very difficult to work with emulsions, and the work produced could be relied upon; but the work of producing the emulsion itself was somewhat ticklish and uncertain in its results.

Herr HARNECKER added that he had experimentally prepared some paper in the way Herr Obernetter prepared his plates—that is, he had first silvered and then iodised it; but he had not found paper so prepared suitable for his purposes. The silver had to be kept very acid, and thus became not very sensitive, while sensitiveness was required by his process.

The CHAIRMAN then made some interesting experiments with collodion cotton, to show that it was not so combustible a substance as it was generally assumed to be. First he set fire to a quantity of collodion cotton, which burned quickly but not explosively. He then struck another quantity of the cotton repeatedly and sharply with a hammer without its showing any tendency to explode. Lastly: he moistened a quantity of collodion cotton with alcohol, and set it on fire, when it burned like ordinary alcohol, only that the flame was somewhat yellower than usual—an appearance which a spectroscopic examination showed to be caused by the calcium contained in the cotton. When the greater part of the alcohol was consumed the cotton in the corners began to carbonise, and was thus consumed without explosion. These phenomena, he (Dr. Vogel) said, led him to the following conclusions:—1. That it is not possible to set common collodion cotton on fire by a knock or a blow.—2. That collodion cotton moistened with alcohol does not explode on ignition, and that in this condition it is not more combustible than alcohol alone.—3. That even dry collodion cotton, supposing it to be ignited, is not so explosive as to make it likely to cause fire in ordinary circumstances.—The unlikelihood of spontaneous combustion was not so easily demonstrated by experiment; but, so far as he (the Chairman) was aware, no single case of the spontaneous combustion of collodion cotton had been properly authenticated. He hoped, by impressing those conclusions on the authorities, the rigorous prohibition of the transmission of collodion cotton would in time be relaxed.

The meeting was shortly after adjourned.

Correspondence.

EBURNEUMS.

To the EDITORS.

GENTLEMEN,—In your issue of last week, in the article on *Recent Improvements in Carbon Printing*, you allude to the eburneum process of the late Mr. John Burgess in these terms:—

"But owing to the heavy smudginess of the tones and the silver basis few cared to adopt this process in everyday practice."

The blackness of the tone was always somewhat of an objection to my late partner, Mr. Burgess, and at a very early date of carbon printing he adopted it for the eburneum process, but subsequently gave it up owing to the difficulty of getting satisfactory vignettes (as this class of picture formed the bulk of his business), and also from the fact of carbon prints being limited in size by that of the negative, whereas by the camera process any amount of reduction or enlargement is readily obtained with satisfactory definition.

As to the tone: when well done the colour produced by gold is generally liked by my customers; and smudginess, hardness, or excessive coldness of tone are due either to a defective negative or want of skill in the manipulation.

I believe the reason the process was not more generally adopted by the profession was owing to the difficulties which beset it. It needs a rather long experience to produce the exact class of transparency required, and great care is necessary in all the stages of the merely mechanical part, from the varnishing to the final drying; and though to produce one or two is really easy enough, to work it on a commercial scale requires a well-appointed place, experience, and a great amount of thoughtful care.

After an experience of fifteen years I venture to pronounce the eburneum pictures permanent, never having met with a single case of fading in any form. There is not the slightest difficulty in producing eburneums in carbon with or without collodion, and about thirteen years ago Mr. Burgess produced some very clever double-printed eburneums in carbon, introducing fancy margins, lines, &c.

I enclose a few of my *carte* eburneums, and I think you will admit that they are neither smudgy nor hard.—I am, yours, &c.,

Queen-Street, Norwich, May 13, 1878. H. C. Jennings.

[The proofs enclosed are *exceedingly* fine, being much superior to the original productions which elicited the comments we made last week.—Eds.]

GELATINO-BROMIDE.

To the Editors.

Genllemen,—I am desirous of preparing some plates in accordance with the plan described recently by Mr. C. Bennett in your Journal of March 29th, but am deterred at the outset by certain questions arising.

In the first place, Mr. Bennett says:—"Weigh out for a ten-ounce emulsion—

Bromide of ammonium	7 grains.
Best nitrate of silver	11 ,,
Gelatine	20 ,,
Distilled water	1 ounce."

Judging from the quantities given I suppose these must be multiplied by ten.

In the next place, as to coating the plates: must a thick pool be poured on them and left? or should they be tilted and drained like collodion? or should any definite quantity, and if so how much, be used for a plate of any given size?

Finally: should the plates be kept level, and the gelatine liquid until dry? or should the gelatine be allowed to set and then the plates might dry upright? or will either plan answer?

Information will much oblige, yours, &c., D.

Regent-street, London, May 15, 1878.

[Perhaps Mr. Bennett will kindly reply to this correspondent.—Eds.]

VERTICAL AND HORIZONTAL LINES.

To the Editors.

Gentlemen,—By way of sequel to my previous letter, I propose to offer one or two practical considerations arising from what I may now take, I hope, as proved in them, as to the apparent non-parallelism of all lines of considerable length in nature.

It has been suggested to me that I might devote a few words to meeting the common objections to the position I have been attempting to establish. But, in the meantime at least, I prefer to leave the question standing on the simple ground that the top of a high tower must be further from a spectator's eye than the bottom; and, if so, then the breadth of one side of the tower at the top must appear smaller than that of the same side at the bottom. This is only another way of saying that the vertical lines bounding the sides of the tower are not parallel, but seem to slope towards each other by a very small but appreciable amount of inclination.

But in proving that this must be so I am far from offering an excuse for the careless or ill-informed photographer and his tumbling towers and vistas of buildings running off into nothing. He ought to level his camera and use his rising-front; or, if he must tilt his camera a trifle, adjust his swing-back to compensate for it. Nothing should be attempted beyond what his optical means can reach, or nearly reach, without inclining his apparatus.

There may be circumstances—as in many old European cities, their narrow streets and market-places—which defy the shortest-focus lenses of our first makers to do their work without some distortion; but, even so, if the negative must exhibit sloping lines when they ought to be upright, the blemish should be corrected, by means well known to the skilled copyist, before a print or a lantern slide is taken. The public, in short, are getting educated on this point—to discriminate between good and inferior workmanship. People will not buy pictures of architectural subjects in a state suggestive of a violent earthquake and the instant crumbling of "cloud-capped towers and stately palaces."

Photographers are not infrequently glad to get access to a window on the first or second floor of a house, and so improve their position. In extreme cases the thing may be tried; but the height sought ought not to exceed the *entresol*, or at most the first floor. And why? One reason is that the lines below the level of the camera are thrown into violent perspective and resemble nothing seen in actual existence. But that is not the only reason. By mounting high above the street the diminution of horizontal lines by distance *takes effect at the bottom as well as at the top of the house* or other object to be copied. Suppose I want to copy a building across a street forty feet wide, and I mount to a window opposite to it thirty feet from the ground, the calculation I employed in my former letter shows me that my eye is now fifty feet from the bottom of the building I want to copy; the base line of it is, therefore, one-fourth part shorter than the corresponding line on a level with my eye. And this tapering is, of course, repeated upwards as well as downwards, so that the swing-back cannot be put in requisition for the double correction; if you apply it to compensate for one you double the amount of the other. It is well that a photographer who aims at irreproachable workmanship should know when he ought to yield to circumstances; and if his only means of accomplishing something he desires is to be attained by mounting to the top of a house, he would be wiser to forego the impracticable and turn his forces to better account elsewhere.—I am, yours, &c., James Stothert.

Clapham, May 10, 1878.

Bigamy: Sentence.—In continuance of the case which was reported in our issue of the 26th ult., Richard David Turnbull, 32, artist, was indicted, before the Common Serjeant, at the Central Criminal Court, on the 9th inst., for feloniously marrying Eliza Mary Dore, his wife being alive. Mr. Straight and Mr. Tamplin prosecuted, and the prisoner was defended by Mr. Kelly. The evidence went to show that the prisoner was first married in the year 1865, and that the woman he then married was still alive. It was clearly established that the prisoner subsequently went through the ceremony of marriage with at least two other women. The jury found the prisoner *Guilty*, and it was proved that he had been convicted of larceny and sentenced to eighteen months' hard labour. Mr. Straight informed the Court that the prisoner's career had been a very bad one. He was originally convicted of robbing his master, and after he obtained his liberty he went through the ceremony of marriage with several young women, and complaints had been made against him by a number of others, who stated that the prisoner, finding that he could not succeed in seducing them, had at length induced them to go through the ceremony of marriage with him, although he was perfectly well aware that his real wife was alive at the time, and that he had been married to several other women. The prisoner was sentenced to twelve months' hard labour.

Curious Case: Dust *v.* Kent.—This suit was heard on the equity side of the Lord Mayor's court, the judge, Sir T. Chambers, Q.C., taking it without the aid of a jury. The whole question at issue rested upon the construction of certain leases and agreements which had been entered into between the different occupiers of the premises for many years. The plaintiff carries on business under the name of D. B. James and Co., as general photographer, and occupies premises in Cannon-street, at the corner of Dowgate-hill. The entrance door to the photographic studio is at the corner of the building, and opens into a lobby, from which there is a staircase leading to the plaintiff's place of business. At one time those and the adjoining premises, where the defendant was in business as a hosier, were part and parcel, but in course of time they became separate under different lessors. On the right-hand side of the entrance lobby there was a doorway, which for some years had been used by the occupiers of the premises in question whereon to hang specimens of their photographs, &c. In cross-examination by Mr. Hilbury, who was instructed by Messrs. Curtis and Bates for the defendant, the plaintiff, who was asked whether he could seriously contend that the fact of the glass window being placed in the door had injured his business, said Yes; and to a greater extent than for the sum claimed in the present action, which was £800.—Mr. Hilbury: Why?—The plaintiff said that because the defendant was in the habit of displaying coats, braces, and articles of that description, and ladies who were accustomed to visit his place would not like to be confronted with the vision of such things as these. (A laugh.)—The learned Judge observed that it was feasible enough that many ladies who took a fancy in visiting the establishments of photographers would not altogether desire to be placed *vis-a-vis* with a number of young hosiers, whom they must see when this door was open. (A laugh.) He asked the plaintiff whether that was correct or not, and whether ladies under those circumstances did not court seclusion and privacy as far as it could be reasonably obtained.—The plaintiff said, as a rule, that was so.—Mr. Wildy Wright, who was instructed by Mr. Norton, represented the plaintiff.—In the result, the parties agreed to leave it to the Court to say what should be reasonable between them, the defendant offeiing to concede to the plaintiff the right to hang his pictures below the level of an opaque glass window in the door, and to further permit him to exhibit a small case of photographs under his (the defendant's) show-case, the result desired to be effected by the compromise being that the defendant should still have the advantage of light through the door into his shop without interfering with any of the advantages which the plaintiff had hitherto enjoyed.—The learned Judge therefore said he should take time before giving his formal decision.

EXCHANGE COLUMN.

Wanted to exchange, a musical box, playing six tunes, for a Dallmeyer's No. 1B lens.—Address, J. Cooper, 49, Clopton-street, Hulme, Manchester.

A Ross's quarter-plate portrait lens, and shifting back camera for two *cartes* on half-plates, will be exchanged for doublet by any good maker.—Address, W., 46, Haverstock-hill, London.

Wanted to exchange, a Voigtländer extra rapid B. *carte* lens, with stops, in good condition, for a whole-plate bellows camera, or $8\frac{1}{2} \times 6\frac{3}{4}$ medium-angle doublet by Ross.—Address, G. Fear, 36, Fore-street, Trowbridge.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

A. Burns.—Received.

XXX.—Try E. Mander, Birmingham.

W. H. D. (Edinburgh).—The specification will be obtained and forwarded.

S. Bamforth.—We have never tried tin for the purpose; wood answers very well.

L. Hart (Sydney).—The Journals required have been out of print for several years.

R. L. A.—You may depend upon receiving any assistance we can give in such a good cause.

F. Daking.—The method proposed will answer quite well, and will repay the trouble and expense.

Flux.—All will be right if you add carbonate of potash with a little borax, and apply a stronger heat.

W. Harrison (Paris).—Our correspondent's MS. only reached us when the Journal was "made up" for press.

Leo.—The patent for the Scotellari cap has expired. The protection was confined to the six months provisionally granted.

A Stalker.—Make, first of all, a saturated solution of bichromate of potash, and then dilute any portion of this with one-third of its bulk of water.

A. N. B.—Make use of a collodion yielding a transparency in which the whites shall be entirely free from fog. The collodion you now employ does not appear to be suitable.

Old Sub.—The spots are undoubtedly the result of air-bubbles in the albumen, which ought to have been filtered through loosely-matted felt before being applied to the surface of the plate.

Redlander.—Desiccated albumen if dissolved in water containing a trace of ammonia will answer quite as well as fresh albumen for the purpose mentioned. The best strength will be four grains of albumen to an ounce of water.

D. W.—Yes, we are aware that there is such a trade as a manufacturer of brasswork, racks, &c., for cameras; but we are unable to afford further information concerning it. Any of the fittings may be obtained from camera-makers.

N. A. P.—No directory of photographers has ever been compiled; certainly no such compilation has ever been published. To issue such a work would entail a loss of too serious a nature to warrant any publisher undertaking the task.

Carbon Points.—There is no reason why you or any one else may not employ the electric light in portraiture. The patent granted in connection with the subject was not for this application of the light, but for a lamp of a peculiar construction.

A. E. Kralc.—We have some recollection of having noticed such a work being advertised; but not having seen it we are, consequently, totally ignorant of its merits or demerits. Of the various cheap manuals that by Mr. Jabez Hughes is probably the most comprehensive.

F. C. M.—Although not so well adapted for the purpose as a properly-constructed landscape lens, the front lens of a portrait combination will be suitable for producing landscapes of great excellence, provided an angle of view of too great width is not attempted to be included.

Lieut. J. D. Lysaght.—This gentleman favours us with some specimens of rapid work by gelatine plates, prepared according to the formula given by him in our Almanac for the present year (see page 93 of that work.) These specimens bear internal evidence of the great rapidity, indeed, of the exposure.

W. S. Alcock.—So much depends upon the manner in which the enlargement is to be finished that without knowing this it would be impossible to offer advice. It is probable, however, that a very rough drawing-paper will answer, so far as your purpose can be divined from your very vague communication.

J. Wilson.—The transparency is as good as could be expected under the circumstances. We have returned it as directed. The whites may be rendered quite clear by the application of a solution of cyanide of potassium in which has been dissolved a small quantity of iodine. This must be used with great judgment, as it acts most powerfully upon the picture.

S. Fry (Surbiton).—Our correspondent, in a note, says that the "Peripatetic Photographer" is wrong in saying that he (Mr. Fry) is going to give up carbon, for he intends to use both carbon and silver daily for such class of work as he thinks them suited to; and that what he really did say at the meeting in question wasthat he did not purpose to issue at present *cartes* and cabinets in carbon.

F.R.S.—Your five-inch astronomical telescope will answer exceedingly well for lunar photography. It will, however, be requisite to ascertain the precise amount of difference between its visual and chemical foci, for all such objectives are over-corrected to a slight extent. A few trials (which may be made during the day, and on a terrestrial subject) will enable you to determine the difference. It may be worth while to separate the two lenses comprising the objective, employing for that purpose a very uniformly-constructed ring of metal; but this is accompanied by some risk, and will not, we think, prove quite so good a method as that which we have already suggested.

Caledon.—The copyright, if such really do exist at all, is in the photograph, and not in the view itself. You may go to the very same spot from which the picture was obtained, provided a good reason exists for doing so, and take any required number of negatives, with lenses of any desired focus, and upon plates of any dimensions, without incurring the slightest risk of the "dread vengeance of the law." In brief, you must take a negative from nature yourself, and not copy that which has been taken by your rival.

M. R. S.—The want of sharpness in the *carte* may be due to a variety of causes. The lens may be so bad as not to produce a sharp image; or it may be good but the focussing imperfectly done. Again: the lens may be good and the focussing all that can be desired, but the ground glass and the sensitive plate may not occupy precisely the same planes. Bear this in mind: the larger the aperture of the lens with which you are working compared with its focus the more necessity there exists for securing absolute identity between the focussing-screen and the plate. There being no depth of definition, the manipulation is rendered more delicate and "touchy." We know a successful photographer who failed to obtain sharp pictures when using a large "baby lens," solely because the spring in the back of the dark slide was too strong and caused the thin holder to bend.

Instantaneous Photography.—We are favoured by Mr. Charles Bennett with a negative—accompanied by a transparency and a print taken from it—the peculiarity of which is so well described by Mr. Bennett that we make no apology for giving a copious extract from a note enclosed with the above:—"The photograph represents water being poured from a jug on to a group of flowers, the exposure being reduced to that excessive minimum by a mechanical arrangement that it delineates the drops of broken fluid in the act of descending. A magnifying glass applied to the negative places this fact beyond a doubt. The light was not good, the sun being quite clouded; but it being about noon the time was very much in favour of the operation. Upon consideration it must strike the most inexperienced that the difficulty of photographing a moving object so close to the camera—say eighteen feet—is much greater than that of an object further off—say, for instance, people walking, or a stormy sea—as it is obvious that the former will pass across the surface of the plate in the camera *much* quicker than in either of the two latter instances, in addition to the light being *very* much weaker in proportion as the object is brought nearer to the camera. I should like you to examine it to see whether you think that a wet collodion plate under any circumstances could be made to produce the same result; or, better, taking into consideration the rendering of the weaker gradations of light which I have endeavoured to bring out in this negative from the deeper shadows of the hall seen in the rear of the subject. I am told by an adept in the wet process that the same result is *quite* possible with bath and collodion specially prepared, and I do not say 'nay.' In my own hands, however, a good many years back, when I occupied myself solely with wet plates and succeeded in getting very fair instantaneous views of waves and shipping, I failed with a subject similar to the one I have now been attempting; but it by no means follows that others more skilful in the old process should not surpass it entirely. I simply send the negative to you to give your opinion on the matter."——The negative is fully exposed, and an application of a magnifying glass shows very plainly the drops of water trickling down upon the flowers from a jug held on high by the lady whose portrait is taken in this unusual position. The picture is a great triumph for dry-plate photography.

The Queen and Photography.—Mr. M'Lachlan had the honour of submitting to Her Majesty's inspection on Friday last, at Buckingham Palace, the large picture painted by him, from photographs taken purposely and from life, representing the Queen and the Royal Family at Windsor.

Photography from a Paddle-box.—Writing to us, from Sydney, Mr. B. J. Edwards has enclosed a print from a quarter-plate negative taken under circumstances of an unusual kind. He says:—"It is on an emulsion plate prepared last November in England. The plate was kept in the dark slide through the tropics and knocked about in the cabin a good deal during the voyage out, so that I hardly expected any result. The exposure was made from the paddle-box of a small coasting steamer in a very rough sea. I cannot guess the time, but it could not have been more than a quarter of a second, the motion of the vessel being very great and the speed at the time about nine miles an hour." Mr. Edwards adds:—"I find photography flourishing in these colonies, especially in Sydney. I hope to visit Tasmania, New Zealand, and return in the autumn, *via* Fiji, Honolulu, and San Francisco. I hope to get some negatives on the way, but my crippled foot has prevented my doing much work at present." The subject depicted in the photograph is a bold, rocky headland some distance off (the sea intervening), yet sufficiently sharp to enable us to see its general features.

THE BRITISH

JOURNAL OF PHOTOGRAPHY.

No. 942. Vol. XXV.—MAY 24, 1878.

ON THE COMPARATIVE DENSITY OF DRY-PLATE FILMS.

Considerable variety of opinion exists in different quarters as to whether the best results are obtainable upon thick or thin films, each class finding numerous supporters ready to uphold the superiority of their respective favourites. Though latterly the weight of opinion has tended in the direction of a dense, creamy coating, there are still many who retain a liking for the clear, transparent films so closely identified with the ancient tannin and other processes now almost passed out of use, and notably with the "rapid" plates formerly issued by Dr. Hill Norris. Recent alterations and improvements in the conditions attending the preparation and use of dry plates have, no doubt, done much to establish a new series of requirements in this direction; but still sufficient similarity remains between the processes of today and a dozen years ago to render the subject worthy of a passing notice.

A kindred subject—the fineness of division of the silver bromide in emulsions—was discussed in these columns a few months ago; and, though no absolute rule was established, the general opinion was expressed that fineness of division (which was held to be tantamount to transparency of the film) leads to density of image, while a coarse formation of the bromide (giving an opaque film) is conducive to sensitiveness.

If we accept this as a broad rule—we by no means accept it unconditionally—it still leaves our present subject open to a good deal of further discussion. It does not touch at all upon plates prepared by means of the bath; and, even confining ourselves to emulsion films, it is obvious that the density—or *apparent* density—may depend upon widely different causes, such as the physical state of the silver haloid, the proportion in which it is present in the emulsion, the manner in which the films are treated, and, lastly, the nature of the organifier (if any) which may be employed. All or any of these conditions are capable of producing a modification in the appearance of the film—indeed the same emulsion may be made by a very trivial alteration in the mode of treatment to yield films of widely different characters; hence we may consider the subject in its various aspects, and endeavour to trace the connection, if there be any, between the physical properties of the film previous to exposure and the results obtained.

Viewing the subject from a standpoint altogether independent of the mode by which the plates are prepared, we might reasonably expect to obtain certain special properties with each description of film. Thus a dense film would seem to offer the readiest means not only of producing a dense image, but also of rendering a wide range of half-tones. Its comparative opacity would also render it less liable to the defect of blurring, as by its power of arresting the whole or a greater portion of the rays falling upon it reflection from the back surface of the plate would be reduced to a minimum. A thin film, on the contrary, might be expected to yield a more delicate image, devoid of strong contrasts and, in point of actual density, inferior to one produced upon a film richer in sensitive matter. These results, however, are as often as not exactly reversed. We know that the thin, transparent tannin films were capable of yielding an unlimited degree of density, the general tendency, unless carefully treated, being towards harshness of contrast. On the other hand, some of the most opaque emulsion films we have yet seen have exhibited an almost complete incapacity to acquire density under any form of development or intensification.

Again: on the score of blurring, though tannin plates were peculiarly liable to the defect, the employment of a coloured backing, except under very trying circumstances, effectually cured it, whereas some of the denser descriptions of films are equally liable whether the backing be used or not. It may, certainly, be urged that the blurring is not of the same description on the two forms of plates; that is to say, it does not arise from the same cause—reflection from the back surface. With the dense film it is, probably, produced in the film itself by irradiation or reflection from the particles of silver bromide. On a broad view of the question, then, it does not appear that any real advantage attaches to either side, or, in other words, the bare fact of a film being dense or transparent when separated from other conditions has no effect upon the resulting image.

In connection with the comparative sensitiveness of thick and thin films various claims have been made in favour of the former. The late Mr. Sutton held that a dense bromide plate possessed greater sensitiveness than a more transparent one, simply by virtue of the greater quantity of sensitive material it contained. Without disputing the facts as regards the comparative sensitiveness, we are of opinion that Mr. Sutton's conclusions were based upon a misapprehension. If we fix the normal sensitiveness of silver bromide at a certain standard it is impossible to believe that that standard will be either raised or lowered by the mere alteration of the aggregate quantity of materials acted upon; that is to say, if the normal sensitiveness of a single atom of the haloid be fixed at 1, we cannot believe that the mere bringing together of two atoms will raise the sensitiveness to 1½ or 2 in the aggregate. The true explanation is, we think, easily found elsewhere. Mr. Sutton, it will be remembered, worked the bromide process with the bath, in which the employment of a strong silver solution—the chief condition requisite to the formation of a dense film—is also highly favourable to rapidity. Though Mr. Sutton used a highly-salted collodion the absolute sensitiveness of his films would not have been altered had the salting been reduced from twelve to eight grains per ounce, provided the same strength of bath were adhered to, and yet the films themselves would have been inferior in density.

The greater power of a dense film of absorbing the rays of light which pass into it is also stated to result in a higher degree of sensitiveness than, *cæteris paribus*, would be obtained with a transparent film capable of transmitting a large proportion of the rays. There appears to be considerably more reason in this claim than in the last mentioned, for the rays arrested in their passage through the film must of necessity produce a greater result than those which merely pass through without absorption. The effect in the case of a dense film is analogous to, if not identical with, the defect known as irradiation, differing from it only in degree. Thus, a ray of light striking upon the surface of a film capable of completely absorbing it may be supposed to suffer reflection from one to another of the minute particles forming the sensitive layer, until at length it loses itself, or becomes suppressed. It may be readily imagined that the repetition of this process, in which the whole of the actinic force is utilised by innumerable atoms simultaneously, must lead to an appearance of greater exposure than in the case of a semi-transparent film, which transmits a portion of the actinism and allows it to escape.

As a proof of the correctness of this view, it is a well-known fact that if one half of such a transparent plate be painted with a coloured "backing," that portion upon development will exhibit stronger contrasts than the remaining half, and will have the general appearance of having received a less exposure. Such, to a certain extent, is indeed the case, for it has been deprived of the auxiliary effect of that portion of the rays absorbed by the backing. It might be anticipated from what we have stated that the thin films would be less liable to lose delicacy in the half-lights from excessive exposure, and such in practice is generally found to be the case. Though with a proper exposure the finest results are obtainable with thick opaque films, and probably with less care than would be necessary in developing one of the thinner descriptions of film, it is an undoubted fact that a slight amount of over-exposure, which would, perhaps, not noticeably affect a thin film, renders the development of the thicker one an operation of the greatest delicacy, owing to the powerful tendency of the high and middle tints to thicken or become heavy. It is of importance that we distinguish between differences of density arising from the physical character of the film and from a mere alteration of the proportion of silver bromide present. In the latter instance the difference, if any, in the behaviour of the film under development can only take the form of a more or less vigorous deposit, the actual sensitiveness of the plate remaining the same. It may possibly be that with the denser film a given exposure will produce a printable negative when the other will not, owing to there being an insufficient body of matter capable of reduction by the developer. This, however, as we pointed out last week, is not a real difference in sensitiveness, though for practical purposes it may perhaps be considered as such.

We require a new term to more fully express the idea we wish to convey, namely, the distinction between actual and apparent sensitiveness. "Impressibility" has been proposed, and seems to answer the requirements; for, if two plates demand exactly equal exposures to "impress" a developable image, however faint, they may be said to be equal in *actual* sensitiveness. If one plate is capable with that exposure of being worked up to printing density, while the other is not, the first may be said to possess greater *apparent* or practical rapidity. It would be well, in speaking of the performances of dry plates with respect to exposure, if this distinction were always borne in mind, as the difference between "impressibility" and practical sensitiveness is often so great that considerable misapprehensions arise from the confusion of terms.

We shall speak next week of the various means by which the physical character of the films may be modified to suit the taste, and also of the properties exhibited by films so modified. The results obtained in this direction are quite remarkable—so much so that we are led to believe that the mechanical means adopted in the preparation of the film forms at least as important a factor in the final result as does the chemical formula.

CADETT'S PNEUMATIC SHUTTER.

It has been our privilege to describe at one time or another nearly every one of the numerous contrivances that have been invented or proposed for the purpose of facilitating what, after all, is the simplest operation in photography considered as a mere mechanical act, and yet which, as at present conducted, especially in relation to portraiture, is one of the clumsiest and most bungling of operations—we allude to the capping and uncapping of the lens so as to give the requisite exposure in the camera.

The proper method of uncapping a lens has, in the estimation of ignorant people, "something" in it which trenches on the stronghold of fine art itself. Probably the choicest instance of this that has been placed on record is the statement which appeared in the *Daily Telegraph* of a few years ago, to the effect that the great secret of the success attained by Mr. J. E. Mayall, of Brighton, consisted in the method of uncapping his lens, as he had discovered that the removal of the cap on the right or on the left, or from above or from below, caused the shadows on the face of the negative of the sitter to fall right or left, up or down, in accordance with the magic touch of the artist who uncovered the lens. Of course Mr. Mayall was held entirely free from the responsibility of having written such nonsense, or having so much as encouraged it—no photographer could possibly have done so; still, the fact that anyone on the literary staff of an important metropolitan newspaper could have written in such a strain proves that no small amount of ignorance on this subject has been, and perhaps is still, prevalent.

But to pass from the æsthetics to the mechanics of uncapping the lens: it must, we think, be considered as something not altogether in keeping with the refinement of art and the march of scientific methods that a photographer has to "stand by" his camera, and with his eyes fastened upon his sitter, so as to discover the moment when immobility has assumed its sway, ejaculate the stereotyped words, "Steady—please!" and then by a demonstrative action of the hand remove the cap. This action need not necessarily excite any unpleasant expression on the face of the sitter; but from the expression we have seen on numerous faces the result, pictorially, is not very far removed from that obtained by the photographer "Far West," whose formula when ready to expose is said to have consisted of the presentation of a pistol at the head of the sitter with a "daar to move a muscle and I'll blow yer brains out!" *Tempora mutantur!* "Monitors" supplant three-deckers; and finesse takes the place of brute force. So with scientific processes.

Pneumatics is not absolutely unknown in its application to the requirements of the photographer who may have invoked its aid in fixing a plate upon a holder or of whistling through a tube to arrest the ear of an assistant in a distant room; but up to the present period our readers were unaware of its having been pressed into the service of the lens cap for the purpose of exposing a view or any other subject.

One evening last week we received a visit from Mr. James Cadett, who explained that he had invented a new kind of shutter by means of which instantaneous or ordinary exposures could be made without the sitter being aware of it. Now from time to time we have been apprised at an early moment of numerous schemes by which the photographic world was to receive a great impetus in its career of advancement; yet still the measure of our conservatism has grown none the less. It was in this mood we received the new comer. The instrument was said "to supply a want long felt by the profession." All new inventions usually do this. The "parent" of the pneumatic shutter did not, however, waste his or our time by speaking about it; he merely produced the instrument and requested us to fix it to the lens of a camera. This was soon done. The front of the lens was thus covered by a flap of two thicknesses of velvet, and at a distance of twelve feet from the lens we were requested to pinch an india-rubber ball that was easily held in the hand, and which was attached to the lens by means of a tube. Simultaneously with every pinch of the ball the flap flew up, leaving the lens uncovered; when the pressure from the hand was relaxed the lens was covered as before. We request our readers' attention while we describe in what manner and by what agency this was done.

A small mahogany box, about two inches square, is placed on the top of the hood or sunshade of a portrait lens. By means of its peculiar configuration, and with the aid of an india-rubber band, it can be attached to lenses of any size. When thus attached the flat, black velvet disc which forms the shutter is connected with a rotating axis so arranged that by means of a spring the shutter or flap remains tightly pressed against the front of the lens hood. Projecting from one side of the mahogany box is a small bit of brass pipe, upon which is sprung the end of a piece of india-rubber tubing of any desired length—say twelve feet, which in practice has been found o be a sufficient length. The farther end of this piece of tubing erminates in an india-rubber ball of a pear-shaped form. The otating axis which we have described as controlling the flap or hutter is in turn operated upon by a lever which is connected with small bellows in the interior of the box, and the action is such hat when, by pinching the ball at the extremity of the flexible ubing the little bellows is filled with air and expands, it acts upon a ever by which the flap is suddenly raised up from the lens, and which hus becomes uncovered. So instantaneous is the action that concurrently with the pressure of the hand upon the ball up flies the shutter which covers the lens. The release of the pressure is attended by an immediate covering up of the lens.

For a long period we have not seen any application of mechanical science to the camera so ingenious as that now described. Its uses are manifold, especially in the direction of very rapid exposures. The photographer may leave the camera, and, having the ball in his hand, or in his pocket, may go up to and converse with his sitter, may speak to him with great earnestness on any topic of interest, and when he sees that a suitable expression has been elicited he may pinch the ball, keeping on the pressure for as many seconds as his client retains the necessary expression, when by relaxing the pressure all is over and the sitter is unaware of having been "taken." In the case of a baby or nervous individual who becomes timid and trembles when the hand of the photographer is seen to remove the cap what a boon this little invention must prove!

If, however, the apparatus be attached to the inner instead of the outer end of the lens, it will be doubly valuable, because, even though staring at the lens, a sitter will, in the former case, be entirely ignorant of the moment when the internal uncapping of the lens takes place; whereas, when fixed externally, the subject will, most likely, be aware of the act of exposure, although entirely ignorant of the magical means by which the exposure has been effected.

From the fact that Messrs. Marion and Co. have entered warmly into this invention as "distributors," we have no doubt that our readers will shortly become practically acquainted with this most ingenious invention, which enables the photographer to stand by the side of his sitter—whether an adult or a child—engaging the attention while the exposure is being effected.

STREET PHOTOGRAPHY.

By this term we refer to the photographing of views of the streets, and street architecture generally, of our cities and towns; and the present time being, *par excellence*, the best season in the whole year for this particular class of work, we call attention to a much neglected though most interesting branch of photography. There have been, of course, many views of streets in various places taken, especially in the palmy days of the stereoscope; but now one may search an exhibition through, or look over the album of many an enthusiastic photographer, without encountering a single example of street photography. No doubt the subjects are not such as would always sell, and their production is among the most difficult of matters; but we have yet to learn that the latter would deter photographers from attempting the task, to mention a difficulty being to so many of them to raise an army to conquer it.

Thanks to the commercial enterprise of many first-class workers in outdoor subjects we have records—that might be imperishable, but which, alas! too frequently are but written in sand—of the ruined castles, the churches, and countless numbers of stately mansions whose names tell history of noble houses, and which to future generations will be of the highest interest; that is, if permanent photography should take a proper hold, and enable photographers of the present day to produce works of enduring character such as befits the subject—if, in fact, they would be true to themselves. But of the commercial life of the nation—the warehouse of the manufacturers, the marts of the shopkeepers, the palatial offices of our limited companies, the growth of architecture in town buildings (the old, dying away, elbowed out of existence by the new), the quaint relics of old England still existing in corners and byways, day by day growing less and less in number—how many records are there? A few views of places of universal interest, a building known to everybody, and a few representations of some picturesque old spots—and that is about all; and yet we firmly believe that if any photographer in almost any town of the plainest brick and mortar type were to make a point of securing a set of a dozen or two views of the leading thoroughfares of his town linked with some of its more out-of-the-way places—characteristic if plain—he would find it commercially a success.

In time to come such sets would be of priceless value to the archæologist and the antiquarian. Could any of our readers imagine what would be the possible worth now of such a set of photographic views, if the thing were possible, of London, Liverpool, Manchester, and a score of other towns taken two hundred years ago? This view, however, appeals to the sentimental rather than to the utilitarian, as, nowadays, a plan is nothing if not paying to one (and that the largest) school. We lay most stress upon the pecuniarily profitable aspect of our recommendation.

The photographer who first attempts street architecture, particularly if he be a townsman, will be surprised at the difficulty he meets with in obtaining negatives free from fog; in fact, he will find it next to impossible to get clear shadows, and will be inclined to set it down to his chemicals rather than the true cause, which is the constant prevalence of a certain amount of smoke in the atmosphere of all towns. The great secret of obtaining good and clear negatives lies in the power of apprehending the full force of this fact, and of taking advantage of the very few occasions when this smoke-begot haze is at a minimum. To dwellers in towns it is so much a matter of use that it is difficult for them fully to comprehend how rare it is that their atmosphere is not smoke-laden.

A hint we once had from an eminent painter may be useful to them. Walking out in the country, a heavy thunder-cloud being overhead, one of the party, pointing to a heavy shadow in a deep cluster of trees, said he should think it ought to be represented in a picture by pure black paint. The artist laughed, and, raising his arm so as to shade his eyes, and allow the spot we were looking at to be seen underneath the black-looking shade his arm made, said—"Look at it this way." All followed suit, and the vast difference in colour shown between the dark underside of the coat sleeve and the object that was thought so black was most striking.

In like manner, let anyone who wishes to take a street view or even a single building in a street raise his arm and compare the shadows under the eaves (say) with those under the upraised arm, and he will soon be taught how next to impossible it is to get a clear atmosphere; and if he further remember that, owing to the minuteness of the particles constituting the haze causing them to throw off the smallest—that is, the most actinic—light wave atmospheric haze or fog is reproduced more strongly in a photograph than it appears to the eye, he will understand how rare an event it is to be able to obtain a first-class negative in this kind of work.

Not to damp the ardour of the would-be photographer in this branch, we would, however, observe that there are certain occasions when the difficulties are reduced to a minimum and atmospheric conditions place few difficulties in the way; and that, too, just at the time when the landscape man is compelled to stay at home—we mean during the time that high winds prevail. Fortunately brick, mortar, or stone buildings do not sway with the wind whenever it blows hard, and still, more especially after rain, the air is so cleared of its fog-producing particles that almost perfect negatives may be obtained.

At the beginning of our article we alluded to the fact of the present season being the best time of the year. We have plenty both of wind and rain, and we have noticed for so long as a couple of days together that all conditions have been most favourable for this kind of work. Later in the year, when the surface of the earth is heated to a greater depth, the air is heated so rapidly after rain and wind that dust and smoke reign supreme for far longer pericds than they do in the earlier period of the year, and the favourable intervals for street work are fewer and farther between.

It is, perhaps, not necessary to state that early in the morning the air is clearest; but it will be found that in most towns after half-past five the smoke begins to rise from the chimneys for the preparation of the workman's matutinal meal, and then if the wind be wrong there need be no attempt at photography. Again: such views as we speak of are of little interest if the shops are all closed, as they are at such an early hour. There is often a lull in chimney smoke from about ten to eleven o'clock, and this is a highly favourable time.

As to the mechanical means little need be said. A quick lens is a *sine quâ non;* but, as there are now so many quick lenses made capable of giving straight lines in architectural subjects, we need do no more than mention them. Views of the kind we are dwelling upon, to be perfect, should include figures, and if a camera be stationed at an upper window a picture can generally be taken without attracting observation, and so causing the figures to look at the spectator. If the necessary standpoint be in the street itself the difficulties are increased tenfold, so that no one but the most patient of men should attempt the work. The various expedients of dodging the crowds have been too frequently described to need further expatiating upon. The chemicals, bath, collodion, &c., should be in perfect order, but the usual dark-room arrangements need not be in the slightest degree altered. A plate sent from the dark room in the middle of portrait work, and well backed up with wet paper, ought to bear being sent out to the operator with the camera, and be good for developing half or three-quarters of an hour afterwards.

Where for any special purpose great delicacy of detail is required, a small stop is necessary then, of course, instantaneous exposures are impossible, and the best plan is to expose and let the pedestrians pass by. They will scarcely perceptibly show in the picture, though if a white-bloused workman should come within the field of view it would be well to cap the lens till he had gone by. We now leave the subject in our readers' hands.

While we cannot avoid expressing our admiration of the manner in which Mr. Warnerke has dealt with the subject of halation or blurring of the image, in the paper he read before the Photographic Society of France, and which will be found in another page, we must here, as we have done before in Mr. Warnerke's presence, take exception to the definiteness of the proof supporting his theory said by him to be afforded by the experiment with the prism of optical glass. Our reason for this is to be found in the fact that by covering what we shall designate the first surface of the prism with emulsion the conditions under which the light enters are quite changed from those which would exist were no such emulsified film present. In the latter case a ray of light falling upon the surface of the prism would pass straight on until it reached the oblique face, by which it would be reflected in another direction; but in the former case a phenomenon of a different kind takes place, the nature of which we here shortly state:—If a ray of sunlight fall upon a plate of polished glass it is transmitted *as a ray;* but if a plate of ground glass be substituted for that which is polished, the whole surface, if examined from behind, is found to be rendered luminous and the ray is arrested. The light, instead of being transmitted as a ray and in a straight line, is radiated from every portion of the ground surface, and in every direction. As with ground glass so with a pellicle of collodio-bromide of silver. Every atom of bromide of silver in the film becomes, when a ray of light falls upon it, a radiant, which arrests the direct transmission of the ray and distributes it in every direction. For this reason the ray d in Mr. Warnerke's second diagram cannot proceed in a straight line to c, but becomes broken up at the film of emulsion and is then distributed all over the surface b, c, and even over the emergent face of the prism, which we shall assume to be one of a rectangul form, although not correctly engraved as such. These surfac in turn, act the part of reflectors of the radiated light, by whi the back of the film is illuminated to such an extent as to produ fog. This also explains why a plate backed even with red orange will only diminish, not cure, halation; for, as it is we known, bromide of silver is sensitive even to feeble red and orang rays. Notwithstanding what we have said Mr. Warnerke's pap is one possessing exceptional value.

PHOTOGRAPHY AT THE LEAST REFRANGIBLE ENI OF THE SPECTRUM, AND ON SOME PHOTOGRAPHIC PHENOMENA.

[A communication to the Photographic Society of Great Britain.]

There are two subjects connected with the progress of photography that I wish to bring before the meeting this evening. It will be in the recollection of the Society that some time ago I exhibited photographs of the least refrangible end of the spectrum—that is, of the red end, and of those dark rays which lie beyond it, and which are usually called the dark heat rays. After four years' research I have now worked out a process that has almost exceeded my expectation, and allows me to obtain negatives of the spectrum which show the detail of these parts better than any I had hitherto employed. Any one who has used a prismatic spectrum will be aware that the least refrangible end is very much compressed, and that the possibility of getting good definition beyond the red end of the spectrum is almost hopeless, owing to the rapid change in focus of the different rays.

The following table will give you an idea of the way in which the red end is compressed. It is taken from Watts' *Index of Spectra*, and, in considering it, it must be remembered that B is the last line of the spectrum which is easily visible:—

	Dispersion. Crown Glass.	Dispersion. Flint Glass.	Carbon Disulphide.	Diffraction.
B (Red)	0	0	0	0
D (Orange)	236	220	194	381
E (Green)	451	434	400	624
F (Blue)	644	626	590	784
G (Indigo)	1,000	1,000	1,000	1,000

It will thus be seen that in flint glass, which is usually employed for simple prisms, F to G occupies 374 parts of the whole, whilst, with the diffraction grating, it occupies only 216 parts. Again: with the former, D to B occupies 236, and in the latter 381. Of course, the lower down in the spectrum you go the more compressed will be the wave lengths. Now, I have been thus particular in pointing this out, as I have used a diffraction grating instead of prisms for the photographs on which I set most store. I have had placed at my disposal two gratings by Rutherfurd, of New York—one containing 17,280 lines at equal intervals apart to the inch, and the other 8,620 lines to the inch. The former is a beautiful piece of workmanship, silvered at the back; the latter is in speculum metal, not quite so brilliant, but gives such spectra as can hardly be equalled. I need scarcely go into the difference in the spectra of the gratings and of the prism. The one is formed by the interference of coloured rays, the latter by the difference in refractive indices of the various rays. When we throw a beam of light on the grating, if it be a reflection grating (as those are which I am using), and allow the reflected beam to fall on a white surface, we get first a central patch of white light, then at each side of the white patch is a spectrum, commencing with the violet and ending with the red rays. Beyond these pair of spectra are others extending indefinitely outwards, but running into one another till we get a dirty white band formed. I wish you to note this, as we shall see that in some operations (unless precautions be taken) this mixture of spectra is an evil. From theoretical considerations we are told that the white light dispersed in the first pair of spectra on each side of the white patch cannot be more than one-fifth of the quantity of the original beam falling on the grating. It cannot, therefore, be more than one-tenth in one of the pair. Theoretically, also, we find that the white light available for the second pair of spectra is only one-fourth that of the first. Now this would be a serious loss of light; but, when we consider that the second order of the spectrum is spread over twice as much length as the first, the real intensity of any ray is really one-eighth of that of the same ray of the first order, and only $\frac{1}{80}$th of the amount of that found in the incident beam. Similarly, the intensity for the third order is really only $\frac{1}{27}$th that of the full order, or $\frac{1}{270}$ of that of the incident beam. We next have to consider the difference made by the number of lines ruled on the grating. The two I have been employing ill furnish a very good example of what I wish to demonstrate. In the ·ating with 8,640 lines to the inch, the *second* order has the same spersion as that of the *first* order of the 17,280 lines to the inch. he respective brightness of the *white* light available in each for [ual dispersion would be $\frac{1}{40}$ and $\frac{1}{10}$, as before shown—that is, of ›urse, supposing the incident beam to be of the same intensity in ıch case; the dispersion being the same, this would indicate that, r photographic purposes, the first order of the closer-ruled spectrum better to use to shorten exposure than the second of that wider ıled. Further: the first order of the latter grating spectra will only › twice as bright in the first order of the former, since it is only spersed to half the length. In other words, the brightness of any ·der of spectrum varies *inversely* as the cube of the order of the ›ectrum employed, and *directly* as the number of lines in a given :eadth of the grating. It is, therefore, better to employ a lower order spectrum with a closely-ruled grating than a high order with a more idely-ruled grating, remembering that the resolving power, as it is ılled, is the same in both, but the light in the former is much more tense than with the latter.

Now, since my purpose of introducing the subject at all was with a ew of showing its adaptation to photography, I must touch on the ngth of camera which it is best to employ. I must first show you the ·rangement adopted for employment with the grating. We have a ›llimator carrying a slit at one end of a tube, and at the other a ns, to render the rays parallel. Then we place the grating so that the it of the light coming from the sun and reflected by a heliostat, after assing through the slit, falls centrally on the grating. The white patch f the reflected beam is made to clear the collimator, and the camera ith its lens is so placed as to receive the order of the spectrum it may e desired to work with. The effect of lengthening the focus of the ımera lens is to enlarge the area of the spectrum. It, therefore, aries in brightness inversely as the square of the length of the focus. uppose, then, we had to choose between a camera lens of four feet ›cus and one of two feet focus, we must recollect that the image ith the former would only be a quarter as bright as that taken with ıe latter. In choosing a camera for these purposes, a reference ıust be made to the focal length of the collimating lens. That hich I use is twenty inches, and I find that for my work I get etter definition when the focal length of the camera lens is about ıe same; for, be it remembered, that when the two lenses are of equal ›ci the slit and its image will be of the same dimensions. If I used six-foot camera I should prefer to use a six-foot collimator.

Having now cleared the ground, so to speak, I will show you what grating can do. This negative which I hold in my hand is a pho›graph of the spectrum from B to A, the latter line being the ordinary mit of visibility of the spectrum. There are between them 130 per›ctly-defined lines, and, in fact, contains more lines than is shown by ›rofessor Smyth's map of the same region as mapped by visual obser·ation. It was taken with the first order of the closer-ruled grating. The next negative is taken with the first order of the smaller-ruled ·rating, and contains about seventy lines which lie on the dark side f A. Many of these have never been seen by the eye, even by the id of fluorescence. This next photograph is one which is taken with the same camera and lens, but with three prisms. The last ›paque band lies far in the ultra red, and is composed in reality of hose lines which are so beautifully separated in the grating photo›raph. It will be apparent how tremendously compressed the ›rismatic spectrum is when it reaches these great wave lengths.

Here are two negatives of E to C—one taken with the three prisms and the other with the grating. In this case you will note that the ›risms have the advantage over the grating; in other words, for the violet end prisms may advantageously be employed, but for the red he grating is preferable. The line furthest down in the grating ›hotograph has a wave length of about 10,000 tenth metres, whilst hat of A has about 7,600, and of G 4,300, and of E about 5,250, so he photograph shows rays of light as much below A as E is above it.

I must again call attention to the overlapping of the grating spectra. It will be found that the extreme violet end of the second order of he spectrum overlaps the red of the first order; so that, really, when we are imagining we are photographing the red end, we get a picture of the violet end *plus* the red end. The first photograph of B to A was taken with red glass placed before the slit of the spectroscope, hence all the violet and blue rays were cut off. But it struck me that a photographic plate would have a much better chance of perfect results if, instead of absorbing this light (and also a certain amount of the red), we could separate the spectra. To do this, Fraunhofer's plan of placing a prism so as to refract the *length* of the slit before the beam reached the grating was adopted, and here are the results in a photograph taken with a small camera. It will be seen that we have four orders of spectra on the same plate, each one well separated from its neighbour. The photograph which showed the ultra red was taken by this plan, and no doubt you will have noticed that it was curved in its length. The curvature you must have noticed in all the four spectra which I showed, and is due to the irrationality of the dispersion of the prism. Had I used a widely-ruled grating I might have attained a straight band crossing the plate diagonally, but the loss of light would have been so great that I was forced to adopt the prism; for had I used the first order of the spectrum in both cases I should only have been able to utilise about $\frac{1}{100}$th part of the beam of light coming through the collimator, since $\frac{1}{10}$th would have been lost after using the first grating to throw the slit in one direction, and $\frac{1}{10}$th of that would have been lost by the other grating.

Now, as to the process by which the negatives were taken, I hardly know what to say. The process is the ordinary collodio-bromide process, made with zinc and excess of silver nitrate, as I have already published. This, in the ordinary way of making, possesses an orange tint by transmitted light, and is in this state wholly insensitive to the red rays—at least to those below B. If to some of this emulsion we add water, and very slowly distil over the solvents, rinse with alcohol, and then re-emulsify, we shall find that we have a film which is totally different in quality and appearance. The film will be much more powdery, if I may use the expression, the nature of the pyroxyline being altered, and a film showing blue light by transmission.

It is not every blue transmitting emulsion, however, which is sensitive to red rays. Some are insensitive to either the red or the blue, but if you get a film which is purplish in appearance you will probably have a film which is sensitive to both the red and the blue.

The details of the process with the modifications I, however, reserve to another occasion.

I must, however, point out the principles which have guided me in my researches. They may be briefly stated to be to find a sensitive salt which will absorb the rays in the portion of the spectrum which it is endeavoured to photograph. In the present days it is scarcely necessary for me to point out that absorption by any body indicates that work of some kind must be done in that body, either by separating the molecules of a body further from one another, or by the disintegration of the molecules themselves. In the first case we have heat developed, and in the last we have chemical action, producing what may be a developable compound. Now, in order that the red rays may affect a compound chemically they must absorb it, and by getting a blue film we get the desideratum. As you are aware, at first I obtained this by adding resins to the bromide, and thus effecting what I call a weighting of the molecules. In the last process the bromide itself, or its hydrate, weighs them and makes them swing in accordance with the red waves, and thereby absorbs them. If the pyroxyline be of the character to obstruct what are called the dark heat waves, we cannot expect to get much action of the spectrum on the sensitive compound occluded in it, and experiment serves to show that a horny collodion is not transparent in these heat rays, and is, therefore, not easily affected by the ultra red. A powdery pyroxyline, on the other hand, seems to be diathermous, and with a collodion made with it we have an effect in the ultra red, if the sensitive compound be absorbent of these rays.

Vogel found, if a bromide film was *slightly* dyed, that it became in some cases sensitive to the rays the dye absorbed, and in one paper seemed to indicate that it is the dye *per se* which is effective. My own experiments show that the dyes (much or little of them) only have effect when combined with silver, as I published in May, 1876, and I believe that Dr. Vogel found the same thing. The question, then, resolves itself into this: How is it that when the minimum quantity of dye is added to a film in which there is free silver that an image can be developed? The answer is easy: The compound of silver and dye is changed by light, and I have already shown that a film that is totally unacted upon by light may be developed by placing it in contact with one which has received an image; the changed organic compound of silver is in close contact with the bromide, and the image impressed on the dye is thus developed on the bromide silver.

When there is not sufficient silver nitrate in the film to combine with the dye (always supposing the dye will combine with the silver, which is the only case in which the employment of dyes have proved effective), the excess of dye acts very much in the same way that free bromide acts on an ordinary emulsion plate and prevents the impression of an image, the reduced compound being immediately reconverted into the normal undevelopable compound. The case of eosin is very much to the point, as it is an organic bromide. When combined with silver it is easily reduced by the light it absorbs, but if an excess of it be present this is reconverted into the normal salt. I may call your attention to the possibility of the existence of different weights of molecules. Faraday found that gold leaf, which is green by transmitted light, when heated became red, and remained so. If the red molecular gold were rubbed with an agate or other hard body, it would return to its green molecular form. In the same way, when we rub the film of silver bromide, which transmits the blue, we get the form which transmits the orange light. I venture to prophesy that the science of chemistry is on a fair way to be firmly mated with molecular physics, and the two combined will before long take a greater bound in advance than they have done as yet.

W. de W. Abney, F.R.S.,
Capt. R.E.

(To be concluded in our next.)

ON THE SOLARISATION AND OTHER RESULTS OF OVER-EXPOSURE: THE CAUSE AND THE REMEDY.

An Observation which may be Useful for the Explanation of the Formation of the Invisible Photographic Image.

[A communication to the Photographic Society of France.]

It is well known that the sensitive plate prepared by any dry or wet process ought to receive a definite time of exposure, so that the resulting negative should be good. Over-exposure is as fatal to the result as insufficient exposure. The object which I propose to myself this evening is to indicate the real cause of a bad result occasioned by too lengthy an exposure. As to the remedy it will be evident.

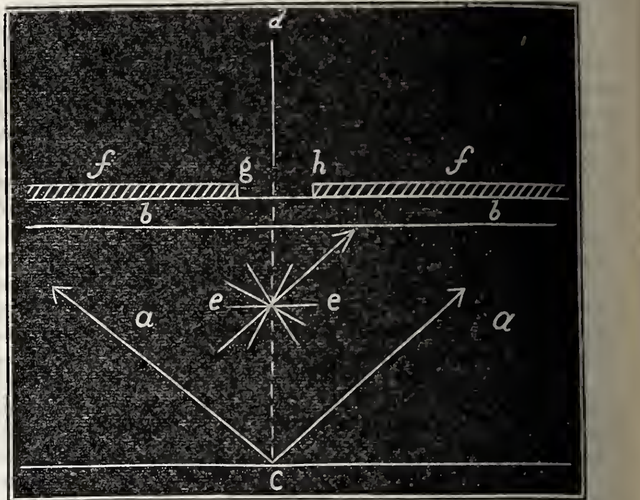
I will commence by a demonstration that will support my assertions with greater force than any arguments I could produce.

I present before you two pieces of black paper perfectly opaque, and from which several figures and openings are cut out that will serve for my negatives. Here is a glass plate prepared with an emulsion of bromide of silver. One-half of the back of this plate is covered with an orange-coloured backing. This other sheet is one of my sheets of sensitive tissue, consisting of a pellicle of collodion formed upon a sheet of paper, and covered by a sensitive film prepared with an emulsion of bromide of silver perfectly identical with that employed for the preparation of the glass plate. Thus we have two sensitive preparations made by the aid of the emulsion—the first being on glass, while the other is upon the tissue. I place both in a printing-frame under the negatives of black paper with the cut-out figures.

To obtain an exaggerated result, I give an enormous exposure to the brilliant light furnished by the burning of a yard of magnesium ribbon moved to and fro in close proximity to the printing-frame. The image produced is so visible one might say that it was produced upon sensitive albumenised paper, which proves that the exposure has been really very long. The two images are now developed together by ordinary alkaline development; but in order that the image may appear slowly the quantity of bromide of potassium is augmented, and there are but a few drops of the solution of carbonate of ammonium and pyrogallic with a considerable quantity of water. Now, let us examine attentively the appearance of the images. The first action of the developer produces effects nearly similar, but shortly afterwards we begin to observe a great difference between the two images. Look at the one on the tissue. Its outlines are very sharp; it gains in intensity the longer the developer acts; and after four or five minutes, when I consider the developing solution has lost its power, the image remains completely black and intensely opaque upon a white ground. Upon the glass plate the aspect is entirely different. At the commencement the image resembles that upon the tissue; but before the expiration of five seconds there forms round the opaque image a halo which extends with the development, and that part of the glass plate without orange-coloured backing is quite blackened by the progressive extension of the blurring. The other half of the glass plate resists more effectually the general extension of the darkening effects of the blurring, but it is, nevertheless, strongly pronounced round the outline of the image. After thirty seconds of development a new change appears before our eyes—the black parts of the image commence to become enfeebled; and now they are already more transparent than the halo or surrounding parts. The effect of the solarisation is become complete, and the image of the negative is changed into that of a positive.

To resume: here is the aspect of the phenomenon:—1. A glass plate having been exposed a very considerable time gives, on developing, at first a negative image. 2. Later on it becomes gradually enfeebled, and disappears under the continued action of the developer. 3. Around the image there forms a halo, which really is the cause of the image becoming transparent, and appearing positive upon the background of the halo. The orange colour applied to the back of the glass plate enfeebles the halo, but does not prevent its appearance entirely. 4. Neither the halo nor the solarisation appear in any degree upon the sensitive tissue.

In studying the cause of the blurring I am persuaded that it ought to be attributed entirely to the reflection and dispersion of the light by the substance of the glass of the plate. Its absence in the case where the glass plate is eliminated is a proof; but let us study more minutely the course of a luminous ray which strikes



a sensitive glass plate. *a a* represents the glass plate in section, and *b b* the sensitive film of collodion. The light in passing in the direction *d* can act upon the sensitive film *g h*, whilst the rest of the film is protected by an opaque body, such as the black paper *f f*. The sensitive film not being opaque the ray *d* will traverse it; it will meet still less obstacle in traversing the thickness of the glass. After having arrived at the point *c* it will be reflected by the back surface of the glass, and these reflected rays, in acting upon the sensitive film *b b*, will produce the effect of the halo.

We can, nevertheless, by painting an orange colour on the back surface of the glass, render innocuous the reflection from the posterior surface, and the reflected, non-actinic rays will no longer have the same chemical effect upon the sensitive film.* But the ray *d*, before arriving as far as the point *c*, meets with particles of glass *e e*, which become luminous under the lighting action of the ray *d*, reflecting in their turn the light in all directions. It is clear that they will produce the halo by acting upon the sensitive film as well as the reflected ray we have first examined; but, however, with this difference—that they cannot be rendered harmless.

After this explanation it is clear why the halo is more marked on the uncoloured part of the glass plate than on the other, which has been coloured; and it is also clear why there is no halo upon the tissue. I may mention here that this explanation of the cause of the halo has been questioned. It has been objected that the glass is too transparent for the particles in it to reflect light; but these sceptics cannot upset or render doubtful the results of this palpable experience. They have attributed the halo produced, notwithstanding the orange-coloured backing, to the colour not being sufficiently non-actinic, and consequently hold that the halo is produced alone by the reflection of the back surface of the glass plate. I shall, however, describe other experiments which will enable me to verify the exactness of my theory.

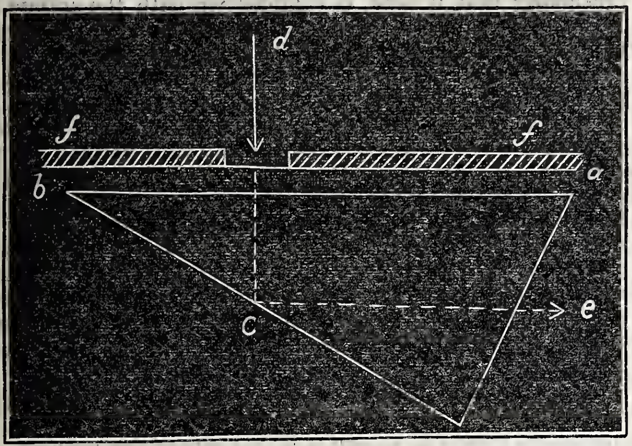
I have replaced the glass plate by a prism of optical glass. The surface *a b* of the prism was covered with a film of sensitive emulsion, and exposed to the light under a negative of black paper, with figures cut out as in the previous experiment, *f f*. It is easily understood in this case that the ray *d c*, in falling upon the surface *b c*, will be reflected in the direction *c e* in such a manner that the halo ought not to be formed in this case by the reflection of the posterior surface. Notwithstanding, a fine halo was obtained on developing in this experiment, which supports me in my supposition of the cause of the blurring.

Let us return now to the phenomenon of solarisation. The opinion of eminent authors whose attention has been occupied with the question of solarisation is very varied as to the cause of this

* All orange or brown colour, ground up with water, with a feeble addition of gum and glycerine applied with a brush, is good for this purpose. Moist colour may be had ready prepared at the colour merchants'. It is very easily applied, and has the advantage of being easily washed off before development. Collodion coloured with aurine can also be used for the same object, making, with the aid of pyroxyline, an opaque and powdery film.

phenomenon. Some call it the "reverse action of the light;" all attribute it to a mysterious property of light, and even see in that *an evident proof that the cause which produces the latent image is not chemical but purely physical.*

In taking as a base, however, the experiments made before you, I wish to propound a very different opinion. I commence by recalling to your mind that the glass plate at the commencement of the development presented to us a normal aspect; that is to say, the



exposed parts became black, and it was only afterwards that the black matter commenced to become enfeebled, and so continued up to complete effacement. It is not, therefore, light which produces the reversed effect, but the normal image obtained at first disappears under the prolonged action of the developer.

For the sake of clearness I shall propound a theory, and I shall prove it step by step in applying it to the explanation of the facts we have observed.

By the action of light the force which unites bromine with silver in the bromide of silver is weakened in proportion to the quantity of light which has acted upon the combination; nevertheless, these forces are not completely broken, because the liberated bromine does not evaporate as we might expect a substance so volatile, but remains near the place where it has been formed, and it manifests itself when circumstances present themselves.

Thus it is the bromine which occasions solarisation, in uniting itself to the water of the developer to form hydrobromic acid, which, in its turn, attacks the metallic silver scarcely formed by the action of the developer.

We have observed that solarisation does not take place on the tissue. This fact was for a long period a stumbling-block to all my hypotheses, but accident rendered itself a very useful auxiliary. The experiment which I have had the honour of presenting before you I was repeating in the presence of several of my friends, when one of these gentlemen accidentally opened the holder which contained a piece of tissue already exposed under the black paper with its cut-out figures. I stopped him quickly in this act of thoughtlessness, but not before the sheet of tissue had suffered general exposure, although very feebly in comparison with the previous one. Here is what followed: the image appeared as ordinarily, but the entire sheet was fogged, as one might expect. I held the sheet inclined to a corner so that the developer might run off, and then observed that the uniformly fogged tint commenced to disappear in the proximity of the figures already developed, and streaks were formed in the direction favoured by the inclination of the sheet as if some substance oozed out from underneath the black figures, and, obeying the law of gravity, descended slowly, dissolving the silver which formed the general veil. I concluded then that upon the tissue, also, the bromine liberated itself in a similar manner as was the case upon the glass plate, only the silver forming the image found itself in a different condition, probably caused by the film of caoutchouc which preceded it, and ought not to be attacked by the hydrobromic acid. To convince myself of the truth of this theory I have varied the experiment by covering with emulsion a silvered glass. After the exposure and the development I dissolved the film of collodion with its developed image by the aid of ether and alcohol, and then to my great joy I observed that the layer of silver on the glass had been attacked by the bromine just under the developed image. Thus, supported by this fact, I am authorised in saying that solarisation proves by the evidence here given that the cause which has produced the invisible image is purely chemical.

In the phenomenon observed I believe I am able also to find the reason why dry plates do not keep for a long time after exposure. It is the bromine liberated by the light which, little by little, other circumstances aiding, recombines itself with the silver and restores it to the same condition in which it was before exposure. Thus I find myself face to face with the problem of the day—how to prepare dry plates that will keep during an indefinite time after exposure.

Although I have not yet arrived at the point of unravelling this problem, I believe that the solution may be found in the introduction of some substance which, by preventing the recombination of bromine with the silver, preserves the breach formed by the light in the forces which united them before exposure.

It remains for me to observe that the absence of the blurring and solarisation upon my tissue enables me to employ it with advantage in the reproduction of negatives for combinations and enlargements. It is also for the same reason that the carbon process is justly recognised as superior to all systems where glass is the support of the sensitive film. Emulsions strongly coloured will be good if the colouration used does not affect or diminish their sensitiveness.

L. Warnerke.

ON DRY-PLATE PROCESSES.

[A communication to the Photographic Society of Great Britain.]

Having been requested by our President to detail the result of my experience in dry processes, I must say that, while responding to that request, I yet feel that it is somewhat presumptuous on my part to do so, mainly from the fact that I have nothing particularly new to communicate; but I trust that these few remarks may lead to a discussion which will enable many present who have had experience and long practice in this branch of photography to give us the result of their experiments.

You are all, doubtless, aware that Mr. Paget has offered a very handsome prize for a dry process which, with good keeping qualities, shall give results as good as those obtained with wet plates. As this offer may, perhaps, induce many photographers to devote more of their attention to the preparation of dry plates, I premise that it would not be inopportune for me to mention briefly some of the dry processes used in the early days of photography, and to call attention to the various methods which have been practised from time to time, and which in certain hands have been successful, particularly when long-keeping qualities were not a desideratum.

It is now about fifteen years since I commenced dry-plate work. My first experiments were with the Abbé du Prat's resin process, which consisted of the addition of one grain of resin to the ounce of collodion; but unfortunately (for the process is a very simple one) the sensitising bath would become disordered after the immersion of a few plates. I tried various resins and gums with a view to overcome this objection, but in every case the bath quickly deteriorated.

About this period Major Russell's tannin process was published, and for a considerable time became very popular. I worked it at that time myself, and was quite successful when the plates were freshly prepared, but showed a disposition to solarise, and, after long keeping, to produce hard negatives.

I was next induced to try the Taupenôt process; but this requiring a double bath—the sensitising of the plates a second time, besides other tedious preparations—led me to adopt a modification of it, and which modification was published by me in 1869. This, I found, gave better results, and required but one bath. The following is a short *résumé* of the method:—After sensitising the film, a solution, consisting of one part of albumen to one of water, was poured over the plate, which was then rinsed, and a fifteen-grain solution of nitrate of silver applied, a final washing finishing the process. These plates were developed with alkaline pyro.

I mention this process as being one of my early loves, and one with which I was most successful, having produced thereby some 300 negatives of Rhine scenery. But in spite of my lingering affection for it, I must confess that its keeping qualities were not altogether satisfactory, and I reluctantly gave it up for the gum-gallic process of my friend, Mr. Russell Manners Gordon. Great credit is, I think, due to him for that process, as it was a great advance upon what had been done before, so far as the keeping qualities of the plates were concerned and the beautifully soft negatives produced. Many, I believe, still follow the process, and I have an example amongst the series of Swiss views shown this evening, and taken in 1870. Mr. Gordon has, I am informed, great faith in the keeping qualities of this process, but my own experience has not borne out this view. I have found that when the plates have been exposed and developed soon after preparation, that negatives of excellent quality—leaving, in fact, little to be desired—could be obtained; and I would strongly recommend it to amateurs as a very good and simple process, but one not perhaps so well adapted to the requirements of the professional photographer, who must necessarily, at times, prepare his plates many days, and perhaps weeks, before he has the opportunity of using them, and then frequently a long interval between exposure and development.

I can also speak very highly of Captain Abney's beer process. The negatives taken by me, and the prints from which obtained the award at the last exhibition of this Society, were produced by a modification of his process, and which I will briefly describe. To any good commercial collodion is added (in addition to the usual iodiser) two grains of bromide of cadmium. The sensitising bath to be of not less strength than from forty to forty-five grains to the ounce, the plate remaining immersed from four to five minutes. After removal from the bath, and before applying a preservative of beer only, the plate is thoroughly washed. The plate should then be dried, and before exposure in the camera a wash of pyro. solution, one grain to the ounce of water, should be applied to the plate and again dried. Captain Abney gives the formula for the preservative as beer to each ounce of which one grain of pyrogallic acid has been added. Through an accidental occurrence I have modified this, and will here describe it. While working the process during my stay in Switzerland, nearly two years since, I was attempting to develope a plate with the plain pyro. developer, but to my surprise no image would make its appearance. On consulting my diary of exposed plates I found this particular one had not been exposed at all, so that my failure was easily accounted for. After washing the plate I placed it in the drying-box with the intention of exposing it on some future occasion, being curious to know what the result might be. About a fortnight after, having a little leisure, I placed this plate in the camera, and gave it a little longer exposure than I should have given a wet plate. Much to my surprise I obtained a very perfect negative—in fact, superior to those I had been previously obtaining. Not feeling, however, quite confident, I prepared another plate in the manner above described, and after drying moistened one half with water, and poured over the moistened film a one-grain solution of pyro., then rinsed slightly and dried. This plate, stereo. size, I exposed with twin lenses, and on development the half which had been treated with the final pyro. wash showed greater sensitiveness and better quality, particularly in the deep shadows, which were very perfectly developed, and was altogether more in harmony with the high lights than those in the half not so treated. I now felt such confidence in this modification of Captain Abney's process that I confined my operations solely to it, and produced nearly 200 negatives during my stay in Switzerland that season. Amongst them were some very trying subjects, which tested to the utmost extent its capabilities. I may also add that these plates kept well, both before and after exposure.

As you are aware, there are several other dry processes—the coffee and its modifications, also the morphia, the latter giving very sensitive plates, but with no keeping qualities. These and other processes I have had experience with, and should have preferred to have made some remarks upon them would it not be taking up too much of your time, and perhaps trespassing a little too much on your patience. I have latterly, however, worked zealously at the collodio-emulsion, and with very promising results, and shall endeavour to test it in every possible way with a view to ascertain if the keeping qualities of the plates may be relied on before and after exposure. Certainly, an emulsion process has considerable advantages, not the least being its simplicity, and the non-requirement of a sensitising bath. Although I have worked it for several months past, the results, to my mind, have not quite equalled the before-mentioned process; but I am in hopes, with some experiments now in hand, to be more successful; and should I be so shall have much pleasure in affording you all the information in my power. I have not entered into the details of the various dry processes, as their manipulation is now so generally understood; and I therefore make no mention of Colonel Stuart Wortley's uranium process, nor of the gelatine process of Mr. Kennett, and some others which I have tried, but have not followed up sufficiently to enable me to give information which may be of any service.

Before concluding I must strongly impress upon every one working a dry process the necessity of exercising the greatest care in the selection of pure chemicals, and in the cleanliness of all the various manipulations. Drying the plates in a pure atmosphere should be particularly attended to. There is no question that to be perfectly successful more care and nicety is required than in the ordinary wet process. WILLIAM ENGLAND.

ON THE LATENT IMAGE.

THERE are several points met with in practical photography which, when viewed in connection with the chemical theory of the latent image, are difficult to understand by the light of that theory. One of these is the peculiar action of the bromide of a monad—as potassic bromide—has upon the latent image when again acted on by light. I refer to the "reversing action of light."

Now, as far as I can understand, it is impossible that potassic bromide can give up any of its bromine to the sub-bromide (?) of the latent image. But, then, how does it, presumably, convert the sub-bromide into the bromide of silver? Have we any reason for presuming that it acts, in combination with the actinic rays, catalytically, causing the bromine in combination with the organic matter of the film to re-combine with the sub-bromide?

I suppose that the result obtained by MM. Claudet and Becquerel, who, on exposing one of the silver haloid salts to light, and then placing it under red or orange glass, found the latent image to be destroyed, has not been at any time verified by other experimentalists. Of course the exposure referred to would be a long one*. But this by the way.

At page 39 of THE BRITISH JOURNAL OF PHOTOGRAPHY for 1872 there is a short article by Dr. H. Vogel, in which he shows that the latent image in silver iodide produced under silver nitrate has different properties to that formed under potassic ferricyanide. For the sake of those of your readers who have not the Journal in question to turn to I will transcribe some of Dr. Vogel's remarks. He says:—

"According to the general opinion the iodide of silver is simply reduced to sub-iodide of silver. My experiments show, however, that the case cannot always be so simple as this supposition assumes. The invisible image which is formed when iodide of silver is lighted under nitrate of silver is entirely different from the one which is formed in the presence of ferridcyanide of potassium. The ferridcyanide of potassium accelerates this action of light almost as much as nitrate of silver; but the invisible image of iodide of silver which has been formed under nitrate of silver disappears when treated with iodide of potassium, while the image of iodide of silver which has been formed under ferridcyanide of potassium does not disappear under a solution of iodide of potassium. We find the same difference already in iodide of silver plates which either have been prepared in a fresh bath or in one which has been surcharged with organic substances. The picture on the plate which has been prepared in a fresh bath disappears under iodide of potassium, but the other remains. This shows the influence of organic matter in the bath.

"It is not without interest that not only iodide of potassium, but also ferridcyanide of potassium solution, exercises a destroying influence on the iodide of silver image which has been exposed to light under nitrate of silver, while the ferridcyanide of potassium solution by itself accelerates the action of light on the plate."

This is a very plain statement.

Now it is worthy of notice that Dr. Vogel states that the latent image formed in an iodide plate sensitised in a *fresh* nitrate bath is destroyed by a solution of potassic iodide, and this without exposure to light as in the "reversing action" method. In what way does the potassic iodide act? It would seem that just as by its presence (*not* chemically) it can *prevent* the formation of the latent image, so by its presence also it can *destroy* the latent image. I do not know, however, that we have positive evidence that the latent image would not assert itself on washing all the potassic iodide out of the film, and then applying the developer, so that it is possible that the latent image is not really destroyed.

Another point is this:—According to the generally accepted chemical theory the silver sub-bromide is formed in exceedingly minute traces, even in the high lights; and yet, on development, the whole of the bromide may be reduced to the metallic state. This being so, if a quantity of sub-bromide which may be represented by the figure 4 causes the entire reduction of the film represented by 100, why may not a quantity represented by 1, by a prolonged development, produce the same result? In other words, why are we not apt to find that a prolonged development reduces by degrees the whole of the bromide down to the glass? It may, perhaps, be accounted for thus:—The silver sub-bromide may, in the high lights, be distributed at equal intervals throughout the entire thickness of the film, each molecule being surrounded by silver bromide. This is the effect of an amount of light represented by (say) 50. If the film be acted upon by light represented by 100, we have the effect of the light represented by 50, *plus* the effect of an exactly equal amount of light. What is the effect of these surplus rays more than sufficient to bring about total reduction on development? I should suppose that a certain

* This paragraph now needs some explanation. It was written several weeks before the publication of Captain Abney's recent investigations. It here appears that the red and ultra-red rays are destroyers of the latent image by accelerating oxidation of the latter. It is somewhat curious that some such rays as these have been termed "continuating rays," so that it would here appear that "extremes meet."

number—perhaps not double the number—of molecules of sub-bromide are formed in addition to those formed by the light represented by 50, the reduction on development is thus quicker, the progression or space between molecule and molecule being less.

It would thus appear that in order to reduce the bromide down to the surface of the glass it is necessary that there be molecules of sub-bromide in actual contact with this surface, each molecule forming a nucleus doing work in its immediate neighbourhood, the reduction proceeding especially *upwards;* that is, if a film were reversed after exposure, the exposure being such that a half-tone only would appear on prolonged development, and then reversed face downwards as another plate, on development the film would be reduced totally, as if fully exposed. In the case of the middle tints sub-bromide may not exist in more than the upper or surface portion of the film. Even if this were not altogether the case, and a few molecules were imbedded deeper in the film, it is quite possible that that peculiar action of the soluble bromide—which would be gradually increasing in the developer—would have its effect upon them.

I have already referred to the "upward" tendency of development from the sub-bromide forming what I call the "nucleus." If we do not recognise the influence of the sub-bromide in this particular direction, and in no other, how are we to account for the fact that a church spire, provided there be no halation, occupies in the negative the same space as it does on the focussing-screen, the influence of the sub-bromide not proceeding laterally?

HERBERT B. BERKELEY.

A TOURIST'S PRESERVATIVE DRY-PLATE PROCESS.

[A communication to the Photographic Society of Great Britain.]

As it may not be inopportune for members to describe the dry-plate process which they find the most practically useful, I venture to direct attention to the following. My aim has been principally directed to prepare films by the use of a collodion and bath, combining with long-keeping properties adaptability to the ordinary wet process worked with iron development. The great susceptibility of highly-sensitive films to injury from weak luminous radiations during preparation, exposure, and development render reliable plates of moderate sensibility a perfect desideratum. Such, when worked with others of high sensibility, if easily prepared and developed away from a specially-constructed laboratory, constitute in my view essential requisites for the amateur landscape photographer.

The method I adopt for the preparation of films of the less sensitive type it is my present purpose to describe. Although any collodion of recognised standard excellence for iron development is perfectly suitable, yet I should deem this description incomplete were I to omit a formula equally adapted to this or the wet process. I must confess that, in the manufacture of pyroxyline, I have not found the three-to-one proportion of sulphuric to nitric acid—originally recommended in the patent for explosive cotton, and subsequently ably advocated for the soluble varieties—to be the best. The employment of a larger quantity of nitric acid to the sulphuric yields, in my hands, a better result for the soluble kinds. The following formula is based, therefore, on this consideration:—

Sulphuric acid, sp. gr. 1·84	6 fluid ounces.
Nitric " " 1·42	3 " "
Water	5¾ fluid drachms.
Cotton	150 grains.

Temperature, 155° Fahr. to 145°. Time of immersion, 10 minutes.

The double temperature given signifies that, at the time of the introduction of the cotton, the acids should be at 155°, and the allowable decline must not exceed ten degrees. Six fluid drachms of a plain collodion, made by dissolving from five to six grains of the above pyroxyline in a mixture of four fluid drachms of methylated ether, sp. gr. ·720, and two fluid drachms of pure alcohol, sp. gr. ·820, is to be mixed with a bromo-iodising solution made as follows:—

Sodium iodide	6 grains.
Cadmium bromide	4 "
Iodine	½ grain.
Gum guiacum	¼ "
Alcohol, sp. gr. ·820	2 fluid drachms.

Before coating the plate I apply a substratum consisting of an ounce of liquid albumen and thirty minims of "liquor ammoniæ," sp. gr. ·959, dissolved in an imperial pint of water. After the plate is coated, excited in an ordinary argentic nitric bath and removed therefrom, it is to be freely washed in ordinary water kept in motion, and then treated with the following preservative, poured on and off the film twice or thrice from different parts:—

PRESERVATIVE.

Albumen	1 fluid ounce.
Glucose solution (raisins one part, water five parts)	2 fluid ounces.
Water	3 "
"Liquor ammoniæ," sp. gr. ·959	15 minims.
Ammonium chloride	3 grains.
Ammonium bromide	½ grain.

The film is again to be freely washed with ordinary filtered water, covered with a three-grain solution of gallic acid, and evenly dried. The back of the glass, as a matter of precaution against very trying conditions rather than as an ordinary necessity, should be covered with a non-actinic colour. Burnt sienna, ground in water and mixed with a little gum mucilage, constitutes a good medium for the purpose.

At any convenient interval after exposure the film is washed, and developed with a suitable quantity of solution made in the following proportions:—

Water	4 fluid drachms.
Pyrogallic acid (sixty-four grains dissolved in one fluid ounce alcohol ·805)	15 minims.
Potassium bromide (sixteen grains in one ounce water)	15 "
Sodium carbonate (sixty-four grains in one ounce water)	15 "

Five minims only of the potassium bromide should be added in the first instance, and the remainder upon the earliest indication of an image. As soon as the general details of the picture become faintly visible by reflected light the alkaline developer should be removed, and a three-grain solution of citric acid applied. The intensification may then be effected with pyrogallic acid, citric acid, and argentic nitrate, and the unreduced salts dissolved away with sodium hyposulphite as usual.

T. SEBASTIAN DAVIS.

Correspondence.

MICHAUD'S PHOTO-ENGRAVING PROCESS.—EXHIBITION NOTES.

M. MICHAUD has kindly given me several of his first attempts in photo-engraving, which are very good, taking into consideration the isolated place in which he has lived down in the distant department of the Isere, and far away from Paris and its numerous advantages. He has taken out patents for France, England, and the United States.

Details of the process cannot yet be given; but I have some reason to believe that the principle of the application of metal in a state of fusion upon a bichromated image is involved, which renders the process remarkably expeditious and easily worked by any intelligent person even unacquainted with the numerous processes for obtaining printing surfaces. It is very economical, for I know that a copperplate for which £10 was asked by a photo-engraving company has been made, and as well done, by M. Michaud for twenty-four shillings. It is in this direction, especially, that M. Michaud (who is a country chemist and druggist, &c., and who has had the misfortune to lose one of his limbs) is to be welcomed as a new competitor for public favour, and also for showing that progress may be made without costly machinery and appliances by the comparatively uninitiated in the secrets of photo-engraving, and that to the photographic profession, as well as to amateurs, the course is open to all comers. Contrary to what might be imagined, the heat applied does not destroy the bichromated image.

The following is a copy of the communication made by M. Michaud to the Photographic Society of France at its last meeting, respecting what was designated a process to obtain metallic plates, engraved photo-chemically, without any retouching, and by any artistic design in painting, water-colour drawing, maps, or plans, and for which is claimed the following advantages:—1. It transforms, in a brief period of time, a photographic negative into a metallic plate which can be used at once. 2. The immediate production of a lithographic surface which may be delivered to the trade within twenty-four hours of the reception of the order, and, if pressed for time, even within six hours. 3. The production of a typographic block which can be delivered on the second or third day. 4. The preparation of a type or galvanic mould in relief capable of producing also by the electrotype either a direct plate for the copperplate printer, or—5. A thin plate delivered at once in the form of ornamental jewellery of all dimensions, of surprising beauty and fidelity of reproduction, and giving—6. Another series of productions, properly speaking, called the photo-chemical plate, of simple or of more or less ornamentation, which may replace the ordinary copper-engraved plate; an operator in this style can produce as much as the work of two hundred engravers. And lastly—7. The constant results, as well as the enormous reduction of actual prices, are correlative facts of this new process, the principles of which are so simple and so perfect as to leave no doubt as to the successful applications above stated.

The negatives required must be sharp, clear, full of detail, and vigorous.

The method adopted by M. Michaud for reversing the position of a negative film upon the glass plate is as follows:—Dissolve seventy-five grains of gelatine in three and a-half ounces of water, filter, and, while fluid, float upon this bath for three minutes a pellicle of castor oil collodion, which should be attached to a slip of wood that serves to support the pellicle throughout this operation, and until dry, when the films thus prepared are immersed one after another in a five-per-cent. solution of alum for two minutes. They are then washed, dried, trimmed, and preserved between sheets of smooth paper until required for use. The negative that is to be transposed is, after being fixed and washed, placed in a vessel of water, the film upwards. The gelatined pellicle is placed in another tray of water with a sheet of waxed paper of a larger size than the negative, and when the water runs freely over the pellicle its gelatined side is applied to the negative in the other tray, and the two are raised up together, avoiding the formation of air-bubbles between them. The sheet of waxed paper is then laid upon the pellicle, and the squeegee is applied to obtain perfect contact. The waxed paper is next raised, and it may be reserved for continual use. The glass of the negative is wiped dry, placed in a printing-frame, covered over with a dry and thick sheet of blotting-paper, and the spring back is shut. The frame is then exposed to the sun, or over a drying-stove, when the desiccation is rapid. The dry negative is now placed in a tray of warm water, and after a quarter of an hour or so the film with the image can be detached with the hand, and should be dried as before, when it is ready for immediate use. If the pellicle be very thin, and in consequence very difficult to handle, it may be transposed and re-attached by the squeegee to a glass plate simply gelatined and dried beforehand, and then finally dried as before.

Instead of detaching the negative as above described by means of a pellicle of collodion, which possesses several advantages over gelatine as usually employed, a sheet of simple waxed paper may be used, when treated exactly as before described for the pellicle. These negatives have no need to be attached again to glass; it is sufficient to place them between dry sheets of thick blotting-paper, and to pass over them a hot iron so as to give them the necessary flatness and transparency.

The full printed regulations for photographers in the Paris Universal Exhibition have at length been issued, the *first* copy being sent by M. Bergu, the Director-General of the Foreign Sections, to (as the French newspapers style and print him) "*sir* Cunliffe Owen," and which Mr. England was good enough to show me. According to this document *any* photographic exhibitor has the right to demand a card of admission giving him the privilege to take photographs of the palaces, park, gardens, grounds, and the different groups and classes, except the Fine Arts, for which a special card must be obtained, but which will not be granted by the British Commission. Any photographer persisting to photograph in that portion will be removed by force, *if* necessary.

For photographing in detail anything exposed a copyright permission in writing by the maker or owner must first be obtained and lodged with the Commissaire General; the demand for the card to photograph must also state the number of operators and other persons, and the apparatus and process (wet or dry) to be employed, with other details. The photographer at the same time binds himself to supply the Commissaire General with five copies of each photograph taken, which will become the property of the French State, and, in addition, he must protect his copyright in each photograph or negative published by him in France by the regular deposition at the Ministry of the Interior of four copies of each, otherwise he will run the risk of having his works pirated. Thus, on the whole, he will have to furnish nine copies gratis before being able to legally sell a single print. The hours for working are fixed as being from seven o'clock until ten in the morning for the interior of the exhibition, and until eleven o'clock for the exterior. The photographer will be subject to such further rules and regulations as may be drawn up; also to the general laws and pains and penalties for damage or injury done. The Commissaire General reserves to himself the right to withdraw or suspend the card of permission of the photographer, or any of his operators or other persons employed by him, for any cause whatever.

Mr. England was the first exhibitor who received the printed regulations and card of permission to photograph. Mr. Warnerke, Mr. York, and Mr. Payne Jennings have also applied for permission.

The photographer whom I reported in one of my recent letters as at work on the opening day was M. Appert (brother to General Appert), and who is the official photographer to the French Commission. He is working with wet collodion in a square tent resembling, in outer form, Smartt's tent, and has alone permission to work all the day for the Administration. His focussing-cloth is large and is suspended over rods attached to the top of his camera, hanging so well over the lens and the sides as to form a perfect sky-shade, thus advantageously replacing the usual inefficient cone. The plates used for the opening ceremony were $21\frac{1}{2} \times 17\frac{3}{4}$ inches, and for daily work 16×12 inches. The lens employed was a four-inch one by Auzouz and Français.

M. Queval, who has recently published the Taupenôt process he has hitherto used for his stereoscopic negatives, especially those of his excellent London views, has since the opening day commenced working; but I find he is a convert to the emulsion process of M. Peuch. He prepares each night twenty-five plates, which he encloses in Bristol cardboard slides, and exposes them the following day, developing the same night.

The stereoscopic camera of M. Queval is worthy of notice. By a series of screws, a pair of the heads of which correspond accurately with the focus of each pair of lenses he uses, the glass focussing-screen and cloth are completely suppressed. The carrier end of the camera, to receive the black cardboard plate slides, has only to be placed in contact with the pair of screw heads corresponding to the focal length of the lens used to render it certain that the plate is in perfect focus, and is maintained in that position by the elastic body of the camera. Sight points on the top of the camera indicate the subject embraced by each lens; and the rapidity with which the camera is fixed and the plate exposed in busy thoroughfares before a crowd has had time to congregate around the photographer is delightful. This camera is not new, having been practically tested for years in France, England, and other countries.

MM. Leon and Levy and MM. Lechenal and Co. have also obtained cards as well as the company (limited) working out Braun's business; so that it will not be for want of photographers if the public suffer in the supply of photographic representations of the Paris Universal Exhibition of 1878.

The photographs in the Austrian section are not yet unpacked. Herr Luckhardt is named as a juror for Austria. The United States, Canada, and Portugal are in arrear with the completion of their display.

As the classes 12 and 15, in which we are more particularly interested, are now throughout the exhibition approaching completion, the general aspect is much changed, so that a more mature judgment may be formed of the comparative merits of the various exhibitors.

In connection with the exhibits from the United States I strongly recommend for study five frames of pictures of cabinets and cards by Sarony, of New York. Their individuality, freshness of artistic posing, light and shade, combined with effect and definition, together with manipulative skill, have never been excelled.

There is also near to Sarony's display a new competitor for public favour, especially by the ladies, in the person of Joshua Smith, "instantaneous photographer," of Chicago, who exhibits a sheet $21 \times 16\frac{1}{2}$ inches covered over with portraits of babies and very young children. There are nearly one hundred of these juveniles' portraits arranged and vignetted in such a way as to merge one into the other, thus producing a very excellent effect. There are all the most unaccountable positions that babies alone can take, and that we *cannot* imagine, as well as the hundred-and-one facial expressions so varied and so dear to all doting mammas. This picture is labelled, in quaint American phraseology—"We came all the way from Chicago." The printing is firm, the whites pure (as in all good American printing), and although evidently the most rapid exposures have been given, the half-tones and modelling are perfect, while the shadows are in due keeping. This central picture is surrounded by scores of *cartes de visite* of babies and little children fastened to the background of the frame with drawing-pins, and so clamped down as to make the *cartes* take a vertically round surface. They are vignetted portraits in the "English fashion," as the French have it.

On the wall space on the left hand of the entrance to the French photographic court in the second great transversal avenue is hung the attractive work of M. Victoire, of Lyons, and to which his simple but appropriate fittings add value. He, unlike some of us, has given sufficiently large spaces of dark red purple tones between the gilded chamfers which thus separate advantageously each picture; for when the prints are placed too near each other, as in some English examples, the close contiguity of one to the other injures them most seriously, and in common *parlance vil* this fault is curtly expressed by the phrase, "Oh! by Jove! the frames are too crowded, and there is not breathing room left between the prints!" M. Victoire's works refute the remark generally made by the observer when examining photographs prepared for competition that they do not represent ordinary daily work of the artist, are the result of elaborate retouching, both on the negative and on the print, and of great and unexceptional care throughout, forming no criterion as to the artistic worth of the ordinary proofs delivered to the artist's photographic clients. As an instance of this I may mention the case of a photographer at Landernau! "not a hundred miles from me," who has had awarded to him no end of medals, but whose work, as delivered by him to his *clientele*, I should be ashamed to sign. M. Victoire, in direct opposition to such a system, has obtained from his patrons the loan of the pictures he exhibits, and which had already been delivered and paid for, thus forming his contribution to the French court. These works are sure to be "medalled," and they will thus be returned to their owners with increased value. Such pictures are as much a loan as the numerous oil paintings and water-coloured drawings that, thanks to enlightened connoisseurs, adorn the walls of the British and American fine art collections.

The studio of M. Victoire is placed on the *entresol* at the corner of two streets, with houses on the opposite side of one street three or four stories high and confronted, in the other street, with houses five or six stories high; hence the light was blocked out. In order to remedy this state of things M. Victoire has ground glass for the whole of both top and side lights, and to this may be partly ascribed the beautiful roundness of the heads and arms of the personages photographed, as well as the solidity of their bodies—meaning by this as far as regards height, width, and thickness—which causes the figures to stand out and be well detached from the backgrounds, in contradistinction to those badly-lighted pictures we too often see even in the oil-painted portraits now exposed in the fine art sections in the palace of the Champ de Mars, as if they were only of height and breadth without thickness, or cut out of paper and pasted against the backgrounds. As an instance of contrary treatment the photographic visitor should examine the wonderful portrait of Thiers, by Bonnat. The above good qualities of the pictures of M. Victoire are also due, in a certain measure, to the negatives being, as a rule, always *over-* than *under*-exposed. The lens used for the *cartes* was the three-inch orthoscopic of M. Darlot, of twenty-one inches focus, stop No. 2. The exposures were fifteen seconds for the cabinets and eight seconds for children. The exposure for the 16 × 12 ins. pictures was from thirty to forty seconds, and for the 22 × 18 ins. from forty to sixty seconds. The fine results of these arrangements may be ascertained by looking at the light satin dress of a full-length standing figure of a lady, where the rich sheen and precise texture of the costly material are truthfully and naturally reproduced. A portrait of the same lady, and in the same dress, is shown by another photographer; but the lustrous surface of the dress is not at all properly rendered, and it would be difficult to say of what material the dress was composed, while it can easily be imagined how the "face divine" must have suffered, redeemed only in this case by the theatrical attitude given to the figure.

M. Victoire's collodion (half as much bromide as iodide) and development with iron are as used seven years ago, in accordance with the good old formulæ, and which, after all the novelties, gives the best result. The prints are on albumenised paper prepared expressly with four per cent. of chloride, and sensitised upon a silver bath of sixteen to seventeen per cent. For the toning bath four litres are made at a time with one and a-half to two grammes of gold per litre, thirty grammes of fused acetate of soda, and three grammes of carbonate of soda. The prints are left but a short time on the gold bath, and then well and quickly washed, giving very rich, warm, permanent tones. M. Victoire is an old collotype worker, having gained the gold medal at the International Exhibition of 1872 for the same after the jury had worked out the process in detail in his laboratories. He says that he uses silicate of soda to harden the printing film of gelatine spread upon a copper plate, which enabled him to print hundreds from the same relief, and that chloride of calcium gives the grain in the photo-engraving based on Woodbury's process by M. Rousselon, who has a grand display adjoining occupying a wall space of eight yards wide by three yards in height, but of which more anon. W. Harrison.

Asnières (Seine), May 20, 1878.

RAPID GELATINO-BROMIDE PROCESS: FURTHER DETAILS.

To the Editors.

Gentlemen,—Your correspondent "D" should multiply the quantities by ten if he desire ten ounces of emulsion, and employ, as directed at page 146 of your Journal, four ounces of water for the bromide and two for the silver. He will, before setting it to wash, therefore have for his final ten ounces—

Bromide of ammonium	70 grains.
Nitrate of silver	110 ,,
Gelatine	200 ,,
Distilled water	6 ounces.

The remaining four ounces to make up the ten will be obtained thus:—The gelatine, in washing, will have absorbed (say) two ounces from the washing water, consequently he must add two ounces still further to make up the ten, or otherwise do as follows, which I think is better: let the last two ounces consist of water and alcohol (say three-quarters of an ounce of the latter).

In my previous letter perhaps I observed brevity too much. I offered the remarks found at page 146 to those already experienced in gelatine work, and so did not allude to the *manner* of coating, nor to the *use* of the intensifying dish. The latter is useful in treating a plate accidentally over-exposed and consequently too thin, in which case, after the alkaline development, fix, wash, and dry; then flood with pyro., citric acid, and silver, the same as for wet collodion plates. Density is easy to obtain.

To coat: warm a quantity of plates in an oven, to appear upon touch a little warmer than the hand; place them on the table to the left of your seat, and the emulsion (immersed in a jug of water at 90°) on your right. Coat same as with collodion, but only drain *partially*, leaving enough on the plate to appear about three times as thick as with collodion. Level it as much as possible with your plate-holder for a few seconds, till it has subsided into a perfectly even sheet; then slide it on to a piece of plate glass—say twenty inches square—which has been previously levelled with a spirit level; and, if you are using glasses half-plate size, by the time the plate glass is covered with them the first one coated is probably set enough to slide it to another part of the operating-table, which should also have been previously levelled by placing wedges on the floor under the legs of the table.

If the plates have been thoroughly cleaned the emulsion will flow like collodion; but should it not do so use a warm glass rod to lead it over the plate, and have them better cleaned next batch. For beginners it much helps the coating to double the quantity of alcohol, leaving out water to that extent. The operator should not be alarmed at the peculiar mottling of the film (due to the alcohol) directly after coating; this subsides in a few seconds to an even surface. The extra alcohol does not appear to alter the sensitiveness, and is a great help; but with experienced workers it is not necessary, and the quantity mentioned at page 146 is sufficient to draw the emulsion up to the edges, which is the sole object of introducing it. When no alcohol is used you have always *thin* edges, which is very objectionable, as the negative, of course, will print dark at those parts, and this small addition of alcohol totally rectifies this fault. It is difficult to measure the exact quantity of emulsion required for each plate; one ounce would probably cover *eight* plates of $6\frac{1}{2} \times 4\frac{3}{4}$ size.

By darkening a good-sized room temporarily for coating it obviates the necessity of a drying-box, for if the films can lie on the table for twelve hours they will be dry, or sufficiently so to stack up in an ordinary box. I cannot trespass further on your space, but will gladly answer "D" any further queries through the post, should he desire it.—I am, yours, &c., C. Bennett.

May 21, 1878.

THE "IMPOSSIBILITY OF FADING."

To the Editors.

Gentlemen,—Will you give my compliments to the "Peripatetic Photographer," and tell him I shall be happy to give him a few lessons in English? I have given him a week's grace to see the error of his ways, but as he has not done so he must be pilloried. He states that the sense of the sentence, "to remove all doubt as to the impossibility of fading," which appears in an advertisement of mine, is that the picture alluded to will fade. He is utterly wrong. The thesis to be proved or disproved is, "the impossibility of fading." Doubt being removed, the thesis is established, *i.e.*, fading is impossible; nothing could be plainer.

Further: he wants to know what sort of a basis my "second best" works of art are produced on. I do plenty of "tinted" work—a few shillings for a "tinted" silver printed *carte* in water colour, and as I know, and Mr. "Peripatetic Photographer" knows, or ought to, water colour work in silver prints always fade, I scorn to advertise a lie, and make the public believe that if they pay me half-a-crown for a well-painted *carte* vignette they have a thing of beauty that will be a joy for ever (like my well-known celebrated best work!)

Now, Mr. "Peripatetic Photographer," haul down your flag, and come and take these lessons, and mind you bring some good cigars; also my taste is Glenlivet for preference.—I am, yours, &c., The F.C.S.

[We have also received a copy of the Liverpool newspaper cutting which elicited the strictures of the "Peripatetic Photographer," who, we are bound to say, has not been guilty of misquoting in the slightest degree. Of the identity of the "F.C.S." we were ignorant until we received the present letter. We shall be glad to receive an account of his new process "which removes all doubt as to the impossibility," or possibility, "of fading." We had hitherto believed that in carbon printing we were assured of immunity from fading, hence our desire to know more about the "new" process.—Eds.]

OXYGEN RETORTS.

To the Editors.

Gentlemen,—Having had my attention drawn to Mr. Chadwick's article on *A Novel Magic Lantern*, I beg to say that some four or five years ago I constructed one on exactly the same principle. Since then, and up to the time of disposing of my business at Oldham, I used it publicly throughout each winter, and although Oldham *is* seven miles from Manchester my entertainments were not always at that distance from the city.

I do not wish Mr. Chadwick to think I charge him with copying my lantern, though he may assure himself of the correctness of my statement by going to 24, Yorkshire-street, Oldham, where the original lamp is.

I may also say that I always used a pair of two and three-quarter diameter, four and a-half inches focus, Burr's lenses to my lantern, which gave an immense amount of light on the subject. Any photographer can get a good light at little cost by an extra flange to his quickest lens, fitting it to his lantern, and simply unscrewing his lens from the camera when wanted for lantern purposes. Any optician can make an extra flange at little cost.—I am, yours, &c., S. Beverley.

72, *Church-street, Blackpool, May* 21, 1878.

EXCHANGE COLUMN.

Wanted to exchange, one dozen 12 × 10 views of Yorkshire, all different and good prints, for Hearn's *Practical Printer*.—Address, EDGAR WILLIS, Park Villa, Scarborough.

I will exchange a cabinet rolling-press, nickel silver bed and roller, for cabinet Entrekin's burnisher. A little cash as difference if necessary.—Address, F. J. MATTHEWS, St. John's-road, Ryde.

Wanted to exchange, a pair of quick-acting *carte* portrait and view lenses, three and a-half inches focus, for an American Waltham lever watch, value about £4 10s.—Address, J. T., 64, Sherrington-road, Highfield, Sheffield.

ANSWERS TO CORRESPONDENTS.

PHOTOGRAPHS REGISTERED—

Archibald Burns, Edinburgh.—*Three Views of the Regalia of Scotland.*

John Horsburgh, Edinburgh.—*Two Portraits of Sam. Bough, R.S.A.*

☞ *Correspondents should never write on both sides of the paper.*

B. G. SINCLAIR.—In our next.

ELECTRO.—Try either the electric or the magnesium lights.

J. S. SMITH.—Yes, certainly; but not for several months yet.

W. A. BRICE (Paris).—Received. You will hear from us soon.

R. M. HOWDEN.—Acetate of lead is a mordant for dyeing cloth by means of bichromate of potash.

G. F. (Leith).—If the lens be properly ground it will be sure to work well, as the principle is excellent.

SCHOLL.—Let the inside of the studio be painted a grey colour. Painting in this case is preferable to papering.

HALIFAX OPERATOR.—No great chances in Paris we fear, but you may write to our correspondent, enclosing stamps for his reply.

L. T. M.—The probable cause of the stains on the prints is the careless handling of the paper by some assistant whose fingers have not been clean.

M. P. E.—Try a solution of the persulphate of uranium; it will act better than the nitrate for your purpose. It may be obtained from several dealers.

A. J. CORRIE.—The print may be rendered transparent by means of a solution of Canada balsam in benzole, after which it is painted *behind* with the usual opaque artists' oil colours.

PYRO.—It is quite *possible* to take a transparency on a globe, but it is far from being easy, unless you are familiar with the transferring of films, by which process it must be effected.

M. (Kendal).—There is no book or manual devoted exclusively to photolithography. The process as usually and extensively worked is not patented, and you are quite at liberty to practise it.

AMATEUR.—So far as we have heard the morphia process, like a number of other processes that have been popular in their day, has ceased to exist. We have not heard of any one who now practises it.

OBLIGED READER.—The gentleman you name left this country several years ago, and now resides on the continent. He was in good health when we last heard from him, and is still a reader of this Journal.

L. S. D.—Your letter is far from being as explicit as it should have been; still from what has been stated we think the cause of the mottled skies is the over-iodising of the collodion. The coffee infusion has nothing whatever to do with it.

J. W. NICKLIN.—The print is not as good as the negative is capable of producing. Do not carry the toning quite so far; print in a weaker light, and pay a *little* more attention to the vignetting. Formulæ for varnishes will be found in our ALMANAC.

PHOTOLITHO.—The price of Colonel James's treatise on photolithography was about twelve shillings, but it is very doubtful if a copy can now be obtained except at second-hand bookshops. You may inquire at Longmans and Co., that being the firm by whom it was published.

W. (Budleigh, Salterton) and M. ROW.—We have written to the advertiser named without having received any reply. Of course neither Editors nor Publisher are responsible for statements made in the advertising columns. The matter has been placed in the hands of the Publisher.

S. A. H. P.—Arrange so as to have armholes in the sides of the developing-box, and have these fitted with short, wide sleeves having an india-rubber band round the wrist. This will allow of perfect freedom for manipulating without the danger of any light being admitted at the armholes.

L. G. BIGELOW.—A letter addressed to Mr. W. B. Woodbury, Manor House, South Norwood, London, S.E., will probably secure for you the information required. We regret that it is not in our power to give more details than we published in our ALMANAC for 1876, which we presume you have already seen.

MRS. S.—By the old hypo. toning bath most beautiful tones have been obtained, but such prints nearly always fade. We dare not say that *all* fade, because we have some at present in our possession in Talbot's *Pencil of Nature* that are still fresh and vigorous. We strongly recommend you to dispel your present ideas, and adopt alkaline toning exclusively.

F. B. (Dublin).—1. If you print your opal pictures by the carbon process you will have a guarantee that they will not fade. By adopting any of the other processes named fading is only a matter of time, such period being, in some instances, very short indeed.—2. A solution of sulphide of ammonium is necessary. Let it be diluted with three times its bulk of water.

J.—We cannot say whether or not you would be able to re-cement a lens yourself unless we know something of your capabilities. We have many times published directions for doing so. From your letter we arrive at the conclusion—perhaps an erroneous one—that yours is a case in which it would be much safer to secure the services of a properly-qualified optician, rather than make the attempt yourself.

E. O. P.—A triple achromatic lens of the usual form will not answer for portraiture in a studio unless in an exceedingly strong light; but special triple lenses having a central concave lens of large diameter are still to be met with—although not now manufactured—that admit sufficient light to render them suitable for portraiture. They do not, however, possess the rapidity of a properly-constructed portrait lens.

J. T. BAINBRIDGE (Barnard Castle).—Our correspondent writes to take exception to what Mr. Stothert has written respecting "vertical and horizontal lines." He says:—"It would be a waste of time to again discuss the question of 'the non-convergence of perpendiculars,' for anyone interested in the subject can in a very short time, by experiment, satisfy himself of the truth or untruth of what has appeared on this subject. I maintain that there is no such thing in nature as converging perpendiculars, and I should very much like to see a negative of a high building where the camera, being placed opposite and at an elevation of half the height of same, showed the vertical lines converging at the bottom as well as at the top. I, once for all, say that if the camera be properly levelled, there will be no converging either at the top or bottom, and no amount of arithmetic can alter it."

FADING OF CARBON PRINTS.—On this subject Dr. Monckhoven writes to the *Journal of the Photographic Society*:—"Allow me to give a short reply to the observations made upon my paper. 1. Not being very sure of my English, I wrote the word 'fading' instead of the word 'change.' In my opinion the carbon prints, as long as they contain black carbon, cannot fade. The red matter which enters prints alone can fade. I have been mistaken in the word, and cheerfully retract it. 2. It has been asked how I render the oxide of iron transparent. In this way:—I make a thick jelly and dissolve in it an equivalent of ammonio-citrate of iron. I make another jelly with an equivalent of ammonia, and mix the two. The ferric oxide thus formed in the syrupy liquid cannot precipitate, and, when poured upon a glass plate, is transparent. Prepared in any other manner it is opaque. I add it in this state to the gelatine which serves to make the tissue. 3. I have never said, as Mr. Swan makes me say, that I can make the ferric oxide purple. I produce organic combinations of oxide of iron of a brown-red colour, but never purple. 4. One journal says that I have operated with transfer paper prepared with barium sulphate, which will be altered by the chromic acid forming barium chromate, and that this is the cause of the alteration which I have observed in the prints. This is inexact. I have not employed such a transfer paper, and it is contrary to the most elementary ideas of chemistry to affirm that barium sulphate combines with chromic acid to form barium chromate. No acid, mineral or organic, attacks barium sulphate. I regret that such an argument should have been used. In conclusion: I may say that no one has given any experiments which clash with mine. It has been attempted to prove that the black prints are unalterable—a fact which I have never controverted. I have repeated all my experiments, and I energetically affirm that a simple washing of a carbon print, though it be prolonged for hours, will not eliminate the chromate nor fix the image; but that this object is attained by the addition of one quarter per cent. of sodium sulphite to the alum."

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. STEWARD, Optician,
For the two Weeks ending May 22, 1878.
THESE OBSERVATIONS ARE TAKEN AT 8.30 A.M.

May.	Bar.	Wind.	Wet Bulb	Dry Bulb.	Max. Tem.	Min. Tem.	Remarks

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 943. Vol. XXV.—MAY 31, 1878.

ON THE CAUSES AFFECTING THE TRANSPARENCY OF DRY FILMS.

In considering the various causes which operate in modifying the apparent density of dry-plate films, we have to look at, first, the nature of the pyroxyline, and, second, the method by which the film is prepared, whether with the bath or with an emulsion. If the latter method be employed we have further to take into consideration the nature of the emulsion (whether washed, unwashed, or precipitated), the salt employed in sensitising, and the proportion of silver to soluble bromide. In addition to these causes the result is also more or less affected by the organifier (if any), some of the substances used in this capacity exerting a mechanical action upon the drying of the film of collodion without producing any apparent change while it is wet.

The difference caused by stronger or weaker salting scarcely belongs to this part of the subject, and in so far as it affects plates prepared with the bath it may be altogether dismissed; but its bearing upon emulsion films is worthy of a few remarks. In the old collodio-bromide process there was no inducement to carry the salting of the collodion beyond a certain point; in fact, in order to secure evenness of film and an easy flowing emulsion, it was absolutely necessary to keep the quantity of bromide within certain limits, varying slightly with the physical character of the collodion. But the introduction of washed emulsions, involving the evaporation and loss of considerable quantities of ether and alcohol, brought into vogue the practice of increasing the proportions not only of the bromide and silver employed in sensitising, but also of the pyroxyline contained in each ounce of solvents, in order to economise the latter as far as possible. Theory would seem to offer no objections to this course, but practically it was soon found that by pushing it too far the resulting emulsion suffered very palpable deterioration, not only in its working qualities, but the weight of the dried product fell far short of what should be obtained from the quantities of ingredients used.

In fact, it would seem that a point is reached beyond which it is injudicious to overload the solvents with solid matter, and that if the proportion of pyroxyline or of silver bromide be pushed beyond this point the resulting "pellicle" is sure to be inferior. The most noticeable feature in connection with a carefully-prepared emulsion, containing a moderate proportion of silver bromide, is the extreme fineness of the "grain" of the resulting film; but as we increase the quantity of solid matter in each ounce of solvents the appearance of the film gradually changes to a more granular and semi-opaque character. Nor is the change confined to its appearance; for, in proportion as the granularity increases, so does the image on development become less vigorous—more liable to fog as well as more difficult to intensify. We, therefore, counsel our readers to beware of false economy in this direction.

As regards the nature of the pyroxyline and its effect upon the physical character of the film, it may be accepted, as a general rule, irrespective of other conditions, that the more powdery the cotton the more opaque will be the sensitive layer when dried. In many instances the difference will not be noticeable until the film is dried; and in these cases other conditions—as the nature of the organifier—are capable of further modifying the result. In emulsion work, too, the nature of the cotton has an important influence upon the *formation* of the bromide, with some samples the emulsion remaining thin and transparent for hours or even days, in the presence of excess of silver, while with others half-an-hour or an hour suffices to bring it to the "creamy" or opaque stage.

This effect does not appear to be due to the powdery action of the cotton as produced by high-temperature acids, but rather to variations in the proportions of the latter and in their strength. We have obtained a dense, creamy film, in less than half-an-hour after sensitising, with a sample of pyroxyline made at as low a temperature as 135°, and which gave a collodion film almost as tough as gold-beaters' skin; on the other hand, a specimen of papyroxyline of so powdery a nature that it dried upon glass as a dusty, semi-opaque film, remained thin and transparent as an emulsion for several days after sensitising. This may be taken as the type of another variation brought about by the cotton. The emulsion itself and the film while in the wet state remain beautifully clear and transparent; but upon drying the latter assumes a dull, semi-opaque appearance, and under a magnifier of moderate power exhibits distinct traces of structure and granularity. This sort of pyroxyline is to be looked upon at least with suspicion; for, though on development an image of great density is easily obtained, it is completely ruined by the structural defects of the collodion. Emulsions which pass rapidly into the creamy stage are, on the contrary, inclined to give a feeble, veiled image, and unless containing a good body of sensitive matter are very difficult, if not impossible, to intensify.

The mode of preparation of the emulsion must also be considered in connection with the nature of the pyroxyline; for, though with a given sample of the latter a different character of film will be obtained according as the emulsion may be unwashed, washed, or precipitated, it is possible by changing the cotton to produce films of any desired characteristics by all three methods. As regards fineness of grain in the film the three methods may be ranged in the order they are named if the same conditions be observed in each case; and, though the results obtained by the two first mentioned are frequently difficult to distinguish, precipitation fails under any circumstance to produce an effect quite equal in quality.

As is now well known, the various soluble bromides used in the preparation of emulsions give widely different results as regards the appearance of the films. Zinc bromide is a notable instance of this, yielding as it does films of great density, while ammonium bromide leads to an opposite effect. It is sufficient to note this fact, which has been attributed to the action of the base of the bromide upon the sensitive compound, and possibly also upon the cotton itself. A greater or less degree of sensitiveness has also been attributed to emulsions prepared with different bromides; but whether any connection exists between the latter quality and the comparative density of the film we are not prepared to say. Certainly it would appear so, for the zinc salt, according to Mr. Warnerke's published researches, stands highest, and ammonium one of the lowest, upon the scale of sensitiveness.

Lastly: we come to the comparative effect produced by excess of silver and of soluble bromide respectively in the emulsion. A general opinion prevails that excess of silver is necessary to the formation of a dense, creamy film; and, while agreeing in the main with this view, we do not think the effect *invariably* follows the cause, or that it is impossible to produce a creamy (by which we mean a semi-opaque) film with bromide in excess. With a considerable excess of the latter—say two or three grains to the ounce—it is possible to retain an emulsion for many months in the transparent stage; but if the proportions be so nearly balanced as to leave but a mere trace of bromide unconverted, a few weeks, or even days, suffice to change the character of the emulsion and its working properties. Similarly a slight excess of silver brings on the creamy stage in a few hours; but if the quantity be increased to six or seven grains per ounce over and above the combining equivalent the emulsion will remain in a comparatively transparent state long after it has passed into a hopelessly foggy condition.

It seems probable that the solvent action of the excess (whether it be on one side or the other) upon the silver bromide already formed in the emulsion has something to do with the transparency or opacity of the film, and that an emulsion in which the salts are nearly balanced is in the most favourable condition to pass into the creamy state, that result being produced, not by the free silver, but by the action of the decomposition salts and the free acid. In proof of this a washed emulsion giving a thin, transparent film was treated with silver nitrate and potassic nitrate in separate portions—the former being added in the proportion of two grains to the ounce, the latter eight grains, or approximately the quantity which would be formed by double decomposition in sensitising. The result was that both emulsions soon became unworkable; but, whereas the appearance of the first remained unchanged for several days, the other gradually became opaque and granular. The first also was restored to working condition by treatment with cupric chloride; the latter was hopelessly ruined.

Having enumerated the principal causes which affect the physical character of the dried film, we may conclude by stating that an extended experience with different descriptions of plates, and during the last two or three years numerous comparative experiments with emulsions, have induced us to give a decided preference to moderately transparent films. A certain amount of opacity has its advantages; but where it is gained by modifications of the structural qualities of the film, or by the production of a coarse formation of the silver bromide, the advantage, if any, is more than counterbalanced by the loss in working qualities. A dense layer of fine particles of bromide, when it can be obtained concurrently with uniformity of coating, is obviously superior to a thinner film of coarser and more opaque particles.

TYPICAL PHOTOGRAPHS.

When, a few weeks ago, Mr. Francis Galton, F.R.S., President of the Anthropological Section of the British Association, explained to us his method of taking, or rather of *making*, composite portraits we thought the scheme was one much more likely to lead to failure than success. He has, however, made good his intentions, and, in a paper submitted to the Anthropological Institute, he has not only described his *modus operandi* in every detail, but has exhibited numerous specimens of this decided novelty in photographic portraiture. Mr. Galton has kindly favoured us with a set of these specimens, which possess great interest.

The joke of "three men rolled into one" is a standing one. But we have before us not only *three*, but *four*, *seven*, and even *eight* persons in one. The effect of these can easily be seen by taking two or three negatives of different individuals all posed and lighted alike, and placed at the same distance from the camera. From these let very thin transparencies be printed and overlapped, in the manner adopted by M. Leon Vidal when he first produced his polychromatic pictures. One face will then be blended with another, the result being the average of both.

It is a very easy matter for those who have acquired the art of seeing a pair of binocular pictures as one, without the aid of a stereoscope, to combine a pair of portraits of different individuals by placing these portraits side by side and causing them to unite in the brain; and it was long ago suggested that by forming in this way a "composite" of a husband and wife some idea of the physiognomical peculiarities of their children might be obtained. Experience has not, however, shown that much reliance is to be placed upon such a means of forecasting the appearance of the coming children, although there is no doubt that it has proved correct in some instances.

A photographer, from his being intimately conversant with the technical requirements of his art, will naturally arrive at the conclusion that a "composite" picture must prove to be a confused, blurred mass, in which it will be wellnigh impossible to trace a feature. This is not the case. One of the "composites" given to us by Mr. Galton, and which is made up out of three components, possesses in the face the degree of sharpness peculiar to a portrait printed, not from a collodion negative, but from a paper or Talbotype negative, there being certain peculiarities of dress which convey the threefold origin of the picture. No one feature in this special "composite" appears identical with that of any one of its components; but it contains a resemblance to all, and is not more like to one of them than to another. Those of our readers who are interested in anthropological subjects will read Mr. Galton's paper in another page with much pleasure.

ARTISTIC "KEEPING."

It is not a long time ago when the perfection of a landscape photograph was, by the majority of workers, considered as obtained when every object depicted was given with hard and rigid exactitude, being, as it was termed, in "sharp focus all over," and the whole capped by a perfectly white "sky," free from spot or stain or the slightest irregularity that might suggest cloud possibilities. And when this phase was past, and the printing-in of clouds became a recognised part of the routine of first-class work, much was the merriment often caused among the critics by the haphazard way in which a cloud picture was tumbled on to the top of the landscape, without any regard being paid to artistic keeping or natural possibilities.

Afterwards, when the so-called composition pictures became more popular it was rare that one or other of them did not transgress some of the most elementary canons of propriety. Thus, as a minor example in a picture of great merit in this class, which was shown at one of the exhibitions, clouds were introduced the lighting of which proved the sun to be at a point exactly opposite to that required by the illumination of the figure subjects in the same picture.

Photographers, however, in their turn have now an opportunity, if they wish, of rejoicing over—we can scarcely say their rivals—the artists of the brush, who are so chary of admitting them to be workers in fine art. Mr. Norman Lockyer's paper, in *Nature*, entitled *Physical Science for Artists*, has shown how easy it is to overpass the boundary line which separates possibilities and artistic imagination and as his remarks possess an interest for photographers equally as well as for artists of the brush, we have taken the present opportunity of calling attention to them. Commencing with an impeachment against the skies of a number of pictures, he points out how they are contrary to nature, and would be impossible of realisation owing to certain unchangeable physical laws. For example: moonlight effects have often been tried in photography with but indifferent results, the heaviness of the sky generally being so conspicuous; but of one of the pictures in the present Academy exhibition Mr. Lockyer feels compelled to speak very slightingly—"unnatural moonlight, and impossible shadows." The softness and colour show that the artist had never studied "moonlight." Of other pictures he speaks of "brickdust beams of light proceeding from nothing, unnatural sunset colour, and distribution of light wrong, interesting as a foretaste of the future when the sun shall have cooled," and so on. We thus see that if photographers err they do it in good company; but that we hold to be no excuse at all. Photography ought now to be quite able to hold its own, and its professors to point to results in double or combination printing which should be beyond cavil.

Subjects including reflections in water are favourite ones for those who produce these pictures, and such are the kind in which usually we may see natural laws set at defiance in the representations of reflected objects. Mr. Lockyer has presented the question of reflections in such a popularly understandable form that we here make an extract in his own words. He has tried to show how the actions involved in sending a telegraphic message may help us to form a mental image of what is going on before the sensations of light is produced:—"We have a sending instrument, a medium, and a receiving instrument. The first under all circumstances is a molecule or series of molecules in vibration, and the quality of the light depends upon the vibration either inherent in the molecule or dependent upon the quality of the energy which sets it in vibration or controls the vibration. The second is the ether, which does for light what an atmosphere does for sound. Competent to transmit vibrations of all lengths without loss of energy, it behaves with perfect fairness, so to speak, to light of all kinds. The third, the receiving instrument, in our case is the eye of the artist above all things, but not to the exclusion of everything else, because every object which reflects light must receive it first, and sometimes important modifications are brought about in the act of reflection."

Further on Mr. Lockyer says, with great cogency, for photographers "the laws of reflection can also be studied without any higher knowledge of the properties of light, and the difference between 'specular reflection,' the case in which light is reflected as in a mirror, and 'scattering,' in which in consequence of the roughness of the surface on which it falls it is thrown off in all directions, will be at once recognised." The great stumbling-block, as we have pointed out, is the proper mode of representing objects as seen by reflection in the water; and here we feel compelled again to quote, for better chosen language could not be employed to embody the scientific principles necessary to guide the printer when he wishes to produce from a reversed negative a reflection in water of any portion of his picture, this being a point of great difficulty to do correctly:—

"If a painter will imagine a vertical plain passing through the object reflected—say a hill top—and his eye, and plot a section with the height of his eye and the hill top above the water and the distance between them roughly to scale; and, if he will further recollect that the lines which connect the reflecting point of the water with his eye and the hill top must make equal angles with the water level, he will find all he needs to ensure correctness."

Similar reasoning shows us how relatively to place a moon or sun to obtain the beautiful rippling water which shows so prettily in a picture; the fact that artists of eminence have sinned by placing this wake across the picture, in positions it could never take in nature, is pointed out in the same place.

Any effective natural rainbow is very seldom shown in a photograph, but there is no reason why a factitious one should not be introduced with considerable effect by a little dodging in printing; but care must be taken that the cast shadows be in proper keeping with the position of the rainbow. An otherwise beautiful Constable, which we noticed in the last Grosvenor Gallery exhibition, was marred by such a physical absurdity as the shadows being cast almost across an imaginary line at right angles to the centre of the bow. In photography, void of colour as it is, the opportunities of producing pictures deficient in truth to natural requirements are comparatively rare; but on that very account, and from the reputation it has for exactitude and accuracy, it behoves every one who in the slightest degree introduces, by double printing or otherwise, a representation of what is not in its due place in the field of view at the time of taking the negative to be as careful, conscientious, and accurate as possible, or the results obtained would become gross absurdities on account of their very ambitiousness.

The introduction of studio backgrounds has fallen into utter disgrace from this very cause of want of proper keeping, though we have been pleased to note that for some time painted screens of the highest merit have been placed in the market, and they leave so little to be desired, from an artistic point of view, that it is likely a reaction may set in.

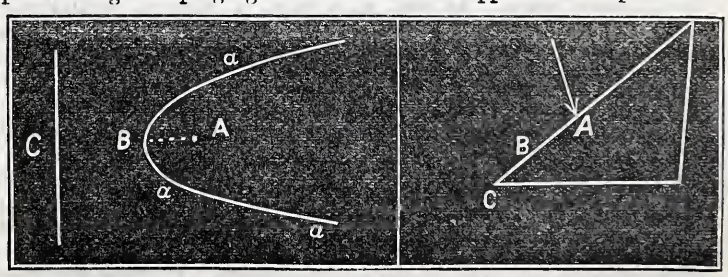
At a meeting of the Society of Arts, last week, there was, in connection with a Water Conference that was being held, an exhibition of numerous appliances of the most modern and improved description having a bearing on the object of the conference. At this exhibition we observed, among other things, a simple piece of apparatus which bore the designation "The *Indispensable* Patent Double-Acting Filter," and in the belief that it will prove very useful to photographers we give the following account of it. Although exhibited by Mr. James Sinclair, 104, Leadenhall-street, it is designed and patented by a foreign firm—Berlon, Frustenhagen, and Wildt. It consists of a metallic attachment to the nozzle of any water tap, so constructed as, by means of a two-way plug, either to allow the water to run straight away from the orifice of the tap, *unfiltered*, or to pass first through a cylinder made of pewter and closely packed with felt from top to bottom. As this cylinder is three inches in length, with an emission aperture at its lower end, it is obvious that the water which passes through such a thickness or length of felt must be indeed thoroughly well filtered and set free from every kind of mechanical impurity; even the most infinitesimal animalculæ would find it a hard matter to wriggle their way through such a formidable barrier to the transmission of anything but the most limpid fluid.

BLURRING, SOLARISATION, AND REDUCTION OF THE PHOTOGRAPHIC IMAGE.

I have just read Mr. L. Warnerke's communication to the Photographic Society of France, published in your last number, and think it right to offer a few remarks on it, as it is likely to cause a misconception of the easy explanation of certain phenomena. Your short sub-leader on the subject is much to the point, and in it you adopt the explanation of blurring, to which, I believe, I was the first to call attention in the *Philosophical Magazine*, namely, that the particles of the silver compound scatter the rays, and the kind of rays scattered depend much upon the fineness of these particles. If Mr. Warnerke had used a turbid glass the diagram showing the reflection from a minute particle in it would have been correct, but could not in any way account for the *halo* seen round the images.

The standard case of irradiation may be taken to be a ray of light such as that coming through a pinhole impinging on the film, in which case we have, on development, a black dot with a well-defined ring round it. If we measure from the centre of the black dot to the nearest blackest edge of the ring, and also the thickness of the plate, we shall find that the latter corresponds exactly to the rays striking at the angle of total reflection, or "critical angle," of the glass used. Mr. Warnerke's explanation would never account for the ring, whereas the theoretical explanation does. Other instances of the forms of halos given by small triangles, squares, crosses, &c., cut out in black paper and placed upon a film, which is then exposed to the action of light, are very readily explained by carrying out the argument derived from this last experiment. If I may be allowed to refer Mr. Warnerke to my article in the *Philosophical Magazine*, which also appeared in The British Journal of Photography, I think he or anyone else will see that there is no necessity to propound a new theory for the turbidity of glass, which palpably to the eye is transparent, whilst we have a much more turbid film to deal with.

Now, regarding Mr. Warnerke's prism experiments: I am at a loss to understand them. He states that he gets the same halations, and, therefore, presumably, the same definite figures, when he used a prism instead of a plain glass plate! Now this is contrary to all my experience. The following is a diagram of what I get when using a pinhole point of light impinging on the film when supported on a prism:—



The figure is an hyperbola, which should be the case mathematically. a a a is the locus of the darkest parts of the halo surrounding the point A. The nearer A is to C, the edge of the prism, the shorter B A becomes; in other words, the focal distance alters, as it would do theoretically, supposing the light to be scattered by the silver film. Unless Mr. Warnerke's prism is of most extraordinary material I doubt very much if he ever gets a circle surrounding his points. It may be an ellipse, and the ratio of the major and the minor axes entirely depends on the angle of the prism. I may briefly state that the figures the halo will assume will be—first, a circle if the two surfaces of the glass be parallel; an ellipse when the critical angle is greater than the angle made by the two surfaces; an parabola when it is the complement of the angle; and an hyperbola when it is less than the angle made by the two surfaces. The second and fourth were the cases experimented with.

Now anyone may try for himself what figure he will get without the trouble of photographing it. Take a short-focussed lens—say a couple of inches in focal length—and let him make a little cardboard box and put the lens in the front, and at the back place the prism, the surface coated with the film being placed in the position of the sensitive plate; take out the top of the box, and turn the lens towards the sun so as to cast an image of the sun on the prism. On examination through the top of the box an hyperbola or ellipse of light will be seen to surround the image of the sun. Blacken the opposing surface and the figure at once disappears. The explanation given by Mr. Warnerke fails in this case as well. Should anyone wish to test what effect turbid glass has on an image let him try it on opal and he will see how totally different it is.

Now as to the theory of solarisation propounded in the same paper: it is ingenious, but hardly answers to general facts, though it apparently does in the particular case mentioned. Solarisation takes place in the presence of free silver nitrate. How can this salt exist in the presence of liberated bromine without combining with it, and forming silver bromide and bromate? If a plate be exposed to the action of light when absolutely *immersed* in a solution of silver nitrate solarisation takes place. This explanation can hardly hold; but in connection with my late researches I can offer a perfect reason for the phenomenon without leaving free bromine in the silver. It would be too long to refer to here, but I shall have something to say about it at a future date.

In one paragraph Mr. Warnerke describes coating a silvered plate with emulsion and noticing that bromine had been absorbed by the metallic silver on exposure of the film to light, and makes a deduction therefrom, which is—"Thus, supported by this fact, I am authorised in saying that solarisation proves by the evidence here given that the cause which has produced the invisible image is purely chemical." Now this very experiment was originated by M. Poitevin ten or twelve years ago, and he gave this as a proof that the chemical theory of the photographic (I prefer not to call it latent) image was correct. This experiment I repeated and quoted two years ago in a lecture at South Kensington, and have referred to it since. This seems to me not to prove solarisation to be due to the liberated bromide, but seems rather to point to another direction. I throw out as a hint that it is hard to produce solarisation when any impurity is to be found in contact with the silver salt, be the impurity a preservative or india-rubber.

In Mr. H. B. Berkeley's communication we have other ground broken, and there are one or two points in it on which I may comment. As regards the red and ultra-red rays being termed "continuating rays," and yet accelerators of oxidising action, there is no anomaly in the two cases. I have no doubt, from experimental proof, that the continuating action which Becquerel and Claudet noticed when red or orange light was allowed to act on silver iodide was really and truly an oxidising action, and that this action only took place where actinic light had previously altered the sensitive salt in composition, and in absorptive properties for light; and, as I have already pointed out in my paper read before the Photographic Society of Great Britain, the reversing action and probably solarisation are due to the same cause. In that same paper I tried to explain how a minute quantity of silver salt which had been altered by light formed a nucleus on to which the bromide could be reduced; and the difficulty Mr. Berkeley mentions seems to be done away with. We are all aware that in the case of what is called "over-exposure" the half-tones are developed by the alkaline method right through the film, as are the highest lights; and the point of exposure seems to be sufficient when the sensitive salt nearest the back of the plate is affected by the highest lights, and the half-lights to not such a great extent. Recent experiment seems to show that silver bromide cannot exist as such in *absolute contact* with metallic silver, but becomes the dark-coloured sub-bromide. If, then, the altered molecule of silver bromide be reduced to the metallic state, the next molecule combines with it to form sub-bromide. Thus—

Original sub-bromide gives silver and bromine absorbed by the developer.

$$Ag_2\,Br \quad = \quad Ag_2 \quad + \quad Br$$

Silver and silver bromide give two equivalents of sub-bromide.

$$Ag_2 \quad + \quad Ag_2\,Br_2 \quad = \quad 2\,Ag_2\,Br.$$

This new sub-bromide is immediately amenable to development. The *particles* of sub-bromide, be it remembered, are not molecules but a group of molecules, and a microscopic examination shows that each particle may be somewhere about $\frac{1}{30,000}$th of an inch in diameter. Such a particle may be entirely reduced and yet not be in such close contact with a neighbouring particle as to cause its reduction. And since alteration in the composition of a sensitive molecule requires the expenditure of a certain amount of work, it is obvious that the length of exposure and intensity of light, after passing through a certain thickness of the film, may be insufficient to cause the necessary change in every molecule of the particle beyond that thickness; hence we have the development of all degrees of intensity of light.

Mr. Berkeley asks why (if this action take place in every direction) it is that a church spire, provided there be no halation, occupies the same space in the negative as it does on the focussing-screen. My answer to this is that it does not, for reasons stated above. Even if the lens be perfect, there must, however, always be *as much* lateral halation as the thickness of the film (if the particular part be developed right through the film). The thickness of the film varies. It is certainly less than $\frac{1}{100}$th of an inch; hence, except for very accurate measurements, it escapes detection. If we have a particle of bromide $\frac{1}{30,000}$th of an inch in diameter, and a ray of light of the same diameter or less impinging on it, it is quite possible that only that particle would be reduced and no other adjacent to it, provided there was no scattering of the ray.

My communication is already too long, but I shall hope at another time to explain those experiments by Herr Vogel quoted by Mr. Berkeley.

Capt. R.E.

STEREOSCOPIC TRANSPARENCY PRINTING.

MR. BREESE'S METHOD.—No. II.

As only a few of the main points of the copying camera were treated of in a former communication, the substance of the description of this piece of apparatus given there is again brought forward on which to base a more detailed account.

Stated generally, this instrument consists of two boxes dead-blackened on the inside, viz., one to exclude all light between its front, which carries the negative, and its back, through the apertures in which the lenses are pushed; the other one performs the same office between the lenses and sensitive plate. Both of these require to be partitioned down their centres to confine the light transmitted through each half of a stereoscopic negative to its own compartment. They must also have telescopic or bellows bodies to enable the variations of length necessary for the slight enlargement or reduction of the picture sometimes desirable to be conveniently made. If a pair of double-combination lenses of about four or four and a-half inches focus be employed and the transparency be slightly reduced, as is generally the case in copying the negatives of the usual stereo. size, the length from back to front of the first box, when half expanded, may be about ten inches, and that of the latter, or camera proper, having the fittings for lenses and dark slide, under like conditions, about nine inches. Provision must be made in the negative's carrier for its motion both horizontally and obliquely—for the latter the kind to be obtained being similar to that from a parallel rule opened out, to hold the negative between its two portions, each one of which is fastened in the same perpendicular on the front of the box by a screw passed through the middle of its length. A framework constructed and secured in this manner affords a ready means for making the slightest alteration for the purpose of bringing any two corresponding objects in each half of the slide into the same horizontal position. The apertures at the back of the box fitted with this arrangement must be of sufficient size to allow the movements of the lenses described further on to be made freely. The front of the other box mounts the lenses, and requires, besides a rising motion of the usual description, a means for separating or approaching them. One of the best methods of accomplishing this is by having a right- and left-handed pitched screw—not in one piece, as usually supplied, but divided and keyed together in the middle, a little plug being provided for in the longitudinal direction of the joint, so that the slight fluctuation in its length resulting from variations of temperature may not disturb the position of the fronts to which it is attached. Each thread of the screw passes through its respective nut fastened one on each portion of the separating front, the length of that end of the shaft terminating in a milled head being sufficient to project from the side of the camera within easy reach of the hand. This kind of screw, as its name implies, gives motion to the two pieces in opposite directions at the same time, and is susceptible of fine adjustment.

The object of having the screw divided and keyed together is this:—During a hot summer's day, or, in fact, any day, the temperature rises to a maximum and then gradually falls. A delicate adjustment made in the morning, such as a moon placed at its proper distance in the apparent space of the stereoscopic picture, with the screw shaft in one piece, will, as the temperature increases, expand the metal and separate the lenses, the moon from this cause having the effect of making a retreat into the star depths. On the other hand, if the fixing in position is performed when the temperature is highest, the moon's motion, as that falls, is reversed, appearing to come forward into the region of the earth's atmosphere. When a whole day has been spent in printing from one negative required for the combination effect of a subject—fifty copies, perhaps, being made—there will be a serious expenditure of time and labour in cutting the plates asunder and in fixing them in position when superposed on other portions of the picture, the operation needing to be constantly viewed through the stereoscope during its performance. Through the employment of a screw of this kind Mr. Breese experienced much annoyance, the cause of which he had not detected up to the time I parted company with him. Mr. Oakes will probably recollect that the camera he saw him use was fitted up with this disregard for thermal variations, it being so when it was handed over to Mr. Breese.

When these portions of the copying camera have been completed they will have to be mounted on a board or table behind each other, the fore part of the first one described being made a fixture, the latter fitted between guides through which it can easily slide to or from the former one, a separation of about three inches being always preserved, the lenses requiring that space to make them accessible for operations with diaphragms and the rackwork motion upon them. A wooden cover, constructed of sufficient length to project beyond the negative to shield it from oblique rays without obstructing the necessary light by shading the reflector, and the opposite end not extending quite to the aperature for the dark slide, can be hinged along one of its sides to the table, will be found very convenient and useful in protecting the camera from dust, light, and heat.

To the front of the table may be hinged, or otherwise conveniently fastened at an angle of about 45°, a reflector of the kind I have before indicated. A very good plan to follow in making one is to have a slight frame of wood grooved round its inner edge; this clamped down to a piece of glass serves as a mould, into which pour the following mixture:—Break up all lumps and finely sift a sufficient quantity of plaster of Paris, which has been previously coloured a faint sky blue with powdered French ultramarine; mix this up with water coloured with sufficient of Judson's magenta dye to strike a violet tint when the proper quantity has been added, and work the whole into a smooth paste of about the consistency of cream. As different samples of plaster vary in the degrees of yellowness to be neutralised, a definite formula cannot be given. Fill up the mould, smooth off the surplus with a straight edge, and allow to set for an hour or two, when the slab and its frame may be unclamped from the glass and stood up in a warm room to dry. The whole operation of mixing should be performed as quickly as possible, as the plaster soon sets and becomes unmanageable. The frame is to be left on, being of value in giving strength to the slab, which firmly holds into the grooves provided for the purpose. When dry the glossy surface must be removed by rubbing with glass paper, the result being a beautiful matt surface of pearly whiteness, its actinic value exceeding by many times that of cardboard and white paper so often recommended. The surface, as it becomes dirty, can be removed by glass papering, which may be repeated, when necessary, till only a mere shell of plaster remains.

Having had three or four years' experience as a retoucher, I feel some confidence in recommending the use of the above reflector to the notice of my fellow-brethren in that craft. I have found that the printing value of retouching, either with colour or lead, is, provided the colour be matched in tint with that of the negative, the same as it appears to the eye upon the negative when viewed with light reflected through from a white matt surface. Such is not the case when a mirror, ground glass, or the like is used, the retouching having to be made much heavier with these to give the negative a finished appearance to the eye when so viewed—the consequence being that nearly every touch stops back too much light, and renders touching on the print a necessity. The easy and economical means for always ensuring a clean surface, combined with its other advantages, has induced me to digress from the particular subject I have in hand to make these observations, which, I hope, will be justified by being of some benefit to the fraternity.

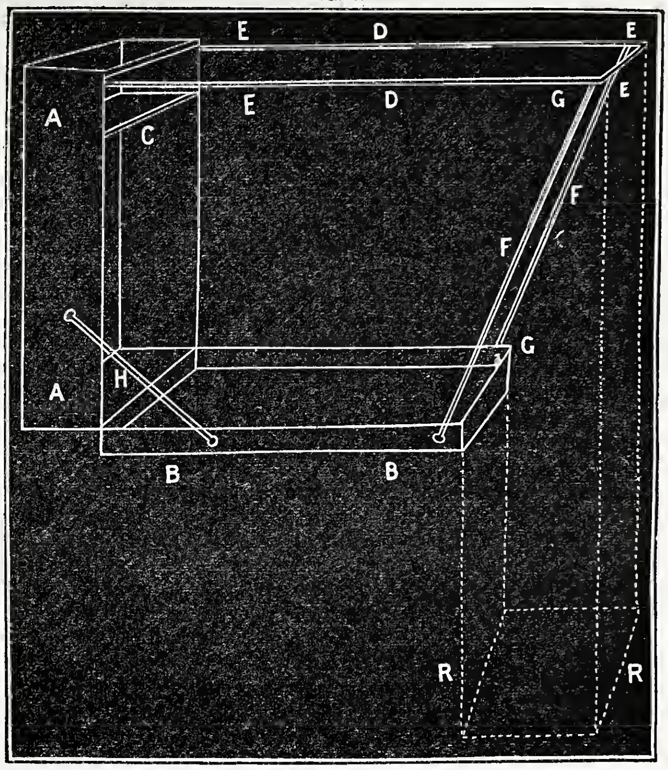
To return: when a negative is very dense or a very powerful light is required to produce any special effect, recourse must be had to a heliostat, or, as a substitute, such a primitive one as may be supplied in directing by hand the reflected sunlight from one or more mirrors, as needed, through a piece of ground glass fitted into the side light of the studio, care being taken that the camera be some distance away, so that no element of coarseness may be introduced into the transparency by bringing the grain of the glass into focus when a small stop is made use of. The same applies for any reflector possessing grain or marks of any description whereby the light is irregularly reflected.

John Harmer.

MY DARK TENT.

Fig. 1 represents the tent open but without the cover, which is made of black twill; *fig.* 2 is the tent closed; *fig.* 3 is the end of the interior, showing window and pockets for bottles.

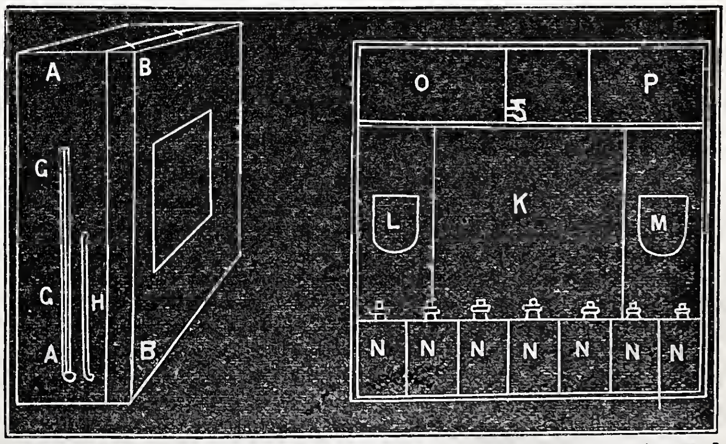
FIG. 1.



The tent consists of two trays AA and BB, one of them being 24 × 24 × 6 inches, and the other 24 × 24 × 3 inches, hinged together so as to form a box. They should be made of half-inch deal. The largest one should have a hole one foot square cut out of the bottom, which, when covered with yellow calico, forms a window. C is a shelf to hold water tank.

EE is a light wooden framework which, being hinged at D, folds into AA; it is supported by GG, which are hinged at F and fold so as to lie on each side of BB. On this framework is suspended a

FIG. 2. FIG. 3.



cover of twill that hangs down to RR, and being there wound round the operator's legs keeps out all light except that which enters through the window K. The two trays are kept at right angles by a hook H.

In *fig.* 3 L M are pockets for extras; N N N N N N N are seven pockets for bottles; O is a tank for water into which the plate-box fits; and P is the bath.

This tent, when closed, will contain a half-plate camera and bath, &c., and measures 24 × 24 × 9 inches. It is kept closed by two hooks-and-eyes. A. A. Campbell Swinton.

PHOTOGRAPHY AT THE LEAST REFRANGIBLE END OF THE SPECTRUM, AND ON SOME PHOTOGRAPHIC PHENOMENA.*

I now come to the second part of the subject which I have to bring before the Society, and I have brought it forward as it has an intimate bearing on the success of red end photography—so much so that I am in hopes of obtaining results in a much more expeditious manner than I have done at present, as soon as my new apparatus is fitted up. It will be remembered that I brought before the Society last year a paper on the destruction of the photographic image by means of various oxidising agencies, and I concluded a communication to the *Philosophical Magazine* by stating that if the red rays should prove to be accelerators of oxidising action, that then we should have an explanation of the reversing action of the red rays as explained by Draper, and probably also an explanation of photography in natural colours as shown by Becquerel and Niepce de St. Victor. Into the latter I do not wish to enter tonight, as my investigations are incomplete, though I may say I have succeeded in producing the spectrum in its natural colours by similar means in a very short time. I have already announced at the Royal Society that I find the red rays and ultra-red rays are accelerators of oxidation. I will briefly give an outline of the experiments carried out. Plates were prepared with what I will call red end emulsion and exposed to diffused light for two or three seconds, and then immersed in one or other of the following oxidising solutions:—Potassium permanganate, potassium bichromate, nitric acid or hydroxyl.

The solutions were very weak indeed. Take, for example, nitric acid—five or six drops of concentrated nitric acid in four ounces of water. Whilst thus immersed the plate was exposed to the action of the spectrum for about seven minutes, when on development it was found that the red rays had not only stopped the reducing action of the light, but had cleared away the fog from the plates where the red light had acted, leaving the Fraunhofer lines as opaque lines on a transparent background, instead of transparent lines on an opaque background. Such a photograph I now show. To test the matter further, it occurred to me that if the solutions were further diluted, the oxidising action ought to be more balanced by the reducing action, both being at work at the same time. This proved to be the case. The photograph now shown was obtained under precisely similar circumstances, with the single exception that the oxidising solution was reduced to half the strength. Iodide and bromo-iodide of silver films behaved in precisely the same way. These were washed first, then exposed in the solution, and developed with pyrogallic acid and silver. By a singular mistake a plate of bromo-iodide of silver was placed outside the cell next the spectrum, instead of in the cell and exposed to the spectrum; in this case *the same results were obtained*, showing that in a film on which the red rays have no reducing effect the oxidising action is effective, even where no special means are taken to help the oxidation.

I wish you to note, however, that this last experiment, when combined with the fact that, at will, on a film of silver bromide, a reversed or non-reversed negative can be obtained, shows that, in all photography of the rays of low refrangibility, we have a powerful oxidising accelerator to contend with; and, further, that unless the sensitive salt employed be one in which the reducing action more than counterbalances the oxidising action of the oxygen in the air, together with its acceleration by the red rays, a non-reversed negative of this portion of the spectrum is impossible. This being so, it is obvious that, if you exclude all oxygen, the negative should be obtained more readily. This is what I am at present trying, and shall be able to speak more authoritatively on the matter on a future occasion. I may point out, however, that this at once explains the insensitiveness of the bath process with silver bromide for the red rays, the presence of nitric acid being necessary to obtain freedom from fog. By saying that red rays are accelerators of oxidation I do not mean to say that the other rays, such as the blue, are not equally so—in fact, they are; but their reducing action is far greater than their acceleration of oxidisation. If, however, all the silver salt accessible to the light (of which there is not a very large proportion in comparison with the volume employed) be reduced, then the oxidising action at once takes place and the image is destroyed, and we get what is known as solarisation—a phenomenon well known. Here I have a photograph of a spectrum, in which the oxidising action takes place in the blue as well as in the red. There is one experiment I have seen noted in Hunt's *Researches on Light* which bears upon this subject. Hunt exposed silver chloride in the closed end of a bent tube to light, the other end dipping in water. He remarked that, after some days' exposure to light, the water rose in the tube. From this he inferred that, since the water would absorb the chlorine, the altered silver chloride must absorb oxygen; and so it did, but the experiment was not followed out. Now, it may be said, how do you know that oxidation takes place? Well, a simple experiment will show. Take a film of silver bromide and expose it to light till it darkens all over, and then drop on it a little peroxide of hydrogen, potassium bichromate, or permanganate, and let the drops remain on a short time, and then wash the film; there will appear to be but very little alteration in the colour, if any. Pour over it sodium hyposulphite, and it will be seen that, where the drops have rested, the film is quite clean and bright, whereas over the rest of the plate is a very thin film of (presumably) silver.

I could detail other experiments, but I am afraid I shall weary you out, so I now conclude, with a hope that what I have detailed may be of interest not only to this Society but to the scientific community at large. I must acknowledge the great assistance I have received in these later researches from Corporal Davenport, R.E., without whose aid my experiments must have been more prolonged than they have been. W. de W. Abney, F.R.S., *Capt. R.E.*

* Concluded from page 244.

TRANSATLANTIC NOTES.

Knowing that the readers of The British Journal of Photography are, from reports of American societies and original articles, tolerably conversant with the state of the art in the larger cities, I have, whenever possible, tried to ascertain rather what is being done in the smaller towns and villages. This is more easily accomplished here than in the "old world," as railway tickets are good for any length of time, and the journey may be broken at any or every station on the route.

My last letter was closed in Waverley, at which I was induced to stop for a few hours. Like almost all the villages which have recently sprung up in the country it is indeed beautiful. Waverley may be taken as a type of hundreds of villages that have within the past few years been called into existence, and therefore I may describe it in a few words. The junction of two railways, two rivers, or other modes of conveyance is generally a place where men are found to congregate. Business or pleasure—but in this country more frequently the former—keep them ever on the move, and a junction generally implies waiting, and waiting necessitates a hotel, a hotel full of visitors attracts the attention of some of the shopkeeping community, and so the foundation of a village is laid.

Waverley is beautifully situated on the southern border of the State of New York, close to the Pennsylvania boundary, in the charming Susquehanna Valley, at the junction of the Susquehanna and other beautiful rivers and several lines of railway. It consists of one principal street of about half-a-mile in length, with two hotels in the centre, and lesser streets at right angles to it. The former is entirely devoted to business purposes, having stores from end to end—some of brick and some of wood, and quite as varied in their architectural features as in their contents. The latter contain the dwelling-houses of the storekeepers and other residents, and are at this season lovely beyond what those who know only the prosaic villages of the old country can conceive. The streets are not less than eighty feet in width, with clean-kept wooden side walks that are always dry, and lined on either side by rows of the charming and rapid-growing maple trees, which give, even in the hottest days of an American summer, a shade so delightful as to make walking pleasant. The houses are in most cases of wood, each standing in the centre of a garden, locally called a yard, and generally surrounded by maples, elms, pines, &c. Of course the term "wooden house" conveys the idea of something comfortable enough, perhaps, but altogether deficient in beauty from an architectural point of view; but this is a mistaken idea, as wood lends itself more readily, and at much less cost, to the vagaries of the architect than either brick or stone. In most of the American villages the visitor has no difficulty in finding exquisitely-beautiful examples of all the popular styles, from the earliest "Gothic" down to the most modern "mixed." Then, too, their beauty is enhanced by the fact that they are not much seen till the spectator is right in front, when they burst upon his view in all their loveliness, as on standing at the end of a street and looking along it appears just as a beautifully-shaded lane. Such houses are mostly the property of the occupiers, Americans generally preferring to build or purchase rather than rent their houses, and equally generally finding the means of doing so. But, of course, there are exceptions, and they must be profitable to landlords. Lumber is cheap, and such houses, consequently, cost much less than equal accommodation in stone or brick, yet the average rent is fifteen dollars per month, or nearly forty pounds per annum.

Such are Waverley, Owega, Binghampton, Athens, Ulster, &c., &c., beautiful as Paradise, and inhabited by a people keen in the pursuit of business during business hours. Sober, so far as an outsider can see, as if distillation had not been discovered; and, consequently, as far removed from poverty as the Seven Dials from St. James's.

But, of course, this is not photography, and I suppose that is what my readers wish especially to hear about; and, therefore, for their sakes, I am sorry that there is little to be said regarding it. Photographers are there in plenty, and in most cases a tolerably good trade is being carried on. I write "trade" advisedly, as, with very few exceptions, the work done is destitute of every vestige of art—inferior, indeed, to most of that to be found in the out-of-the-way villages of the old country.

An American photographer rarely speaks of his "studio" or "glass house," but almost always of his "skylight;" and in most cases the name is well applied, as the light is in nearly every case a top light only, with a very steep pitch, a large expanse of glass, frequently covered with tissue paper, rarely curtained, and when so only with thin white cotton—shadows being got, when got at all, by the use of hood, or rather stand, screens. In a word, the great mass of pictures made in such towns as I have named are simply patches of white and black, without any pretension to the delicate gradation or variety of middle tint absolutely essential to a good photograph.

This was at once admitted by nearly all that I called upon, but excused on the ground of insufficient payment. Something like the following was almost invariably said:—"What can you expect for $2.50 for cards and $5 for cabinets (10s. 3d. and 20s. 6d.), and we can't get more? Besides, it's only the commoner people we get, who don't know a good picture from a bad one, and would rather have the white faces than not, especially the coloured ones. Bless you! *they* would'nt have a bit of shadow in their face, not for any money. The rich folks all go to New York, Philadelphia, or Boston, where they willingly pay twice my prices; and, of course, get better 'fixed'"—this "fixed" being a verb of universal application for anything that has been done, from the cleaning of one's boots to the erection of a palace. By-the-bye, speaking of cleaning boots, I would seriously advise all who may purpose visiting this country to take a few lessons in that useful accomplishment. For some reason that I have altogether failed to discover it would seem to be considered a kind of degradation for any one to clean the boots of another person. A servant girl who will do almost anything else would rather throw up her situation than touch a blacking brush, and the wife of even a labouring man would sit quietly by and see her husband doing it himself, or let him go with boots as brown as the road on which he has to walk. So much is this the case that I have within a few days actually seen two gentlemen—one a landed proprietor owning almost as much as the eye could see of one of the most highly-cultivated and beautiful vallies in the United States; the other the president of one of the most flourishing banks, and both keeping numerous male and female domestics—actually brushing their own boots! Even hotel servants are not exempt from this curious prejudice, and, as a rule, there is nothing gained by leaving one's boots outside the bedroom doors. Of course there are "boot blacks" in the larger cities; but even they would seem to look on the occupation as one for which some compensating advantage was necessary, and, consequently, require a fee of fifteen cents for the performance of the operation. Surely sevenpence halfpenny is a *leetle* too much for a touch of Day and Martin!

But the notions of independence of some of the American women are sometimes even more troublesome than in the matter of boot-cleaning, and extend frequently to a determination to sit only as they please when being photographed. Nor are they exempt from the privileges not infrequently claimed by their sisters on the other side, *i.e.*, of changing their minds as often as, and whenever, they please. An amusing instance of this I saw while in a studio in one of the villages already named. The lady was tolerably pliable while being posed, only stipulating that she should "not be took like them foolish people as had'nt more'n half a face, or had bin a fitin and ashamed to let the other eye be seen;" but just as the usual word of caution had been given, and the cap removed, she suddenly exclaimed—"Stop, Mr. Photographer! I ain't used to bin fixed this way! I guess I can fix myself better," and, crossing one leg over the other, and folding her arms, continued:—"Now get along, and don't you stop a bit too soon, as I shan't have it a bit less than the biggest of them in that glass box!" Of course a second plate was prepared, and then the exposure was made. Before payment was made there was a little difficulty, as she wanted to see "how it was;" but on being assured that "the machine" had gone long enough to make a picture sufficiently large to fill the card she seemed perfectly satisfied.

A visit to the United States would not be complete unless it included Niagara, and so in my next I shall have something to say of the peculiar class of photography practised there and of the men who practise it. JOHN NICOL, Ph.D.

COMPOSITE PORTRAITS,

MADE BY COMBINING THOSE OF MANY DIFFERENT PERSONS INTO A SINGLE RESULTANT FIGURE.

[A communication to the Anthropological Institute.]

I SUBMIT to the Anthropological Institute my first results in carrying out a process that I suggested last August in my Presidential Address to the Anthropological sub-section of the British Association at Plymouth, in the following words:—

"Having obtained drawings or photographs of several persons alike in most respects, but differing in minor details, what sure method is there of extracting the typical characteristics from them? I may mention a plan which had occurred both to Mr. Herbert Spencer and myself, the principle of which is to superimpose optically the various drawings and to accept the aggregate result. Mr. Spencer suggested to me in conversation that the drawings reduced to the same scale might be traced on separate pieces of transparent paper and secured one upon another, and then held between the eye and the light. I have attempted this with some success. My own idea was to throw faint images of the several portraits, in succession, upon the same sensitised photographic plate. I may add that it is perfectly easy to superimpose optically two portraits by means of a stereoscope, and that a person who is used to handle instruments will find a common double eyeglass fitted with stereoscopic lenses to be almost as effectual and far handier than the boxes sold in shops."

Mr. Spencer, as he informed me, had actually devised an instrument, many years ago, for tracing, mechanically, longitudinal, transverse, and horizontal sections of heads on transparent paper, intending to superimpose them, and to obtain an average result by transmitted light.

Since my address was published I have caused trials to be made, and have found as a matter of fact that the photographic process of which I there spoke enables us to obtain with mechanical precision a generalised picture—one that represents no man in particular, but portrays an imaginary figure, possessing the average features of any given group of men. These ideal faces have a surprising air of reality. Nobody who glanced at one of them for the first time would doubt its being the likeness of a living person. Yet, as I have said, it is no such thing; it is the portrait of a type, and not of an individual.

I begin by collecting photographs of the persons with whom I propose to deal. They must be similar in attitude and size, but no exactness is necessary in either of these respects. Then, by a simple contrivance, I make two pinholes in each of them, to enable me to hang them up one in front of the other, like a pack of cards, upon the same pair of pins, in such a way that the eyes of all the portraits shall be as nearly as possible superimposed, in which case the remainder of the features will also be superimposed nearly enough. These pinholes correspond to what are technically known to printers as "register marks." They are easily made; a slip of brass or card has an aperture cut out of its middle, and threads are stretched from opposite sides, making a cross. Two small holes are drilled in the plate, one on either side of the aperture. The slip of brass is laid on the portrait with the aperture over its face. It is turned about until one of the cross threads cuts the pupils of both the eyes, and it is further adjusted until the other thread divides the interval between the pupils in two equal parts. Then it is held firmly, and a prick is made through each of the holes. The portraits being thus arranged, a photographic camera is directed upon them. Suppose there are eight portraits in the pack, and that under existing circumstances it would require an exposure of eighty seconds to give an exact photographic copy of any one of them. The general principle of proceeding is this, subject in practice to some variation of details, depending on the different brightness of the several portraits:—We throw the image of each of the eight portraits in turn upon the same part of the sensitised plate for ten seconds. Thus, portrait No. 1 is in the front of the pack; we take the cap off the object-glass of the camera for ten seconds, and afterwards replace it. We then remove No. 1 from the pins, and No. 2 appears in the front; we take off the cap a second time for ten seconds, and again replace it. Next we remove No. 2, and No. 3 appears in the front, which we treat as its predecessors, and so we go on to the last of the pack. The sensitised plate will now have had its total exposure of eighty seconds; it is then developed, and the print taken from it is the generalised picture of which I speak. It is a composite of eight component portraits. Those of its outlines are sharpest and darkest that are common to the largest numbers of the components; the purely individual peculiarities leave little or no visible trace. The latter being necessarily disposed equally on both sides of the average, the outline of the composite is the average of all the components. It is a band and not a fine line, because the outlines of the components are seldom exactly superimposed. The band will be darkest in its middle whenever the component portraits have the same general type of features, and its breadth or amount of blur will measure the tendency of the components to deviate from the common type. This is so for the very same reason that the shot-marks on a target are more thickly disposed near the bull's-eye than away from it, and in a greater degree as the marksmen are more skilful. All that has been said of the outlines is equally true as regards the shadows, the result being that the composite represents an averaged figure whose lineaments have been softly drawn. The eyes come out with appropriate distinctness, owing to the mechanical conditions under which the components were hung.

A composite portrait represents the picture that would rise before the mind's eye of a man who had the gift of pictorial imagination in an exalted degree. But the imaginative power, even of the highest artists, is far from precise, and is so apt to be biased by special cases that may have struck their fancies that no two artists agree in any of their typical forms. The merit of the photographic composite is its mechanical precision, being subject to no errors beyond those incidental to all photographic productions.

I submit several composites made for me by Mr. H. Reynolds. The first set of portraits are those of criminals convicted of murder, manslaughter, or robbery accompanied with violence. It will be observed that the features of the composites are much better looking than those of the components. The special villainous irregularities in the latter have disappeared, and the common humanity that underlies them has prevailed. They represent, not the criminal, but the man who is liable to fall into crime. All composites are better looking than their components, because the averaged portrait of many persons is free from the irregularities that variously blemish the looks of each of them. I selected these for my first trials because I happened to possess a large collection of photographs of criminals through the kindness of Sir Edmund Du Cane, the Director-General of Prisons, for the purpose of investigating criminal types. They were peculiarly adapted to my present purpose, being all made of about the same size and taken in much the same attitudes. It was while endeavouring to elicit the principal criminal types by methods of optical superimposition of the portraits, such as I had frequently employed with maps and meteorological traces,* that the idea of composite figures first occurred to me.

The other set of composites are made from pairs of components. They are selected to show the extraordinary facility of combining almost any two faces whose proportions are in any way similar.

It will, I am sure, surprise most persons to see how well defined these composites are. When we deal with faces of the same type, the points of similarity far out-number those of dissimilarity, and there is a much greater resemblance between faces generally than we who turn our attention to individual differences are apt to appreciate. A traveller on his first arrival among people of a race very different to his own thinks them closely alike, and a Hindu has much difficulty in distinguishing one Englishman from another.

The fairness with which photographic composites represent their components is shown by six of the specimens. I wished to learn whether the order in which the components were photographed made any material difference in the result, so I had three of the portraits arranged successively in each of their six possible combinations. It will be observed that four at least of the six composites are closely alike. I should say that in each of this set the last of the three components was always allowed a longer exposure than the second, and the second than the first, but it is found better to allow an equal time to all of them.

The stereoscope, as I stated last August in my address at Plymouth, affords a very easy method of optically superimposing two portraits, and I have much pleasure in quoting the following letter, pointing out this fact as well as some other conclusions to which I also had arrived. The letter was kindly forwarded to me by Mr. Darwin. It is dated last November, and was written to him by Mr. A. L. Austin, from New Zealand, thus affording another of the many curious instances of two persons being independently engaged in the same novel inquiry at nearly the same time, and coming to similar results:—

"To Charles Darwin, Esq. "*Invercargill, New Zealand, Nov.* 6, 1877.

"SIR,—Although a perfect stranger to you, and living on the reverse side of the globe, I have taken the liberty of writing to you on a small discovery I have made in binocular vision in the stereoscope. I find by taking two ordinary *carte-de-visite* photos. of two different persons' faces, the portraits being about the same sizes and looking about the same direction, and placing them in a stereoscope, the faces blend into one in a most remarkable manner, producing in the case of some ladies' portraits in every instance a *decided improvement* in beauty. The pictures were not taken in a binocular camera, and therefore do not stand out well, but by moving one or both until the eyes coincide in the stereoscope the pictures blend perfectly. If taken in a binocular camera for the purpose, each person being taken on one-half of the negative, I am sure the results would be still more striking. Perhaps something might be made of this in regard to the expression of emotions in man and the lower animals, &c. I have not time or opportunities to make experiments, but it seems to me something might be made of this by photographing the faces of different animals, different races of mankind, &c. I think a stereoscopic view of one of the ape tribe and some low caste human face would make a very curious mixture; also in the matter of crossing of animals and the resulting offspring. It seems to me something also might result in photos. of husband and wife and children, &c. In any case the results are curious if it leads to nothing else. Should this come to anything you will no doubt acknowledge myself as suggesting the experiment and perhaps send me some of the results. If not likely to come to anything a reply would much oblige me.

"Yours very truly, "A. L. AUSTIN, C.E., F.R.A.S."

Dr. Carpenter informs me that the late Mr. Appold, the mechanician, used to combine two portraits of himself under the stereoscope. The one had been taken with an assumed stern expression, the other with a smile; and this combination produced a curious and effective blending of the two.

* *Conference at the Loan Exhibition of Scientific Instruments*, 1878. Chapman and Hall. Physical Geography Section, p. 312, *On Means of Combining Various Data in Maps and Diagrams*, by Francis Galton, F.R.S.

Convenient as the stereoscope is, owing to its accessibility, for determining whether any two portraits are suitable in size and attitude to form a good composite, it is nevertheless a makeshift and imperfect way of attaining the required result. It cannot of itself combine two images; it can only place them so that the office of attempting to combine them may be undertaken by the brain. Now the two separate impressions received by the brain through the stereoscope do not seem to me to be relatively constant in their vividness, but sometimes the image seen by the left eye prevails over that seen by the right, and *vice versâ*. All the other instruments I am about to describe accomplish that which the stereoscope fails to do; they create true optical combinations. As regards other points in Mr. Austin's letter I cannot think that the use of a binocular camera for taking the two portraits intended to be combined into one by the stereoscope would be of importance. All that is wanted is that the portraits should be nearly of the same size. In every other respect I cordially agree with Mr. Austin.

FRANCIS GALTON, F.R.S.

(To be concluded in our next.)

A WRINKLE FOR THE PRINTER.

WHEN a great quantity of paper has to be prepared in limited room, and when this has to be done so as to have it ready for use as soon as possible, the ordinary process soon proves itself useless, since almost everywhere, with few exceptions, the room for the preparation of paper is awarded, in a very stepmotherly manner, an area seldom exceeding four square metres in floor measurement. If in such a small laboratory an operator has his large silver bath, or perhaps even two—one for salted and the other for albumenised paper—and then has to hang up six or eight sheets to the lines, there remains but little room for anything else; so when a great quantity has to be prepared the first batches must be completely dried by artificial means.

In this case, as when the paper is left to dry spontaneously, the drying does not proceed equally, but the upper part of the sheet is already dry while the under edge is still wet. This is accompanied by many drawbacks which will at once suggest themselves to the worker. A sheet dried in this way will never have the same tone throughout; one half will be warmer and the other half colder. This peculiarity will be of but little consequence if the sheet be cut up for *cartes* and not used for large pictures. Such sheets are also affected unequally by the fixing bath, those parts which remained longest wet requiring to remain longest in the soda. All these things are, however, but trifles, and were not the principal reasons why I looked out for another mode of preparing the paper. My weightiest reason was the want of room for preparing large quantities of paper and the difficulty of getting it ready for immediate exposure. To attain this twofold end I proceed now in the following way:—

All paper, but especially albumenised paper, is stored in an unheated room, so that it may not become dry and brittle, but always remain soft and supple. In the heat of summer, when it might be too hard and brittle, I take it some hours before silvering it, or the night before, and place it in the damp room so that it may attract a little moisture, as nothing is more perverse than paper that will not lie flat upon the bath but always rolls up, except, perhaps, when air-bubbles make their appearance. This dry paper also does not take on the silver so equally as that which contains a certain quantity of moisture; and, in fact, the whole process goes much more smoothly with the latter sort. I now place my sheet upon the bath and let it float, with a gentle movement, for a minute and a-half or two minutes. In order to produce the same result the time of floating should be the same for all the sheets. At the end of that time I draw each sheet slowly out of the bath and place it, wet side lowermost, upon a sheet of chemically-clean blotting-paper, placing above it a sheet of strong, smooth packing paper, and with the palms of my hands I smooth it out in all directions, giving the pressure, which, having the sheet between my hands and it, it can now bear, so that all the moisture may be sucked up by the sheet of blotting-paper below it. Of course the table upon which the three layers of paper are laid ought to be perfectly flat. The paper may be rubbed until it is almost dry, and then be laid aside at once, but that is not necessary, as without it by the time I come to the fourth sheet the first will be ready for use.

Of troublesome blisters there can be no question with this mode of preparation. Blisters are principally caused by unequal drying; when the wet sheets are hung up to dry the moisture collects in little drops, which evaporate very slowly and separate the albumen from the paper, as is seen afterwards in the toning and fixing baths. If very woolly filter paper has been used for drying it is well to rub down each sheet of albumenised paper with wadding or a fine rag before laying it out for use, in order to remove any small fibres that may have stuck to the somewhat adhesive albumenised surface. The filter paper may be used for a long period, only from time to time it should be laid aside as it becomes at length too wet to fulfil its purpose, and should then be dried at the stove either in the dark or in the evening, as the blotting-paper should not contain any reduced silver. From time to time a fresh sheet of blotting-paper is laid on the table, but the old one is always left under it.

At first I feared that this way of preparing the paper would be more expensive than the ordinary way, but I soon came to be of another opinion. One surprising fact is that the silver bath always became stronger—though not, perhaps, according to the argentometer, which is unreliable, and is generally wrong, because albumen and other organic substances which have meanwhile been communicated to the bath interfere with its action—but by the practical test of the gradually increasing depth and brilliancy of the prints. I was induced to investigate the cause of this remarkable phenomenon, and have succeeded in discovering it.

The following experiment should be made with the old preparation process—that is, by that in which the sheets are hung up wet:—Take a silver bath and sensitise on it as much paper as will allow the same quantity of silver containing fluid to drip from it and to be collected in a bottle as shall equal in bulk the quantity of silver solution left in the bath. Evaporate each separately, and it will be found that the solution which has dripped from the paper does not contain half as much silver as the preparation bath does. What is the inference? That the chlorine contained in the paper has combined chemically with the greater part of the silver contained in the solution, and has allowed the water to retain and carry off but a small proportion of silver. The greater the chlorine contents the weaker will the solution run off apparently be, as a proportion greater of chlorine can, of course, reduce more silver. The original bath, on the contrary, into which no weak silver solution drips, and which, being kept in an open dish, must lose no inconsiderable proportion of its water by evaporation, will always become more concentrated. This concentration, indeed, frequently reaches a point when it becomes necessary to add more water. From these observations I have arrived at the conclusion that there is really not much silver absorbed by the blotting-paper, since what it does suck up is merely the solution that would otherwise run off and which contains but little silver; so that really there is none lost if, when the blotting-paper can be used no longer, it be reduced to ashes in order to recover the silver.

Besides the comfort of being able to prepare a great quantity at a time, and to expose it soon after, this way of preparing paper possesses the advantage over the other that, owing to the quick drying, the sensitive film is entirely on the upper surface and cannot sink into the substance of the paper itself. The print is, therefore, more upon the upper surface, and is consequently softer and more brilliant and considerably more easily fixed. A very weak soda bath can then be used, five per cent. of the salt being sufficient, and a very small addition of bicarbonate of soda has a favourable effect on the whites.

In the case of solar enlargements this process renders real service. It often happens that an artist has to wait for weeks for the sun, and thus cannot prepare the paper as he would like; but paper prepared by my method may be kept for fourteen days after it is silvered without being exposed. A longer time is injurious, but then it allows one to count upon working with freshly-prepared paper with greater ease and certainty. At length, after long seclusion behind the clouds, the sun peeps out tantalisingly from beneath his invisible cap. The experienced eye of the photographer sees, however, that this splendour will not last long. Still his customers press him so sorely that he is fain to try to take advantage of the bright moment. Now if he work by the wet method, by which he has to wait for hours while his paper dries, his trouble and outlay will in all probability be lost, and the hypocritical Sun will have long ago made up his mind to enjoy himself behind his curtain of grey clouds. Therefore I praise the dry process. The photographer would run and take out his sheet of chlorine or iodine paper, float it on the silver bath, and at the end of two minutes dry it, arrange the mirror, and expose, the whole operation scarcely occupying ten minutes; that is, supposing the negative to be suitable and that he works by development. We can only complete the printing when we can count on steady sunshine. Enlargements prepared and developed by my own peculiar process possess such extraordinary power and depth that it seems almost superfluous to print them out fully.

I have prepared my paper for a considerable time now by the method described above, and can warmly recommend it to all my colleagues as combining in itself a number of advantages. F. W. Geldmacher.
—Monatsblätter.

ON THINGS IN GENERAL.

Are we really going to have a revolution in photographic practice? For years we have been told that dry plates can be made more sensitive than wet; but the pudding has never stood the proof of eating—at anyrate in public; and I, along with the majority, shrewdly suspect I have put down all these statements to the power of that feeling of love that all parents have for their own offspring, which teaches them to see beauties where, to the impartial mind, all is plain or ugly. But now there seems to be a concurrence of testimony, and the pudding is offered for public consumption.

I see plates by Mr. Swan—than whom there could not be a more trustworthy exponent of any new process—Mr. Mawdsley, and Mr. Kennett are being advertised with statements as to their capabilities that make the photographic mouth water. Four times the accustomed rapidity* seems to be the recognised amount of acceleration obtained upon ordinary work by the aid of the new plates. I sincerely hope that these roseate views may stand the ordeal of test, and that there may be no counterbalancing disadvantage in connection with their use, though this would be against all previous photographic rule, as we nearly always discover a loss of some kind for every gain in one direction. I cannot help it, but, somehow or other, I think we have not yet got hold of the photographic philosopher's stone.

* Our contributor is in error here: such a degree of rapidity has not been claimed by any of these manufacturers.

Still, in the same direction, we hear of new processes from France. My readers may recollect my hinting some little while ago that I smelt another process in the wind, and now it is out at last, "exploited" by a gentleman known to fame already—fine art by machinery. M. Klary, of Algiers, has taken in hand the process of M. Boissonnas, of Geneva, by means of which he tells us that we can reduce our exposures to one-fourth or one-fifth, and which he states that even he himself, case-hardened as he must be by daily contemplation of the magnitude of the results obtained by his own process, "is surprised by the almost instantaneous character of the new process," which, he says, "is calculated to produce a profound sensation." It requires neither special apparatus, peculiar manipulation, nor any chemicals beyond what are ordinarily found in the photographer's dark room. He has arranged to show it to any gentlemen visiting the Paris Exhibition, and is ready to grant agencies of every kind—to individuals, for a town, city, or province. I am bound to say that he has some testimonials from photographers of the highest calibre; but, then, was there ever a process exploited that had not? and these names may be supposed to be biassed, as most of them have bought the right for a district. I presume the advertisements which, so far, are confined to continental and American journals, will soon find their way here. The process is being strongly "pushed" in America by M. Lambert under the name of "The Lightning Process."

Some worthy gentleman has been writing to the *Lancet*, suggesting a grand discovery, that a sitter, when in photographic durance vile, should, during exposure, look not at an actual point but over a certain circumscribed space, that his eyes may not be tired or dazed, and rendered expressionless. He seems to have experimented upon the plan with a photographer of some repute; surely the latter must have been merely affecting to the worthy doctor an artificial surprise and interest in his idea, for I cannot believe, that at the present day, any photographer of skill could ask his sitter to confine his gaze to a point instead of allowing it to wander over a space not too large. But the doctor does deserve credit for his suggestion that a moving object be presented, though, as shown by Dr. Nicol's American jottings, the plan is in operation at the present time in America, Mr. Gutekunst employing clockwork to revolve a series of pictures in front of his sitters.

I do not know when we shall hear the last of the coloured glass theory; at the meetings of the Photographic Section of the American Institute they are still hammering away at it, theoretical and practical fancies of the crudest kind being displayed. One gentleman seems to hrve made a most laborious series of investigations with glasses and solutions of all colours. Among one of the remarkable results he obtained was the discovery that if a cell containing a solution of iodine in bisulphide of carbon were placed before the lens, so as to destroy all visible image, the photographing of the object beyond went on perfectly. "In fact," he says, "I believe instead of cutting off it accelerates, because among those trials there was one that required twelve minutes' exposure." * * * "I used a cell of this bisulphide of carbon, made an exposure of four and a-half minutes, and you see the result." The result is not stated, but it is inferred, and with such a gigantic problem before me I must "give up" for this month.

Free Lance.

ROYAL INSTITUTION LECTURES.

On Colour and Absorptive Media.

Lord Rayleigh, M.A., F.R.S., gave the first of a course of four lectures on colour on Thursday, the 2nd instant. Referring to coloured ribbons before him, his lordship explained that the retina of the eye is acted on by light and not by matter; and that, even when there is light, there may be no distinctions of colour. Thus, with the monochromatic yellow flame of soda, he showed that coloured ribbons became black. To understand colour, therefore, light must be studied. Having produced a magnificent spectrum by prisms applied to the electric light, and thus demonstrated the composite character of light, he explained that all the various colours are due to different degrees of bending from the straight line (refrangibility)—red being the least and violet the most refrangible. No ray of the continuous spectrum thus produced, he said, can be further decomposed by a prism; it is homogeneous, but may be affected by polarisation. Natural bodies possess the power of extinguishing or, as it is termed, absorbing the light that enters them. This power is selective. When the light falling on a body is wholly absorbed it is black; when it is equally absorbed, but not totally, it is grey; and, when unequally absorbed, it is coloured. The ray not absorbed is reflected. When all the rays of the spectrum are absorbed except blue, that is the colour of the body—the colour which it reflects. This was illustrated by a series of experiments with coloured glasses and liquids, made with large prisms and the electric lamp, but which, his lordship explained, may be easily performed with small glass prisms and daylight. Thus a red object in the red rays of the spectrum retained its colour, but became dark in the orange and green rays and black in the blue ray. In like manner other bodies retained their colour in the corresponding rays of the spectrum, but lost it in other rays. His lordship showed that cobalt glass allows blue and red light to pass; a blue liquid cut off all but the blue, a red glass and blue liquid cut off all light, and a solution of litmus permitted the passage of red and blue. The spectrum apparatus thus affords the means of analysing compound colours and ascertaining their components. The colour of "Newton's rings" is not due to absorption, but to the differing thickness of a film or air between a lens and a plane surface of glass; and the colour of ruled lines is due to diffraction, the action of the grating resembling that of a prism.

Lord Rayleigh began his second lecture on Thursday, the 9th inst., by commenting on the opinion of Sir David Brewster, that monochromatic light not only stops certain rays of the solar spectrum but also modifies their colour. This, being incompatible with the wave theory of light, led to close investigation by Airy, Helmholtz, and other philosophers, who demonstrated that any such change of colour must be attributed to imperfection in the prism, and that when the colour of the ray is pure it cannot be further decomposed. Lord Rayleigh then showed by experiment the imperfection of visual testimony. The shadow of an object by green electric light appeared red when illuminated by gas light. He next explained the phenomena of fluorescence, as studied by Professor Stokes, who proved that rays of light of such a high degree of refrangibility as to be beyond the violet end of the visible spectrum become visible when falling upon certain bodies, such as a solution of the disulphate of quinine. It was then shown how a very pure green may be obtained by cutting off two ends of the spectrum—the blue rays by means of a solution of bichromate of potash, and the red by means of a solution of sulphate of copper. The same result was obtained from a mixture of the two solutions. His lordship then explained a novel method by which he measured the varying degrees of absorption of different bodies. Two slits, backed by light of the same intensity, having been placed at the green part of the spectrum (for example), their spectra were so thrown on the screen that the green of the one should overlap the green of the other. When the lights of both slits were of equal intensity their brightness was equal; but when an absorbing medium was interposed between the prism and one of the slits a part of the light was held back, and to restore the brightness the slit had to be widened. Thus, by comparing the width of the two slits, a tolerably accurate measurement of the amount of the absorption is obtained. A curve showing the amount of absorption of chromium chloride was exhibited. The change of colour due to various thicknesses of the absorbing medium, termed "dichromatism," was also shown; by chromium chloride, with a great thickness, blue glass became red. Colours, as seen by the eye, are rays which penetrate the coloured body, and which are either seen directly or are reflected by the interior surface back to the eye. Thus, a solution of bichromate of potash in a black vessel had no colour, as seen from the top, but became a bright red when a white plate was placed beneath the surface. The entering rays were thereby reflected back instead of being absorbed.

His lordship commenced his third lecture on Thursday, the 16th inst., by noticing some exceptions to the rule which ascribes the colours of bodies to absorption. For instance, the colour of gold and other metals is due to reflection. The absorption colour, also, greatly depends upon the degree of thickness of the substance through which the light passes. The colour reflected from a body almost opaque is complementary to its true colour (*i.e.*, as green is to red); but if the light pass too far into the substance before it is reflected no colour appears. Lord Rayleigh showed that crystals of the beautiful coal-tar dye magenta, which to the eye appear yellowish-green, become crimson by transmitted light. His lordship then proceeded to the consideration of compound colours, ingeniously illustrated by coloured paper discs, sectors of which could be combined, the different colours being mixed by rotation of the discs placed upon a whirling-table, and thus rendered visible to the audience. For private experiments the discs may be revolved on a large pin. Many interesting results were thereby produced. The rotation of a disc half black and half white gave light-grey; increasing the black reduced the luminosity, the effect resembling that of diminished light. Various shades of any colour were formed by adding black to it in different proportions, and various tints by adding white in a similar manner. This was specially demonstrated with the colour red. A combination of black, yellow, and white discs produced drab, and browns and drabs were shown to be darkened varieties of yellow, orange, and red. Lord Rayleigh, having ascertained by experiments the exact proportions of each colour required to be placed upon the disc in order to procure certain varieties of shades and tints, recorded the figures, and arranged them in a tabular form. This he exhibited; and he showed that, by reference to it, he was able to predict the results of certain combinations of colour, and produce them at will. Thus: a combination of 67 parts red, 49 green, and 50 blue gave the same grey as a combination of 34 white and 132 black. The result of a mixture of 23 green, 44 yellow, and 99 blue matched that of 118 black and 48 white. Among other combinations, it was shown that red and green will produce a match for black, yellow and white; and that a pink, the result of a mixture of red and yellow, may be matched by combining black, white, and red.—*Illustrated London News.*

PHOTOGRAPHY IN COURT.

THE COPYRIGHT ACT.

On Saturday, 25th inst., Asher Grosse, a Dutch Jew, living at 1, Castle-alley, Whitechapel, appeared at the Worship-street Police Court to two summonses, charging him with having infringed the Copyright Act by selling pirated copies of two pictures, called respectively *The Last Kiss* and *Grace Darling*.—The prosecutor was Mr. Benjamin Brooks, fine art publisher, of 171, Strand, and the copyright of the pictures in question was his property.—Evidence was given showing that the defendant was a hawker of photographs of pictures, &c., and was in the habit of standing with a stall in Whitechapel. On the 6th of May a person named Burgess, a private inquiry agent employed by the prosecutor, found on the stall a photograph of the picture *Grace Darling*. He bought it, and on the 7th inst. another copy, and a copy of the picture called *The Last Kiss*. On that occasion he had a conversation with the defendant, the purchase being effected at the lodging of the defendant, and he admitted that the pictures were copyrights and difficult to get, so that they had to be careful as to whom they sold them. He paid 1s. 3d. each for the pictures. The defendant admitted that he had sold three gross of the pictures that morning.—Mr. Brooks said that the pictures were usually sold at half-a-guinea. There was no idea that defendant was the importer or photographer of the pictures. That person was well known, and during the past week a search warrant had been obtained, and negatives of the pictures had been seized upon the premises of the importer or photographer.—Mr. Bushby said that the onus of proving that the defendant knew the pictures were copyright lay upon the complainant, and he had failed to satisfy the court on the point.—The summons would, therefore, be dismissed.——Solomon Wood, a hawker, of the same address, was summoned for a similar offence. The evidence of the witnessess showed that the defendant was hawking pictures in the street, and among them was the picture of *The Last Kiss*. The witness bought it for a shilling, told the defendant that it was copyright, and that he would get into trouble. The defendant said he could not help it and did not care, and that the picture was copyright. He refused his address, and a constable had to be fetched.—Mr. Bushby fined the defendant £5, including costs.

On Tuesday last, the 28th inst., J. Lees, of 60, Exmouth-street, Clerkenwell, appeared before Mr. Hannay, in answer to a summons charging him with infringing the Copyright Act, 25 and 26 Vict., cap. 68, by selling a pirated copy of a picture called *The Last Kiss*, the copyright of which Mr. Benjamin Brooks, fine art publisher, 171, Strand, alleged was vested in him. Mr. Louis Lewis, solicitor, appeared for the prosecution; Mr. Ricketts for the defence. Evidence having been given as to the purchase of the picture, an argument ensued as to a knowledge that the work was copyright being necessary to conviction; and Mr. Hannay, who said he inclined to the affirmative, adjourned the case.——James Dabbs, of 16, Reform-place, Clerkenwell, was summoned for selling pirated copies of the *Soldier Boy's Dream*, *Grace Darling*, and *Evening Prayer*, copyright in which is vested in Mr. Brooks. It appeared that the defendant had several barrows, and had been previously cautioned. About 200 copies were found on a barrow belonging to him. Evidence as to this fact having been given, Mr. Brooks was called, and in his evidence he stated that the pirated copies were issued wholesale to hawkers living in thieves' dens and back slums. He had dogged them about with a view to obtaining information, and had had his nose broken, his head smashed, and his pocket picked. (Laughter.) He had had to get the police to buy copies for him. One of these men was reported to have said last week, "If I see Brooks I will have his liver." Another man had sold as many as a gross of pirated copies in one morning, and had made over £30 by it. Sometimes men stood opposite his warehouse with a barrow, and said, "Outside you pay a penny; inside you pay a guinea." (Laughter.) When witness asked their name they would reply, "That is my name," and put their fingers to their nose. Mr. Ricketts: Has the defendant done that?—Mr. Brooks: I can't say the defendant is the man.—Mr. Ricketts said it was unfair to visit the sins of all the costermongers in London upon the defendant.—Mr. Brooks: I believe he is the man whom I met one day and asked, "Is this a profitable game?" He said, "Yes; I have made fifteen 'quid' today." I then said, "What were you?" and he replied, "I was a costermonger, but I have now taken to the fine arts." (Laughter.) In re-examination by Mr. Lewis, Mr. Brooks said he had 163 cases, and never lost but one till he went before Mr. Bushby the other day. He had prosecuted at Birmingham, Brighton, Hull, and other towns, and only lost one case in reference to a statuette. Mr. Ricketts urged that the defendant was an illiterate man, and probably ignorant of the law of copyright. There was no evidence of a guilty knowledge. Mr. Hannay held otherwise, and fined defendant ten shillings in each case, and the costs.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
June 3	West Riding of Yorkshire	Oddfellows' Hall, Bradford.
" 3	Photographers' Benevolent	160a, Aldersgate-street.
" 5	Edinburgh	Hall, 5, St. Andrew-square.
" 5	Bristol and W. of Eng. Amateur	Museum, Queen's-road.
" 6	South London	Rooms of Society of Arts, John-st.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

The annual general meeting of this Society was held on the 5th ult.,—Dr. Vogel occupying the chair.

The first business transacted was the admission of three new members, followed by the reading of a communication, from Herr Adolph Ott, *On the Action of Light Upon Chromated Gelatine.*

The Chairman then spoke of the action of iodide of potassium upon exposed plates. He said that, if an iodide of potassium solution of one to ten were poured over an ordinary photographic plate after it had been exposed and washed, the invisible picture would be completely destroyed, so that on developing the plate with iron and silver not a trace of the image would be obtained. But if the silver bath in which the plate was prepared was old and loaded with particles of organic matter the still invisible picture would not be destroyed.

Herr Meyer, of Esslingen, sent a formula which he had bought from Herr Pfeiffer, of Guben, for ten marks. He had not been able to use it, but as he believed it to be a good thing he had sent it to the meeting in case any member would like to try it.

Herr Tiator, of Colmar, sent a specimen of a printer's register which he had arranged, and which furnishes the printer with a convenient form in which to make his returns of the quantity of paper used and prints made, &c.

From Herr Richard, of Zurich, came a communication upon the vexed subject of blisters in albumenised paper, which ran as follows :—

"As the gold used in the bath should bear a certain proportion to the thickness of the albumenised film the fixing bath should also be of exactly proportionate concentration.

"The sorts of albumenised paper in the market are usually divided into ten and eight kilo. albumenised paper of greater and less brilliancy; these are registered as such according to their qualitative and quantitative contents, and thus it is easy to understand that the ten kilo. paper blisters more readily than the eight.

"The blisters, which are more apt to occur with ten kilo. paper, often increase in numbers from day to day, and leave behind them pale rings or spots which render the prints entirely useless. The appearance and increase of these blisters are alike caused by the reaction of the positive bath (which should at once be neutralised on blisters showing themselves), together with too little gold being used in the toning bath.

"The ten kilo. paper always requires a stronger gold bath (at least thirty per cent. stronger) than the eight kilo. paper; and it is not strong enough if the prints (on ten kilo. paper) require to remain more than from five to eight minutes in the gold bath.

"When the duration of the toning can be reduced the blisters will also be reduced; but slow toning is favourable to blistering. My long experience has made me an enemy to all 'perforce means' of avoiding blisters, as most of them are based on a weakening of the picture, which not seldom ruins it. In photography we have as a basis certain fundamental proportions the balance of which is disturbed or even destroyed by the admixture of all sorts of injurious substances; but if we adhere strictly to these fundamental proportions we shall seldom be plagued by blisters and similar flaws. The proportions I have adopted are—

"1.—*Gold Bath to Tone* 500 *Prints on Ten Kilo. Paper* :—

Distilled water	2·5	litres.
Chloride of gold and sodium	1	gramme.
Bicarbonate of soda	1	"

Duration of toning for each print, five to eight minutes.

"2.—*Gold Bath to Tone* 600 *Prints on Eight Kilo. Paper* :—

Distilled water	3·5	litres.
Chloride of gold and sodium	1	gramme.
Bicarbonate of soda	1	"

Duration of toning for each print, ten to twelve minutes.

"1a.—*Soda Bath for* 500 *Prints on Ten Kilo. Paper* :—

Hyposulphite of soda	1	kilo.
Water	5	litres.

Time in bath, fifteen minutes.

"2a.—*Soda Bath for* 600 *Prints on Eight Kilo. Paper* :—

Hyposulphite of soda	1	kilo.
Water	7·5	litres.

Time in bath, twelve minutes.

"The positive bath should not be allowed to become too acid, or the number and size of the blisters will increase. If the baths be prepared exactly according to the proper proportions, no *eau de javelle* or other such preparations will be required.

"Should blisters still be formed on ten kilo. paper they may be made to fall again, without leaving pale rings or spots, by drying slowly at a temperature of 12° to 14° R. In this case, however, they are caused by the positive bath, which must at once be reduced by the addition of distilled water, and restored to the proper percentage.

"By always keeping exactly to these formulæ I am but very, very seldom troubled with blisters, and when that does happen I know that they have their origin in the silver bath, and that by neutralising it they may be made to cease.

"I may say that while using the most strongly-albumenised paper I do not for years back remember having blisters on the paper which left spots. I cannot too strongly recommend the active neutralisation of all the baths."

Nearly all the members present agreed with Herr Richard that blisters occur more readily with strong paper than with thin paper; but

Herr Martini said he had often heard complaints of quite the opposite character.

Herr Richter did not think the gold bath had much to do with it, as untoned pictures were often blistered. He thought that too strong a silver bath was more likely to cause blisters than too weak a one.

Herr Bergemann advised those photographers who found they had on hand a quantity of paper which blistered readily to try some of the preventives which had been mentioned at previous meetings as being successful before returning it to the dealer.

Herr Boll used a weak fixing bath and never had blisters.

Herr Marowsky remarked that Herr Boll added a great deal of chloride of sodium to his toning bath.

Herr Haberland had found a warm fixing bath prevented blisters.

The foregoing remark ended the discussion.

A number of objects were then placed upon the table; after which the Treasurer and the Secretary read their tenth annual report. The office-bearers were then re-elected for the ensuing year, and the President thanked, in the name of the Society, those members who had taken the management of the *conversazione* which had taken place the week before. The meeting was shortly afterwards adjourned.

Correspondence.

OXYGEN RETORTS.

To the Editors.

Gentlemen,—I am sorry to have to ask for space in your next number to inform your readers that the oxygen retort, shown as Mr. W. J. Chadwick's in your issue of the 17th inst., is really a very clumsy copy of my patent retort which I showed to a number of members and friends at the meeting of the Manchester Photographic Society, held February 14th, 1878, and which is noticed at page 103 of The British Journal of Photography for 1878. As there was not time to show it in the large room, I then promised to show it again at a future meeting, but ill health has prevented me doing so.

I enclose a sketch, from which you will see that the retort is kept gas-tight without the risk of burning the fingers, any desired pressure being given to the mouth of the retort by the adjustment of an iron weight upon the rod which supports it. There is also a stand for the retort, by the use of which it may be used on the table, floor, &c., being made of baywood. It weighs one drachm forty-two grains, and is, I think, a very portable retort stand, being quite as efficient as if it weighed twenty pounds. I enclose one of the retort stands in this letter.

I ought to say I can use this retort without either springs, screws, or weight, yet regulating the pressure from ounces to pounds on the square inch, and keep the retort perfectly gas-tight. I think this cap could be applied to the ordinary steam safety valve.

I am pleased that my patent oxygen apparatus is worth copying even by Mr. W. J. Chadwick; at the same time, I feel it my duty to caution your readers and the trade against being drawn into profitless trouble by using or dealing in any infringements of my patent oxygen apparatus.—I am, yours, &c., David Young.

Swinton, May 20, 1878.

[Pressure on our space prevented us from publishing this in our last.—Eds.]

THE "IMPOSSIBILITY" OF FADING.

To the Editors.

Gentlemen,—I can bear testimony also that our "Peripatetic" friend quoted correctly the advertisement which has appeared for a long time in a Chester paper, and, without any doubt, we Cestrians ought to feel proud that the carbon process will ultimately give way to "F.C.S.'s" new permanent process, the particulars of which we who are "not in the know" are waiting patiently for divulgence. What a rush to the offices of The British Journal of Photography there will be that day when it is whispered that the "newest" process is "going to come out!"

But how exquisitely refreshing it is to notice the self-complacency with which "F.C.S." fancies he has put the "Peripatetic" into the pillory. What a consolation it is that "F.C.S." is not the only wise "fellow" in the photographic profession; others there are that can reason—with this difference, however, that they can reason logically. It requires no logic, however, to prove whether "possibility" or "impossibility" is right, for a moment's perusal of Webster's dictionary will dispel all "possibility" of doubt.

"F.C.S." wants the "Peripatetic" to haul down his flag. The latter cannot possibly oblige him, for it is *nailed* to the mast. And the lessons —well! I do not know what lessons "F.C.S." wants him to learn; but that cigar suggestion of the "fellow" is not bad, for if there be one luxury I like more than another it is a good—especially a good peripatetic—cigar. Do please request the "Peripatetic" to keep me a few, though I doubt the "impossibility"—I beg pardon! the "possibility" I mean—of his doing so. As for the Glenlivet "F.C.S." wants the "Peripatetic" to get him: if he has got it, cork it well up, for it will keep for future "*preference.*" But I will do the "handsome," and endeavour to sustain the hospitable reputation of the ancient city if the "Peripatetic Photographer" will let me know his "preference," and meet me at the "Grosvenor" any evening after professional hours.—I am, yours, &c., ATTICUS.

Chester, *May* 27, 1878.

P.S.—At the proposed meeting the question of best and second best *permanent* productions will certainly crop up, and the happy termination of that debate depends most certainly upon the "preferences" imbibed; and the "impossibility"—no! I mean the "possibility"—is, that the last song will be, "He fadeth away!"—A.

[Enough has now been said about this matter. We are much pleased to find that photographers in the provinces exhibit a degree of spirit scarcely known in London in connection with the desire of issuing permanent prints, a desire the gratification of which is now easy.—EDS.]

EXCHANGE COLUMN.

Wanted to exchange, Solomon's enlarging apparatus, magnesium lamp with double burner, in excellent condition, for a good camera 12 × 10 or larger.—Address, R. WINGFIELD, 33, Sidbury, Worcester.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

NOTICE.—Each correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a *nom de plume* as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

M. DANKS.—We are not yet in a position to report upon the plates.

LL.B.—When you have mastered the instructions given with so much detail in our last ALMANAC write again.

TECHNOLOGIST.—The cautious addition of a very weak alcoholic solution of nitrate of silver will enable you to effect the necessary balancing of the ingredients.

P. C. STORTZ.—The expression must be held merely to mean that the picture was painted by artists in the employment, for the time being, of the photographer named.

GEO. S. BLACK puts to us a straightforward question, although in a tone that savours of pugilism. He demands—"What have you got to say about the fact of spirit photography?" To which our reply is—"Nothing."

R. B. (Leeds).—The best method to obtain such a degree of density as you require is to flood the negative, after fixing, with a solution of bromide of copper. Wash well after this, and apply a solution of nitrate of silver.

ALPHA.—Although the sensitive paper has become slightly discoloured, it will be quite white again after being toned and fixed. Tear off a bit and place it in a solution of hyposulphite of soda, and you will find this to be the case.

W. E. B.—The paper *appears* to be of good quality, but we cannot undertake to try samples of paper sent to us for this purpose. Both makers are highly respectable and reputable, and the probability is that you have failed to fulfil all the requirements.

THOMAS SHAW.—To tone a collodion transparency, immerse it for a few minutes in a weak solution of chloride of gold. To remove such a transparency from the glass attach a sheet of transfer paper, and when it dries it may be peeled off the glass, carrying with it the film.

J. REES.—The manipulation of the pictures has been good enough and the sharpness all that can be desired, but the lighting has been very badly managed. With a light direct in the face of the sitter and in the line of the camera nothing else could be expected than a flat portrait. By means of blinds arrange so that the light shall fall more from one side, then give a full exposure, and avoid too much intensifying.

"PHŒNIX" takes exception to a remark we made respecting the fewness of the number of those who now practice the morphine process. He says that *he* does so. He somewhat strengthens our position by qualifying this statement with an observation that he has not used his camera for nearly two years, from which it appears that "Phœnix," like many others, at one time made use of the morphine process, but has laid it aside.

H. C. JENNINGS.—Such an addition to the lens you mention would be useless, as the lens must be corrected in a special manner, *i.e.*, have a round field and give freedom from astigmation, in order to display the advantage possessed by the concave interceptor. The lens you name is already corrected for flatness of field at the expense of marginal definition of the first order. If this explanation is not sufficiently lucid, please write again.

P. J. K.—Yours is a genuine case of "Rip van Winkle"-ism. We scarcely know what advice to offer. The details of all the processes named can only be obtained by reading the back numbers of our almanacs or journals; for your requirements the former will be the easier. You should also apply to some good-natured, well-informed photographic friend, who will in a few words "post you up" in all that has been accomplished during the past ten years.

R. R. BROWN, Jun.—1. Let the negative be fully exposed, contain full detail, and be rather too thin for producing a first-class print.—2. Either carbon, collodion, or albumen.—3. Retouch on the enlarged negative.—4. No *book* specially devoted to enlarging has been published, but numerous articles, and series of articles, have been published in, or in connection with, this Journal.—5. It is desirable, although not necessary, to back a transparency with opal or ground glass.

GEO. WHITE.—To prevent the film from becoming dissolved when the varnish is applied, make use of a varnish having a very weak spirit as the solvent of the resins of which it is composed. It is also a good plan to flood the surface of the negative with diluted albumen or weak gum water, and allow this to become dry previous to applying the varnish, which will not then exercise any solvent power upon the film, no matter how strong may be the spirit with which the varnish is prepared.

J. J. M.—We are quite conversant with the conditions under which wet collodion transparencies having a warm tone may be produced; but to give all the information you require would compel us to devote the whole of this page to such purpose. The "Answers" column is always reserved for brief practical hints to such as require them, and a lengthy disquisition on a process would be quite out of place in it. We are the less concerned about not acceding to your wish as the information has been given many times, and is to be found in every good manual of the art.

AMATEUR.—We cannot undertake to answer your queries by post, and from the fact of your not enclosing a stamped directed envelope for the replies you crave it is evident that you did not expect us to do so —1. Use a head-rest.—2. Fifteen grains to the ounce.—3. The patent expired five years ago.—4. Certainly not.—5. Yes; we are so fortunate as to know in what manner retouching varnish is made, and so are our readers—that is to say, those who profit by their reading more than you appear to have done, if your own statement as to being such a careful reader be correct.

W. WAINWRIGHT, Jun.—Our correspondent, who exhibited a negative on gelatino-bromide at the last meeting of the Photographic Society of Great Britain—a fact to which reference was made in our report of the meeting—requests us to state that it was made from gelatino-bromide prepared for him by Mr. Mawdsley from the formulæ published by Mr. C. Bennett. He does this in order to prevent a misapprehension which appears to have arisen in consequence of his name being similar to that of a member of a firm professionally engaged in supplying or preparing photographic requisites. We may say that our esteemed correspondent, Mr. W. Wainwright, Jun., is the indefatigable Secretary of the Amateur Field Club, and is not connected professionally, in any capacity, with photography.

G. S. H.—1. There is no doubt that, by intercepting the rays by a plane reflector placed at an angle of 45° to the axis, a far more convenient and in every respect superior instrument will be formed.—2. The two forms of telescope differ, at least, in this respect—that a shorter tube is required, in order to obtain a given power, in the Cassegrainian than in the Gregorian telescope. We cannot speak of the former from possessing any practical acquaintance with it; but we have had a great deal of experience with the Gregorian, and are not very profoundly taken with it. It would appear to be a comparatively easy matter to convert one kind of telescope into the other, the only points of difference between the two consisting in the small central mirror of the Cassegrainian being convex, whereas in the Gregorian it is concave. The latter telescope gives an erect image; in the former the image is inverted.

RECEIVED.—J. Cooper; John White; S. B. Hercus; Robert Banks; "An Opal Enlarger;" and others.

OLD LONDON.—The *Athenæum* announces that the Society for Photographing Relics of Old London proposes to publish the following subjects with its fourth year's issue:—Temple Bar; Gate and Courtyard of 102, Leadenhall-street, demolished in 1875; Houses in Gray's Inn-lane, demolished in 1878; Shop in Brewer-street, Soho; The "Sir Paul Pindar," Bishopsgate-street; Houses in Holborn. Mr. Alfred Marks, of Long Ditton, Secretary of the Society, will receive subscriptions.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 944. Vol. XXV.—JUNE 7, 1878.

PREPARATIONS FOR FIELD WORK.

The following remarks are addressed more particularly to those of our readers who are willing to include themselves under the somewhat broad designation of "tyros" in photography. To the many whose experience has carried them beyond that stage the hints we are about to give will be wholly unnecessary; and there exists also, no doubt, a numerous class who, though considering themselves far above the need of such elementary instruction, might possibly find themselves benefited by it would they but take it to heart. Not for these do we write, but for such of our readers, beginners or otherwise, whose experience in field work and the preparations therefor is of so limited a nature as to render the advice acceptable; and we are sanguine enough to hope that our remarks may have the effect of averting much trouble and disappointment if carefully perused by those for whom they are penned.

Thanks to the numerous photographic societies and to the different publications devoted to photography there is, nowadays, no lack of information with regard to the best processes for employment in the field or other matters connected with the chemistry of our art, but comparatively little is written upon the minor details of a more or less mechanical nature which go so far in the production of successful results. Such matters, though frequently discussed at the various photographic meetings, are seldom considered of sufficient importance to gain a place in the published reports, and hence the beginner, unless fortunate enough to belong to one of the societies or to possess a friend experienced in the unwritten mysteries of the art, is doomed to work his way to success through long lanes of failure and disappointment.

We know many cases of amateurs whose experience, extending perhaps over many months or perhaps years, has enabled them to master thoroughly the various manipulations connected with dry-plate work, and who have, nevertheless, been completely "floored" by the preparations which a tour of some duration involves. It is an easy matter to prepare a few plates for a single day's use and to produce from them, when developed the same evening, an equal number of successful negatives; but when some dozens of plates have to be prepared (probably in a limited time), and have subsequently to undergo the vicissitudes inseparable from travelling, it is needless to say the difficulties are increased. If we add to this the uncertainty which arises from the exposure of a large number of plates without any sufficient data as to the time of exposure, or, if the plates be developed *en route*, the inconvenience which attends the operations when conducted on a strange plate, why wonder if the inexperienced sometimes come to grief? Still it is not difficult to ensure at least a fair chance of success, all that is necessary being a little method in the ordering of the arrangements, including the strictest, in every portion of the chemical manipulations.

The choice of process will, of course, depend upon what the operator has been previously accustomed to; for we scarcely expect a man to make his first essay in a new process when about to commence a holiday tour. But it must be borne in mind that many circumstances which are of little moment when the plates are developed shortly after exposure are wholly unsuited to the requirements of the tourist, who may possibly be compelled to leave his pictures undeveloped for days, or even weeks. Thus films prepared with certain organifiers are found to yield excellent results if prepared within a few hours of exposure, but, if left for a day or two, give inferior results, either from fading of the image or from actual decomposition of the film. A similar result will occur from careless manipulation, or if the plates be insufficiently washed to remove all traces of free silver or of bromide; lengthened keeping before or after exposure will develope defects which would not, perhaps, under other circumstances be produced. For plates requiring to be kept any length of time organifiers of a hygroscopic character should be especially avoided, because, in addition to relapsing the film in a state peculiarly susceptible to atmospheric influences, they render it more liable to injury from dust and other causes. We have recently published several reliable processes from which there will be no difficulty in selecting a suitable one—either bath or emulsion.

We will now turn to the dark room, where the novice will experience many difficulties of a mechanical or routine nature, when working on a large scale, which have probably never obtruded themselves on his notice under ordinary circumstances. The first piece of advice we have to give is to keep the different operations entirely distinct from one another. We have known many cases—especially when the bath is employed and the preparation of the plates is necessarily slow—where the whole of the operations, from cleaning the glass to drying the prepared plate, were carried on considerably; while one plate was sensitising the next was being polished and got ready for collodionising. We cannot too strongly condemn the practice of cleaning or polishing the glass in the dark room—at anyrate when other operations are being conducted; it raises dust and disseminates minute filaments of cotton or silk from the polishing cloth, besides which the glass, if used at once, has not time to part with its electricity, and is in a state highly favourable to attract and retain the matter thus set floating in the atmosphere.

The cleaning and polishing of the glass should be performed, if possible, in another apartment; but at anyrate it should be made an entirely separate operation. It will then be more effectively done; for, the hands not being contaminated with chemicals or moist from contact with the solutions, will be less liable to stain or smear the surface. After polishing the plates the edges are next tipped with india-rubber and reared up in a rack to await the next operation. The dusting should not be done until immediately before coating with collodion. The practice of using a substratum (generally of albumen), once so much in vogue, is now rapidly falling into disuse, as the strong alkaline development generally adopted at the present day acts so powerfully upon the albumen as to render it useless if not absolutely injurious. An edging of india-rubber performs all that is necessary in retaining the film upon the glass.

How far it is possible to keep the remaining operations distinct from one another will depend upon various conditions. If a washed emulsion be used it is advisable to place the plates in the drying-box as soon as possible after coating (that is to say, when thoroughly set), rather than to coat a number and allow them to remain exposed to the atmosphere in the moist state for some time, as they are then more liable to attract dust. If, however, the bath or collodio-bromide processes are used, we advise that the number of plates it is intended to be prepared be advanced only as far as the washing water before commencing to apply the organifier. It is especially dangerous, when using the bath and an organifier containing tannin or gallic acid, to perform the two operations concurrently; the fingers come in contact alternately with the bath solution and the organifier, and the almost inevitable result is seen in stains on the edges of the plates.

Particular care should be observed in every operation to avoid, as far as possible, the great enemy of the photographer—dust or spots. This is doubly the case when using an emulsion, as, from the fact of the latter being thicker and more viscid than collodion, a minute speck of dust upon the plate or in the emulsion itself becomes much more injurious. The emulsion should be carefully filtered from the stock-bottle into a perfectly clean and dry wide-mouthed pouring bottle. It should not be corked, but be fitted with a loose cap, formed by pressing a piece of brown paper over the mouth and neck; this keeps out dust when the bottle is not in use, prevents evaporation, and at the same time there is little chance of small particles of hard emulsion becoming detached from the lip to cause lumps in the film. When the emulsion gets thick after coating a number of plates it is poured back into the filter, the bottle is rinsed out with a small quantity of a mixture of ether and alcohol, which also goes into the filter, and a fresh portion of emulsion added from the stock.

The greatest importance attaches to the careful dusting of the glass immediately before coating. If this be not attended to it is liable to cause spots—not only on the individual plate under treatment, but by introducing specks into the pouring bottle with the portion of emulsion drained back upon each succeeding plate. Should the emulsion commence to show the least tendency to spottiness the best plan is at once to refilter it.

Much trouble is frequently experienced—especially in the absence of a laboratory specially fitted for the purpose—in draining and drying large numbers of plates without attracting dust. An arrangement simple enough as a makeshift, and thoroughly efficient, is as follows:—Procure an old box or packing-case of suitable size, and if necessary fit one or two shelves inside it; paste over the whole of the interior with brown paper or even newspaper in order to form a smooth surface not liable to harbour dust. Some strips of blotting-paper for the plates to drain on complete the apparatus, which is also useful in another direction.

The discomforts attending the preparation of a large batch of plates are in no way lessened by the necessity which exists for working in an extremely non-actinic light; but the degree of illumination may be considerably increased without danger of fogging the plates if the latter be kept as much as possible out of the direct light. As is well known, a sample of orange glass which would fog a bromide plate if allowed to act upon it for several minutes will produce no effect if the exposure be only a few seconds; so that it becomes possible, by suitable arrangements, to use stronger illumination during the preparation of the plates than would be allowable for development. A piece of stiff brown paper laid over the dishes in which the plates are soaking will effect this, and if the draining-box we have described be placed with its back to the light the same effect will be obtained. Should any difficulty be experienced in getting the plates into their places without injury, a piece of white paper or card used as a reflector will supply sufficient light when required for the purpose.

A similar box, with the addition of an opaque curtain over the front, may be used as a drying-box. With the exception of washed emulsion the better plan, in the absence of a proper drying stove, is to allow the plates to dry spontaneously, which they will do in a few hours without any fear of drying marks.

THE CARBON SENSITISING BATH.

At the present time it would be rather an act of temerity to tell such a thrice-told tale as to describe in detail the peculiarities of the silver bath for floating albumenised paper upon, the experience of thousands having all been laid under contribution from time to time till it would be difficult to say anything whatever new upon the subject. Not so, however, with carbon, which is quite a thing of today in comparison with its older sister, silver printing. It is right, however, to say that even in silver printing it was a long while before its possibilities were all known; indeed, it had been in constant use for many years before the fact of its being possible to obtain good pictures with a weak bath was at all commonly known.

We may, therefore, confidently feel that with the carbon process many hints will have to be given from time to time before we can consider ourselves *au fait* with all the details of manipulation peculiar to carbon work in general. One interesting point in carbon printing which at first was entirely neglected, but which afterwards had more attention given to it, is the age of the bichromate bath. This, even when worked down to the last drop, sensitises the paper evenly and sufficiently—a quality quite different from the silver bath, one important reason for which being the fact that the action of the sensitiser is quite different in the two cases. This is a point it would be well always to bear in mind. Thus, each sheet of albumenised paper immersed or floated withdraws a portion of the bulk of the solution with it, but not until the whole solution has been weakened by the precipitation and abstraction of a certain amount of silver by the chlorides in the paper. In the immersion of the tissue, however—which has no salt in its texture—no precipitation occurs, so that each piece merely withdraws a certain amount of solution, that remaining behind being of its original strength. It, therefore, follows that the strength of the bichromate solution would be unimpaired and uniform down to the last drop, except in so far as evaporation by exposure to air would tend to strengthen it.

But, though the strength remains uniform, the solution is not altogether unaltered, for the tissue gives up a portion of its more soluble components, which accumulate in the bath till its character is considerably altered, as shown both by its appearance and its working qualities. The colour indicates a chemical change; but this, though possibly affecting the working quality, would do so in virtue of its own characteristics and not by changing the strength of the solution, the amount thus altered being quite insignificant in proportion to the whole quantity of bichromate present.

We have recently made a number of experiments to ascertain the direction of the change of quality produced by the constant use of the bichromate bath, and we seem to have arrived at a consistent conclusion. The difficulty of doing this is much enhanced by the fact that the tissue itself is so altered in property according to the time allowed to elapse between sensitising and printing, and that the state of the atmosphere so largely affects the printing qualities; thus disturbing elements have to be eliminated mentally before forming a judgment.

We have found, first, that, contrary to our expectations, the dark-looking bath has no perceptible effect in staining the whites of the picture, the colour, such as it is, being washed away in one part or another of the process of development. But though the whites do not suffer through the use of an old and dark-coloured bath, the character generally of the pictures is markedly changed, and not for the better. The developed picture is soft and delicate, but at the expense of vigour and brilliance.

An important characteristic of the carbon process is that it gives, when fairly treated, the most delicate tones and *nuances* of shade, the tending to excess of softness too often resulting in a flat picture. This, again, may be considerably modified by the process of "boiling," as carbon printers term the treatment by water of extra heat. It is again, of course, very easy, on the other hand, to fall into the opposite extreme of hardness, through washing away of the half-tone during development, when even water, as cold as is possible to be made use of, is employed. This, again, is not difficult to remedy, being generally caused—as we were the first to point out—by using tissue too freshly prepared. Thirdly, the tissue sensitised on a much-used bath is usually much more sensitive than that prepared with a new bath—a quality which may be an advantage at times, but which generally is the reverse.

This latter property leads to a consideration of the cause. Sensitiveness and softness usually go together in carbon printing, so that the latter of the two properties we have been naming is the corollary to the former, and may be different modes of stating the same fact. This state of tissue being that which usually would be produced by long keeping, leads to the suspicion that possibly both one and the other may be set down to the hygrometric state of the tissue; that is, as tissue prepared on a new bath gradually absorbs moisture when kept, its state may be assimilated to that prepared on an old bath and used at once.

If this were found to be the case, it would open a very interesting field for experiment. Tissue might be prepared containing little, if anything, besides the gelatine and pigment, and all the other materials now put into the tissue itself might be dissolved in various relative proportions and various strengths in the bichromate bath, which would thus almost be absolutely invariably uniform—a consideration of paramount importance and usefulness.

RECENT PATENTS.

No. VIII.—NESBITT'S PHOTOGRAPHIC TINTING APPARATUS.

This tinting apparatus has already been referred to in this Journal, but no account of it has yet appeared. The following is all the particulars given in the patent specification :—

My invention relates to an improved construction of apparatus for tinting photographs, whereby a single frame is adapted for tinting any size or shape of picture instead of, as hitherto, a separate tinting apparatus being required for each size or shape of picture.

I propose to make my improved apparatus for tinting or giving a border to a photograph of a frame with a back of the exact size of photograph to be tinted, this back being hinged on so as to open and shut to receive the picture, and when it is in to shut and press down tightly on the printing plate. It will also have a rabbet to receive the tinting or name plate (whichever may be required), and a groove in front of this for the introduction of a glass with any size or shape of mask to cover the parts of portrait to be tinted. Thus, in lieu of a separate frame for each size or shape of picture, it will only be necessary to have a separate glass with different size or shape of mask.

I propose to make my improved tinting apparatus of wood, cardboard, or of any other suitable material or combination of materials.

What we have given above is the *provisional* specification, for Mr. G. Nesbitt (of Bournemouth) did not proceed farther than the probationary period implied in this term.

No. IX.—PHOTOGRAPHIC BURNISHERS.

This invention, which like the former only received provisional protection, stands in the names of Messrs. James Wilkinson, James Hardman, and Richard Birtwhistle, of Accrington, and is entitled "Improvements in the Mode or Method of Burnishing Photographs and in the Machinery or Apparatus used therefor."

This invention has for its object the burnishing of photographs, pictures, or portraits so as to give them a more lifelike aspect than hitherto, and consists in passing them, when mounted on cardboard or paper, through a pair of metal rollers heated by gas or steam, whereby the picture or portrait is made to stand out boldly as it were in relief, and give a very natural and lifelike appearance.

To carry out this object the rollers are mounted in suitable bearings having means of adjustment for different thicknesses of paper or cardboard, and provided with a handle at one side to give them motion. At the opposite side to the handle an ordinary gas pipe perforated with a number of holes is passed into each roller, and the gas being turned on and lit, and the photograph put between the rollers, the handle which is fastened to the bottom roller gives motion to it, and by means of wheel gearing to the upper roller, so that the photograph passed between the picture side comes out, as before explained, and the back part of the card with a highly-glazed surface.

When the back of the card is not required to be glazed or burnished, but only the face of the photograph, one heated roller will suffice; but in that case care has to be taken that the picture is put in right side upwards, for which reason we prefer to heat both rollers, as less attention is required in feeding the machine.

No. X.—STANDS FOR PHOTOGRAPHIC ALBUMS.

This invention, or "discovery," is said to be partly made by Herr Hermann Lehmann, of Offenbach-on-the-Maine, Germany, and partly by Mr. George Arthur Hasler, of London, who appears before us as the patentee, and who, for the purpose of this invention, constructs a stand, support, or holder in two portions—an upper one and a lower one. The upper one holds the album in an oblique direction or position in order that its contents may be easily viewed, and it drops or fits on to a spindle or pivot secured to the lower portion. It is free to revolve thereon (with the album attached thereto) in a direction parallel with the plane of the table or surface on which it is placed.

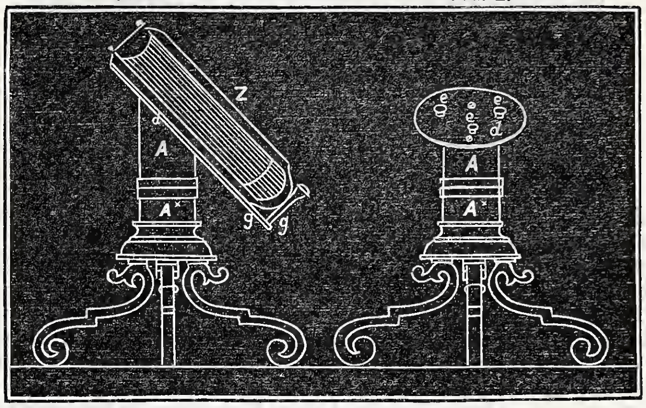
For fixing or attaching the album to the stand, support, or holder, a plate carrying studs, hooks, or other similar contrivances is secured to the upper or revolving portion of such stand, support, or holder, and the studs or hooks engage in slots provided in a corresponding plate to receive them, and which is contrived in the under side or under cover of the album. The album may, however, be readily detached when it is desired to place it on a table.

To prevent undue strain or injury to the back of the album when opened, angle pieces forming stays or brackets are secured to the under side or under cover, and they extend under the back of the album so as to keep it supported.

Such a stand, support, or standard constructed according to the invention is described as follows, aided by the diagrams :—

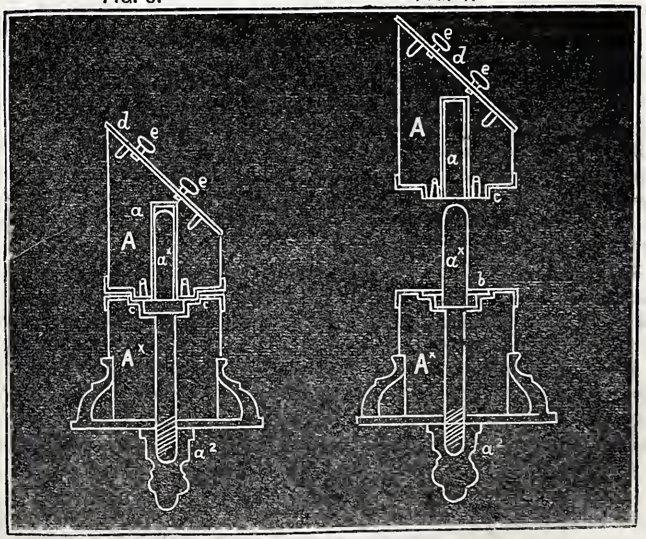
Fig. 1 is a side elevation of a stand with its album attached thereto. *Fig.* 2 is a front elevation of the stand, the album detached therefrom. *Fig.* 3 is a vertical section showing the revolving and stationary portions fitted together or combined; and *fig.* 4 is also a section, but showing these portions separated or detached.

FIG. 1. FIG. 2.



A is the upper and revolving portion, and A× is the lower and stationary portion. The upper and revolving portion A is the one which carries the album Z, and it has a longitudinal orifice a formed in it, into which the pivot or spindle $a\times$ fixed to the lower and stationary portion enters. This upper portion A (with the album) is free to revolve on the pivot or spindle $a\times$ in a direction parallel with the plane of the table or other surface on which the stand is placed.

FIG. 3. FIG. 4.



The pivot or spindle $a\times$ passes through the stationary portion A×, and is secured thereto by means of a nut a^2, tapped to correspond with the lower extremity of the spindle, which is screw-threaded for such purpose. *b* is a circular groove or recess formed in the lower and stationary portion A×, and into which a projection *c* on the upper and revolving portion fits when the said portions are combined. This projection and recess act as a second pit and orifice, and give greater strength and support to the portion holding the album.

In order that the album, when attached to its stand, may be readily inspected, I prefer to hang or attach it thereto in an oblique direction, and for this purpose a plate *d* carrying hooks or studs *e*, or other equivalent contrivances, is securely fixed to the upper and revolving portion A, and these studs fit into corresponding slots *f* in another plate *d*× contrived in the under side or under cover of the album, and hold the album and revolving portion securely together, at the same time permitting them to be revolved.

FIG. 5.

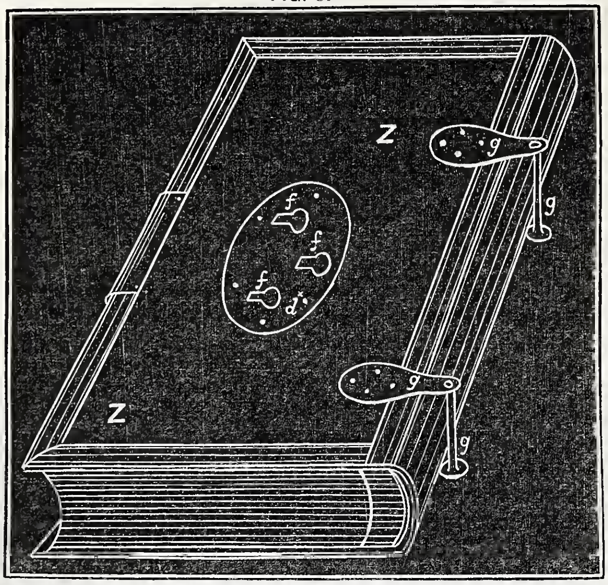


Fig. 5 shows the album Z detached from its stand in order that the plate *d*× and slots *f* may be clearly seen. The album may, however, if desired, be used detached from its stand like an ordinary album.

In order to prevent undue strain or injury to the back of the album when opened, I employ angle pieces *g*, which I rivet, screw, or otherwise attach to the under side or under cover of the album, and they extend under the back thereof, as seen in *figs.* 1 and 5, so that when the album is opened they form rests or brackets for the back, and keep it well supported.

The spindle or pivot may, of course, be fixed to the upper and revolving portion A, and the longitudinal orifice formed in the lower and stationary portion A×.

Although I have described the invention as applied to an album, it may be applied in obviously similar manner to ladies' companions, portfolios, and the like.

Having now described the nature of the said invention, and in what manner the same may be performed, I declare that I claim—

1. Constructing stands, supports, or standards for photographic albums, ladies' companions, and other like articles, in two portions, the upper portion carrying the article, and being capable of revolving on the lower and stationary portion, as described.

2. Fixing or attaching the album or other like article to the stand, support, or standard by means of hooks, studs, or other equivalent contrivances disposed on a plate, secured to the upper and movable portion of the stand, such hooks or studs engaging in a slotted plate fixed in the album or other article, as described.

3. The employment of angle pieces fitted to the album or other like article, and forming stays, supports, or brackets for preventing undue strain or injury to the back when such article is opened, as hereinbefore described.

4. The general arrangement and combination of parts constituting the improvements in the construction of stands or supports for holding photographic albums, ladies companions, and other like articles, as hereinbefore described and illustrated in the annexed drawings.

The ferrous oxalate developer, about which so much has recently been written, does not appear to be altogether free from the unpleasant and, at the same time, inexplicable, vagaries to which so many of our photographic chemicals are subject. In proof of this we may cite a personal experience. A quantity of the solution prepared a little over a month ago has been carefully preserved in a stoppered bottle, the latter being filled to the neck, and the more completely to avoid any chance of oxidation from atmospheric influence the glass stopper was coated with wax. A few days after preparation the solution commenced to deposit upon the sides of the bottle a dirty, yellowish-brown crystalline sediment. We did not attach much importance to this, but were unable to account for it, as the solution was made with *cold* water and was carefully filtered previous to bottling, so that it could not have been supersaturated originally, nor did there appear to be any possibility of such a state of affairs having arisen from evaporation. Upon opening the bottle a few days ago, however, the solution (which upon filtration exhibited no signs of having gone wrong) was found to be completely devoid of developing power. To such an extent was this the case that a plate purposely immersed in the solution for half-an-hour showed not the faintest trace of either image or fog. It was then washed carefully and treated with weak alkaline pyro., when a clean and vigorous image was rapidly formed. But the most surprising feature in the case is that another portion of *the same solution*, from which we had been working almost daily, and which had therefore received a good deal of exposure to the atmosphere, worked perfectly to the last drop, and was only finished on the same day that the reserve bottle was opened. The only difference in the circumstances connected with the two portions of the solution was that the one in constant use was diluted (after filtration) with half its bulk of water. Can it be that the concentrated solution is unstable, while in the diluted state it is endowed with keeping properties? If so, what is the change which occurs to deprive the solution of its power? We are trying the regenerating power of a coil of iron wire, as suggested by Mr. J. W. Swan, and trust it may prove effective.

A NEW SUBSTRATUM.

As so much attention is now being devoted to dry processes generally, and to washed emulsions with and without subsequent preservatives in particular, I hasten to call the attention of all dry-plate workers to a substratum which I believe to be new, and which is giving most satisfactory results in my hands.

I have been working a good deal lately with washed emulsion films treated with strongly-alkaline albumen, somewhat after the fashion of the excellent process introduced by Capt. Abney, and entitled *An Emulsion Process with Beer and Albumen*, and I have found a good substratum a great desideratum. For small plates, such as cabinet, no substratum is necessary, an edging of paraffine and india-rubber, dissolved in benzole and applied before development, being quite sufficient; but for larger sizes it becomes imperative if the highest class of negative be aimed at, owing to the excessive wrinkling of the film. The film is so expanded by the solutions during development that on drying it is apt to form ridges, which become more apparent on varnishing.

I tried all the known methods for holding the collodion film tightly to its glass support, including albumen of various strengths, gelatine, india-rubber dissolved in chloroform or benzole, and French chalk; but all without success. The strongly-alkaline albumen invariably so loosened the film that blisters made their appearance before the negative was finished.

One day, when almost in despair at the apparent impossibility of getting anything to answer, it occurred to me I had never tried gelatine rendered insoluble by means of chrome alum. I hastened to prepare some plates to try whether such a plan would be practically useful, and whether there were any drawbacks connected with it. My first trials were most encouraging, and I am now able to state that it answers most admirably under very trying circumstances. At first I rather feared the chrome alum might make the film less sensitive; but such is not the case. In fact, in some instances the presence of the substratum seemed to render the emulsion film slightly *more* sensitive.

I trust I may not be claiming as a novelty something which is not one; but, so far as I am aware, gelatine rendered insoluble by chrome alum has never before been used as a substratum for the collodion film.

And now to describe, in a very few words, how I have used it. I am not yet certain the proportions I have employed are the very best, many more experiments being necessary before that point can be determined. All I can say is they answer very well. I am just now trying the effect of varying the amount of aqueous dilution, and when my trials are complete will report progress. Soak sixty grains of Nelson's photographic gelatine in water, drain, and pour on enough boiling water to make eight fluid ounces. Now add two drachms of a ten-grain solution of chrome alum, and stir vigorously for a minute or two. Filter the solution through paper* into a clean measure, keeping it warm, and avoiding air-bubbles.

To save trouble a large quantity of each of the solutions—the gelatine and the chrome alum—may be prepared and will keep for a long time if a little pure carbolic acid be added to each. No more must be *mixed* than is required for the batch of plates, as when the compound solution has once become cold it cannot be again liquefied with heat. The measures and filter used must be well washed with warm water as soon as done with, for the same reason.

The cleaned plates are immersed in a dish of warm water. They are taken out one by one, attached to a pneumatic holder, swilled with warm water, and the surface flowed twice with the gelatine solution (which must *not* be returned to the pourer, but may be to the filter); and if care be used very little will run over the back of the plate.

After coating, the plates are placed in a light deal box, the bottom of which is covered with three or four thicknesses of clean filtering paper, in such a way that only one corner touches the side of the box. The lower edge rests entirely on the filtering paper.

Cover the box to exclude dust whilst the plates are drying. They are ready for use very soon, though they improve much by keeping for a day or two; hence it is advisable to prepare a good number at one time.

Although all this sounds troublesome it does not take so long to prepare the plates in the manner just described as it does to dry and polish them in the ordinary way, and I trust that all who may try the method may be as well satisfied with it as I am.

HENRY COOPER.

* Glass wool appears a better medium than paper. I have only tried it since the above was written, but prefer it much.—H. C.

OUR APPARATUS.

No. VII.

PRINT-WASHING APPARATUS.

CONTRIVANCES for washing silver prints are legion, and of all photographic appliances none have been more varied than those designed to effect this purpose. The fact was soon discovered that prints lying close together in a small quantity of water for the purpose of eliminating the deleterious soluble matters contained in them did not answer, even if allowed to remain soaking for several days. Design after design was submitted to the notice of photographers as the most perfect and efficacious plan; but so much depends upon the available water supply, both as to quantity and quality, no one plan could be practicable in all cases. Given, however, a constant and plentiful supply, a trough with a false bottom, regulating syphon, and flapper, worked by a water wheel to keep the whole in constant and slight motion, is, perhaps, as effectual a method as any. In a general way, unless silver prints are washed with a plentiful and continuous change of water their permanency is very doubtful. Prints may be freed from obnoxious soluble matter, providing each is carefully and thoroughly subjected to sponging with warm water, pressing and draining, frequently repeated; but where much work has to be got through the tediousness of such a process is the great bar to its adoption. Where the supply of water is limited, a vessel with a false bottom and regulating syphon to empty it once in every few hours, and the water supply forced through a pipe pierced with very minute holes against the side of the containing vessel to give a rotatory motion to the contents, answers very well if the prints are small—say not larger than cabinet size. The rotatory motion is apt to crumple up larger proofs and so spoil them. Any arrangement by which the proofs are kept in gentle motion, and the water frequently and thoroughly changed, will be found to be tolerably satisfactory.

BACKGROUNDS AND ACCESSORIES.

In these matters, perhaps more than in any other, the photographer has the opportunity of displaying his individual taste or want of it. Backgrounds are of several descriptions—the roller background, the revolving background, those stretched tightly on frames like huge painters' canvases, those arranged after the manner of curtains hung by rings on a rod, and the alcove form. The exigency of the situation generally determines the kind to be adopted. Nothing is better than canvas stretched on a frame and painted in oil colour or distemper—oil colour by preference, as being less liable to injury and more easily cleaned. If a *flatted* oil surface be desired it is almost a necessity that it should be of an uniform and even tint over the whole, the difficulty of blending shades nicely in *flatted* oil being almost insuperable. With ordinary oil painting this is easily managed, and any amount of shades and gradations may be worked on according to the taste of the photographer. The glazed surface of ordinary oil colour is unobjectionable, provided the background be set to lean forward a little at the top, so as to reflect any light falling on it on to the ground and not into the camera. The general effect on the photograph of a leaning background is preferable to one at right angles to the camera. This is especially noticeable if no accessories are used, giving more distance and doing away with that inlaid effect sometimes seen.

These remarks, of course, apply to plain backgrounds. If an interior or architectural design of any kind be painted on it the position must be upright. These designs are, unfortunately, very popular, and are purchased as being pretty things in themselves; but, generally speaking, as soon as a figure is introduced the balance of lines is upset, and an inartistic result is almost certain. Most of our leading men now thoroughly understand that the quieter and more subdued the background is the better. Plain or merely shaded surfaces are usually preferred, unless for some special purpose, as such cannot violate any particular canon of art, or by bad drawing and false perspective offend the eye of the educated critic.

Another objection to sham scenery is that, however accurate the drawing and good the lines with reference to the figure, unless the camera be perfectly level and at right angles to it the drawing will, of necessity, be distorted and bad effects produced. If we call to mind how very rarely this position is used, the camera being seldom kept at the same relative position with regard to the background for any two sitters consecutively, we shall at once see why a plain background is most suitable.

CARPETS.

A carpet of a very decided pattern, of whatever kind it may be, is quite unsuitable for the photographic studio. In selecting them care must be taken not only to avoid a too pronounced pattern but also to choose a good colour—one that will not photograph too dark or too light. A dull crimson (not red) is a nice colour, bearing in mind that any woollen material lying on the ground will come out several degrees lighter than the same hung up directly in front of the camera. A good stout felt drugget is as good as anything, from an artistic point of view, with no pattern on it to speak of. Green carpets are not suitable, as they reflect sufficient non-actinic colour to materially lengthen the time of exposure. The colour of the surroundings should be borne in mind when painting or upholstering a studio, as it has more influence in lengthening or shortening an exposure than one would imagine, unless they had tried it.

Having now reviewed most of the apparatus in general use in a photographic business, I can do little more than reiterate the directions—that care and cleanliness are of all things requisite to keep our apparatus in good and serviceable condition fit to produce those works of art which are the goal of the ambition of so many of us. I conclude by parodying the well-known lines of the immortal bard:—

Costly thy outfit as thy purse can buy,
But nothing sacrificed to ornament;
Well-seasoned and of sound construction,
For apparatus oft proclaims the man.

E. DUNMORE.

NOTES ON PASSING EVENTS.

BY A PERIPATETIC PHOTOGRAPHER.

A LEADERETTE in a recent number of this Journal, devoted to giving the details of a method of filtering, recals to my recollection a mode which was introduced by Mr. F. W. Hart ten or twelve years ago. I do not know whether or not the apparatus is now being manufactured, but I *am* aware of one who prefers it to all methods of filtering the silver bath. For the benefit of those who have entered the field of photography subsequent to the period at which I have hinted, I will give a brief description of this filter:—

In a glass jar or bottle having a *very* wide mouth is fitted a cover or bung containing two holes—one of them pierced through it near the centre, the other towards the margin. In this latter is inserted a glass funnel with its mouth uppermost, so as to permit liquids to be poured into the jar with ease. In the central hole is also inserted a glass funnel, but in this case it must be mouth lowermost, so that when the bung is inserted the mouth will be inside the jar; and, not only so, but the length of the funnel pipe must be such as to allow the mouth to reach within an inch of the bottom of the jar, while the small end stands an inch or two clear above the cork. The mouth of this latter, or inverted, funnel is covered by a cap of thin, close-grained felt, which is retained *in situ* either by an india-rubber band or, preferably, by a piece of string tied round it. To the upper or projecting small end of the funnel is attached an india-rubber tube (pure rubber being necessary for this purpose), the length of which is such that it must, when hanging down, reach to a slightly lower level than the bottom of the jar. To use this filter it is only necessary that the silver solution be poured into the jar through the funnel constructed for that purpose, and the flow of the silver is then started upwards through the felt-covered funnel. This can be effected by suction by the mouth, by an india-rubber ball, or by several other methods familiar to all acquainted with the principle of the syphon. The bath or receptacle into which the filtered solution is to run must, of course, be placed on a lower level than the shelf upon which the jar stands. At the end of a day's work the bath solution may be poured back into the jar as a stock receptacle, and sufficient be drawn off the next merning to suit the requirements of the day. This system is worthy of the highest commendation.

At the last meeting of the Photographic Section of the American Institute a subject of interest was brought under the notice of the members. The Secretary intimated that certain lenses in the possession of a friend of his had become much slower in action than they were eight or nine years ago. I may observe that this fault almost invariably arises from the lenses having been constructed of glass possessing a great degree of density. This description of glass possesses high refractive power, and if obtained quite colourless certainly confers upon the optician the ability to make his lenses with a slightly larger aperture, having, consequently, greater rapidity of action; but in course of time the glass, previously colourless, assumes a yellowish tint and becomes slower than before. In the case mentioned it was said that the lenses had been used for out-of-door work, and that they had been much exposed to light. In saying this, the sole cause of the change was hit upon with infallibility. It has been proved to demonstration, by Mr. Gaffield and others, that by exposing very dense glass to sunlight behind a mask having figures cut in it such figures will, in a very short time, become printed upon the glass in decided yellow tones. Query: is it the lead in the dense glass that renders it sensitive to light? or may it be attributed to a trace of silver having been introduced along with the lead?

It is a happy idea of Messrs. Johnson and Sarony to facilitate the preparation of eburneum pictures by keeping the eburneum material in sheets, to which the picture may be transferred. The old method —which consists of levelling the glass transparency and then pouring upon it enough of a solution of gelatine and white pigment to form when dry a translucent card capable of being handled—answers the purpose quite well; but it necessitates long waiting until the gelatine has set and become sufficiently dry to warrant its removal. While quite admitting, as I cheerfully do, the beauty of an "eburneum," I think that there is still room for improvement in the *plaque* itself. It is of too pronounced an *old* ivory tone of colour, the yellow character prevailing to an extent which would be better if lightened. But here arises the difficulty—in what way or by what means can a layer of gelatine of the thickness of a card, and holding in suspension throughout its substance a white pigment, be obtained in which the yellow colour shall be subdued so as to be at its minimum force? Would it not be possible to obtain some substance in which the colour will be less marked than gelatine? A castor-oil collodion containing sufficient zinc white to render it translucent might probably answer better; but I write this without having tried it.

At the age of sixty-six Herr Friedrich William von Voigtländer, the celebrated Brunswick optician, has been "gathered to his fathers." He enjoyed the reputation of being an operative optician of a much higher order than the majority of his continental brethren; indeed he belonged to a family who had been renowned as opticians for more than a century. In 1840 he became acquainted with Professor Petzval, from whose calculations and under whose directions he constructed the first double portrait combination, Petzval about that time also supplying the formulæ for the orthoscopic lens, which was brought out by Voigtländer seventeen years afterwards, and which was the occasion of much bitterness of feeling between these two noted men of science. Two years after he became acquainted with Petzval he introduced the twelve-lens opera-glass, which has, for the better class of instruments, entirely superseded the pre-existing kind. He has been described as a stately, imposing-looking man, with a florid complexion and long red beard. He was the recipient of several national honours and distinctions during his lifetime. His son, who bears the same name, continues to carry on the business.

(To be continued.)

THE PHOTOGRAPHIC PRINTING PROCESS USED IN THE PORTUGUESE STATE PRINTING ESTABLISHMENT.*

VI.—Heliogravure after the Copperplate Style.

A.—Chromated Gelatine Process.

Reproduction (Without Half-Tones) of Engravings, Printed Matter, Manuscripts, and soforth.

A perfectly level and polished copper plate is coated with chromated gelatine. To dry the films a very simple apparatus is used, consisting of a sheet of cast iron seventy-five centimetres wide, moved quickly or slowly about in a box by means of a crank. Under this movable sheet of iron several gas burners are placed, and the gelatinised plate is laid on the iron and moved about until the film is dry.

The exposure is given either in the sun or by electric light (produced from a Gramme's machine) under a positive *cliché*. The electric light is preferable, as it furnishes extremely sharp and very fine prints. The *cliché* must be very good, but it is not necessary that it should present such sharp contrasts as are required for photolithography—these, indeed, are here rather objectionable than otherwise; still the *cliché* must be pretty powerful and rich in details.

The picture is etched with chloride of iron, which, on the one hand, renders the gelatine insoluble, and, on the other, attacks the copper in inverse proportion to the action of the light. The perfectly-lighted parts of the gelatine act like an etching-ground. If there are both very broad and very fine lines in the drawing the former will not be broad enough to print from; one must then either deepen them with a graver or etch these lines again in the manner to be hereafter described.

Reproductions from Nature: Engravings with Half-Tones.

This time the level and polished plate is first dusted equally over with finely-pulverised resin, and then gently warmed in order to make the resin sticky and cause it to adhere to the plate. The latter is then coated with chromated gelatine in the usual way.

The exposure under the positive *cliché* takes place either in the sun or by electric light. The back and corners of the plate are varnished, and any retouching that may be required is given. The plate is now placed in a solution of chloride of iron, which quickly penetrates the gelatine in the unexposed parts—more slowly the half-tones—and leaves the fully-lighted parts unchanged. The resinous powder lying upon the metal gives a fine granularity of texture, without which the picture could not be printed. The resinous powder, however, does not, unfortunately, admit of getting at the same time both powerful tones and delicate half-tones. The picture is seldom sufficiently dense, and when that is the case the outlines are almost always of exaggerated sharpness. This principally arises from the fact of the granularity of the plate not representing with the same good effect the different parts of the picture. This fault may be somewhat lessened by biting in the stronger tones with a strong solution of chloride of iron, and the half-tones with a weaker solution; or, better still, by etching the same plate twice, for which two *clichés* will be required, differing only in the amount of contrast in the tones that they offer: one must be weak and one strong. It should, however, be remarked here that on account of the exactitude with which the two pictures have to be placed one above the other this double operation presents great difficulties, and can only be successful in the hands of a very skilful operator.

According to the latest experiments an insoluble, dark granular substance may be added directly to the chromated gelatine without affecting either the gelatine or the chloride of iron. (Pounded earthenware has stood the test.) By this procedure the details are more perfect, and the whole is richer and finer than when powdered resin is used.

B.—Asphalte Process.

Reproductions of Pen and Ink Drawings, Prints Without Half-Tones, Manuscripts, &c.—When there is a question of reproducing very fine work it is decidedly best to work according to the chromated gelatine process given under the heading A. Geographical charts, maps, and that sort of thing turn out best with asphalte.

A solution of asphalte in benzine and oil of lavender should be prepared of such a consistency that this varnish, even when thinly put on, resists the etching water. It is poured like collodion over the copper plate, and dried with warmth. This plate is exposed under a *cliché*, either in the sun or by electric light. Should the plate, after being exposed, be still warm, it must first be allowed to become cold, and then be dipped into turpentine until all the asphalte which has not been affected by the light is dissolved. When the drawing stands out clear, then proceed to etch it with aqua fortis.

* Continued from page 232.

Zinc Etching in Relief.

The object of this process is the production of a metallic *cliché*, which may be used with type in the letterpress printing press; that is, may replace the as yet generally-used woodcut. The drawing may be produced on the asphalte with chromated gelatine directly either by hand or by photography, or by transferring a fatty picture which serves to resist the etching.

In all these various cases the drawing must be strengthened, either by a special covering or in some other way before etching. The work is then almost limited to repeated rolling with ordinary lithographic rollers after each time of etching, however slight, over those parts of the metal sufficiently bitten in by the acid, in order to protect them from its further action. The further the etching proceeds the more difficult does this rolling become, because the ink must be forced as far as necessary into the hollows.

For this purpose an oven, having a cast-iron plate, is used as a table; this plate should not be made hotter than 200° C. During the rolling the zinc plate should be laid upon this hot plate. The ink then sinks because the heat makes it more fluid, and so it runs down and fills the finer hollows. The nitric acid must be used diluted at first, and for each succeeding etching it should be taken a little more concentrated. All the time the acid is etching it must be kept moving evenly, and as long as the plate lies in the etching tray the latter should be turned round regularly, either by hand or by a small steam engine.

When the first etching has gone on long enough the zinc plate is taken out of the tray and washed with a brush with benzine, turpentine, or petroleum, and a weak solution of caustic potash or caustic soda. It is then dried upon the not very hot plate of the oven and rolled, but only until the finest lines are filled with the grounding ink. It is then etched again, and one goes on alternately coating with ink and etching until the drawing stands out in sufficiently high relief. The faulty parts must then be corrected and retouched. The plate is now ready to be mounted upon wood, and printed in the letterpress printing press, where thousands of proofs may be pulled from it.

In the following paragraphs a few words will be said of Gillot's high relief etching process, which is now used in many establishments.

Typographic Heliogravure.

For this process a zinc plate furnished with a coating sensitive to light is exposed under a negative. It is the quickest and cheapest process.

It is very important that good metal should be chosen; and the plates must be made *very level*, so as to lie close to the negative and to be equally rolled. The zinc also must be homogeneous in texture, so that the acid may act equally upon it. It must be very compact and have no rents, and it is well to beat it before using it, as that lessens the porosity of the metal and makes it stronger.

It is easily known whether the plate is flat enough if one look at the image of the picture as reflected in its upper surface and bounded by certain lines.

The thickness of the plate may be varied from one to three millimetres; the larger the picture and the greater the distance between the lines the thicker the plate should be. Too thin plates are often difficult to fasten down to the wood. José Julio Rodrigues.

(To be concluded in our next.)

COMPOSITE PORTRAITS,

MADE BY COMBINING THOSE OF MANY DIFFERENT PERSONS INTO A SINGLE RESULTANT FIGURE.*

The best instrument I have as yet contrived and used for optical superimposition is a "double-image prism" of Iceland spar. The latest that I have had were procured for me by Mr. Tisley, optician, 172, Brompton-road. They have a clear aperture of a square half an inch in the side, and when held at right angles to the line of sight will separate the ordinary and extraordinary images to the amount of two inches, when the object viewed is held at seventeen inches from the eye. This is quite sufficient for working with *carte-de-visite* portraits. One image is quite achromatic, the other shows a little colour. The divergence may be varied and adjusted by inclining the prism to the line of sight. By its means the ordinary image of one component is thrown upon the extraordinary image of the other, and the composite may be viewed with the naked eye or through a lens of long focus or through an opera-glass (a telescope is not so good) fitted with a sufficiently long draw-tube to see an object at that short distance with distinctness. Portraits of somewhat different sizes may be combined by placing the larger one further from the eye, and a long face may be fitted to a short one by inclining and foreshortening the former. The slight fault of focus thereby occasioned produces little or no sensible ill-effect on the appearance of the composite.

The front and profile faces of two living persons sitting side by side or one behind the other can be easily superimposed by a double-image prism. Two such prisms set one behind the other can be made to give four images of equal brightness, occupying the four corners of a rhombus, whose acute angles are 45°. Three prisms will give eight images; but this is practically not a good combination. The images fail in distinctness, and are too near together for use. Again: each lens of a stereoscope of long focus can have one or a pair of these prisms attached to it, and four or eight images may be thus combined.

FIG. 1.

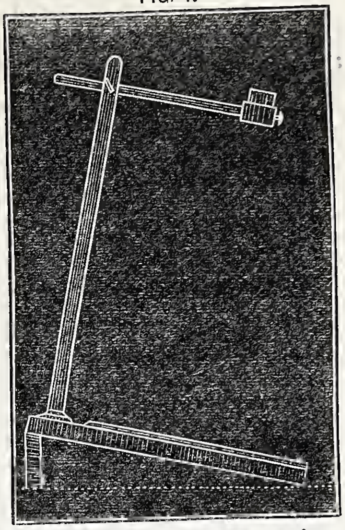

Fig. 1 shows the simple apparatus which carries the prism and on which the photograph is mounted. The former is set in a round box which can be rotated in the ring at the end of the arm and can be clamped when adjusted. The arm can be rotated, and can also be pulled out or in if desired, and clamped. The floor of the instrument is overlaid with cork covercd with black cloth, on which the components can easily be fixed by drawing-pins. When using it one portrait is pinned down and the other is moved near to it, overlapping its margin if necessary, until the eye looking through the prism sees the required combination; then the second portrait is pinned down also. It may now receive its register marks from needles fixed in a hinged arm, and this is a more generally applicable method than the plan with cross threads, already described, as any desired feature—the nose, the ear, or the hand—may thus be selected for composite purposes. Let A, B, C, . . . Y, Z, be the components. A is pinned down, and B, C, . . . Y, Z, are successively combined with A, and registered. Then before removing Z take away A, and substitute any other of the already registered portraits, say B, by combining it with Z; lastly, remove Z and substitute A by combining it with B, and register it. *Fig.* 2 shows one of three similarly-jointed arms, which clamp on to the vertical rod. Two of these carry a light frame covered with cork and cloth, and the other carries *fig.* 3, which is a frame having lenses of different powers set into it, and on which, or on the third frame, a small mirror inclined at 45° may be laid. When a portrait requires foreshortening it can be pinned on one of these frames and be inclined to the line of sight. When it is smaller than its fellow it can be brought nearer to the eye and an appropriate lens interposed. When a right-sided profile has to be combined with a left-handed one it must be pinned on one of the frames, and viewed by reflection from the mirror in the other. The apparatus I have drawn is roughly made, and being chiefly of wood is rather clumsy, but it acts well.

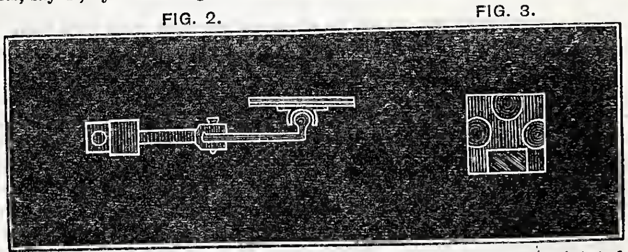
FIG. 2. FIG. 3.



Another instrument I have made consists of a piece of glass inclined at a very acute angle to the line of sight, and of a mirror beyond it, also inclined, but in the opposite direction to the line of sight. Two rays of light will therefore reach the eye from each point of the glass; the one has been reflected from its surface, and the other has been first reflected from the mirror and then transmitted through the glass. The glass used should be extremely thin, to avoid the blur due to double reflections; it may be a selected piece from those made to cover microscopic specimens. The principle of the instrument may be yet further developed by interposing additional pieces of glass successively less inclined to the line of sight, and each reflecting a different portrait.

I have tried many other plans; indeed, the possible methods of optically superimposing two or more images are very numerous. Thus I have used a sextant (with its telescope attached); also strips of mirrors placed at different angles and their several reflections simultaneously viewed through a telescope. I have also used a divided lens, like two stereoscopic lenses brought close together, in front of the object-glass of a telescope.

* Concluded from page 258.

I have not yet had an opportunity of superimposing images by placing glass negatives in separate magic-lanterns, all converging upon the same screen; but this or even a simple dioramic apparatus would be very suitable for exhibiting composite effects to an audience, and if the electric light were used for illumination the effect on the screen could be photographed at once. It would also be possible to construct a camera with a long focus, and many slightly-divergent object-glasses, each throwing an image of a separate glass negative upon the same sensitised plate.

The uses of composite portraits are many. They give us typical pictures of different races of men, if derived from a large number of individuals of those races taken at random. An assurance of the truth of any of our pictorial deductions is to be looked for in their substantial agreement when different batches of components have been dealt with, this being a perfect test of truth in all statistical conclusions. Again: we may select prevalent or strongly-marked types from among the men of the same race, just as I have done with two of the types of criminals by which this memoir is illustrated.

Another use of this process is to obtain by photography a really good likeness of a living person. The inferiority of photographs to the best works of artists, so far as resemblance is concerned, lies in their catching no more than a single expression. If many photographs of a person were taken at different times, perhaps even years apart, their composite would possess that in which a single photograph is deficient. I have already pointed out the experience of Mr. Appold to this effect. The analytical tendency of the mind is so strong that out of any tangle of superimposed outlines it persists in dwelling preferably on some one of them, singling it out and taking little heed of the rest. On one occasion it will select one outline, on another a different one. Looking at the patterns of the papered walls of our room we see, whenever our fancy is active, all kinds of forms and features; we often catch some strange combination which we are unable to recal on a subsequent occasion, while later still it may suddenly flash full upon us. A composite portrait would have much of this varied suggestiveness.

A further use of the process would be to produce from many independent portraits of an historical personage the most probable likeness of him. Contemporaneous statues, medals, and gems would be very suitable for the purpose, photographs being taken of the same size, and a composite made from them. It will be borne in mind that it is perfectly easy to apportion different "weights" to the different components. Thus, if one statue be judged to be so much more worthy of reliance than another that it ought to receive double consideration in the composite, all that is necessary is to double either the time of its exposure or its illumination.

The last use of the process that I shall mention is of great interest as regards inquiries into the hereditary transmission of features, as it enables us to compare the average features of the produce with those of the parentage. A composite of all the brothers and sisters in a large family would be an approximation to what the average of the produce would probably be if the family were indefinitely increased in number, but the approximation would be closer if we also took into consideration those of the cousins who inherited the family likeness. As regards the parentage, it is by no means sufficient to take a composite of the two parents; the four grandparents and the uncles and aunts on both sides should be also included. Some statistical inquiries I published on the distribution of ability in families* give provisional data for determining the weight to be assigned in the composite to the several degrees of relationship. I should, however, not follow those figures in the present case, but would rather suggest for the earlier trials first to give equal "weights" to the male and female sides; thus the father and a brother of the male parent would count equally with the father and brother of the female parent. Secondly, I should "weight" each parent as four, and each grandparent and each uncle and aunt as one. Again, I should weight each brother and sister as four, and each of those cousins as one who inherited any part of the likeness of the family in question. The other cousins I should disregard. The weights as previously mentioned would be bestowed by giving proportionate periods of exposure.†

Composites on this principle would undoubtedly aid the breeders of animals to judge of the results of any proposed union better than they are able to do at present, and in forecasting the results of marriages between men and women they would be of singular interest and instruction. Much might be learnt merely by the frequent use of the double-image prism as described above, which enables us to combine the features of living individuals when sitting side by side into a single image.

I have as yet had few opportunities of developing the uses of the composite photographic process, it being difficult without much explanation to obtain the requisite components. Indeed, the main motive of my publishing these early results is to afford that explanation, and to enable me to procure a considerable variety of materials to work upon. I especially want sets of family photographs all as nearly as possible of the same size and taken in the same attitudes. The size I would suggest for family composites is that which gives one-half of an inch interval between the pupil of the eye and the line that separates the two lips. The attitudes about which there can be no mistake are—full face, an exact profile (say), always showing the right side of the face, and an exact three-quarters, always showing the left; in this the outer edge of the right eyelid will be only just in sight. In each case the sitter should look straight before him. Such portraits as these go well into *cartes de visite*, and I trust that not a few amateur photographers may be inclined to make sets of all the members of their family, young and old and of both sexes, and to try composites of them on the principles I have described. The photographs used for that purpose need not be in the least injured, for the register marks may be made in the case into which they are slipped, and not in the photographs themselves.

FRANCIS GALTON, F.R.S.

* *Hereditary Genius*, p. 317. Column D. Macmillan, 1869.

† Example:—There are five brothers or sisters and five cousins whose portraits are available: the total period of desired exposure is 100 seconds. $5 \times 4 + 5 = 25$; $\frac{100}{25} = 4$; which gives $4 \times 4 = 16$ seconds for each brother or sister, and four seconds for each cousin ($5 \times 16 + 5 \times 4 = 100$).

A TRIO OF SUGGESTIONS.

OUTSIDE of the absolutely necessary paraphernalia of a photograph gallery, I would suggest as one of the most useful a good, reliable amateur printing press, with from six to a dozen, or even more, small founts of various size and styles of types. Woodcuts and electrotypes are now made very cheaply from any design furnished. Photographers can have special designs of their own always ready for printing the ends of their stereo. views, backs of card-mounts, &c., in just as neat a manner as they can be executed by most practical printers, if proper care be taken. For printing envelopes, business cards, circulars, and the thousand and one things of the sort required about the gallery, it will save itself over and over again every year. A "Novelty," in use in our gallery since 1873, has not cost a penny for repairs, and still works like a charm. About twenty founts of type and as many electrotypes have accumulated. In nearly every establishment one can be found who will delight to work it.

Another very essential article, not only in the gallery but any business place, is the letter copying press, or one of the various copying books that require no press, several of which I know from practical experience do their work. Much inconvenience and annoyance is avoided by keeping copies of all letters and orders, and not unfrequently cash is saved and made.

Lastly, and to complete the trio, I would suggest, as almost indispensable, a good clothes-wringer—not to wring your pictures through ten or fifteen minutes after they came from the hypo., as I have seen recommended, for that is all bosh, but after they are thoroughly washed. Take from the water one at a time, and place on top of others till you have three or four dozen, put between two pieces of cardboard, or, better still, between one piece *folded*, pass through the wringer, and mount in that condition if prints have been cut before toning; if not, hang up or spread out to dry. Pictures wrung out dry in half the usual time. And now, perhaps, it would be well enough to "suggest" that the writer has no interest in the sale of any of these articles, but does have an interest in the welfare of his fellow-craftsmen, and is always ready to contribute anything that may be of value to them. W. H. TIPTON.

—*Phil. Phot.*

ROYAL INSTITUTION LECTURES.

COMPOUND COLOURS.—COLOUR BLINDNESS.

LORD RAYLEIGH began his fourth and concluding lecture on Thursday, the 23rd ult., by showing that a combination of yellow and blue liquids produced green, and then explained that the result was due to the impurity of each colour, and that if they had been absolutely pure the mixture would have been colourless. Various methods of combining colours were then exhibited. Thus, with polarised light, greenish-yellow and reddish-yellow gave white. With Professor Clerk Maxwell's apparatus two or three slits produce two or three spectra, and by their overlapping definite portions of the spectra may be mixed. The colours thus formed, or the white light thus produced, may be resolved by the prism into the component parts, and do not give a continuous spectrum. Lord Rayleigh said that red and yellow might be supposed to produce orange, the colour of the spectrum between them, and Maxwell's experiments support this idea; but going upwards from the red, the intermediate colours are not always produced by mixture. Thus, purple—a combination of red and blue—is not represented in the spectrum at all. The yellow of the spectrum can be exactly imitated by mixing red and green, and with due proportions of those colours all the shades of yellow and orange; hence it is concluded that green and not yellow is a primary colour. By rotating discs with sectors of red and green a match was produced of yellow, white, and black; and his lordship obtained a yellow liquid by the mixture of chemical solutions, bichromate of potash (red), and litmus (blue). This colour, when passed through a prism, gave red and green, without yellow, on the screen. To specify any colour three elements are required—purity, depth (by black), and tint (by white). The three colours in the spectrum by which all others can be produced are red, green, and blue; but these colours, his lordship said, are not quite primary. In regard to the sensation of colour, reference was made to Dr. Thomas Young's theory that we have three sets of nerves—for red, green, and blue respectively, the degree of colour of the body looked at depending upon the amount of excitation of each of the sets of nerves. The threefold character of colours favours this view; but the explanation must be sought in the eye itself, as no one colour can be pre-eminently termed primary, and Helmholtz has proved that the sensation of colour partly depends on the state of the eye itself. Thus, after it has been fatigued by gazing on red and blue, the eye will be more excited by green. In the peculiarity termed "colour blindness" blue and green are the only sensations produced in the eye, and to these all tints are referred. To persons who have this defect scarlet geraniums and their leaves are alike in colour, and yellow is dark. Their eyes are not affected by any compound colour into which red and blue enter. This was strikingly illustrated by the rotation of discs to produce matches of colour, selected by a colour-blind person. The colours which appeared green and blue to him were pink and pale blue to persons with normal sight. With these interesting experiments the course was closed.—*Illustrated London News.*

Our Editorial Table.

American Pictures, Drawn with Pen and Pencil. By the Rev. Samuel Manning, LL.D.

London: The Religious Tract Society.

With the work above named we associate in this notice several stereoscopic and other photographic views in America received from Messrs. George Mason and Co. as productions of the camera of Mr. Joseph Collier, formerly of Inverness, and others received (some time ago) from Messrs. Anthony and Co., of New York.

We are placed at a great disadvantage in the examination of views of foreign places and scenes by a want of knowledge as to the nature and history of such scenes, and we felt this in a special degree in the case of Mr. Collier's views, taken during a tour in the Rocky Mountains—a tour made amid scenes replete with romance, and not free from great danger. The outfit of Mr. Collier for his photographic outing contained provisions for two months, with everything likely to be required on an arduous journey over unknown regions, including a miniature tool chest, needles, darning needles, thread, worsted, buttons, and similar articles. He and his companion were armed to the teeth, carrying a revolver attached to each saddle pommel, a large sheath knife, used for all purposes, a rifle packed somewhere handy, and a heavy whip. During this excursion our friend had not only to take photographs but to discover the subjects suitable for photographing—no easy matter in a country almost uninhabited save by rattlesnakes and by other equally pleasant "natives."

The large collection of stereoscopic photographs obtained by Mr. Collier during his long sojourn in the Rocky Mountains and their vicinity possesses a singular degree of interest in themselves as pictures; but there was still something wanting, and that "something" is most ably supplied in the volume now before us. It contains numerous illustrations, which are, for the most part, skilfully and faithfully drawn from photographs, of which, thanks to Messrs. Anthony and Co. and Messrs. Mason and Co., we possess copies. In *American Pictures* we find a graphic account of that strangely-wild and picturesque "Garden of the gods," in the vicinity of Denver; of the Californian geysers; of the Yosemite Valley; and the Yellowstone River, with its hot springs, its falls, its giant geysers, and its gorges. The scenes from Chicago to Niagara, those in the "New El Dorado," in Boston and New England, in the Empire State, in Philadelphia, and Washington are all here illustrated with a profuseness we have rarely seen equalled, the engravings being most effectively done. A book so replete with descriptive matter of scenes such as we have hinted at imparts a double value to the photographs we have alluded to, although, in an illustrative sense, the volume is complete in itself.

Rouch's New Negative Collodion.

London: W. W. Rouch and Co.

This collodion, we are informed, is the outcome of numerous experiments made with different descriptions of pyroxylines and various haloids having different bases, all being mixed together in different proportions. Seeing that several hundreds of changes can be rung upon these materials we can very easily understand the numerous experiments that may be involved in the elimination of any one of the numerous items that interfere in obtaining perfection—a quality which is, of course, unattainable unless a very low standard be set up.

Of the sample of Rouch's new collodion, upon which we have been requested to give our opinion as we find it, we are able to say that, mechanically, it flowed easily and gave a clear, even, structureless film—a matter in the determination of which we called in the aid of the microscope. Having sensitised plates by means of a thirty-five-grain bath, we obtained a film possessing the acme of uniformity; and on exposing plates thus prepared in the camera we obtained, with a very brief exposure, negatives which were as rich and full of detail as any that we could desire to see. There is a bloom and vigour about them which is very attractive. We are unable at present to institute a comparison between the "new" and the previous collodions of Messrs. Rouch and Co., but from our recollection of the latter we recognise in the new claimant for public favour certain qualities not wholly possessed by its predecessor, and for this reason we expect that this collodion will secure a large share of public favour.

Phantom Flowers, and How to Produce Them.

By Mrs. D. H. Cussons, Southport.

With the appropriate motto attached—"A thing of beauty is a joy for ever"—several stereoscopic views of skeletonised leaves, tastefully arranged, secured upwards of fifteen years ago a large share of public favour. Such leaves are most assuredly "things of beauty," and it is scarcely to be wondered at if their production occupies many of the leisure hours of the fair sex, for this kind of work tends to elevate the taste and refine the feelings of those who engage in it.

Mrs. Cussons, the authoress of the *brochure* before us, is entitled to speak with all the force conceded to an artist who has received both the silver and the gold medals of the Royal Horticultural Society for the technical perfection and artistic grace of arrangements of skeletonised leaves; and in *Phantom Flowers* we find many useful hints upon the method of producing these fairy-like forms. There is a very useful table given from which we ascertain the time approximately required for boiling the various classes of leaves mentioned in order to their being skeletonised. We should have preferred that the talented authoress had not been so reticent in giving formulæ for the preparation of the liquid itself; but we may state that we have seen several exquisite results obtained by boiling the leaf in a strong solution of the common washing powder that is sold in halfpenny and penny packets. Mrs. Cussons says:—

> "We can imagine no more fascinating work for leisure hours in the country than that of dissecting leaves or capsules for household or dress ornamentation. Let the amateur first aim at securing perfect specimens. It may be admitted that even imperfect leaves, when purely bleached and nicely mounted, form pleasing objects; but we say—never rest satisfied with anything short of absolute perfection in anatomy and colour; then strive to display your specimens in an artistic and elegant form."

We cordially endorse these sentiments.

Non-Actinic Muslin.

London: J. Solomon, 22, Red Lion-square.

The non-actinic muslin introduced some years since by Mr. Solomon has for a long period satisfied the requirements of photographers, especially those who have practised the wet collodion process; but within the last two or three years and now, in consequence of the greater use of bromides than previously, a demand has been made for diaphanous material of a still more non-actinic nature than before.

It is easy to perceive that the yellow and orange light, under which iodised films have been worked, is quite unsuited for the experimentalist with the extremely sensitive preparations which are now being so extensively employed; and Mr. Solomon, to keep pace with the times, has entirely changed the colour of his non-actinic muslin. A sample which we have received is of a peculiar ruby-orange colour, which, upon trial, we have found highly effective as a medium through which to admit light into the operating room. The muslin is merely the textile basis upon which is spread a flexible substance, like oxidised oil of a deep ruby colour, and which is highly transparent. This material is very handy for extemporising a dark room in any place where such is required; for, from its transparency and flexibility, it can be adapted to almost any conceivable circumstances connected with lighting. For example: a piece of cardboard may be bent round like a cylinder to surround a candle, and an aperture cut in this, and "glazed" with the muslin, provides a safe means of illumination for manipulating even the most sensitive plates. Or a window totally obscured by means of brown paper can have an aperture of any desired dimensions fitted with the muslin, which will thus admit a sufficiency of daylight by which to see to work, shorn of all its chemical influences. The various trials to which we have subjected the muslin prove that it is an appliance of a most useful character.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
June 11	Photo. Society of Great Britain	5a, Pall Mall East.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

The usual monthly meeting of this Association was held on Thursday evening, the 30th ult., at the Free Public Library, William Brown-street,—Mr. H. A. Wharmby, President, in the chair.

The minutes of the previous meeting were read and confirmed.

Mr. W. E. Potter exhibited two prints from the same negative, the one being so decidedly superior to the other that Mr. Potter was asked to explain how the difference arose. He said that on varnishing the negative it proved insufficiently intense, giving a weak print with no contrast. Following the advice of the President he heated some alcohol by placing the bottle in hot water, and when sufficiently warm poured the alcohol on and off the negative until the varnish was all dissolved off the plate. When this was the case—which he ascertained by dropping a drop into cold water without producing milkiness—he proceeded to intensify the negative while still wet with pyrogallic acid and silver in the usual manner. He (Mr. Potter) found no difficulty in taking off the varnish and intensifying, and was delighted at the manifest improvement of the negative, for which he had carried his camera a bicycle journey of over forty miles to obtain.

The Rev. T. B. Banner exhibited some prints from Liverpool collodio-bromide plates which had been prepared ten years ago. They developed easily, and showed excellent keeping qualities without having lost their sensitiveness.

It was decided to defer the visit to Speke Hall until July, when an excursion could be made there instead of the usual monthly indoor meeting.

Several of the members related their photographic experiences at home and abroad, and the meeting was adjourned until the 27th inst.

Correspondence.

The Transit of Mercury.

It affords me much pleasure to be able to transmit to you the report to the Minister of Public Instruction of the observations made in Ogden, California, which, under date of May 7th, has just been received here. This report is signed "Ch. André," and is as follows:—

Monsieur le Ministre,—I have the honour to address to you the summary report of the observations made at Ogden on the 6th of May. The general plan that we adopted was the following:—

1. *Direct Observation of the Phenomenon.*—M. Halt, Hydrographic Engineer of the Marine, and myself had at our disposal, each of us, an equatorial of six inches in diameter. The observation of the first internal contact was for the purpose of ascertaining whether the black ligament, black drop, or bridge produced itself necessarily when the whole of the six inches opening was used and the solar image received by the eye in all the intensity that this organ can support; whether its dimensions and its intensity increased when the opening of the lens was diminished; and, finally, if we could reduce at our will the dimensions and intensity of the ligament in gradually increasing the absorptive power of the blackened glass employed for the observation. The observation of the second internal contact ought to have served to complete the results of the first internal contact, and to try a screen of a particular nature formed of narrow rings or diaphragms alternately open and closed, and which former experiments lead me to believe excellent for the purpose. The external contacts ought, besides, to be watched with care, and during the duration of the passage each of us were to examine the surfaces of the sun and of Mercury, and especially the environs of the solar disc in the whole of the space surrounding the planet.

2. *Photographic Observations.*—The photographic observations were directed by M. Angot, Professor of Physics at the Lyceum Fontanes. M. Angot proposed to compare the two results of the French photoheliograph and that which the American astronomers had employed during the last passage of Venus, as well as the different processes which were habitually used for such observations, and, finally, to study the influence that the duration of exposure can have in this case upon the sharpness of the images. M. Angot took charge of the photoheliograph, and confided the American instrument to Mr. Francis Klett, Civil Assistant of the Geographic Service of the United States, to the west of 100° meridian, and to Mr. Hoffman, photographer, of Ogden.

The state of the sky did not permit us to realise entirely the above programme—at least for the direct observation. In fact, on the afternoon of Sunday, the 5th, the weather, which for a week had remained fine, suddenly changed, a strong wind sprung up, bringing to us clouds of dust and sand, and the heavens were covered. The barometer fell rapidly, and we were soon obliged to nail the canvas roofs of the cabins and observatories, which up to that time had been fixed with cords, and which the wind now threatened to carry away. During the night a little snow fell; nevertheless, at four o'clock on Monday morning the heaven was bright and the wind had nearly ceased, the barometer had risen, and we thought that the storm was ended. But towards 6.30 a.m. the clouds again invaded the sky, and at 7.30 the snow recommenced to fall in small flakes. We saw Mercury, notwithstanding, several minutes after its entry upon the solar disc. At eight o'clock the snow fell abundantly, the wind rose again very violently, and we were in the middle of a hurricane—no longer of sand like the day before, but of snow; and, as on Sunday, we were obliged to closely nail down the roofs of our cabins. This horrible weather lasted until 11.45; a gap then appeared in the clouds, and M. Angot was able to take several photographs. From this moment the weather improved, little by little; the openings in the clouds became more and more frequent and lasted longer, but never, during the whole duration of the passage, was the sky entirely clear. Towards 2.45 a great gap was made in the vicinity of the sun, and, the moment of the final contact of Mercury approaching, hope returned to us. We were not deceived. That part of the sky around the sun remained pure until the final issue of Mercury, which we observed under excellent conditions, but a minute after the observation of the external contact and separation the sun was again concealed by the clouds.

As the results of the direct observation—our non-ability to see the entry having modified our first programme—our efforts were directed to the study of the black ligament. M. Halt made use of the full aperture of his equatorial. At 3h. 14m. 9s. (Ogden time) he perceived the first trace of the ligament. It was then a simple obscure train reuniting the margin of Mercury to that of the sun. Bringing, then, in front of his eye a portion of the graduated black glass, he saw the ligament disappear. Soon after it reappeared, and he made it disappear again by the same means, and so on alternately, until the moment when the two celestial bodies appeared in actual contact at 3h. 14m. 28s.

I had reduced down to four inches the six inch opening of my equatorial. At 3h. 14m. 5s. I saw the first trace of the ligament. After the lapse of several seconds it became very large and very obscure, comparable sensibly in dimensions to those of the diameter of the planet itself. Upon removing the diaphragm I saw the ligament reduce itself more than half; but on replacing the diaphragm, and then using a graduated blackened glass, I made the black ligament to disappear. The two stars then appeared very sharply, distant one from the other. Restoring the darkened glass to its original position the ligament reappeared very large and very intense, and this was repeated a second time with the same results. At 3h. 14m. 32s. the two stars appeared in contact.

These two observations appeared to me to resolve the first part of the programme enunciated above; and, in employing the simple and methodical plan which M. Halt had used during the observation of a contact of Venus, but was much more easy than that of a contact of Mercury, it seemed to me to attain an *approximation of at least two seconds of time*.

We have not remarked anything particular, neither on the planet nor upon the regions of the sun which surrounded it successively.

The Exit.

1st contact,	3h. 14m. 32s.	M. André.
"	3h. 14m. 28s.	M. Halt.
2nd contact,	3h. 17m. 18s.	M. André.
"	3h. 17m. 26s.	M. Halt.

The Photographic Observations.—An accident which occurred during the storm of Sunday to the photographic apparatus, which the astronomers of Washington had lent to M. Angot, prevented him from employing it during the brief period that the sky was clear, so the number of photographs obtained with this instrument was restricted to thirty. With the photoheliograph, on the contrary, profiting by all the gaps in the sky, M. Angot has been able to obtain forty-eight photographs of the phenomenon. Thirty of them have already been examined, and even those which have been taken when the sun was veiled by light clouds are good. Precise measurements alone will permit an exact opinion to be formed upon the relative value of the two instruments and of the different processes employed. This requires much time. M. Angot will commence these measures as soon as he returns to France, and he will have the honour to communicate to you the results and the conclusions to be drawn.

To the foregoing report I have merely to add a word of explanation. In the original the term "different *collodions*" has been employed, but as it is obvious that *processes* were meant I have adhered to the latter term.
W. Harrison.

Asnières (Seine), June 3, 1878.

Gelatine and Chrome Alum.—Carbon Printing at the Antipodes.—What is Art?

I have just been making a few experiments with some gelatine and chrome alum. Many, I daresay, have remarked how different samples of gelatine take the latter substance, and oftentimes I have found out too late that I had too much chrome alum present, although using the same formula as usual. Having with me two or three samples of Nelson's gelatine and one of Swinbourne's patent gelatine, I made a solution of each of the strength of two drachms of gelatine to two and a-half ounces of water. The temperature of my room was 84° F., and the water bath in which they were dissolved and mixed 104° to 108°. The accompanying table will give you the results. Of course this does not say much, as solutions of a more concentrated form would, in all probability, take less in proportion to the amount of gelatine.

Nelson's Opaque.	Nelson's Amber.	Nelson's Flake—1.	Nelson's Flake—3.	Swinbourne's Patent.
Three and a-half grains of chrome alum to two drachms of dry gelatine.	Three grains of chrome alum to two drachms of dry gelatine.	Three grains of chrome alum to two drachms of dry gelatine.	Three grains of chrome alum to two drachms of dry gelatine.	Four grains of chrome alum to two drachms of dry gelatine.

When mixed with bichromate of potassium they seemed all to take a little more chrome alum—particularly Swinbourne's patent gelatine.

I hear that one of the capitals of Australia is shortly to be honoured with a visit from a French gentleman—an operator in photo-mechanical printing—to see if there be room for him to start in that line. I fear he will find the country a little too young yet, as there are really not a sufficient number of manufacturers to supply work in that branch, while the Government is already provided with one in the person of your correspondent.

I find to my delight, and I hope also to that of all disinterested photographers, that the carbon process is likely to be pretty well worked in this country. One house showed me some prints taken a few days ago. They were portraits, and very fine impressions. The tissue was prepared in a bath containing only one-half per cent. of bichromate of potash, and sensitised in a room with the thermometer standing at about 89° to 90°. This ought to give encouragement to carbon workers.

While on the subject of carbon let me remind such of my *confrères* who are troubled with reticulation of the very simple method of collodionising a glass plate (previously waxed or rubbed over with talc powder) with normal collodion. Let it dry, and when the paper is taken out of the bichromate bath lay it on the plate, and rub down gently with a squeegee. In making some transparencies a few days back I was troubled with it, but on using the collodion it entirely disappeared.

I am afraid I shall get into trouble here with our friends the artists. I often think how monstrous it is for a class of persons, working with colours and brush, trying to imitate nature with more or less success, and calling that "art." What art? The art of mixing colours and imagining all sorts of unnatural combinations, leaving out the very essence of nature, and then standing upon a pedestal, exclaiming—"Ours only is art!" Let us take a leaf. The photographer by his tools—camera, lens, chemicals, light, &c.—represents every dot or form that Nature has given it, but does not by itself give colour. The artist or colourist, by a few dabs of his brush, produces something resembling in colour the leaf, but wofully deficient in those parts that make the leaf what it is—Nature's own work, and which photography only can do. These two agents are therefore imperfect; one has not colour, and the other lacks detail. How, then, can the one tell the other he is deficient? I think the days are gone by when the colourist can call his own imaginings "art," and those of photography "artless." Seeing that good photography and skilled men—men who have art in them, but after Nature's will and not after man's old-fashioned notions—now find admirers for their works when the *soi-disant* artist (who only condescends to permit the existence of photography to suit his own purpose of copying or getting tit-bits) is gradually becoming alive to the fact that "Othello's occupation" is *going*. L. H.

Sydney, March 16, 1878.

OXYGEN RETORTS.

To the Editors.

Gentlemen,—Once more in self-defence I crave your indulgence.

In your last issue Mr. Young charges me with copying his "patent retort," which he states he exhibited to a few members and friends at the Manchester Photographic Society's meeting on February 14, 1878. He should also have mentioned that the exhibition was made privately, as he was informed officially that he must not exhibit the apparatus before the company.

On this same evening I myself was fully occupied, having a paper to read, some experiments to perform, and a lantern exhibition to conduct, and was therefore not able to give attention to Mr. Young's private exhibition. Up to now I have never seen the apparatus in question, nor have I since (to my knowledge) had conversation with any one who did see it. That Mr. Young can now claim a safety-valve arrangement to an oxygen retort seems to overtop his previous claims, for in this Journal, June 15, 1877, page 287, *he denounced the principle as worthless!* I am, however, glad to see he has had the good sense to adopt the principle (which is mine), and which was first published by me.

Mr. Young is in error when he states that his apparatus is worth copying. No one needs to copy his, knowing full well (as nearly every lantern man in Manchester does) that the so-called Young's retort is directly obtained from Mr. Noton's, both in principle and shape; and that the gas-holder is a feeble copy of that of Mr. Samuel Highley.

It was as an amateur that I published my retort, and only through the cantankerous spirit of Mr. Young, and frequent solicitations from others, was I driven into the manufacture of the same. I am now making dozens, and shall continue to do so in spite of any empty threats emanating from Mr. Young.

In conclusion: I beg to say I object to using your "Correspondence" column as a medium for advertising; and, moreover, a controversy has already taken place in which Mr. Young not only lamentably displayed his weakness, but was left fully aware of the invalidity of his so-called invention. As a renewal of the same would, I am sure, be monotonous to your readers, I must decline to hold further argument in the matter (at the same time remaining quite satisfied that I have maintained my own *unpatented* invention), and must treat further correspondence from the same source on this subject with silence.—I am, yours, &c., W. J. Chadwick.

Prince's Bridge, Manchester, June 3, 1878.

APPLICATIONS FOR NEW PATENTS.

January 14, 1878.—"Production and Preservation of Coloured Photographs. No. 176."—Gertrude Dale.

February 2, 1878.—"An Improvement in Illuminating Objects to be Photographed and the Interior of Public and other Buildings. No. 446."—H. V. Weyde.

February 5, 1878.—"Preparing for, and for Imparting to, Photographs and other Illustrations of all kinds the Tones and Tints of Natural Colours, for Rendering these Representations more Real and Lifelike, and for Improvements in Mounting them and Coupling them together, and in Enclosing them in or between Glass, Metal, Leather, Wood, Vulcanite, and other Frames, or Cases, or Ornaments, Parts of all of which are Applicable to other Useful Purposes. No. 481."—H. R. Newton.

February 28, 1878.—"Folding or Portable Tents. No. 818."—L. Field.

March 6, 1878.—"A New or Improved Chemical Process for Converting or Transforming Paper Photographs into Oil Paintings upon Canvas, Wood, Metal, or other Materials. No. 906."—A. Prager.

March 19, 1878.—"New or Improved Pneumatic Arrangements for Facilitating the Uncapping, or Exposing and Capping, or Shutting the Lenses used in Apparatus for Depicting Persons or Objects by Photographic Means. No. 1097."—J. W. T. Cadett.

April 9, 1878.—"Producing and Correcting Negatives, without Photography, by the Aid of Paper Types. No. 1407."—C. Wayte and C. Herzog.

April 11, 1878.—"Means and Appliances for Producing Powerful Artificial Lights for Photographic and other Purposes. No. 1442."—G. E. Alder and J. A. Clark.

April 11, 1878.—"An Improved Photographic Camera. No. 1448."—S. W. Rouch.

April 12, 1878.—"Reproducing, by Photography, Designs for Lace, Net, or other Woven Fabric; and, at the same time, Producing Guide Lines by which the Openness or Closeness is determined. No. 1458."—N. Garthwaite.

April 15, 1878.—"Producing Stippled Tints, Backgrounds, and Vignettes upon Photographic Pictures. No. 1502."—M. Gutterburg.

April 24, 1878.—"Improvements in or in connection with Photographic and other Pictures. No. 1646."—H. Brassinne.

April 25, 1878.—"Improvements in or connected with Stereoscopic Slides and Frames. No. 1675."—E. J. Hebert.

May 17, 1878.—"Improved Photo-Chemical Process for the Production of Metallic Plates for Printing Purposes in General, for Jewellery, Signboards, and Plates. No. 1979."—A. Michaud.

May 18, 1878.—"Means or Apparatus Employed in the Manufacture of Carbon Tissue or Pigment Paper. No. 2007."—O. Sarony and J. R. Johnson.

May 30, 1878.—"An Improvement in the Production of Enlarged Photographs with Artistic Finish. No. 2174."—A. Harman.

Photographic Society of Great Britain.—At the next meeting of this Society, which will take place on Tuesday next, June 11, at 5, Pall Mall East, the following papers will be read:—*Alizarine: its Nature, Properties, and Applications to the Arts, and Particularly to Photography*, by J. R. Johnson; *The Alleged Fading of Carbon Prints*, by T. Bolas, F.C.S.; and *Photographic Notes from Travels in Russia, with Exhibition of Works, Materials, and Apparatus Presented and Collected in that Country*, by Leon Warnerke; also, an original method of preparing pigment and transfer papers will be shown by O. Sarony.

EXCHANGE COLUMN.

Wanted to exchange, a Tench's No. 2 baby lens (£20) for a good cabinet lens.—Address, Tear, 12, Clapham-road, S.W.

A first-class French lens, four inches in diameter, with mahogany camera for the same, is offered in exchange for anything useful.—Address, W. Slater, 166, Grange-road, London, S.E.

A universal accessory for the studio, eight changes (cost £8), will be exchanged for a rapid *carte* lens, six inches focus, or anything useful in photography.—Address, G. Bates, 12, Ryland-road, Birmingham.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

W. Weston.—Received. In our next. A proof will be forwarded to our correspondent.

J. B. H.—The cause of the granularity must be sought for in the condition of the silver bath.

Tyro (Brixton).—By making the hyposulphite of soda bath much stronger you will in future be free from the stains which now destroy the prints.

B. P. S.—To prepare the insect for being photographed, place it in a solution of caustic potash according to the directions given in treatises on the mounting of microscopic objects. It must finally be mounted in balsam.

E. C. (Edinburgh).—The statement which you saw in a former number of this Journal is quite correct; it is *not* legal for any photographer to retain a still in his possession, even for the purpose of distilling water, without the permission of the Excise.

G. P. (Jersey).—We find in our own practice three inches a suitable distance at which to mount the lenses apart. This gives a sufficient degree of relief for the majority of subjects, and, when making use of plates seven or seven and a-half inches in length, leaves a small space at each end for marginal defects.

J. Brodie.—From the description of the lens we have no hesitation in pronouncing it to be one of the orthographic *genus*. It is probable that you will find it to be an excellent instrument, defining well with a large stop upon a field of limited dimensions. By making use of a small diaphragm—*e.g.*, $\frac{f}{30}$—it will cover a 12 × 10 plate well.

An Opal Enlarger.—We have no doubt that you have, as you state, made upon opal glass hundreds of pictures which have not faded; but before we know the value of this statement in connection with the "answer" to which it gave rise, we would require to know whether you adopt any of the processes we condemned. For example: do *you* tone with mercury?

Geo. Fox.—It is of little consequence whether the negative be intense or not, provided it possess a fair degree of relative density. Intensity is of the greatest importance in a negative that is intended to be printed from upon paper, but not so when it is to be used for printing upon a sensitive dry collodion plate; for upon the latter the intensity may be controlled to any desired extent by means of the developer.

G. P., Jun.—To ascertain the solvent powers of the various samples of cyanide of potassium in which you feel an interest, make solutions of each of a definite strength—say twenty grains to the ounce of water—and then saturate each with oxide of silver. Proceed in such a manner as that you may tell with accuracy the relative quantities dissolved by each solution, and in this way a fair idea of the solvent powers of each may be ascertained.

Forged Lenses.—Our attention has been drawn to the fact that on the continent some forged English lenses have recently made their appearance. One of these which we have seen is a whole-plate French lens of the most common type, having engraved on the mount in very large and imposing letters, "Dallmyers 3-B 3880 A.B. patent." Quite apart from the error in the spelling of the name, no one who has ever seen a lens manufactured by Mr. Dallmeyer could possibly be mistaken in supposing such instrument to be one of his productions. Still, it is possible that unwary people, especially on the continent, may be deceived. This points to the desirability of making purchases only from respectable or well-known persons.

W. Danks.—Having given a moderately-quick exposure to the plates sent by you, we found it an exceedingly difficult matter to get an image developed; but by dint of patience we eventually got images on both plates, these images being very beautiful and full of detail, but so feeble that a cursory observer would at first sight pronounce the plates to be free from any picture. The developer we employed was alkaline pyro. without any bromide in one case, a few grains of Epsom salts having been dissolved in the water in order to prevent the puckering of the film, which we expected to take place, but of which there was no indication. Your request will be forwarded to the gentleman named as soon as he returns from the continent, where we understand he is at present. There was no appearance of fogging on your plates.

W. L. R.—1. Make in one bottle a solution of four grains of pyrogallic acid and three grains of citric acid in two ounces of water, and in a second bottle a ten-grain solution of nitrate of silver. To intensify, after washing the plate, apply sufficient of the pyro. solution to cover the surface thoroughly, and then pour it off into a measure containing two or three drops of the silver solution, after which the whole is applied to the plate. The proportion of silver may be increased, but it is always desirable to use as little of it as possible.—2. The placing of blotting-paper behind a plate will not answer as a substitute for a proper backing to it unless the blotting-paper, which we assume to be of a red colour, has been made wet and is closely pasted to the glass. It is much better to employ a mixture of gum water, glycerine, and Spanish brown, the proportions of the glycerine being such as merely to prevent the gum from drying too hard. The most suitable proportions are attained when by the first application of a wet sponge to a dry backing it shall become sufficiently soft to be easily removed by washing with water, and such proportions may be found by making one or two trials when preparing a supply of backing material.

Geo. Reid.—Provided you can have the solar camera mounted in a very rigid manner upon the equatorial stand it will answer quite well; but we imagine that it will be found much more convenient in practice to adopt the system upon which Dr. Monckhoven constructs all his best cameras, viz., to have it placed in a horizontal, stationary position, and direct the solar light by means of a heliostat.

Erratum.—In Mr. J. Harmer's article, in our last number, on *Stereoscopic Transparency Printing*, at page 254, second column, eighth line from foot, for "plug" *read* "play."

Artistic Mounts.—Mr. Robert Banks, of Manchester, has submitted for our examination several specimens of a style of mount that is being manufactured by him, and the nature of which may be ascertained from our description of one or two of them. Imagine a photograph of a picture frame with very ornate surroundings, including curtains and other elaborations, the photograph being mounted on a card mount in the usual way, but the centre or vacant space in the picture frame cut out *a la passe-partout*, or "cut-out" mount, and a fair idea of Mr. Banks's system of mounts will be obtained. It will be obvious, of course, that a portrait may, by the simple act of placing it behind the aperture, be "framed" as well as mounted in a few minutes. Whatever opinion may be expressed as to the artistic value of mounts in which the ornate element is strongly pronounced, there can be no doubt as to the technical excellence of these productions of Mr. Banks.

"A Mistake Corrected."—Under this heading our excellent transatlantic contemporary, *Anthony's Photographic Bulletin*, points out an error into which we have inadvertently fallen in attributing to that journal a statement which was in reality made by a writer in another American contemporary. The editor of the *Bulletin* says:—"In The British Journal of Photography of the 5th of April, the Editor by an oversight has attributed to this journal an article which in reality was published in the *Philadelphia Photographer* over the initials 'W. B. C.' As this article is a hysterical denunciation of carbon printing, and a general condemnation of anything outside of the ordinary humdrum routine, it might very well appear in the Philadelphia journal '*without comment*.' We hope that the Editor of The British Journal of Photography will correct this error, and thus relieve the friends of carbon printing of the impression that we, who have been the firm friends of carbon printing and general improvement in this country, could thus go back on our own record and make no sign." Our explanation as to the occurrence of this mistake is simple, and will, we trust, be accepted as satisfactory by our brother of the *Bulletin*. To suit the exigencies of space, our printer was compelled to remove a small paragraph on a different subject which immediately preceded the one in question, and in which the *Philadelphia Photographer* was mentioned, and it was to this latter journal, and not to the *Bulletin*, we alluded when we made use of the words "in the same periodical"—an error the occurrence of which, we need scarcely say, we much regret.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician, *For the two Weeks ending June 5, 1878.*

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 945. Vol. XXV.—JUNE 14, 1878.

ALIZARINE IN PHOTOGRAPHY.

It is rather difficult to say what is or is not a subject of interest to bring before a photographic society; but we believe that many of our readers will be inclined to class *alizarine* as one of those topics not calculated to evoke much sympathetic feeling in their minds. Not that the subject is unimportant, for, on the contrary, as we shall show, it should be, and doubtless is, replete with interest, especially to the manufacturers of carbon tissue; but by the general public it will be classed as on a par with a disquisition on certain phases in the preparation of the glass used by opticians for constructing lenses. All are benefited by the production of good tissue and good lenses; but the technicalities of their respective manufacture are considered sufficiently safe in the hands of the manufacturers. Thus much in the interests of that large portion of the public who do not care in what manner the colouring matter of carbon tissue is prepared, so long as good tissue is supplied by those who make a speciality of its production.

It must be admitted that the paper read by Mr. J. R. Johnson at the meeting of the Photographic Society of Great Britain, on Tuesday evening last, was the means of imparting more information with respect to the nature and properties of alizarine than has ever before been presented to the public in an equally condensed form. Mr. Johnson, being an experienced chemist, can speak on such a subject as that in question in an authoritative manner; and, if in the discussion that followed, some exception was taken to certain of his remarks *apropos* of the general subject, the remainder of his observations were received in an unquestioning spirit.

Alizarine, we may here once more observe, is the colouring matter of madder, and its use in photography is to impart a warm tint to carbon tissue, which, without some such modifying pigment, would be of a more purely black tone than is desirable. In the early days of carbon printing carmine was added for this purpose. Experience, however, showed that the bloom communicated by this beautiful pigment was fugitive; hence the necessity for securing some more stable colouring matter that would bestow a similar bloom.

It is well known that the dyestuff known as "Turkey red" is one of the most stable of the cotton dyes; Mr. J. W. Swan naturally, therefore, sought to use this material in lieu of the unstable cochineal. The colouring principle of the dye is derived from the roots of madder, and, as Mr. Johnson has explained, it is known through the East under the designation of "alizarine." It is one of the triumphs of modern chemistry that the colouring principle of madder is capable of not only being separated from the root itself, but has also been extracted from that fertile source of brilliant colours—common coal; and this colouring principle, when thus isolated, receives the special name of "alizarine" whatever be the source from which it may be derived. Thus alizarine is imported into carbon printing to serve the useful purpose of imparting a warm tone, which mere carbon alone will not do.

But, recently, Dr. Monckhoven challenged the propriety of the use of this colouring agent, and he denied to it that property of permanence which Mr. Swan and others believed to be its characteristic. Mr. Johnson, as an early advocate for the use of alzarine, has taken up the cudgels in favour of this pigment, and offers his paper as a reply to the statements made by Dr. Monckhoven. The matter, therefore, stands at present as under discussion between two distinguished men, each of them more or less qualified to speak on the subject. Mr. Johnson very frankly accuses Dr. Monckhoven of both imperfectly understanding his subject and inefficiently introducing the pigment into tissue as a colouring agent; and he gives his reasons why Dr. Monckhoven has failed to secure the stability of this pigment, and also, by inference, why he (Mr. Johnson) has succeeded.

We can scarcely consider the matter as settled till we have heard the further rejoinder of Dr. Monckhoven. Meanwhile, however, our readers will now understand not only what alzarine is, and its importance, but also why the subject should be specially discussed, seeing that its efficiency has been so decidedly challenged. For full particulars we must refer the reader to Mr. Johnson's paper, which will appear in our next issue.

It may be thought that the matter might very well have rested between Mr. Johnson and Dr. Monckhoven, but, strangely enough, the discussion has resolved itself into a "triangular duel;" for Mr. Johnson, not content with exposing what he believed to be the fallacies of Dr. Monckhoven, considered it also his duty to twit the Autotype Company with both ignorance and neglect of this useful colouring agent. Upon this Mr. J. R. Sawyer rose, and in his turn, as representative of the Company, assailed both Dr. Monckhoven and Mr. Johnson, and thus it is "a very pretty quarrel as it stands," but one from which the public will be the gainers. It is a matter for sincere congratulation that those interested commercially in the preparation of carbon tissue should display so much assiduity in presenting productions possessing such a degree of excellence as to be beyond reproach.

OPERATORS AND APPARATUS.

It is, perhaps, a little unusual to link together the animate and the inanimate in this fashion; but, as in actual photographic life they hold together so much, they may be coupled in describing their virtues and their vices.

Possessing, as we do, opportunities of frequently visiting the *ateliers* of photographers of all grades and of all degrees of skill, we naturally come across operators of varied attainments and idiosyncracies; and we have found in the course of our experience that the habits of the operator may generally be predicated from an examination of his apparatus. As it may be quite as useful to point out occasionally what not to do as what to do, we shall this week give some idea of a recent experience we have had in manipulating ethics, so to speak.

We happened to form one of a number of friends who were being subjected to the painful operation of posing and photographing in a group. Our first entry into the studio gave us an idea of the operator. In various places were hung examples of his skill, which, there is no doubt, is considerable, though in the practical method of displaying it a large amount of waste, we are sure, must have been incurred. The cameras were all dirty, and covered with that peculiar hazy film which French-polished articles ignorant of the effects of an occasional polish are so liable to become coated with if they are not frequently rubbed with a cloth. The brasswork of the lenses was all rusted—if such a term may be used to brasswork—and the extra dark slides and every piece of apparatus not made use of in everyday routine were covered with dust and dirt, so that to handle them was to get our hands thoroughly well soiled at the outset.

Now, how easy to avoid these initial causes of annoyance! A dry cloth used to the lens mounting once a week would enable it to be preserved for years in its pristine brightness, and a slight cupboard would have been all that was necessary to keep the stray apparatus free from dust and dirt. A cupboard there was in the dark room and conveniently placed for the dark slide—evidence of the carefulness of a predecessor—but it was almost disused; and there were two or three slides lying against the bath-holder instead, ready for use and dusty. Of course, as there had been a lull, the system was carried out by there being no plate for cabinet size ready polished; for we saw that operation hastily performed while the models were waiting in the glass-house. Of course, also, a large assemblage of odd things were massed at the sitter's end of the studio, and required to be moved aside before our large party could be accommodated with space to expand during the posing. As the whole length of the studio was required there seemed to be a complete collection of *etceteras* which had to be pushed away to make room for the camera.

All these things, trivial in themselves separately, were collectively the cause of much loss of time; but, as it happened, the operator was gifted with an extraordinary amount of *sang froid*. He was by no means flurried or fussy in his manner, and we must confess he arranged the group otherwise expeditiously and skilfully. To his credit, we may further say, his dark slide was all right, in so far as it did not stick nor jar—a failing very common with gentlemen of this class. We, however, did not notice whether it was new or not.

With the freemasonry which connects all brethren of the craft, of whatever walk, we were soon *en rapport* with this unquestionably skilful manipulator, and were invited into the dark room during the development, which was performed without the slightest regard to the integrity of his hands—the plate being poised upon the tips of the fingers and thumb of the left hand, and the developer flowed over the plate and down on to the hands.

Our readers will be prepared to find from this description that the dark room arrangements were in keeping; and, indeed, so they were. The dark slide containing the exposed plate was placed, not on a shelf or a bench, but actually in the developing trough while the plate was being taken out, and then laid in its proper place on the table against a wall. Such a cynical disregard of the most ordinary precautions against stains we do not remember ever to have seen, the good negatives we saw in the same establishment having been made rather in spite of, than because of, the system. Naturally we did not see the failures; but it could not fail to be the case that they were not "few and far between," as in all properly-regulated laboratories ought to be the case. There should be "a place for everything, and everything in its place," and we assure those of our readers who are comparatively inexperienced that more than ordinary attention paid to this rule will enable them to conquer more than half their difficulties.

We may add further to this advice for the same class, by pointing out one particular direction in which care and cleanliness are of paramount importance, and that is in wet-plate work in tents. We have seen professional operators, as soon as their work was over, pack up camera, slide, and tent just in the state the last plate left them. The apparatus being used so often it would not have time to get thoroughly unworkable without a serious defect being noted and, perhaps, cured at once, and the chief ill result here would be their employer's pocket, as their apparatus would not last one-third the time it would under ordinary circumstances.

For the amateur, whose use for his apparatus is only occasional, the utmost care and attention will be needed, so that when he does unpack his instruments for a day's work he may find them at all usable. He must follow the practice of a professional worker who once delighted us by the way he packed up after a good hard day's work in photography. He first wiped out his two slides most carefully, running blotting-paper along all the grooves to take out any chance drop of moisture that might have been spilt in draining. He then wiped and polished them outside, wiped, dusted, and polished his camera all over, and then locked it up in its case. The tent received similar scrupulous attention. A sponge and towel freely used left it clean and dry as when new; and, when all was done with order, principle, and celerity, as it was, the time occupied seeming scarcely a minute or two more than the haphazard man would have taken, he turned round on our complimenting him and said—"It will be ready for use at a moment's notice, if I do not want it for twenty years." This, we think, is the principle which should guide every one in the use and care of his apparatus.

DEVELOPING POWER OF CUPROUS SALTS.

In a communication sent to The British Journal of Photography about this time last year I gave the results of some experiments made on development by salts of cuprous oxide. I have lately returned to this subject, using different salts from those employed last year, and now send the results, premising that the interest involved is purely a scientific one, as none of these developers equal in power the double oxalate of ferrous oxide and potash.

To obtain *cupro-ammonic oxalate* I first endeavoured to use a reaction mentioned in the Graham-Otto treatise. Sodium hyposulphite decolourises a solution of blue vitriol, and the resulting solution is well adapted, according to the treatise just named, for exhibiting all cuprous reactions. It is certain, however, that it will not give a precipitate of cuprous oxalate. It was invariably found that, when a precipitate was obtained from such a solution by oxalic acid or an alkaline oxalate the solution had not been completely reduced and a cupric salt was present, the precipitate was always cupric oxalate.

I then precipitated cupric oxalate from a solution of blue vitriol, dissolved the precipitate in neutral ammonia oxalate, and effected the reduction subsequently by the aid of zinc filings. Cupric oxalate dissolves readily in ammonium oxalate, affording a clear, light, greenish-blue solution. Zinc filings were left in contact with this solution (avoiding to add too much of the zinc) for about ten days. The result was a mixture of cuprous and cupric oxalate dissolved in the ammonia salt. This solution, considerably diluted, afforded a tolerably active developer, thus establishing the fact that cuprous oxalate has the power of bringing out the latent image.

I next prepared *ammoniacal cuprous oxalate* by dissolving cupric oxalate in liquid ammonia, and reducing by zinc filings. The oxalate dissolves readily and abundantly in strong liquid ammonia, producing an intensely dark-blue solution, which, by prolonged contact with zinc filings, gradually becomes paler, and at last almost entirely colourless. As in the former case, an excess of zinc filings must be avoided.

This solution exhibited considerable power as a developer. Its action, however, was difficult to manage. Employed in the proportion of ten or twelve drops to the ounce of water the image flashed out, and soon a general fogging followed. In the proportion of about two drops to the ounce scarcely any action followed. With three or four drops a tolerable development resulted, but not in any way comparable with that obtained with ferrous oxalate, and less regular than in the case of cupro-ammonic oxalate previously described.

Although these results do not give a promise of practical usefulness, they are, nevertheless, of considerable interest. They confirm the statement made last year that cuprous salts have undoubtedly the power of developing the latent image. Previously but a single metal had been known to possess that power; but it is now conclusively proved that copper salts, as well as those of iron, can exhibit the power of development.

Although cupric salts have not, like cuprous, the power of development, yet they stimulate the action of gallic acid and ammonia very considerably.

It has never, I think, been observed how nearly gallic acid used with liquid ammonia equals pyrogallic in the development of dry films, and the presence of a copper salt seems to stimulate the action. This may be shown in many ways. For example: if we make a pretty strong ammoniacal copper solution by adding liquid ammonia to a strong solution of blue vitriol until the blue precipitate redissolves completely, and then to this add a sixty-grain alcoholic solution of gallic acid, a copious bronze-green precipitate follows, rendering the liquid thick and pasty. If the gallic solution has not been added in excess the whole precipitate redissolves by adding an equal bulk of water; or if the copper solution has been a little more dilute the precipitate may not form. This solution added to water in the proportion of ten to twenty drops to the ounce gives a clean and vigorous development; or the ingredients may be separately added to water. We may take—

Water	2 ounces,
Cold saturated solution of blue vitriol	15 minims,
Strong ammonia	15 ,,
Sixty-grain alcoholic solution of gallic acid .	15 ,,

adding them in the above order.

This solution gives a very rich and beautiful development. A comparative trial was made between it and the ordinary pyrogallic and ammonia carbonate development. The cupro-gallic development gave a finer image, of an exceedingly rich, warm brown colour, but required a trifle longer exposure. I do not propose this development to take the place of the ferrous oxalate or of the pyrogallic, but it is interesting as showing how much more dry-plate development can be varied than has been hitherto supposed. A year ago no one believed that a good dry-plate development without pyrogallol was possible. The mode of treatment here described may interest those who are fond of experiment and like to vary their methods. There is probably no treatment that will give a better image and more richly shaded than this. Still, the ferrous oxalate developer deserves the preference, except where time of exposure is no object.

The following experience in development seems worth adding here—although it has no connection with copper salts—as showing how difficult it is to reason on the development of dry films:—It was found that when *ferrous acetate* was formed by dissolving iron in dilute acetic acid, and getting the acetic acid pretty well saturated, the resulting solution had considerable developing power. The action was slow, but regular and very clean, and by giving a long time to act a good image was got. Now, in forming ferrous acetate in this manner the acid is never quite saturated, because when it reaches a certain stage of dilution it ceases to act on the metal. Acid always checks development; and it, therefore, seemed probable that with a perfectly neutral solution of ferrous acetate a vigorous development would result. A perfectly neutral salt is easily obtained by mixing solutions of baric acetate and ferrous sulphate, and decanting from the baric sulphate formed. This neutral salt, however, exhibited scarcely any developing power. For a long time no result appeared; but, by making the solution four or five times as strong as in the preceding case, and letting it act for two hours, a weak image was obtained which nearly disappeared in a weak fixing solution; whereas in the other case a bright image had resulted which easily bore the action of the fixing bath. The whole result was the exact reverse of what analogy would have led one to expect.

Philadelphia, May 21, 1878. M. Carey Lea.

ON THE "CONTINUATING" ACTION OF CERTAIN RAYS, AND THE REDUCTION OF SILVER BROMIDE BY THE ALKALINE DEVELOPER.

I hope that Captain Abney will pardon me if I say that I do not fully appreciate his explanation of some of the phenomena touched upon in my last communication.

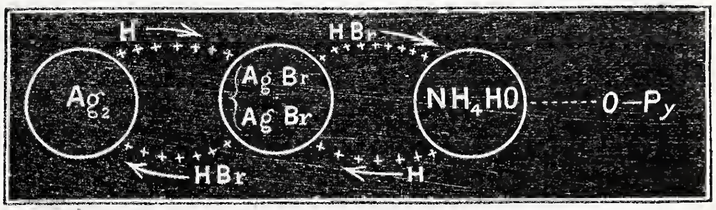
Now I understand that the effect of the rays, at one time called "continuating rays," on the invisible image was supposed to be in this wise:—A sensitive film could be exposed to the action of the actinic rays until a certain slight change was produced, whereby perhaps (say) a trace of an image might be obtained on development. Instead, however, of developing, the plate was exposed to the rays passing through a "non-actinic" glass for a considerable time and then developed, the result being that a much *more vigorous* image was obtained. I cannot reconcile this with Captain Abney's experience that "the continuating action which Becquerel and Claudet noticed . . . was really and truly an oxidising action." If the action be an oxidising action it would appear to be a *destroying* action, and this term would appear to me to be the more applicable one.

Before I go on to the next point I will explain my view of a former experiment of Captain Abney's—not for the sake of affording an explanation, because this has been already done by Captain Abney, but the better to make plain what follows.

A bromide plate might be exposed to light over its whole surface for a short time, and then cut into three pieces. The first might be developed with the alkaline developer, and, after allowing full time, the bromide might be found to be only reduced half way through the film. The second portion of the film might be transferred to a support impermeable to the developer, the surface which was previously in contact with the glass being now uppermost. On applying the developer the bromide would be found to be reduced *all through the film.* Again: the third portion might be taken and coated with emulsion. On development the upper coating would be found to be reduced all through, as well as the lower film as far as the light had acted, but no further. Before proceeding, let me ask—Have I stated the case correctly? I will suppose the answer to be in the affirmative. Then what I have to say is this—When we expose a plate, as in the first instance, and develope it in the ordinary way, it is found impossible to reduce the bromide through more than the upper half of the film; yet, if we reverse an exposed film identical in every respect, and then develope it, we obtain a total reduction of the bromide. Now, are not the particles of silver bromide in precisely the same relative mechanical position after the reversion of the film as they were before? And, if so, how are we to account for the marked difference in the behaviour of the films? From this it appears to me that Captain Abney's theory of the influence of the absence of "absolute contact" does not apply in this case.

I think that my readers will now understand my reasons for stating that the influence of the light-altered bromide is, at least mainly, in the *upward* direction, and not downwards or sideways. So far as I am aware no explanation has been given of this phenomenon. It appears to me that electro-decomposition may have something to do with it, and that the electric current passes from the ammonic hydrate (the positive pole) to the metallic silver (the negative pole). There is, evidently, a physical cause for the reduction of the silver bromide; for the same solution will not effect the same change chemically in the ordinary way. It must be also noticed that the particles of bromide are equally in contact, or out of contact, whichever way the case may really be. And if it be a fact that silver bromide cannot exist in absolute contact with metallic silver, as enunciated by Captain Abney, we seem forced to the conclusion that some insidious force passes through the particles of matter, disconnecting the particles of bromide, and effects the reduction of these latter.

I have an idea which I will explain by means of a diagram:—



The pyrogallic acid has a great affinity for oxygen, and takes it from the ammonic hydrate; at the same time the hydrogen of the semi-molecule of hydroxyl passing through the molecule of silver bromide, $\left\{\begin{matrix}Ag\ Br\\ Ag\ Br\end{matrix}\right.$, reduces it to the state of sub-bromide, Ag^2 Br, hydrobromic acid being formed. This combines with a molecule of metallic silver, whereby more sub-bromide is produced, and the hydrogen passes back to the former molecule of sub-bromide and entirely reduces it to metallic silver, while the other molecule is reduced by the developer. The hydrobromic acid, which is again formed, combines with the radical, ammonium, of the ammonic hydrate, producing ammonic bromide, the hydrogen liberated going through the same process again, except that instead of the hydrobromic acid combining at the end with the radical, ammonium, it combines with ammonia gas, producing ammonic bromide—$NH^3 + H\,Br = NH_4\,Br$; or with the ammonic hydrate, forming ammonic bromide and water—$NH_4\,HO + H\,Br = NH_4\,Br + OH_2$.

Whether this theory be in consonance with known facts I leave others to judge; it is, at least, an attempt to explain what Captain Abney has proved to be a fact. It may, at the same time, induce others to favour us with an explanation of the phenomenon.

Herbert B. Berkeley.

NOTES ON PASSING EVENTS.*

By a Peripatetic Photographer.

The "composite" principle which has recently been applied to portraiture demands a word or two, as being the latest "fad" called into existence by our suggestive art-science. In order to acquire correct information as to the true Jones-Robinson type, a portrait of "component" Jones is thinly printed upon glass or paper, and a portrait of "component" Robinson, taken in the same position as the foregoing, is superimposed and printed upon that of Brown,

* Concluded from page 268.

their noses being the points of agreement in the print, which now becomes a "composite." Woe betide the printer if he be not careful to refrain from giving an undue degree of prominence to one or the other components, otherwise it will lead to confusion. Emma Jones and Maria Robinson will scan the composite production with a—"Lawks! Mariar, ain't it funny! its your par and my par too!" To which Maria indignantly replies:—"How *can* you be so silly, Emmar? You're quite welcome to the resemblance if you like it, for its a horrid fright, and ain't a bit like any member of *our* family!"

I have been so fortunate as to see several composite portraits, and have recognised more than two ears on some of them. But, granting the general soundness of the composite system, why confine it to portraits? I have some intention of visiting, camera in hand, scenes at a distance from home—an intention shared in by many at this time of year—and I desire to obtain correct types of the average residences of the natives of the country selected for my tour. With my mind imbued, as it is, with the composite idea, I am at this moment a little uncertain as to whether I shall make use of the chemical or the mechanical method of "compositography." By the former, I mean the taking of two different subjects—say a lord's mansion and a peasant's hut—upon one and the same sensitive plate; by the latter is to be understood the employment of two separate negatives of these subjects in the printing of one picture. The former, alas! is no novelty, as every one who has had the misfortune to inadvertently expose a plate twice only too well knows. But, then, in practising this system some regard for the decencies of pictorial art and possibilities must be shown; for it is scarcely in keeping with either of these to bring home from a tour—as did a friend of mine—a plate which, when developed, displayed a group of happy children disporting themselves at a cottage door in the middle of Dublin Bay! A "composite" arising from the lordly mansion and the crofter's hut, if properly done, would, I imagine, evolve a very decent suburban villa. So much for "composites" and "components."

The trigger was touched, and down fell the "instantaneous" exposing shutter with a thud that made both camera and camera-stand to vibrate most violently. "*That* plate is spoiled, anyhow," said my friend Innocent, who was standing by watching the operation with interest; "the camera is actually still in a state of tremor, and the image is sure to be blurred." "Now, my friend," I observed, "let me give you a brief lecture on exposing instantaneously and on the effect of agitating the camera. The spring (continued I) by which the shutter is propelled is a strong one, as you can observe; but by the touching of the trigger the aperture in the shutter flew past that of the lens. What I want to impress upon you is this—that it is neither the liberation of the spring-bound shutter, nor its motion, but its sudden cessation of motion, that causes the jarring by which the vibration of the camera is commenced. But as this only takes place *after* the exposure has been made it cannot possibly affect the sharpness of the image already impressed upon the plate."

In this, permit me to say, lies the philosophy of instantaneous exposures, or, to put it more accurately, of the construction and proper action of instantaneous shutters. Now, please, my reader, don't take me up before I fall: there is no such thing as instantaniety in exposure, or in anything in physics. Even a box on the ear is not "instantly" felt by the unfortunate recipient of such an application of physical discourtesy. A certain interval of time must elapse ere the sensory nerves can convey the intelligence to the brain. It is not a *very* long period, I grant; but for the purpose of the present argument it is a definite interval. Here is my definition of a theoretical instantaneous exposure—it is one the termination of which is coincident with its commencement. If I am correct this removes it from the region of mechanics. Photographically, the nearest approach to instantaniety I have known was when, at midnight, during a thunderstorm, I had a camera standing with lens uncapped ready to receive such an impression of external nature as the vivid lightning might yield. My senses told me that a carriage was being driven with great rapidity across what, if it were daylight, would have been the field of view of the camera, when suddenly came a blinding flash that made me start. It is known that in presence of grand natural phenomena one cannot always sink the sentient being in the philosopher, so I started and felt half-terrified. When I developed my plate the carriage appeared as if it had been motionless during the whole time of exposure.

But I am losing sight of what has originated these remarks. The pneumatic shutter of M. Cadett is bound to prove a success in the hands of those who know how to make use of it aright; but an unthinking operator may be apt to jar the camera to some slight extent if he employ it in obtaining quick exposures. By the pressure of the india-rubber ball the shutter flies up, and while moving upwards no jar can possibly take place; but when the shutter has attained its maximum elevation this act will be accompanied with a slight concussion, because a force exterior to the camera is acting upon it, and for which reason I conclude that for exposures demanding the most extreme rapidity the pneumatic shutter will not be applicable. But, so far as I have seen, this kind of work is not claimed to be performed by this shutter; and for such subjects as can be taken in one or more seconds it appears to be most admirably suited.

The general idea of the pneumatic shutter is excellent, but its ingenious inventor need not be surprised if before a month elapses he find a whole host of imitators and modifiers in the field. I know photographic history too well not to be aware that this is sure to be the case.

Apropos of this, here is an anecdote which is now published for the first time:—The late Voigtländer, when conversing with the genial and late William Callaghan, of Bond-street, *anent* the tendency of one optician to "improve" upon the works of another, remarked, with grim bitterness—"I believe that if the Creator of the Universe were to send to mankind a *perfect* photographic lens it would not be out three weeks before some London optician would be found to improve upon it." Mr. Callaghan told this to your "Peripatetic" correspondent with great gusto, for Callaghan was one of the most agreeable, jolly souls that ever lived, and one who dearly enjoyed a bit of banter; but, as was remarked at the time, Voigtländer had no occasion for indulging in this *innuendo*, for he had throughout his whole career abstained from bringing out any novelty in his own name. He professed to work according to the formulæ or principles of Petzval and Sommer; and, so far as I am aware, it is not impossible that the gift of improving upon pre-existing, or of devising new, forms of lenses may have been conferred upon others than the gentlemen here named—even upon London opticians. When the hypothetically "perfect" lens makes its appearance it will be time enough to speak with respect to the principle of "finality" in this direction. The popular idea of the coming (and *coming* it ever will be) lens is that it will have an aperture abnormally great, a focus abnormally deep, and the included angle of view abnormally wide. But we live in a wonderful age; we can now *see* a sound, hear the tramping of a flea's foot, and the gnashing of his jaws as he expresses disappointment at the result of some of his "little games;" and we can transmit these sounds—equally with those representing the *cavatina* of the latest *prima donna*—to the antipodes in the guise of an indented bit of tinfoil, there to be reproduced for the edification of the musical ear of the antipodean masses. Hence it is not safe to speculate upon optical possibilities, even though these may be held in check by mathematical limitations.

PRECIPITATED BROMIDE EMULSION.

[A communication to the Photographic Society of France.]

Having made during the past month my provision of dry plate emulsion for the current year, I submit to the Society several observations I have made, and which may possess a certain interest.

I have used, on this occasion, collodion prepared with a combination of bromide of cadmium, ammonium, and zinc, after the formulæ of M. Chardon. It has been kept one year to deposit, and was, in consequence, admirably limpid. Taking quantities of 400 c.c. of collodion prepared with the resistant cotton, and 200 c.c. of collodion made with the pulverulent cotton, I sensitised successively each of the 600 c.c. of mixed collodion with 18·30 grammes of pounded nitrate of silver, which is after the rate of 3·05 grammes per cent. I have thus obtained an emulsion containing a very small but constant excess of silver. After having neutralised this excess by the necessary addition of chloride of cobalt collodion, I precipitated the emulsion with hot water, which, when dry, gave me from twenty-nine to thirty grammes' weight of a precipitate. After redissolving the dried emulsion precipitate it gave me excellent results; but the character of the film was entirely different from that which I had obtained during my previous experiments with collodion prepared and aged only a few weeks.

In the first place the negatives, after development and fixing, presented, when dry, an uniform whitish and opaline tint, which at first sight might be considered the result of incomplete fixing; but such was not the case, however, and the varnish restored to the negative all its pristine transparency. Several months ago M. Davanne had announced this fact in an original article prepared for, and inserted at page 146 of, The British Journal Photographic Almanac, 1878.

In the second place—and this part of my observations has its importance—the fixed film was soluble in alcohol at 40°, and sometimes even in diluted alcohol. I have thus been obliged to abstain from washing the negative with alcohol before development; but I have had no cause to regret the film being so porous—in consequence, no doubt, of the age and ripeness of the collodion—which also causes a rapid development without having recourse to the previous washing with alcohol. For the same reason I have ceased to use alcoholic varnish; in consequence, the images obtained with this emulsion are of perfect purity, and it is scarcely possible to fog the images with alkaline development, even when pushed to the extreme limit of intensity.

I have equally tried, after analysing the excess of the silver in the collodion before precipitation, to neutralise it with iodised collodion instead of chlorised collodion. The reaction seems more slow, and, notwithstanding a considerable excess of alkaline iodide, I have still remarked the presence of a trace of free silver even forty-eight hours after the addition of the iodide. The film, when poured upon the glass plate, had a very good appearance, and on developing the image came out easily, even after a short exposure. Unfortunately the negative, without actually fogging, was very slow in attaining vigour, and I have not been able, even with the aid of pyrogallic acid, to obtain the degree of opacity necessary to yield a good printing negative.

In conclusion: I ought to state that, having tried the remainder at the bottom of a bottle of emulsion dissolved more than twelve months, to my great astonishment it gave a most excellent negative. I avow that I am not habitually so fortunate, and that generally my emulsions, after six weeks' dissolution, give me a film which splits very finely and cannot be utilised. I do not know the cause of this anomaly, but I draw this deduction, which has its value—that it is possible to keep indefinitety, in some manner, a dissolved emulsion. The question is—What are the conditions requisite to obtain this result?

Ch. Audra.

THE PHOTOGRAPHIC PRINTING PROCESS USED IN THE PORTUGUESE STATE PRINTING ESTABLISHMENT.*

Reproductions of Engravings.

Good typographic printing plates may be produced in the following way:—The sensitive mixture should be put on the zinc plates in as thin films as possible, and after being dried it is exposed in the printing-frame under a negative and rolled with ink as before. This process requires great care and skill so as not to allow the picture to be spoiled, as the acid is apt to attack the gelatine. It is, therefore, advisable to take the first copy upon a sheet of tinfoil, as in the process given for photolithography, and to transfer the fatty picture produced upon that to the zinc plate, and then to etch. This process is to be recommended for making plates of large dimensions.

Generally the process with asphalte is easier and more to be depended upon. The asphalte itself must be rather hard even at a considerable heat, and must still dissolve almost completely in benzine or in petroleum whose boiling-point lies between 80° and 100° C. The watery contents of the solvent are previously removed by enclosing it with calcic chloride. The following solution is then prepared:—

Benzine	100 grammes.
Oil of lavender	3 ,,
Asphalte	8 ,,

In order to find out the degree of sensitiveness of the preparation and its power of resisting oil of turpentine, which is used to develope the picture, coat a plate with the asphalte solution, let it dry, and lay upon it a figure cut out of black pasteboard; then expose from fifteen to twenty-five minutes to the action of the sun's rays. Now let the plate become cold, after which place it in a dipper and dip it into a vessel filled with cold turpentine. If after the lapse of a minute at most the figure shows sharp and clear, while the unlighted parts of the film are dissolved, then the solution is usable.

As the heat of the sun makes the asphalte sticky and might thus spoil the negative, it is well, before exposing, to rub both the negative and the asphalted zinc plate with a soft cloth and powdered talc. The negative ought also to be coated with a very hard varnish, that given under the heading No. I being very good. Before removing the plate from the negative, after the exposure, it must be allowed to become quite cold; the cooling is hastened by cleaning the back with a damp sponge.

* Concluded from page 269.

The admixture of oil of lavender hinders the solution from drying and makes the film equal in thickness. As soon as the solution is spread upon the plate lay the latter on the sheet-iron plate, mentioned at the beginning of (A) *Chromated Gelatine Processes*, which has previously been covered with a smooth sheet of paper. This sheet-iron plate should be turned until the film no longer smells of the oil of lavender.

When the picture has been developed in oil of turpentine it should be well washed with water from a tap furnished with a rose, in order to prevent the development from going too far. If it be found then that all the asphalte on the unexposed parts has not been dissolved, the plate should be dried between sheets of fine blotting-paper, and dipped again for a few seconds into the turpentine, and then rinsed at once with a good deal of water. The zinc plate is now drawn through very dilute nitric acid, slightly gummed, and rolled with ink.

The vessel in which the picture is developed should be polished at the bottom, so that the impurities of the bath may not injure it. It should be filled with cold turpentine, and the plate, when it has become cold, is placed in it. The development often occupies but a few seconds. The picture must not be left too long in the bath, and one should bear in mind the time which is lost between the drawing of the plate out of the bath and the washing.

Typographic Heliogravure with Half-Tones.

The production of *clichés* in half-tones for printing in the letterpress press is still an unsolved problem; still the experiment about to be described may lead to good results.

Some substance, such as sugar, starch, carbonate of lime, or carbonate of lead, which is soluble in water or in nitric acid, is rubbed into a solution of asphalte in oil of lavender. This is rubbed down upon a palette to an uniform, doughy mass, and as much benzine is added to it as produces a fluid of sufficient consistency. With this the zinc plate is coated, but not too thickly. When this coating is dry expose as usual, dip it in turpentine, and when the picture is taken out of that put it immediately into a bath of dilute nitric acid, as if to etch it. The acid penetrates the resinous film by dissolving the substance which gives it granularity, and perforates it in inverse proportion to the protecting action of the light, thus bringing out the half-tones. This etching process should not be continued too long. Parts that have been accidentally stripped bare are to be covered with varnish or lithographic chalk. The plate is then rolled with grounding ink and etched as usual.

José Julio Rodrigues.

AMMONIO-ARGENTIC IODIDE.

When silver iodide is exposed to ammonia gas it absorbs 3·6 per cent., and forms, according to Rammelsberg, a compound in which an atom of ammonia is united to two of AgI. Liquid ammonia instantly whitens AgI, and every trace of the strong lemon colour disappears. The behaviour of the ammonia iodide under the influence of light differs singularly from that of the plain iodide, and will be here described.

The affinity of AgI for ammonia is very slight. If the white compound be thrown upon a filter and washed with water the ammonia washes quickly out, the yellow colour reappearing. If simply exposed to the air the yellow colour returns while the powder is yet moist, so that the ammonia is held back with less energy than the water. So long, however, as the ammonia is present the properties of the iodide are entirely altered.

AgI precipitated with excess of KI does not darken by exposure to light even continued for months. But the same iodide exposed under liquid ammonia rapidly darkens to an intense violet-black, precisely similar to that of AgCl exposed to light, and not at all resembling the greenish-black of AgI exposed in presence of excess of silver nitrate. (This difference, no doubt, depends upon the yellow of the unchanged AgI mixing with the bluish-black of the changed, whereas in the case of the ammonia iodide the yellow colour has been first destroyed.)

When the exposure is continued for some time the intense violet-black colour gradually lightens again, and finally quite disappears; the iodide recovers its original yellow colour with perhaps a little more of a greyish shade. This is a new reaction, and differs entirely from anything that has been hitherto observed. It has been long known that darkened AgI, washed over with solution of KI and exposed to light, bleached. This last reaction is intelligible enough, for KI in solution exposed to light decomposes, and in presence of AgI darkened by light gives up iodine to the AgI, and so bleaches it. The above experiment is quite different. The darkened substance may be washed well with water (during which operation it passes from violet black to dark brown), and may then be exposed to light either under liquid ammonia or under pure water; in either case the bleaching takes place, though in the latter case more slowly.

If the experiment be performed in a test tube the bleaching under ammonia requires several hours; under water from one to three days. But if the iodide be formed upon paper, and this paper be exposed to light, washing it constantly with liquid ammonia, the darkening followed by the bleaching requires little more than a minute. In this case, however, the bleaching is not so complete, perhaps because of the influence of the organic matter present. The bleaching appears to depend upon the escape of ammonia; for if the darkened ammonia iodide is covered with strong liquid ammonia, and the test tube well corked, the bleaching does not take place.

It became a matter of interest to know whether the darkening under ammonia was accompanied by any decomposition—whether the ammonia took up iodine from the silver salt under the action of light. For this purpose AgI was precipitated with excess of KI, and subjected to a long and thorough washing; it was then exposed for several days to light under strong liquid ammonia. As AgI is not wholly insoluble in ammonia, the mother-water was first evaporated to dryness at a heat but little over ordinary temperatures. The traces of residue were washed with water, and this water gave distinct indications of iodine. The iodine present is in so small quantity that it may easily be overlooked, but it is certainly there. The washing given to the AgI was so thorough that it seemed impossible to admit that traces of KI remained attached to the AgI; but in order to leave no room for doubt the experiment was repeated, using an excess of silver nitrate in making the precipitation, followed by thorough washing. Iodine was still found in combination with ammonia, and under these conditions there could be no doubt that AgI had been decomposed.

When AgI is blackened under ammonia in a test tube, and the uncorked test tube is set aside in the dark for a day or two, the AgI assumes a singular pinkish shade. It thus appears that AgI under the influence of ammonia and of light gives indications of most of the colours of the spectrum. Starting with white it passes under the influence of light to violet, and thence nearly to black; this violet-black substance washed with water passes to brown. The brown substance covered with ammonia and left to itself in an open test tube becomes pinkish in the dark, yellow in sunlight. These curious relations to colour which we see in the silver haloids, from time to time exhibiting themselves in new ways, seem to give hope of the eventual discovery of some complete method of heliochromy.
—*Silliman's Journal.* M. Carey Lea.

TRANSATLANTIC NOTES.

There are few who visit the "States," at least for the first time, who do not manage to include in the tour a few hours at the far-famed Niagara, or "The Falls," as the Americans universally designate them; and as everyone tries to describe them, and many succeed much better than I could hope to do, I shall confine myself to matters more or less related to "Falls photography," which is considerably different from photography at any other place.

As on the occasion of a previous visit to Niagara I took up my abode on the American side I this time went over to the Canadian side, and soon found that although the Falls themselves are practically unchangeable it is very different with their surroundings. Then there was only one building for the accommodation of the sight-seing public on the latter side—the Clifton House (the word hotel does not seem to be in favour with Americans), a good half-mile below the Falls. Now from thence up to right opposite the Horse-shoe Fall is one continuous line of hotels, refreshment rooms, museums, curiosity stores, photographic establishments, &c., &c., &c., and the pedestrian is besieged at every step by touters, whose united confession of faith would seem to be that he is suffering from hunger and thirst; has no other object in life but the collection of Indian curiosities (which, by-the-bye, the Indians never saw); wants to be driven from place to place as rapidly as possible for the purpose of seeing them; that he is quite unable without their aid to secure a shelter for the night, and requires above all, and in addition to all, a supply of "Vanity Fair." The latter, however, is not the well-known production of Thackeray, but a special kind of tobacco, which would seem to be as well advertised as Holloway's pills, as during a run of over sixteen hundred miles there was hardly a rail fence on which the advice to "smoke Vanity Fair" was not painted, and that even in localities where but for the strip of clearing through which the train ran one might easily have supposed never to have been visited by man. But, deaf alike to all their entreaties, I took up my quarters in Prospect House, and as I don't know even the name of the proprietor, may, without being suspected of writing an interested puff, say that, situated about equidistant between the two Falls, its windows and piazza afford the most magnificent view of those grand natural wonders; and that for comfort, economy, and all that makes a hotel desirable, I have found none better either in the States or Canada. True, there is one little drawback which is somewhat troublesome at first, but one to which the visitor soon gets accustomed. The commotion in the atmosphere caused by the rapid motion of such an enormous mass of water produces in doors and windows an amount of vibration at first painfully visible to both eye and ear, and is apt, in the minds of the more timid, to raise doubts as to the stability of the structure. A careful examination, however, of the building shows that it is perfectly steady, and a glass brimful of water when placed on the doorstep gives no indication of motion, and by-and-bye even the most timid ones come to enjoy the not unmusical accompaniment during dinner or when enjoying the after-dinner cigar.

Early in the morning after our arrival I began my search for matter relating to photography; and, as the operators seem to believe in the early bird catching the worm, I had not far to go before I found one hard at work. Right in front of the Horse-shoe Fall, and close to the overhanging bank, a group of four were seated in a rude garden chair. They were dressed in oilskins, including hoods, that completely covered the figures, the face only being visible, and looked more like arctic explorers than tourists in a temperate clime; but having just visited below the Fall, they were easily persuaded to take the bait—"Have your photographs taken with the Fall as a background? Ye'r friends will be so amused to see you in the 'spray dresses.'" A few yards in front there was a pyramidal wooden erection, not unlike the cone used by the farmer in building his corn rick or stack. It appeared to be from ten to fifteen feet high, and had a camera firmly fixed on the top, but placed at such an angle that the centre of the plate took in the chair and its group of sitters. Such an arrangement was hardly suited for the most artistic work; but, as the operator subsequently remarked to me—"The Falls is the thing they most want. As they don't mostly come a second time we see the colour of their money before they go, and as we send the pictures a long way after them we rarely hear how they please." In a few minutes he came out, dark slide in hand, and climbing up the framework, without taking the trouble to adjust or focus, gave an exposure of a few seconds, and invited me to see the plate developed. I did not expect much, and therefore was not disappointed; but came to the conclusion that it was good for the proprietor that "payment in advance" was a *sine quâ non*, and that the sitters "did'nt mostly come again." On the whole, however, good work could hardly be expected under such adverse circumstances. The spray from the Falls, unless on very exceptional days, envelopes the place in something quite as aqueous as a "Scotch mist," which soaks both operator and apparatus, and brings about, always in the latter and sometimes also in the former, a state of dilapidation that makes success difficult. The proprietor, whom I subsequently met, and who "*runs*" the "Falls House"—a liquor bar, a curiosity store, and a *camera obscura* in addition to the photographic establishment—assured me that the latter paid very well when he succeeded in getting and keeping a touter who understood human nature well enough to discover the weak points of the visitors, and play on them till he had them in the sitting chair.

A little further down, and immediately opposite the American Fall, I saw another camera ready for action, but this time mounted on an ordinary tripod; and as the spray rarely reaches this part it was in more respectable and better working condition. As I passed along, a fine specimen of the orthodox nasal-twanged Yankee crossed over, and presenting a really excellent 7 × 5 print, assured me that I could not do better than let him take me; that the day was peculiarly favourable and he had a plate ready, and wonld not keep me more than a few seconds. Rarely, indeed, could the Fall be so well included in the photograph, and more rarely still were such fine clouds to be obtained, while my attention was directed to the specimen in his hand as a proof of what could be got if I would only sit at once, as the effects were fleeting, and a composition so perfect might not again occur for months. But the charmer charmed in vain. The fact was that the beautiful specimen had been printed, and beautifully printed, from three negatives—figures, Falls, and clouds—and of course I told him so, adding that although I did not want to be photographed I did want information on matters photographic, and thought he was just the kind of man to give it. This was followed by a cordial invitation to examine his place and work, and an offer to tell me everything he knew, or to give me any information I wanted. The inspection was in every way satisfactory, the majority of the specimens being of a high class, although there was just a tendency to make the clouds a little too pronounced, but that, he assured me, was really necessary to meet the tastes of his patrons. During our chat he kept "whitling" at sticks, but not in the aimless way said to be characteristic of the Yankees. They were of beech, hazel, and hickory, and he was rounding them and putting on ferrules preparatory to varnishing and selling them for fifty cents each.

His name—Mr. Davis—is not unknown in American photographic circles, as he it was who took, under difficulties that would have frightened less courageous operators, most of the magnificent negatives from which the famous pictures of the Yo Semite Valley are printed. I believe he was commissioned to produce one hundred 24 × 18 negatives, and received for his ardous task eighteen hundred dollars, or about twenty pounds each—a rather poor recompense, seeing that some six months were occupied in their production. During that time, however, he also made many hundred stereo. and other sizes, some of which were sold for good prices, and the rest remain in his hands "a dripping roast" still.

While thus engaged, two fresh arrivals made their appearance, and Mr. Davis at once pounced upon them, repeating again the arguments with which he plied me, but with a better result, as in a few minutes he had secured a good negative of a group of two, got an order for half-a-dozen copies each, to be forwarded to Galashiels and Selkirk respectively, and pocketed twelve dollars (fifty shillings) for the work—not such a good price as at first sight it may seem, as each print had to be produced from three separate negatives.

Mr. Davis is also strong in winter work at the Falls, and shows some very fine prints from 24 × 18 negatives. Those negatives, however, he sells, as he does not seem to care for the publishing part of the business. He speaks enthusiastically of the winter work, and evidently delights in overcoming the difficulties incident to a temperature often far below zero, when the so-much-admired frozen spray effects are best obtained. For this purpose a descent to the bed of the river, considerably over one hundred and seventy feet, is necessary, and there he erects a tent, or rather wooden house, in which he keeps himself and his solutions far above the freezing point by a large American stove liberally supplied with blazing logs.

Like nearly all American photographers he manufactures his own collodion and is fond of experimenting; but, unlike most of them, he communicates the results very freely—at least to those who are not above being taught—and he boasts of being able to work with an exposure of at least one-sixth of what is generally required. This he has frequently demonstrated, and his assertions have been confirmed by several persons that I have since seen. I made a note of the formula for both collodion and developer, and shall publish it in my next letter, my note-book being at present sixteen hundred miles from where I write, but is rapidly following me.

Crossing over to the American side I visited the establishment of Mr. Curtis—a name almost universally known in connection with the publication of stereoscopic slides of the Falls. It is situated in a quiet side street in Niagara Village, and, so far as external appearance is concerned, shows nothing of the extensive trade that is carried on within. Unfortunately for me Mr. Curtis was from home, but his polite assistants showed me over the whole place. In Europe the decline, or almost extinction, of the demand for stereoscopic pictures has long been a source of complaint; but they are still very popular in America, and in this establishment alone many thousands are produced every week, of the Falls and their surroundings. The skeleton stereoscope—introduced, I think, by Mr. Wendell Holmes, and almost universally used in the United States—admits of the use of larger pictures than those usually found in the old country; and here I saw in process of production immense quantities measuring 7 × 5 inches, or perhaps a little longer. Great, however, as is the stereoscopic trade at present, it is not nearly up to that of former years. With a view to keep his assistants employed Mr. Curtis has recently commenced to produce enlarged transparencies from the stereo. negatives, and they are becoming very popular. The sizes are from 10 × 8 up to 20 × 14, backed with glass obscured by an opaque emulsion, and have a broad margin. This margin has lines or designs made by removing portions of the opaque backing, and the whole is bound with dark paper in the usual manner. The smaller sizes sell for about ten shillings, and form beautifully-attractive window ornaments. More recently still he has introduced the same articles coloured in oils, which are really charming, and, I think, must be a success. At present they are made on wet collodion plates; but, from what I have since seen in New York, I know that carbon transfers will be in many respects better and more easily managed, and would advise all who wish to try their hands at this work to adopt that method.

I had also the pleasure of examining a large number of Mr. Curtis's negatives, and have no doubt that much of the beauty of the transparencies is due to their extreme delicacy. They are very thin, full of charming detail, and perfectly free from spot or blemish of any kind. Somebody advertises for sale "the collodion used by Mr. Curtis at the Falls." If the clearness and beauty of his negatives are due in any way to the materials he employs his formulæ are very much to be desired; but I strongly suspect that in this, as in most other cases, the excellence belongs more to the man than to the material.

Much more might be said of photography at the Falls, but this letter is already long enough. I must, therefore, reluctantly bring it to a close, and in my next shall cross Niagara again, and note what is doing in Canada and the West, and especially how some exquisitely-beautiful snow scenes, including the various winter amusements of the Canadians, are produced. John Nicol, Ph.D.

PARIS EXHIBITION.

The following is the list of jurors appointed in connection with photography, photographic apparatus, and photographic instruments and appliances, so far as gazetted, to the present time:—

Group 2.

Jules Simon, *President* (France).
1st *Vice-President* (United States).
M. Delisle, 2nd ,, (France).

Jury, Class 12.—M. A. Davanne, Comte Réné d'Heliand, M. A. Martin (France).

Jury, Class 15.—MM. Cornu, Laussedat, Mouchez, Perrier (France); Lord Lindsay (England).

Class 12.—Photographs and Apparatus.

England and Colonies.—(Not gazetted yet).

United States.—(Not gazetted yet).

Austria-Hungary.—Herr Frederic Luckhardt, photographer to the Imperial and Royal Court at Vienna; Herr Louis Lechner, *commissaire-adjoint* of Hungary, Councillor of the Direction of the Society of Engineers and Architects, representative of Buda-Pesth.

Russia.—M. Levitzski, photographer to the Court.

Holland.—M. J. J. van Kerkwyk, member of the Second Chamber of the General States of Holland.

France.—MM. A. Davanne, President of the Society of Photography, Juror in 1867 at Paris, Vice-President of the Jury at Vienna in 1873, President of the Committee of Admission at Paris, 1878; Heliand (Réné Comte d'), Secretary of the Committee of Admission and Installation, Paris, 1878; Martin Adolphe, Professor of Physics, member of the Committee of Admission at Paris, 1878.——*Supplementary Juror:* M. Franck de Villecholles, photographer, Professor at the Ecole Centrale, member of the Committee of Admission at the Exhibition Universal, 1878.

Class 15.—Instruments of Precision.

England and Colonies.—Lord Lindsay, M.P.

Sweden and Norway.—Dr. O. J. Broch, Professor of Mathematics at the University of Christiania.

Italy.—Professor Guiseppe Colombo.

Austria-Hungary.—Dr. Ernest de Fleischl, Privy Professor-*adjoint* of the University of Vienna.

Switzerland.—M. Louis Soret, Professor à Geneva.

France.—M. Cornu, Professor of Physics at the Faculty of Sciences and at the Ecole Polytechnique, Member of the Jury in 1867, Member of the Committee of Admission, Exposition Universelle, 1878; M. Laussedat, Colonel of Engineers, Professor at the Conservatoire of Arts and Métiers, Member of the Committees of Admission and Installation, 1878; Commandant Mouchez, Member of the Institut of France; Commandant Perrier, Member du Bureau de Longitudes, Member of the Jury of the Exhibition of Philadelphia, Member of the Committees of Admission and Installation, 1878.——*Supplementary Jury:* M. Bardoux père, Ancient Judge of the Tribunal of Commerce, manufacturer of optical instruments. W. Harrison.

FOREIGN NOTES AND NEWS.

Volhardt's Method for the Volumetric Analysis of Silver Baths.—Herr Strumper's Patent.—Discontinuation of the *Lichtbildkunst.*—Dr. J. M. Eder on the Solubility of Silver Salts in Alcohol.

At a recent meeting of the Berlin Photographic Association Dr. Vogel gave the following account of Volhardt's method for the volumetric analysis of silver, which is adapted to the determination of the silver contents of photographic baths, and which only differs from Vogel's test by using sulphocyanide of ammonium instead of iodide of potassium as the testing solution. The usual burette and pipette are used:—

"Dissolve six grammes of sulphocyanide of ammonium in 1,000 grammes of water; fill the *burette*, and determine the solution first of all.

"For this purpose take a silver solution containing exactly ten grammes of the silver salt in 100 cubic centimetres, and to one cubic centimetre of this solution add one cubic centimetre of a solution of five parts of ferric sulphate in a hundred parts water.

"This is coloured of a deep red by sulphocyanide of ammonium, but in the presence of a salt of silver the colour disappears, owing to the formation of sulphocyanide of silver.

"Add the sulphocyanide solution drop by drop until the red colour so produced remains even when the vessel is shaken. Supposing that to produce this effect has required 7·8 cubic centimetres, that would prove the presence of exactly one-tenth of a gramme of silver, or, in other words, of ten per cent. Then take 780 c.c. and dilute it to 1,000 c c. and you will then have a solution which, when added to a cubic centimetre of the silver solution, proves the presence of one per cent. of the silver salt for every cubic centimetre of itself that is required.

"The determination of the sulphocyanide testing solution is not easy for photographers who are not also chemists, and it would be more convenient if manufacturers would prepare it for the market of the proper strength.

"The sulphocyanide test has the advantage of only requiring one fluid—the ferric sulphate—as an *indicator* (to show when the precipitation ends), while by Vogel's silver test two fluids are required—a fresh solution of starch and nitrous acid. Still, the blue colour produced by Vogel's test (being complementary to the yellow of the iodide of silver) is more easily distinguished than is the yellow of the sulphocyanide of iron."

Herr J. H. Strumper, of Hamburg, has just patented a process for burning-in lichtdrucks upon glass and porcelain.

From the *Monatsblätter* we learn that MM. Braun and Co., of Dornach, intend to discontinue the publication of the *Lichtbildkunst.*

The *Mittheilungen*, quoting from an article on the solubility of silver salts, which appeared in a chemical journal, says that, according to Dr. J. M. Eder—

"100 parts of a spirit of wine solution

Of............	95	80	70	60	50	40	30	20	10	Volumetric per cent.
Will dissolve at 15° C	3·8	10·3	22·1	30·5	35·8	56·4	73·7	107	158	Parts by weight of nitrate of silver.
,, ,, 50° C	7·3	—	—	58·1	—	98·3	—	214	—	
,, ,, 75° C	18·3	42·0	—	89·0	—	160·0	—	340	—	

In pure ether, as well as when it is saturated with water, only traces of the nitrate of silver are soluble. The addition of a little alcohol to the ether increases the solubility of the nitrate of silver considerably. 1. A hundred parts by weight of a mixture of one part by bulk of 95 vol. per cent. alcohol with one part by bulk of pure ether will dissolve at 15° C 1·6 part by weight of nitrate of silver. 2. A hundred parts by weight of a mixture of two parts by bulk of the same alcohol, and one part by bulk of ether, will dissolve 2·3 parts by weight of nitrate of silver. 3. A hundred parts by weight of water saturated with ether was able at 15° C to dissolve 88·4 (? 4·88) parts of nitrate of silver.

"A second series of experiments determined how many grammes of nitrate of silver were contained in every 100 c.c. of the various solutions when saturated, with the following results:—

In 100 c.c. of solution of spirit of wine

Of............	95	80	70	60	50	40	30	20	10	Volumetric per cent.
Contained at 15° C..	3·0	8·6	21·0	27·1	33·4	52·8	60·6	89·1	130	Grammes nitrate of silver.
,, ,, 75° C..	12·5	33·6	—	51·0	—	108	—	—	—	

At 15° C. a hundred c.c. of a mixture of equal bulks of (95 per cent.) alcohol and ether contained in solution 1·4 grammes nitrate of silver."

These figures are valuable in working out the emulsion process or Obernetter's process, though, of course (as the editor of the *Mittheilungen* remarks), the properties of the collodion cotton will exercise a certain influence on the solubility of the silver salt in collodion. The experience of the latter gentleman is that an ordinary cotton for wet plates, treated according to Obernetter's formula, furnishes a perfectly clear silver collodion, while an English dry-plate cotton gives a collodion from which the silver salt is thrown off in the form of crystals. The result of Dr. Eder's paper treats on the solubility of sulphate of silver.

PHOTOGRAPHY IN COURT.

THE COPYRIGHT ACT.

On Monday last, the 10th instant, Henry Reastern, a hawker, of Osborne-street, Whitechapel, was summoned before Mr. Bushby at the Worship-street Police Court by Mr. Benjamin Brooks, fine art publisher, of the Strand, for selling pirated copies of copyright pictures. Mr. Silberberg, solicitor, defended. The evidence of prosecutor and of a witness named Burgess, a private inquiry agent, showed that the defendant was seen going from publichouse to publichouse and selling there and in the streets photographs of pictures known as the *Soldier Boy's Dream*, the *Light of the World*, and *Cattle of Brittany*. The witness Burgess first accosted the defendant, and cautioned him that he would get into trouble if he continued to sell the photographs, as the pictures were copyright. Mr. Brooks some two or three minutes afterwards went to the defendant and purchased as a stranger a copy of each, and then got a constable to obtain the defendant's name and address. Mr. Brooks produced the assignments from the painters of the pictures, Holman Hunt and others, to publish and print the same, and said that two of them had cost him 100 guineas each, besides all the expense of engraving and printing. They were properly registered and published. An objection taken by Mr. Silberberg that the assignments required stamps was overruled. Mr. Bushby, however, considered that he could not convict the defendant, for the Act required knowledge on the part of the seller, and there was no proof that he knew the works were copyright. Mr. Silberberg made the usual defence that his client had only been a few months in London and did not know the language or the pictures which were sold him by the photographer. Mr. Brooks said he had instituted proceedings against a "manufacturer," but it was difficult to catch them or get evidence against them. Last week he discovered in the cloak-room of a railway station a large parcel of the photographs, the "manufacturer" who employed the hawkers keeping them there so that the hawkers might meet him when necessary and he supply them. Mr. Bushby dismissed the summons, but said he sympathised with Mr. Brooks.

On Tuesday last, at the Lambeth Police Court, Albert John Sanders, of 2, Albert-terrace, Church-road, Upper Norwood, appeared to five summonses taken out by Mr. Benjamin Brooks, fine art publisher, of 171, Strand, for having without his consent sold photographs of engravings of which he had the copyright. Mr. Dutton appeared for the defendant. Mr. Brooks stated that he had spent thousands of pounds in the purchase of works of art, and it certainly was hard to find persons making photographs of many such works and selling them for a few pence. Such a system was extensively carried on. Evidence was then called proving the purchase at the defendant's shop of photographic copies of engravings entitled *Patience and Tribulation*, *The Emigrants' Farewell*, *Obedient to the Laws*, *Saved from the Wreck*, and *Brittany Cattle*, all being the copyright of the complainant. Mr. Dutton, after some discussion as to the law on the matter, said his client would plead "guilty," although he did not know he was doing wrong at the time. He wished also to state that the defendant was in great pecuniary difficulties and unable to meet his creditors. Mr. Chance required the defendant to pay a fine of 20s. on each of the five summonses.

THE ENGLISH PHOTOGRAPHS AT THE PARIS EXHIBITION.

The correspondent of the *Daily Telegraph*, under date of the 9th inst., has made the following observations on this department of the International Exhibition :—

In the synopsis of classification followed by the Exhibition catalogue a group which demands particular note is that defined under the heads "Education and Instruction : Apparatus and Processes of the Liberal Arts." Classes from 6 to 16 are herein comprised, and it would be manifestly impossible to deal with them analytically, or even in a cursory manner, within the compass of an article. All kinds of stationery and bookbinding, of painting and drawing materials, of printing and books, of mathematical and philosophical instruments, and of photography with its adjuncts and appliances, are to be found in that part of the British section which is nearest the pavilion built from the plans of Mr. Gilbert Redgrave, the architect to the Royal Commission, for the Prince of Wales. It may suffice if I now indicate the most important exhibits here attracting the eye of the visitor, and fulfil my intention of bringing prominently into notice such objects as illustrate an advance in old paths or a promising entry upon new ones.

A great encouragement to such an attempt is the manifest excellence of these classes, furnished as they are by English exhibitors, or at all events by those who pursue their skilled vocation in England. Photography has made marvellous progress in all countries, from the time of its first discovery down to the present day; nor have the strides of improvement and invention in this art been fewer or less noteworthy within the past few years than in any period of its interesting history. The specimens of brilliant and artistic work, secured from fading by the carbon process, are in the highest degree creditable to such accomplished photographers as Signor Lombardi, of Brighton and Pall-mall. This skilful artist, as usual, affords a conspicuously striking and meritorious show of large portraits, which are arranged in a handsome case of silk velvet, the colour of the ground being maize, and the other portions ruby and gold. The design of this framework is due to Messrs. Messrs. Dupuis and Co., whose fine-art gallery in West-street, Brighton, adjoins the studio of Signor Lombardi; and, as a piece of workmanship, the case in question is worthy the magnificent examples of photographic art which it contains. An enlarged portrait, on permanent tissue, of Mrs. Bligh, is the first work in this collection to call for notice; it measures about 50 inches by 40, and in its splendid carved frame of Florentine character makes a very imposing show of itself, being in fact of a size which, were the subject not so gracefully feminine, might be termed Herculean. Another likeness to which the most careless vision could not but be attracted is that of a lady who, no very long time since, made a considerable stir in the ears of society. The details of this strikingly-truthful portrait of Mrs. Bravo are remarkable for wonderful texture and finish, and the entire work is a crowning success of heliography. Without enumerating the whole of Signor Lombardi's collection, I must find space to mention a triad of heads which he aptly calls "The Three English Graces," being character-portraits of Lady Wentworth, as Mary Queen of Scots; Mrs. Turner, as a Hungarian Vivandière; and Mrs. Bligh, as Marguerite.

Portraits from life by M. Boucher, also of Brighton, indicate the exercise of great care and taste, guided by the skill which is only acquired through long practice and diligent application. The heads are characterised by a reality of light and shadow, answering to the effect of roundness and fine modelling, and the resemblances are all impressively lifelike and agreeable. The London Stereoscopic Company makes a specialty of portraiture, comprising a gallery of distinguished persons in France. Mr. Robert Slingsby, of Lincoln, shows some good photographic portraits of large size, taken direct from life, together with a few nature studies combining portraiture and landscape, with excellent effect. An exhibition *per se* is Mr. Vanderweyde's collection of likenesses taken by the electric light. Their effect is legitimately pictorial, while retaining the quality of truthfulness to an almost realistic but still pleasing extent. Obviously, a great advantage of the process is the fact that it overrides the influences of fluctuating daylight, and accommodates the convenience of ladies who may desire to be portrayed in ball or drawing-room dress. Messrs. Elliott and Fry have a large exhibition of photographic portraits, exemplifying their well-known delicacy of execution. In landscape, and especially the natural variations of foliage, ground vegetation, and cloud-shadow, Mr. Vernon Heath shows his mastery of subject and means. Examples are displayed by him of the enlarged autotype prints by which he has represented a series of more than 200 well-known places, country mansions, and celebrated trees in the British Isles.

Landscape photographs, in a well-known style, are also contributed by Mr. Bedford; and the representation of natural scenes is effectively carried out by Mr. T. M. Brownrigg, with the wet collodion process. Combination pictures are exhibited by Mr. H. P. Robinson and Mr. Samuel Fry; and there are some excellent studies of animals, by Mr. Alfred Fisk, Mr. David Hedges, and Mr. Frederick York, the last-named photographer exhibiting transparencies of carnivora and other objects of brute life, from the Zoological Gardens, arranged for use with the magic lantern. The large architectural photographs, by Mr. W. H. Wheeler, of Oxford, have an especial value for artists and students. Mr. Herbert Watkins has a display of positives printed in silver as well as in carbon; and there is a show, well worth observation, by the Liverpool Dry Plate and Photographic Printing Company, of framed subjects printed from negatives made on "Liverpool" emulsion plates. So much has been said of the drawbacks of climate, in the operations of English photography, that visitors to the Champ de Mars will stare with agreeable disappointment at these specimens, and at others which I may have inadvertently left unmentioned. It may be that chemistry has played an active and useful part in enabling British followers of the practice to counteract all atmospheric difficulties. As examples of the splendid result to be obtained with the collodion of Messrs. Mawson and Swan, this Newcastle firm shows a series of twenty-five admirable portraits, taken by Messrs. Lock and Whitfield, for *Men of Mark*, and certainly as fine as anything produced by Paris or Vienna.

Meetings of Societies.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

The concluding meeting for the session was held on Tuesday evening last, the 11th inst.,—the President, Mr. James Glaisher, F.R.S., occupying the chair. He (the Chairman) introduced to the members Lieut. Darwin, R.E., as the gentleman who had been elected by the Council to fill the office of honorary secretary, vacated by the retirement of Mr. H. B. Pritchard. He also referred to a letter he had received from Mrs. J. A. Spencer, in which she acknowledged the kind letter of condolence transmitted to her and her family on the recent death of her husband.

Mr. Thomas Bolas, F.C.S., then read a paper *On the Alleged Fading of Carbon Prints*, which will appear in our next number. No remarks followed the reading of this communication.

Mr. J. R. Johnson read a paper *On Alizarine: its Origin, Properties, and Applications.* Until this paper is published, which will be in our next issue, we shall abstain from giving the remarks, by Mr. J. R. Sawyer and Mr. W. S. Bird, made on Mr. Johnson's communication, as these gentlemen's observations could not be properly understood in the absence of the paper by which they were elicited.

The Chairman tendered to Mr. Bolas and Mr. Johnson the thanks of the Society for their papers, and also thanked Mr. Sawyer for his able remarks on the subject. He (the Chairman) stated that the paper announced to be read, and the illustrative exhibition, by Mr. Warnerke would be deferred until a future occasion. Captain Abney, he further said, had a paper ready, but it was impossible to read it at that late hour; it would, however, appear in the Society's *Journal.*

Mr. Werge exhibited a number of negatives taken on Swan's dry plates.

The Chairman having announced that the exhibition of the Society would be opened on October 18th, the proceedings terminated.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

The last meeting of this Society, held on Thursday, the 6th inst., was devoted to the revising of the laws and to private business. Hence we do not give the usual report of the transactions.

EDINBURGH PHOTOGRAPHIC SOCIETY.

The eighth ordinary meeting of the session was held at 5, St. Andrew-square, on the evening of Wednesday, 5th June,—Mr. J. Lessels, President, in the chair.

The following new members were unanimously elected:—Messrs. W. Jenkinson, P. Conning, J. R. Cooper, and J. T. Gerard, by Mr. W. Leitch; Mr. Ross, by Mr. W. D. Young; Mr. Henry White, by Mr. Anderson; Mr. Peter Ferguson, by Mr. Tod; Mr. James Abbot, Jun., by Mr. Matheson.

A number of very beautiful prints from negatives produced at the recent outdoor meeting at Tantallon Castle and Tynningham were handed round for inspection, and were much admired.

It was urged by several members present that, if possible, transparencies for the lantern, from the best negatives secured during these interesting trips, should be prepared, and become the property of the Society. It was maintained that very great interest would specially attach to these works of the members from their local associations, and also because many of them are unique, being unobtainable elsewhere, and of very high artistic value. If such a project could be conveniently carried out the Society would soon be possessed of an extremely large and valuable series of transparencies, available for the use of the Society at its "popular evenings," and accessible to individual members for illustration and entertainment. The difficulties in the way of securing uniformly high-class transparencies suitable for the lantern require that some members make this work a speciality in order that justice may be done to the negatives, and that they may be a credit to the Society as a large and influential body specially devoting its energies to the advancement of photography. It was understood that several members would make experiments towards attaining this end, so that by the time the next session opens some simple and reliable method might be perfected providing a soft, pleasing colour and delicate rendering of every subtle detail.

The presentation prints were next distributed to those members who were present, and it was agreed to send a copy to other kindred societies, and also a copy to the editors of the two English journals devoted to photography.

Mr. W. Nelson, in a few graceful remarks, proposed a vote of thanks to Sir Noël Paton for his permission to reproduce the picture forming the subject of the presentation. This was seconded by Dr. Hunter, supported by several other members, and unanimously adopted.

A vote of thanks was then most heartily accorded to Mr. W. H. Davies for the charming way in which he had printed the pictures, and the tasteful manner in which he had mounted them. In reply to a question as to the mounting,

Mr. Davies said that the trimmed carbon prints were mounted upon a suitably-tinted cartridge paper that had previously been stretched damp upon a board and allowed to dry. When the carbon print was dry the cartridge paper was cut out with appropriate margin, and the whole remounted upon the thick cardboard as seen. From his great experience he said he was justified in holding that to be the best way to finish large prints, the beauty of the result amply repaying the extra time and labour involved.

Some conversation next took place concerning the ferrous oxalate developer, the coming outdoor meetings, and the next annual holiday and trip, after which a vote of thanks to the Chairman terminated this, the last, meeting of the session.

The second outdoor meeting for the present season was held at North Berwick, on Thursday, the 31st May last.

The party left Edinburgh by the 7 a.m. train, arriving at Berwick about 8.30 a.m., when, having partaken of breakfast, a conveyance was procured, and a start made for Tantallon Castle. The weather was simply beautiful, and the drive through the delightful country was most thoroughly enjoyed. On reaching the Castle a number of plates were exposed.

The party then proceeded to Tynningham, the seat of the Earl of Haddington. The members were amply repaid, for a more beautiful place they have never visited. Some very choice "bits" were secured in the woods, and with these, and the mansion situated in magnificent grounds, the supply of plates soon became exhausted.

A return drive of seven miles made the party enjoy a substantial and *towsy* tea at North Berwick. Edinburgh was reached about 8.30 p.m., all being delighted with the day's outing.

THE PHOTOGRAPHIC SECTION OF THE AMERICAN INSTITUTE.

A meeting of this Section was held on the 4th January last,*—Mr. H. J. Newton, President, in the chair.

After the transaction of some preliminary business Mr. Roosevelt offered some remarks on the subject of producing tints by fine ruling.

The President: The effect of coloured glass in copying objects with a variety of tints was introduced at the last meeting, since which time I have made some experiments with blue glass in copying. It was claimed by Mr. Chisholm that he photographed a coloured object, or an object with a variety of colours, much quicker when a piece of blue glass was interposed near the diaphragm of the lens. Mr. Chapman

* Through oversight this report was omitted to be published at the proper time. We now give it in order to keep up the continuity of the proceedings of the Section.

doubted the correctness of the conclusions at which Mr. Chisholm arrived, and gave his reasons, which you have heard read in the report. He did not think that the wave lengths of the light reflected from the object were changed at all in their actinic properties by passing through a coloured medium. But there appeared to be such a variety of opinion upon the subject that I prepared several glasses, and have brought one here. I took very thin 8 x 10 glass and coloured one-half of it blue. I covered sections of a chromo. with the blue glass and photographed it. Here is the chromo. and the prepared glass (exhibiting with the resulting negative and print a chromo. entitled *Now I'm Grandmother*, and a piece of glass, one-half of which was coloured blue). He (the President) then explained how he placed the glass over the chromo. so as to have one half of the picture covered with the blue glass and the other with the clear glass, the line running straight down the centre of the chromo., the effect being to turn the reds to crimson, the yellows to greens, and the browns to a darker brown on the half of the chromo. covered with the blue glass. He also covered smaller sections of the picture with blue glass, leaving larger sections uncovered. In making negatives of the chromo under these conditions it would be perceived by examining the negative and print that there had been no perceptible difference in the photographic action between the part covered by the blue and that portion covered by the clear glass. He had always held to the theory that the whole was more than a part, and had always maintained that blue light was not as quick in its actinic action theoretically (he had not tried it) as white light.

Mr. Chapman: Mr. President, what proposition do you make with regard to the oovering the object with glass one-half of which is coloured blue?

The President: That it makes no difference.

Mr. Chapman: Cover half with glass and leave the other half uncovered; is there any difference then?

The President: I took a piece of blue glass and covered one-half of the picture, leaving one-half without glass. There was no difference; there was no line.

Mr. Chapman objected to the experiment, claiming it to have been faulty, and that the blue would make some difference. It would make the same difference in proportion as ten times the amount of blue used; that the length of exposure would materially modify the experiment—a short exposure showing a variation not to be seen by a long exposure. The proper way was to test it by an actinometer.

Mr. Mason expressed his gratification at seeing the result so near as he claimed it would be. He did not understand that Mr. Chapman's proposal to test it with the actinometer would be exactly fair, as Mr. Chapman's actinometer was so constructed that by standing the glass in front of the instrument, the light being at one end, the angle would be continually differing; and if they put the glass perpendicularly to the light, then the polished surface of the glass would refract or reflect more light in proportion to its distance from the gas flame.

Mr. Chapman: I think the picture is made slower by glass being over it in this way. I should prefer to place the blue glass near the diaphragm.

The President explained that the half of the picture not covered with the blue photographed precisely the same as the covered half.

Mr. Chapman: I think that blue glass placed directly in front of the lens would work a little quicker, because the rays of light strike upon it more perpendicularly.

The President: I do not believe that the position of the glass would produce any difference of effect. He (the President) further said: I have another matter, which is in relation to a developer that was given to me confidentially by Mr. W. Willis, Jun., the author of the platinum printing process. It will be recollected that he exhibited a large number of pictures printed by that process at our meeting in May. Immediately after that meeting he came to my house and gave me a new developer for developing emulsion plates, either wet or dry. For certain reasons (stated) I did not feel at liberty to make the process public. A few days before Mr. Willis's return to Europe, in November last, he again called on me. He stated that he should direct the editor of The British Journal of Photography, with whom he had left the manuscript giving all the details of the process, to publish it about the first of the present month. I therefore now feel at liberty to give the process here, as it will undoubtedly appear in the foreign journals before it does in our published proceedings. The composition of the developer is as follows:—Forty or fifty grains of neutral oxalate of potash dissolved in one ounce of water; add sufficient ferrous oxalate to the solution to produce an orange colour. Or a more simple method is to add to the oxalate of potash solution a few drops of a saturated solution of protosulphate of iron, to produce the orange colour. Then add two drops of acetic acid, No. 8, or enough to make a slight acid reaction on litmus paper. This solution is then flowed over the exposed plate in the ordinary manner. The image developes more slowly than with the alkaline pyro. developer, but proceeds satisfactorily and without fog. So far as my experiments go I am inclined to the opinion that a little longer exposure is necessary with this developer than with the carbonate of soda. You will see by the prints exhibited that the action in the shadows and dimly lighted portions is very marked and peculiarly fine. (The President then exhibited a number of negatives produced by this process, and prints from them.)

Mr. Mason: Did you immerse or flood the plates in developing the image.

The President: I flooded them. I have tried it only on wet emulsion plates. My experiments with this developer have been limited. I have not discovered anything peculiar in its action, so far, other than stated, with this exception, perhaps, that it can be used repeatedly without limitation, a little addition of the iron occasionally only being necessary. Neutral oxalate of potash is very easily prepared. The most simple way is to make a saturated solution of carbonate of potash in hot water; then add to this solution oxalic acid in crystals, until neutral. This will give a precipitate of the neutral oxalate of potash, the natant liquid being a saturated solution of the same salt, which can be used by being reduced to the required strength.

Dr. Higgins: Chemically pure oxalate of potash is a commercial article and sells at $2 00 a pound. I would like to ask the President if he had tried the alkaline developer for strengthening negatives made with the oxalate developer before fixing.

The President: I think I did, but I am not quite certain. In reference to the expense of the oxalate of potash, I would say that I have prepared it with both the chemically pure carbonate of potash and oxalic acid and also with the ordinary commercial articles, and discovered no essential difference in the developing properties of either. The cost of that obtained with the commercial salts would not exceed fifteen cents a pound, exclusive of the labour of preparing.

Mr. Mason: What guide had you for determining the amount of the ferrous oxalate?

The President: It does not appear to make a great deal of difference. Ferrous oxalate is not soluble in water, but it is to some extent in the oxalate of potash solution. Mr. Willis said he had introduced it to a gentleman in Paris, a worker in dry plates, well known; he found it was very much quicker than the developer he had been using.

Mr. Chapman moved that the subject of keeping bromide emulsion dry plates after exposure and before developing be placed in the hands of the experimental committee for determining how long after exposure the image could be successfully developed. He had found it difficult to develope the image if the plate were kept several months after exposure. His trouble might be that the preservative solution was not of sufficient strength. He would like to have the subject investigated by the committee.

A vote not being necessary on the motion, the Section then adjourned to the first Tuesday in February. [See report of the February meeting on page 211.]

Correspondence.

Meeting of the Photographic Society of France.

The usual monthly meeting of the Photographic Society of France was held on the 7th instant,—M. Davanne occupying the chair. After the election of two new members, MM. Bocher and Mulnier, M. Perrot de Chaumeux, Secretary for the Foreign Correspondence, read the extracts and translations from the French and foreign journals, which have already been published.

M. Alfred Chardon presented a sealed letter containing the details of improvements in the bromide of silver process, for which he is the "laureate" of the Society, and begged it to be placed among the archives of the Society so as to take date from that evening. He took the opportunity to remark, at the same time, that the account recently given in the *Bulletin Belge* of the process of Mr. Warnerke presented several points similar to his own, but the latter having been described *in extenso* during the meeting held on the 6th of April last year, although lodged for the competition in November, 1876, consequently entitled him clearly to priority of publication.

Among the strangers present were M. Lewitsky, of St. Petersburgh, and Mr. G. W. Simpson, of London.

Remarks on Mr. Warnerke's paper were read, also a *verbatim* translation of the sub-leader thereon which appeared in The British Journal of Photography; on Mr. Carey Lea's papers on ferrous oxalate development; on Dr. Van Monckhoven's paper, read before the Photographic Society of Great Britain; on Obernetter's recent process; on Albert's (of Munich) colouring process;—all of which were reproduced from or have been published in the pages of The British Journal of Photography, and gave rise to several reclamations by the Secretary on behalf of M. Poitevin, M. Ducos du Hauron, M. Chardon, and others.

M. Davanne said that as at the present time Paris was favoured by the visits of representatives of all nations, it had been thought proper to invite to dinner, under the auspices of the Society, the different foreign jurors and distinguished visitors, who, with photography as a common centre of union and attraction, would make its acceptance right welcome. The feelings of the members were unanimously in favour of the proposal. M. Davanne therefore suggested that, as the photographic syndicate had nobly done its duty in the matter of the Universal Exhibition, he had pleasure in proposing that M. Berthaud, its president, and some of its principal members, should be conjointly named *commissaires* or stewards. Accordingly, MM. Davanne, Berthaud, Perrot de Chaumeux, Franck de Villecholles, Audra, Truchelut, and

Bardy were appointed to take the necessary steps requisite to do honour to all concerned.

M. Janssen submitted to the Society an eighteen-inch print of the surface of the sun, enlarged three times the size of the original negative, with an exposure, by the new system, of $\frac{1}{3000}$th parts of a second, and which shows the granulations in certain parts effected by the ascensional currents of hydrogen.

M. Liebert presented to the library of the Society the third edition of his work entitled *La Photographie en Amerique*, which, in contradistinction to that of M. Janssen, is an observatory of mind and photographic matter, and in which will be found the last word on the various new photo-engraving processes.

M. Audra exhibited some English cometless collodion bottles in orange coloured glass, which, under certain restrictions, would be useful to emulsion workers. M. Balaguy, a clever amateur, showed a box of bromide of silver negatives of great purity, the washed emulsion being made by himself and M. Puch. The views were taken in the Avenue of Foreign Nations at the Universal Exhibition. M. Guillot, of Lyons, exhibited portions of 40-yard pieces of unbleached silk impressed with large medallions and portraits the whole breadth of the piece. There was no information supplied as to the manipulation, but M. Michaud said he knew the manufacturer, and believed the impression was with the salts of silver—probably iodide—with development. In my own practice, formerly, I obtained much more agreeable colours with the use of a citrate of silver, and for fans, fire-screens, and library folding-screens secured nearly as good an impression on both sides of the silk.

M. Klary, conjointly with M. Franck, showed a *carte* and cabinet negative, and print therefrom, by the extra-rapid process of M. Boissonnas, of Geneva. No. 1 *carte* received an exposure of two seconds; No. 2 of three seconds; and Nos. 3 and 4 cabinets of five seconds—all for head and bust. The lens used was Dallmeyer's three-inch portrait lens. The exposures took place in the afternoon at 3.50, the sitter being Mr. G. W. Simpson. I think M. Klary is to be blamed for taking these effects at too late an hour of the day, requiring a decided *tour de force* to accomplish the object. The photographer's universal excuse is—catch your personages when you can get them; if not at the hour you would like to have them, catch them when you can. A full length figure of a young girl was taken with a six-inch lens stopped down to four inches on a $14 \times 10\frac{1}{2}$ plate in twelve seconds, and which was well exposed, well lighted, fine in the details, and, added to good development, there was thus produced a well-balanced print, no intensifying being required.

M. Lacan desired to add his testimony with respect to the experiments of M. Klary. He saw the portrait of a lady taken with three seconds' exposure. She was fair, with a light complexion, and wore a dark velvet dress, the two extremes of light and dark meeting in one picture. The photographic difficulties were overcome, and the head-rest might be discarded. M. Lacan, with M. Franck, created considerable amusement by saying they were right glad of the universal dislike of the head-rest which was gaining ground, and which was appropriate during this period of progress. They might now get rid of the head-rest, and supersede it by "a guide." M. Franck added:—"I can now say to my fair sitters—'Ladies, I am most happy to inform you that there shall be no more head-rests; I substitute in its place, with great pleasure, a guide.' This tickles their fancies, and they take agreeably to a simple guide."

MM. Braun et Cie exhibited a collection of their nicely-mounted late impressions in fatty printing ink.

M. Audra then read a short paper on *Precipitated Bromide Emulsion.* [See page 278.]

M. Davanne, referring to M. Audra's statement about the want of vigour when he had neutralised the free silver in his emulsion with iodide collodion, said that he had never had any difficulty with his Taupenot plates. He used one-third iodide with two-thirds bromide. He employed alkaline development, and never had experienced any want of vigour, his plates always behaving exceedingly well.

M. Michaud asked if the remainder of the emulsion at the bottom of the bottle was crystalline.

M. Audra stated that such was not the case, for he had the habit of well shaking up his dissolved emulsions at least three times a week. Long keeping, however, as a general rule, produced granulation, while the emulsion was not limpid.

Professor Stebbing laid stress on the fact that if once the soluble emulsion became limpid it was impossible by re-shaking to re-dissolve it completely, and hence granulation.

M. Lewitsky had experience with the preparations of M. Warnerke, and he believed that that which he had kept since 1877 was better than that newly made in 1878. He found that, to a certain extent, age was decidedly advantageous. His portrait ticket to give him admission as a juror to the Champ de Mars was, indeed, a fine one, and had had only half-a-second's exposure.

M. Marion showed Cadett's patent pneumatic shutter for portrait lens, and also the double-nickeled rollers and hollow steel roller by which heat can be quickly, most efficaciously, and uniformly applied for glazing prints without scratching. The simplicity of the movement upwards and downwards was very apparent. This press merits success in France as well as in England.

M. Peignot exhibited a number of enamelled portraits, possessing perhaps, the purest and richest warm tones that it has been my pleasure to see. They comprised both *carte* and cabinet sizes. He did not divulge his process, but said the charming high lights were pure photography, without retouching or the application of hydrochloric acid to whiten them or to render them more transparent.

M. Michaud read some further observations on his photo-engraving process, as well as on the advantages of square-sided vases for the galvanic battery.

MM. Fouquet and Guetem exhibited what appeared as an elegant enclosed American stereoscopic stand, which would hold glass or paper slides, *cartes*, cabinets, or general views. The ground glass illuminating the transparencies moved backwards and forwards to suit the focal lengths of the graphoscope or stereoscopic lens, with a candle or globe light fixed upon a gilt elbow-jointed arm to swing round to any required point in front of the ground glass for evening use.

Mr. Woodbury's name was down on the programme to present Woodburytype prints on transparent pellicles instead of paper or glass, and also specimens obtained by him during his tour in Italy with Liverpool emulsions. Unfortunately for the members, who highly esteem Mr. Woodbury, that gentleman was obliged, just at the hour of the meeting, to leave Paris to keep an appointment in London. His unavoidable absence was much regretted, for he would have been welcomed with great enthusiasm; however, let us hope that it is an adjournment for a short time only. In his absence I was called upon to make the presentation in his name, and such is the estimate here of Mr. Woodbury's labours, that the President and Vice-President of the Society will esteem themselves happy to become the possessors of his presentation prints. W. Harrison.

Asnières (Seine), Paris, June 11, 1878.

MR. H. COOPER'S CHROME ALUM GELATINE SUBSTRATUM.

To the Editors.

Gentlemen,—I was pleased on reading Mr. Henry Cooper's experience on this subject. If I could find time for experimenting on all that suggests itself to me, besides taking a few pictures sometimes, I should have tried the above substratum some months ago, but with a slightly different object. It would have been shortly after my experience in developing gelatine plates at Gibraltar, of which an account was published in your Almanac of this year.

Among other expedients which I wished to try for preventing the reticulation of the gelatine film in development was that of a substratum of gelatine, rendered insoluble by means of chrome alum. I was prevented from making the trial by much other work on hand, and, as it may still be some time before I can do so, I venture to throw out the hint in case any of the numerous zealous experimentalists in this direction may think it worth a trial.

I may, however, remark that with some of the most correctly-prepared gelatine plates I had failed to prevent the reticulation of the film by means of Epsom salts, notwithstanding its recommendation by those in whose experience I place the greatest reliance, although I used at the same time spring water as cold as I could obtain it.—I am, yours, &c.,

20, *Cornfield-terrace, Eastbourne, June* 8, 1878. Wm. Washam.

SELF-DEVELOPING PLATES.

To the Editors.

Gentlemen,—It will be remembered that, in the issue of The British Journal of Photography for August 24, I referred to a process for producing visible pictures direct in the camera. It will be found on page 408 of last volume. I there ask if it is anything new, but have not received an answer. I now give the formula:—

Prepare an ordinary bath plate; wash slightly, or till greasy lines disappear. Next flow over it a solution composed of—

Glycerine	20 drops.
Catechu (previously softened in spirit of wine)	15 grains.
Water	1 ounce.

Expose as for an ordinary wet plate, or, preferably, twice that time; and at the end of five minutes after exposure all detail will be visible, but thin. An ordinary pyro. and silver redeveloper brings it up to printing density at once. These plates acquire density easier than any other I ever tried. Sensitiveness, success, or failure—all depends on the amount of washing before the organifier is applied.

You cannot over-expose, even if such be extended to one hour in bright sunlight, provided other matters are attended to.

The organifier should be filtered before use, and too much washing makes the plates insensitive. The organifier is not washed off until detail is out.—I am, yours, &c., W. Weston.

Swinton, near Manchester, June 5, 1878.

[We have received a subsequent communication from Mr. Weston, in which he says:—"I am sorry that my engagements prevent me from producing the required proof, and beg to say the formula is reliable; but possibly more glycerine might be an improvement. I will forward a proof—either print or transfer—in a few days."—Eds.]

OXYGEN RETORTS.

To the Editors.

Gentlemen,—I have just had my attention drawn to Mr. W. J. Chadwick's letter in last week's Journal. His statements are, I am sorry to say, incorrect as usual. He says that I was informed officially that I must not exhibit my apparatus, &c. The truth is that I was asked by our Honorary Secretary to choose another night, as some members of the Liverpool Amateur Photographic Association, who were present, had to leave early; and I am sure that almost every member present at the meeting alluded to will remember the President announcing that any member could show what he had brought, or something to that effect. This was after I had promised to have another night.

Again: when I tell your readers that Mr. Chadwick actually handed me a piece of the apparatus I had left out when packing, your readers will form their own opinion of Mr. Chadwick's tale about not being able to give any attention when I showed my patent safety oxygen apparatus.

If those interested will go to the trouble to refer to page 287 of the Journal for 1877, as named by Mr. Chadwick, they will see in my letter something to their advantage; and, as he has repeatedly tried to mislead your readers by saying my apparatus was simply a copy of Mr. S. Highley's gas-holder and Mr. M. Noton's retort, I think in justice to your readers this matter ought to be settled. I would ask them to compare my gas-holder with Mr. Highley's, and they will find it quite different. Mine is very much stronger, and at least thirty per cent. lighter than if made like Mr. Highley's, while mine does not require any screws, nuts, or pins, to put it to work.

As to my generator being like Mr. Noton's, Mr. Chadwick knows, or ought to know, that Mr. Noton's generator could not be re-charged whilst hot, nor could it be used with chlorate and manganese until the same had been made into plugs and dried; whereas mine may be re-charged whilst red hot, and the chlorate and manganese may be used without any preparation.

I have no wish to claim anything that does not belong to me. I am quite willing to test my apparatus against any other, and so save your readers being misled by false statements.—I am, yours, &c.,

Swinton, June 11, 1878. David Young.

EXCHANGE COLUMN.

I will exchange a 20 × 20 mahogany camera and slide for a 12 × 10 swing-back camera.—Address, F. J. Matthews, photographer, Ryde, Isle of Wight.

Wanted, a landscape lens, in exchange for lenses and camera to take three to twelve medallions on half-plate (wants dark slide).—Address, W. Tylar, 165, Well-street, Birmingham.

A four-inch lime-light dissolving view apparatus, splendid set, four different powers, with or without slides and accessories; also, a pair of Carpenter and Westley's improved oil-light dissolving lanterns. What offers in exchange?—Address, A. Wilkinson, 15, Holmeside, Sunderland.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

J. Cooper.—Received.

S. B.—The best cement for the purpose is marine glue.

M. Heslop (Christchurch, N.Z.)—Received. Thanks.

William H. Metcalf (Milwaukee, U.S.A.).—Draft received. Thanks.

J. Roarty (Sydney, N.S.W.).—Amount of subscription received. Thanks.

Argus.—Thanks for the information, which we shall make use of in an early number.

William A. Brice.—We shall try the microscopic experiment indicated, and report the results.

Styx.—Either of the addresses upon a letter will ensure its reaching the person for whom it is intended.

L. T. W.—If the plate had been more thoroughly washed after it was fixed there would not have been any markings apparent.

A. W.—To retain the polish on the steel rub it over with a cloth charged with oil. Before making use of the burnisher wipe it clean with a dry cloth.

M. R. and B. R.—The symptoms indicate a developer possessing a degree of strength far greater than ought to be the case. Reduce it very much. Commence by adding an equal volume of water.

Dunoon.—Phosphorescence is not fluorescence, the two being quite distinct. What you have described is *fluorescence;* and we advise you to try the effect of a very strong solution of sulphate of quinine.

Lenticus.—The occasion for the letter has passed away, and it will be better to allow the matter to rest where it is, especially as no good could result from discussing the special phase to which you confine yourself.

A. M'D.—Return the cards without delay. If they really are such as you describe them to be the firm by whom they were supplied will, for the sake of their own reputation, be only too glad to take them back.

X. Y. Z.—The subject does not possess any interest, except for a few readers—probably not more than five or six. This being the case we must decline acceding to your request to devote an article to it, until some new phase of it turns up in which many would feel interested.

H. Smith.—Mr. Bennett's negative, showing the pouring out of the water in drops, together with a transparency and a print on paper from the same, are still on exhibition at our editorial office. They have been seen by numerous visitors, including the representative of the newspaper mentioned.

An Obliged Reader.—The law in France appears to be this—that if a sitter renowned in art, science, or literature give to the photographer by whom he is taken the right to sell his portrait, that right ceases as soon as the original of the portrait expresses his desire that such publication shall cease.

J. B. M. (Manchester).—No other form of sterescope that has ever been introduced is so convenient, or possesses an equal number of advantages, as the lenticular instrument. Of lenticular sterescopes, no other form that we have yet seen approaches in convenience that of Oliver Wendell Holmes, of America. It is not so well adapted for examining transparencies as the closed-up box, but for prints upon paper it is unrivalled.

Geo. F. Slater.—For wetting the surface of a dry plate previous to developing it we have found methylated spirits of wine answer quite as well as pure alcohol. In our own practice we do not dilute it, but apply it just as it is, returning the spirit to the pouring bottle, which is a six-ounce stoppered bottle having a very wide neck, with a lip well turned over and somewhat broader than usual. We prefer a bottle of similar form for coating the plates from.

H. H. P. (Wick).—Try malic acid. It may be purchased at a cheap rate, or may be prepared by heating the juice of rhubarb stalks, neutralising with carbonate of potash mixed with acetate of lime, and filtering. To this add acetate of lead to form a precipitate of malate of lead, which by the addition of sulphuric acid is decomposed. The crystals obtained upon evaporation are those of malic acid; this will prove for your purpose the best acid with which we are acquainted.

A Tyro.—The cause of the want of sharpness at the sides of the picture arises from the lens having been worked with either too large a diaphragm or with no diaphragm at all. Ascertain the focus of the lens, and then make use of a stop the aperture in which is about one-thirtieth of the focus. This will necessitate your giving a longer exposure, and the resulting picture will be very sharp, even to the margin. Next employ a stop with an aperture somewhat larger than the foregoing—say one-twentieth—and by means of this tentative method you will soon discover the best aperture to make use of.

G. C.—Can you adduce any good reason why the gentleman named should not have secured his invention by patenting it? An inventor has quite as much right to the results of his brain work as you have to the money you make by exercising your occupation of taking portraits. Take your own statement in your letter:—You avow your readiness to have availed yourself of the invention in question provided you could do so without being found out, and, as a consequence, being involved in a lawsuit for infringement. The principle involved in this is the same as that by which certain classes would willingly appropriate the watches and diamond rings of the public were it not for fear of the consequences. Look at yourself in this mirror.

Received.—*Light* (Macmillan); *La Photographie en Amerique*, by A. Liebert; and examples of M. Michaud's new process of photo.-engraving. Notices of these will appear in an early number.

Exhibition of the Manchester Photographic Society.—This Society is to hold an exhibition in August next. All particulars respecting the forthcoming exhibition may be ascertained on application to the Honorary Secretary, Mr. Charles Adin, Memorial Hall, Manchester.

The Boissonnas Process.—It will be remembered that about twelve months ago we spoke in terms of high commendation of a number of groups and instantaneous portraits taken by M. Boissonnas, of Geneva, by means of a process by which an exceedingly brief exposure was required. At that time it was intended to introduce the process into this country to all who, upon certain terms, chose to become acquainted with it. Owing to the incertitude of the results this intention was not fulfilled. We now learn from M. Boissonnas that he has entirely altered the process—indeed to such an extent that it may be considered as no longer the same process as formerly. As the method is now being daily worked by MM. Klary and Franck de Villecholles, in Paris, we strongly advise those of our readers who are about to visit the "gay capital" to avail themselves of a cordial invitation given by these gentlemen to visit 18, Rue Vivienne, Paris, and see it in action.

GENERAL ARRANGEMENTS FOR FIELD WORK.

A fortnight ago we devoted an article to the subject of preparations for outdoor work intended specially for those of our readers whose practical experience in that direction is limited, and we now supplement our previous article by a few remarks upon the arrangements necessary when actually in the field. Before speaking of the apparatus we may premise that our observations are made with a view of assisting, in the choice of appliances, those who may not be completely fitted out rather than with the desire of altering any existing arrangements; and our hints will be of value to those who may be at a loss to decide upon the instruments which will best suit their individual circumstances.

The first point to be considered is the part which photography is to play in the matter—whether it forms the chief and primary object of the tour, or is only a secondary consideration to be utilised when circumstances shall admit in securing permanent mementoes of a pleasure trip. In the latter case the photographic arrangements must be of such a character as to interfere as little as possible with the comfort and convenience of the tourist, and, in the majority of instances, the pocket camera will be selected as most nearly conforming to these conditions and, at the same time, satisfying all pictorial requirements. But when the main object of the journey is the production of pictures in the true sense, in contradistinction to casual "shots" by the way, the small-sized plates we have mentioned cease to be worthy of the extra care and trouble which the artist is willing to lavish upon them. In casting about for the best size to work the novice at tourist work is apt to err in the opposite direction, and, by attempting too much at first, to spoil the results of the whole trip and probably also to acquire such an experience as will deter him from ever making a second attempt.

The advice we would give to the young amateur about to make his first essay away from home is to be moderate in his ambitions, both as regards size of picture and quantity of work to be done. In a general way it is, of course, impossible to say what size of plate is the best to work, or that any given size better satisfies pictorial requirements than another; but in the present instance we have no hesitation in saying that, for the sake of comfort and convenience, to say nothing of the quality of the results obtained, the whole-plate is *quite* large enough for any one to try his "'prentice hand" upon. We would even recommend one of the smaller "cabinet" sizes—$7\frac{1}{4} \times 4\frac{1}{2}$ or $7\frac{1}{2} \times 5$—which, while making a very pretty single picture, combines the advantages of the stereoscopic plate as well.

The actual weight of the apparatus forms a comparatively trivial item in the argument in favour of small plates, though even on that point a week's experience of travelling photography will be amply sufficient, probably, to develope some new ideas as to the real amount of labour involved in the transport of even a $7\frac{1}{2} \times 5$ camera and its adjuncts. The real difficulties are found more in connection with the packing and safe stowage of the plates and of the numerous *etceteras* which an absence of two or three weeks from home render indispensable, and these difficulties become greater in proportion to the size of the plate.

We may be allowed to say a few words upon the subject of lenses—not from a theoretical, but from a purely practical, point of view. If the amateur desire to be complete in his equipments and in a position to secure *any* subject which may be presented to him he will, of course, require a variety of lenses for each size of plate he works. This not only entails very considerable expense, but adds greatly to the bulk and weight of the *impedimenta* which it is his chief object to keep down as much as possible. But the question presents itself as to whether it is desirable that the amateur—at least the inexperienced—should go thus armed *cap-à-pie* ready to tilt at anything and everything. We think not; rather should he be content to attempt only such subjects as his means, whatever they may be, enable him to do successfully, and to have the courage to pass by those which are beyond his powers.

Lenses may be divided into three classes—wide, medium, and narrow angle—each of which has its advantages for special classes of work. In selecting a lens, then, which is to do the whole, or, at anyrate, the greater part, of the work some attention should be given to the class of subjects it will be principally required to render. In mountainous districts or for open landscapes the most pleasing and natural results are undoubtedly obtained with long-focussed lenses, as the angle of view included approaches most nearly to that given by the eye. But a great variety of pure landscape subjects require a wider angle for their proper rendering, or what we term a "medium" angle. Wide-angle lenses properly so called are wholly unsuited for general landscape work, and though *occasionally* of the greatest use, their injudicious employment has done much to bring discredit upon landscape photography. For architecture, especially in confined situations, they are, of course, invaluable; but unless the amateur intends to confine himself to that class of work he would be unwise in the extreme to select a short-focus lens as his only one.

The most suitable lens for general work will, therefore, be a medium angle; for a $7\frac{1}{2} \times 5$ plate eight or eight and a-half inches will be a convenient focus, and if the lens be chosen of the doublet form, giving straight lines, it will be equally adapted to landscape work and to architecture when the subject is not too much enclosed. For pure landscape nothing excels the old single combination. A most useful adjunct to the lens—in many cases an absolute necessity—is a sunshade. These are frequently supplied by the optician; but, failing that, an efficient substitute consists of a tube of stiff material—stiff paper, for instance—fitting upon the front of the lens in place of the cap, and cut away transversely, so as to shade the sky portion of the plate without interfering with the view. The projecting portion may be turned in any direction, so as to arrest the direct rays of the sun; and when not in use it may be folded and placed away, and occupies literally "no space." The inside should, of course, be blackened.

The next point of importance is the package and conveyance of plates. With regard to those required for the day's use it is a matter of taste whether a changing-box or double slides be used; each method has its advocates, and provided the workmanship be equal in each case we cannot see that either possesses an advantage which may not be balanced by another on the other side. The package and carriage of the reserve plates, however, is a matter which has exercised the ingenuity of many, and in connection with which there-is still room for considerable improvement. Grooved plate-boxes, though perfect for mere storage, are far too bulky for purposes of transport; hence many attempts, more or less satisfactory, have been made to dispense with them.

The simplest plan, and the one which may be taken as the type of the rest, consists in packing the plates in pairs, face to face, with a narrow strip of thin cardboard or folded paper between the edges; this is liable to the objection that unless the packing is very carefully performed the strips of cardboard find their way from the edge to the centre of the plate, and there leave an indelible mark upon the tender films they are intended to protect. An improvement upon this is the method adopted with some of the commercial plates, in which a strip of stout paper is folded zigzag fashion, like the camera bellows, and the successive folds inserted between the edges of the plates. Perhaps the most perfect method in action, but a rather costly one, is to insert between each pair of films a "mat," formed by cutting out the centre of a piece of cardboard the exact size of the plates in such a manner as to leave a margin an eighth of an inch wide all round. If such "mats" could be supplied at a moderate price they would last for a very long time, and would practically remove every difficulty in the package of our dry plates.

Numerous other plans of a similar kind have been recommended from time to time, but we need not weary our readers by describing them. Whatever system be adopted, two or three pair of plates thus separated are wrapped up together in brown or orange paper, each package being marked with a distinctive letter or number for future identification. It will be found more convenient, and perhaps prevent accidents, if the plates are divided in fours or half dozens as we direct, instead of into dozens as is frequently done. It is not often that the tourist succeeds in exposing a dozen plates in the day; and, consequently, in opening a package of one dozen unexposed plates to replenish his slides he must either repack his exposed plates separately and increase his number of parcels, or else mix exposed and unexposed plates together—either of which courses leads to confusion.

We next have to provide the means of identifying each individual plate in order that the development may be performed with some idea as to the subject, exposure, and treatment it is likely to require. If the plates are "backed" with colouring matter nothing more is needed, as the latter forms a convenient surface upon which a distinguishing mark or any particulars may be written with a lead pencil. Failing the "backing," a small label must be attached to one corner of the back of the plate; on no account should it be placed in the centre, as it is then liable to cause a mark from unequal reflection.

There remains but one more point which comes under the head of preparations, and upon that our remarks will be brief; we allude to the means of carrying the apparatus when "on the march." By all means adopt the knapsack plan; the gain in comfort can only be estimated after a practical trial. Upon a level road nothing is necessary but the ordinary shoulder straps, but if there be any climbing to be done the addition of a belt or strap to keep the knapsack firmly against the back will be found an improvement, especially in going *down* hill. We have in this manner "done" twenty miles a-day without the slightest discomfort, and carrying a weight which *in the hand* would have necessitated a rest at least every half-mile.

MIXING EMULSIONS.—A CURE FOR PINHOLES.

Those who have experimented much with emulsions, or even with collodions of any kind, have found that a great accumulation of bottles and samples takes place.

There are very few photographers, especially amateurs, who do not possess what they designate with more expressiveness than Latinic elegance and accuracy their *omnium-gatherum* stock-bottle. It is that which forms the common receptacle of all the fag-ends of the contents of bottles of collodion by various makers, and iodised by formulæ of the most diverse kinds. It is in accordance with the experience of many that the "*omnium-gatherum*" collodion is frequently found to possess the good qualities of almost all the component parts of which it is formed, with an entire lack of the bad properties of any; and it has often been with a sigh of regret that the last drop of this heterogeneous mixture has been used. This has led to several photographers mixing together, *ab initio*, the preparations of three or four different manufacturers, and using this mixture in preference to the collodion of any special maker—a practice adopted by some of the most successful artists of the present period.

Such a mixture as that described we recently made, collodion emulsions rather than bromo-iodised collodions forming the component parts of the "*omnium gatherum*." Into a large receptacle we poured the whole contents of seventeen bottles, containing washed emulsions prepared according to different formulæ. Some of these samples were organified, others were not; some were three or four years old, others did not number so many weeks. Knowing, as we well did, the diversity and variety of the materials of which this mixture was formed, we were very curious to ascertain what sort of negative would result from a plate coated with it; and to our surprise and no small delight we have found that it produces most excellent pictures. The negatives are rather too thin for printing if developed with alkaline pyro. alone; but when we use this for developing the image, and follow it up with acid pyro. and silver to intensify such image—a mode of procedure we have long recommended, and which is now very generally adopted—the negative acquires printing intensity to any desired extent.

In connection with this subject we desire to record the means we have adopted to overcome a certain peculiarity possessed by one particular washed emulsion that is exceedingly sensitive, and which yields images of the most charming description, but possessing the unfortunate and most serious fault of giving negatives full of transparent holes—not "pinholes," but circular holes of about the apparent dimensions of a pin's head—similar to those to which we have previously drawn our readers' attention, and whose precise nature and cause have not yet been discovered. Reasoning from the well-ascertained fact that such defects are never found in an emulsion plate that has been washed after the film being formed upon it, and previous to the application of the organifier or preservative, we coated a plate with the emulsion in question, and after the film had been allowed to set we immersed the plate to the extent of one-half only in a bath of water, where it was allowed to remain until all the greasy appearance had disappeared; after which we treated the washed end with a ten-grain solution of tannin, and allowed the plate to become thoroughly dry. Having exposed this plate in the camera we found, upon developing and finishing the picture, that the holes, which are in reality "aureoles," were as plentiful as ever upon the unwashed end of the plate; while upon that which had been treated in the manner just described there was not only no hole visible, but upon scanning the surface with a powerful magnifier there was not even an approach to that or any other surface defect of a similar description. The collodion emulsion with which this experiment was tried is one that is, but for the single fault indicated, so very excellent that we are much pleased at having found a way by which it can all be utilised.

Since the date of the experiment just recorded we have tried several further experiments in the same direction, employing different preservatives and organifiers. Among those to which we at present give the preference are (first) a strong infusion of coffee, and (secondly) common table beer to which has been added pyrogallic acid, as recommended by Canon Beechey. By making use of either of these preservatives we have obtained negatives possessing such admirable gradation, and with such entire freedom from spots, that we can unhesitatingly advise the use of these under the circumstances mentioned.

Conversing recently on this subject with Colonel Stuart Wortley that gentleman suggested, from the result of his experience, the washing of the plate without the application of any preservative subsequently. While we quite believe that he is right in cases where the plates are not intended to be kept for any length of time after their preparation, we are inclined to think that, quite apart from its organifying influence, the mechanical part played by the preservative as a varnish to shield the bromide of silver from the action of the atmosphere renders its use indispensable in all cases in which it is desired that the plates be kept for several months, or even weeks or days, after preparation.

We desire it to be understood that the treatment described is recommended solely for the purpose of getting rid of a certain defect, and that we should not think of washing and organifying a film obtained by an emulsion which gave freedom from spots. That collodion emulsions of such a character are to be met with we cheerfully acknowledge; but in the fact that other emulsions giving spots are also to be encountered will be found the *raison d'être* of this article.

RETOUCHING.

Our opinions upon the value to be set upon a retouched negative have been sufficiently frequently enunciated to need no repetition, but the process has taken firm root in all directions, and for good or for evil must be accepted; and, as it is always our aim to put our readers *au courant* with the practice of the foremost workers, it is our purpose, in this present article and in one or more to follow, to give practical and succinct instructions how to set about retouching according to the mode of the leading artists. We shall not confuse our readers with a multiplicity of processes, but shall give them working details of one leading method of procedure.

There are so many cases where an accidental blemish may be easily remedied by careful retouching that, apart from the power of working upon the face of a portrait, it is well to know how to handle the pencil to free the negative from such defects, and we have conquered the antipathy we, in common with so many, have felt against retouching in general owing to its abuse in particular cases; and that our readers may know the best manner of working we have supplemented our own practice by a knowledge of the mode in which the "amelioration" of negatives is practised by the first retouchers.

The legitimate functions of retouching are the removing of blemishes and the correction of such inequalities as those caused in photographic reproduction of colours, which are often untrue to nature. Its debatable sphere is the softening of shadows and lines in the feature, in conjunction with attempts to alter the expression. Whatever the instructions we give our readers should bear in mind that, though it is an old sin of the painter to flatter his sitters, a photographer should never forget what is due to his own especial art.

Retouching has been done by the aid of both brush and lead pencil; but, still, as the latter is so much easier of attainment, we shall only dwell upon its use, though we believe we are correctly informed that one of the earliest—if not *the* earliest—systematic retouchers in this country, whose photographs have a deserved repute (Mr. Edge, of Llandudno), used the brush and Indian ink almost entirely for many years. But on the continent the use of the blacklead is universal, and since the secret of its employment is now so completely disclosed it is not likely that Indian ink, except under certain circumstances, will ever again be employed.

The first and most important operation to be carried out is to prepare the surface of the negative so as to enable the pencil to bite. There are two methods of doing this, either of which may be made use of. The first is to roughen the varnish by an abrasive powder—finely-powdered pumice stone, such as is to be purchased at many chemists' shops, being most preferred. It is important that the right material be purchased, there being a coarser and rougher kind made for the use of cabinet-makers, which is quite unsuitable, and would scratch the negative. It is employed by putting a pinch, or dusting a small quantity out of a muslin bag, upon the place to be worked upon, and then rubbing it with the end of the finger with a circular motion till the surface is deadened, and a tooth like fine ground glass is given. The entire absence of gritty particles must be ensured, or minute scratches which would ruin a face would be the result. This method enables the greatest amount of opacity to be produced by the lead laid on, and hence is best for those negatives where large masses of bare glass have to be covered.

The second method to be described may be used in the majority of cases, and the abrasive method only occasionally, or the latter may be made use of entirely. We recommend the second method, with the very occasional employment of the other. The formula for the composition to be used is gum dammar, twenty grains; Venice turpentine, five grains; turpentine, one ounce. The gum is to be powdered and the mixture well agitated for a few minutes; it will then dissolve quickly, and the Venice turpentine will easily liquefy and mix with a little shaking. If any difficulty be experienced in getting true Venice turpentine it may be replaced by one-half of its weight of ordinary black resin. A drop of the solution is placed on a small pledget of cotton wool, and rubbed for a moment over the surface to be worked upon so as to leave a mere visible trace behind (if too much be put on, the surface will be too sticky or tacky). The negative is placed aside for a few minutes and is then ready for use, and a number of negatives may be done one after another so as to save time. A score of them may be treated in a couple of minutes, while with the pumice-stone process each negative occupies perhaps half-a-minute or more—a length of time which when many require to be treated becomes a serious item.

An important point to be considered with regard to this treatment is—Does it injure the negative or render it liable to crack? The infinitesimally small quantity of gum left behind after the rubbing is not likely to harm any varnished surface, but, to render the matter entirely free from doubt, we have made inquiries among professional photographers who have employed the plan, and we have ascertained that, at anyrate in five years, which was the oldest case we could trace, no harm whatever had occurred to the negative. Hence we may safely subject the most valuable negative to the process without any fear of danger.

Some retouchers make a special varnish which requires no after-treatment to enable the pencil to bite; but our experience of such is not favourable. We do not consider them likely to be so durable as other well-known, recognised negative varnishes, and the saving of time is so very slight that it does not counterbalance the inconvenience of having two kinds in use—one for negatives to be retouched, and one for ordinary work—and they possess no other advantage over the methods we recommend.

We know one gentleman who possesses a touch so fine that he is able to retouch upon the dried film of an unvarnished negative, and we have seen one of a group where a large number of faces were so retouched by him; but this is a mere *tour de force*, not to be attempted in ordinary practice, and only made use of by the artist in question under unusual circumstances.

We conclude this part of the subject by describing a method suitable for occasional employment by any one who wishes to improve a negative and has no special materials at hand. It is simply to dilute ordinary negative varnish with about an equal part of methylated spirit, pour on the negative *cold*, and allow to dry spontaneously. If the right proportion of spirit be employed a surface of most exquisite delicacy is obtained, but of rather too fragile a nature for ordinary workers. It possesses the advantage of being able to withstand a second coat of varnish applied with heat in the ordinary manner, and thus secures the retouching from all danger, with even the utmost amount of hard printing. On this latter account it may, at times, be of great usefulness, the other methods not allowing of any fixing of the pencilling beyond that of mere surface nature, and for this reason we may give a little more fulness of details, the gentleman who communicated them to us informing us that he employed this method for one or two years, and liked the surface better than any he had ever worked upon previously.

The great point is to have the varnish diluted to the exact strength, and this can only be found by experiment. If too strong the varnish dries too bright; if too weak it leaves a dead and rotten surface, easily scratched, and taking too great a hold of the blacklead. Further: when a negative is under-exposed or forced in the development the film has a different texture and requires a modification of the varnish, greater strength being then needed. Instead of thickening the varnish, a second coating—always cold—will almost, but not quite, answer as well.

The drawbacks to this process are the nicety required in adjusting the strength of the varnish and the great tenderness, even at its best, of the surface, which should be exactly analogous to the gloss of an eggshell, and is most beautiful to work upon but for one defect, a special pencil being necessary. This part of the subject, however, will be dwelt upon in our next.

In another column Mr. W. Washam reverts to the old idea of a sensitive substratum (or, in other words, a double film), for the purpose of securing certain advantages not possessed by a single film. We speak of the idea as being old, because the Taupenôt process—one of, if not *the*, earliest of dry processes—was essentially a double-film process, though the conditions pertaining to that method are widely different from those proposed by Mr. Washam. In the latter case the particular part to be played by the sensitive gelatine substratum is the formation of an intense image; but in this anticipation we cannot avoid the conclusion that the author partly loses sight of the distinction which he himself draws between density and intensity. The experiments of Captain Abney in connection with double films, in addition to explaining much that was previously obscure, showed us the action which an exposed film has upon an exposed one placed in contact with it during development. Judging from recollection of the behaviour of these double films, we can readily understand that an exposed gelatine emulsion film, coated after exposure with a slow, dense collodion emulsion, would develope an *intense* image; but, by adopting Mr. Washam's suggestions, we should expect to obtain a *dense* image, which might or might not be intense according as other conditions favoured intensity. In fact, we should anticipate no greater difference than would exist between the results given by two films of different thickness. We do not attach the same importance to the order in which the films are applied as Mr. Washam does—at least for the same reasons. A dried collodion film does not possess sufficient absorptive power to so far arrest the rays passing through it as to protect a second film placed under it; and, even granting that a gelatine film is capable of exercising a greater arresting power, the result, we apprehend, would be merely a slight diminution in the sensitiveness. We shall probably in the course of the next few weeks have an opportunity of practically testing Mr. Washam's suggestions, and shall then be in a position to speak more definitely as to their value.

RENDERING THE DAGUERREAN IMAGE VISIBLE BY THE ACTION OF RED LIGHT.

Though rather pressed for time it would be discourteous to Mr. Berkeley—whose experimental work and deductions therefrom we all admire—if I did not give a short reply to his last communication, in which there is much food for reflection, and which requires more time than I can give at the present moment entirely to digest. Either Mr. Berkeley or myself have misinterpreted Becquerel's experiments, to which we both have referred. I will give my version of them as I read them.

The film used was silver iodide on the surface of a silvered plate which had a short exposure given to it in the camera—hardly sufficient to give a visible image. The plate so exposed was placed beneath red glass, and the image appeared by the action of the red transmitted light, and not by mercurial development. This is the way in which I think the experiment was carried out, since this is explicitly given in Gaudin's repetition of them. The oxidised image, in other words, was a visible image, according with the results I have obtained. The image on an iodide plate, when just visible, is of a dark colour, and the invisible image should be made up of the same material hidden by the unaltered compound, and this dark compound would absorb red light and necessitate the expenditure of work upon it, either in the shape of rise in temperature or in producing chemical change. This latter seems to be the case where oxygen is absorbed, which my later experiments seem to show. In the coloured spectra I have produced this is unmistakably the fact, and there seems to be no reason against it in the form of experiment which we are considering.

I am not quite certain whether Mr. Berkeley's experiment with the bromide plate (cutting it into three pieces, and treating each piece in a different manner) is a suppositious one or not. Some time ago when he suggested a similar one I tried it, and the conclusions that he arrived at were not entirely borne out in my hands, as I found the image developed upwards and downwards. Any deficiency in the latter direction I attributed at the time to the fact that the developer when it arrived half way (say) through the film was weakened by dilution with that already employed to develope the image above, and that there was also an increase of soluble bromide formed in the act of development. In transposing the top and the bottom surface of the films this would not be the case, since the developer would arrive at the image in an undiluted form, and the reducing action would take place more equally in both directions.

These experiments I shall repeat when there is an opportunity, and until then I should not like positively to commit myself. Perhaps Mr. Berkeley would kindly say whether he has tried these experiments himself, and repeated them more than once. Instead of using the words "*absolute contact*" of the silver bromide with metallic silver, I should probably have been wiser had I said "when the silver bromide and metallic silver are within the sphere of sensible action of the molecular forces."

W. de W. Abney, F.R.S.,
Capt. R.E.

ON ALIZARINE: ITS ORIGIN, PROPERTIES, AND APPLICATIONS.

[A communication to the Photographic Society of Great Britain.]

The English traveller who visits for the first time the South of France, and particularly the fertile district round Avignon, will be surprised at seeing large tracts of land covered with the foliage of a plant entirely unknown to him. On inquiry, he will find that this novel agricultural product, so largely cultivated, is the celebrated "garance," the *Rubia tinctoria* of botanists, and the madder of the English calico printers—one of the most important of their dyestuffs.

In France it is very largely used to dye wool of the red tint so well known in consequence of the trowsers of the French army being made entirely of cloth dyed of that colour; so that, with our neighbours' "*porter la garance*" (to wear madder) is synonymous with being a soldier or becoming a soldier. It is also used for dyeing the red, purple, and blacks of our bandana silk handkerchiefs; the fast purples and pinks of our cotton prints; the perfectly permanent red, pink, lilac, chocolate, and black tints of our often gorgeous furniture prints; and, lastly, it furnishes colouring matter of the brilliant and universally-appreciated Turkey red.

The colouring principle of the plant resides chiefly in its roots; these are taken up from the ground at the proper season, dried, and sent to market either in their natural state or ground to powder, and packed carefully in air-tight casks.

France and Holland send us large quantities of ground madder. From Greece and Turkey it comes to us in its more natural state, under the title of "alizari," by which it is known all over the Levant; hence, when the colouring matter of this dyestuff was first isolated, it received the name of "alizarine."

It would waste your time and try your patience to describe in detail the various processes by which these brilliant tints are produced from this apparently colourless, or but little coloured, root, although to a chemist they are highly interesting and instructive. It will suffice our purpose to say that they consist—

1. In operations by which the colouring matter is converted from a dormant or merely potential state to one of activity, just as starch and dextrine are converted into sugar by diastase, and by an analogous action and transformation.

2. In fixing of the colour on the fabric, by first impregnating it totally when it is to be dyed, but only superficially or topically when it is to be printed, with a base or mordant, and when this is fixed within or upon the textile fibre by saturating it with alizarine, in an infusion of madder roots gradually heated to boiling point in a bath formed of an infusion of madder roots. For red and its various shades, such as pink and rose, the mordant employed is a salt of alumina, and usually the acetate; when violet, purple, or black is wanted the acetate of iron is used—very feeble solutions giving the former tints and strong solutions the latter. For chocolate, brown, and maroon a mixture of the two acetates is employed, the proportions varying with the shade and depth of colour.

3. In the clearing, purification, or development of the true colour from the brown matters with which it is associated, by treating the dyed cloth repeatedly with boiling soap lye and solutions of hypoclorite of lime or soda alternately, the brown matters are attacked by these reactives, and are removed or destroyed; while the alizarine compounds to be fixed on the cloth are only purified, and enhanced in brilliancy of hue.

When we say that, before Berthollet discovered the value of chlorine in dyeing, madder prints were exposed for several days upon the grass between each treatment with boiling soap, it will be seen how highly resistant the alizarine pigments are to light, which bleaches so many colouring matters.

Alizarine is not only one of our most important dyestuffs, but it is also the colouring principle of many of the most delicate, the most brilliant, and, at the same time, the most permanent tints of the artist's palette, whether he employ oil or water as his vehicle or medium.

You see before you some fine specimens of madder lakes, manufactured and kindly lent by Mr. J. Newman, of Soho-square:—

1. You have here brown madder, which will give you some idea of the natural colour of madder lake before the clearing processes have been applied thereto, although in this case the base is neither alumina nor iron.

2. Here you have Rubens madder, a fine red, alumina being the base.

3. Here you have purple madder.

4. Here are the splendid tints of rose madder, pink madder, &c., of which the base is also alumina.

The pigments you see here only differ from those on the fabric by the fact that the mordants or bases are in one case attached to or sealed, as it were, within the cells of the textile fibres; while in the case of the pigments these bases are free, and combine directly with the colouring principle, as in any other chemical species. The combination is usually effected by dissolving the colouring principle in a solution of alkali, and adding thereto a soluble salt of the base. The base and colouring matter are precipitated together, and the compound so formed is called a "lake." This name originated from the fact of the soluble colouring matter of a particular species of coccus which the natives call "lac" *(Coccus lacca)*, which was sent to us from India, in a dry, portable form when so precipitated, under the name of "lac-dye."

Nothing is more easy than to prepare these lakes, yet few things more difficult than to obtain them of the brilliance and purity of the specimens before you—a valuable trade secret.

Even to make an inferior article the madder must undergo—

1. A series of washings to get rid of the soluble impurities when the insoluble colouring matter has been developed.

2. The extraction of the colouring principle, and its precipitation combined with a base.

The preparation of the lighter shades of madder lake is greatly facilitated by the fact that a solution of alum—and particularly alum made neutral by the addition of an alkali until the alumina begins to precipitate—dissolves readily a quantity of alizarine, forming a solution of a fine cherry red, from which acids precipitate the alizarine in nearly a pure state, while alkalies and their carbonates precipitate it as a pink or rose lake.

The necessity of the long and costly operations for the purification of madder colours, whether as dyes or pigments, induced many chemists to endeavour to effect the isolation of the colouring principle in a pure form, so that by using the pure extract instead of the complex natural product the tedious operation of purification might be dispensed with. Robiquet, a French chemist, first published the results of his researches. He believed that madder contained not one essential colouring principle but two, to which he gave the name of "alizarine" and "purpurine" respectively—evidently modifications of one substance. Although Robiquet failed to establish the extraction of the pure colouring matter as a practical manufacture, he nevertheless obtained it in an intermediate or partially purified state, which, under the name of "*charbon-sulfurique*" or "garancine," subsequently became a most important article of manufacture and commerce.

This manufacture was founded on the fact that the colouring principle of madder dissolves readily, and without change, in sulphuric acid, and is precipitated therefrom by water. It was only necessary, therefore, to treat the powdered madder with this acid, and throw the mass into water, to obtain the colouring matter, mixed with carbon, the acid having destroyed or rendered soluble all the other components of the plant.

A long list of chemists might be given each of whom contributed somewhat to our further knowledge of this interesting subject; but all these researches were thrown into the shade, and the importance of the plant itself greatly diminished, by the discovery of a German chemist that alizarine could be manufactured artificially out of a product of coal tar. The changes rung upon the elements of pitch, by which that substance is converted into the splendid colouring matter we have been discussing, are of the highest interest to the chemist, but we have not time to consider them. Suffice it to say that the process is thoroughly practical, is performed successfully on thousands of tons of the raw material, and is already, although in mere infancy, a most important manufacture.

By means of scientific research, so often sneered at by practical men, we thus arrive at a process by which a bit of coal can be converted into the substance which yesterday we only obtained by careful preparation of the soil, by skilful husbandry, by careful manipulation in drying, grinding, packing, and by sundry elaborate operations, the result of the labours of many minds. May we not consider the artificial preparation of alizarine as one of the greatest triumphs of modern chemistry?

The practical photographer will naturally ask—How does all this affect us? What have we to do with alizarine and artists' pigments? We reply, that since the introduction of photographic pigment printing every photographer who has adopted the new system has a direct interest in every new permanent pigment which the chemist may discover. Henceforth the operations of the artist and the photographic printer are intimately associated. One may exercise genius in the production of works of high art, while the other performs a merely mechanical operation; but the object is the same, and the means employed are nearly identical. Each endeavours to produce "a thing of beauty," and whether that shall become "a joy for ever" entirely depends upon whether the pigment employed be permanent or fugitive. The same pigments are employed by each, with certain exceptions; and each employs a vehicle or medium to mould his pigment, and fix it upon the paper or canvas he employs. The painter in oil uses a siccative varnish, which oxidises, dries, and becomes insoluble in the ordinary menstrua of oil. The photographer uses gelatine and a chrome salt—a mixture which becomes insoluble under the action of light.

Now, it is as important to the photographer as to the artist that the vehicle or medium employed be colourless, or as nearly so as to have no appreciable influence upon the hue of the pigment employed. This condition is fulfilled in both cases. The varnish or megilp of the artist is usually of a slight yellow colour in mass, but having no sensible influence upon the colour. The same may be said of the medium of the pigment printer. After washing his prints in warm water and passing them through a bath of alum, the medium, which consists of insoluble gelatine and oxide of chrome, is of a very pale green colour, which might degrade somewhat a delicate shade of rose madder, but has no more action upon the brownish purples of the photograph than so much tawed leather—a compound of gelatinous matter and alumina, which it closely resembles in nature and properties.

I particularly insist upon this point, because it has been alleged by an eminent authority that the medium in question is yellow, and that it has a destructive action upon all colours employed with it of organic origin. I will merely observe, to show the utter incorrectness of the statement in question, although this has been already fully pointed out by competent authority, that if the medium were yellow it would be impossible to obtain pigment prints of a brilliant blue colour—for blue and yellow form a green or greenish colour—and if it had the deteriorating action upon alizarine and other organic matter, as asserted, it would be equally impossible to obtain permanent proofs of a brilliant crimson; yet a frame containing impressions in both these colours, from a negative of Mr. Bedford's, the *Old Mill*, printed by Mr. Swan in 1870, hung for years in the windows of the galleries of the Autotype Company, both in the Haymarket and in Rathbone-place, and must have been seen by all present, and prove conclusively not only that such prints are obtainable but also that when obtained they are perfectly permanent.

Having shown the importance of permanent pigments to the photographer, I will now proceed to show how such a pigment may be procured from alizarine; for, unfortunately, none of the madder lakes I have shown you can be employed successfully for that purpose. The crimson, rose, and pink lakes, which have alumina for their base, when mixed with a small quantity of very black pigment on the palette of the painter and diluted with this medium, yield most brilliant tints, quite equal to those yielded by cochineal, and those which the photographer obtains from albumen and chloride of silver exposed to light and toned with a salt of gold; but when these pigments are mixed with the photographer's medium insolubility ensues without exposure to light, and the pigment paper no longer performs its functions.

Such, at least, has been my experience and that of others. I have always hitherto explained this action by supposing that when the alumina was in sufficient proportion to the alizarine to constitute a permanent pigment, such pigment, when mixed with gelatine and an acid chrome salt, yielded a portion of its base to the acid of the salt, and precipitated the gelatine, as acid salts are well known to do.

The process by which Mr. Swan obtained permanent prints in alizarine having been found to yield uncertain results, unless the greatest care was taken, I succeeded in preparing an alizarine compound in 1872 which was free from this defect, which had no action upon the gelatine medium, which gave beautiful and permanent colours, and which, although capable of yielding double transfer prints of the most brilliant tints; yet this compound appears to have been ignored or abandoned by the company, for on the technical manager of the company visiting me in Paris, in 1876, he was unacquainted with it as a manufactured article. Hence it is not surprising that, on the publication of the fifth edition of their *Manual*, the practice of the art had so far been altered that, in answer to many queries as to the want of permanency of pigment prints, its chief promoters had to admit that to obtain what was termed an "exaggerated" brilliancy fugitive colours must be had recourse to. I would ask whether any brilliancy beyond that yielded by silver and gold upon albumen has been asked for or attained.

I am aware that this admission is now withdrawn and a better practice instituted, but not without some exceptions, for special licensees are still supplied with fugitive pigment papers at their own request. At anyrate, so long as the new practice is maintained a trade secret, I hope that it will not be deemed superfluous for me to describe the mode of obtaining permanent pigments with alizarine, and to explain the conditions necessary for that object.

First, let me say that alizarine, like a great many dyestuffs, is not permanent alone, but must be combined with a due proportion of base. It is not sufficient merely to precipitate the alizarine from its alkaline solution by so much alum as is necessary for the purpose, for alizarine is precipitated by acids, and alum is an acid salt. The lake so produced may be very intense and brilliant, and may be perfectly insoluble in water; but, if it be insufficiently charged with base, it is not the true permanent lake, but that substance mixed with a quantity of the uncombined colour which will yield to the action of the light. Hence it is not surprising, therefore, to find that certain photographic prints made with alizarine have been found to be fugitive, or so fugitive as to destroy the beauty of the tint and the intensity of the shade of colour.

When, therefore, Dr. Monckhoven, in the paper to which I have referred, laid before you prints made by him with pigments which contained alizarine no surprise should have been excited, because in the same paper he furnished you with an explanation of the cause of this fugacity. He informed you that it had been denied that iron and alizarine would produce a red colour, but that this was so provided that the iron was in small quantity. He stated, moreover, that he used or had used such a compound.

Now, I have here a piece of cotton print the design of which is produced by iron and alizarine, the acetate of iron having been first printed on the fabric in two degrees of concentration, and the oxide after due preparation saturated with alizarine in the dye bath. You will perceive, even by this yellow light, that we have two tints—one of violet and the other of black; that is, of violet so intense as to appear black. Judge, then, from these tints—which are those of the natural compound of iron and alizarine, one diluted and the other concentrated—how small a proportion of the iron base Dr. Monckhoven's compound must have contained not to have converted the crimson tint of the pure alizarine into the violet of the pure pigment, and hence its incapacity to resist the action of light.

En passant, I may observe the cotton print before you furnishes us with another proof that in making the statements he did Dr. Monckhoven was in error. Knowing that the notorious permanence of the alizarine compounds on cotton and other fabrics could not be denied, he attributed that permanence to the degree of depth or penetration of the colour into the fabric, thus ignoring one of the axioms of the calico printer, viz., that the topical colour must be of infinite tenuity upon the surface of the fabric to obtain the maximum degree of brilliancy. He effects this in two ways:—First, by the extreme shallowness of the intaglio design upon his engraved copper roller; and, secondly, by thickening his solution of iron or alumina salt with starch, dextrine, or gum, so as to prevent the mordant penetrating the cloth.

You will see in the print before you to what extent this principle has been carried, the light parts of the design lying in an extremely thin plane on the surface, exactly like a pigment print.

We have shown the cause of instability in Dr. Monckhoven's hands. It is possible that the same cause may have operated in the prints made by him from the pigment paper of the Autotype Company, which were also found to be modified by light, and which must have been made with alizarine if, as they allege, all their pigment paper issued since 1876 has contained that colouring matter.

If to render the alizarine compounds permanent a certain quantity of alumina is necessary, and if, when in that quantity, it renders the medium insoluble, how are we to apply this valuable colouring principle so as to render it a proper pigment for the use of the photographer?

I have solved the difficulty completely by using so much alumina only as suffices to develope and maintain the red colour, and then adding another base—a salt of lime or magnesia—in sufficient quantity to render the alizarine not only completely insoluble but also permanent.

Here are numerous specimens of the prints produced from such pigment paper, both in double and single transfer. I will only add that such prints have been tested for stability by Mr. Simpson and others, and stood that test without flinching.

Having given some years of my life to render this beautiful art practical, and its products permanent, I trust I may be pardoned when I say that I read with pain and regret the defence made on a late occasion when the permanence of pigment prints was called in question. It appears to me that, so far from that being a successful defence, it was a mere plea of "guilty" with extenuating circumstances.

It is not thus that carbon or pigment printing should be defended. It needed no such defence when it left Mr. Swan's hands; it was then free from this stigma.

Henceforth I undertake to demonstrate practically that by means of alizarine every tint needed by the photographer can be produced by the pigment printer with a brilliancy equal to any that can be obtained by cochineal, and with the known permanence of madder lake. Let any desired tint be sent to Mr. Sarony, and we pledge ourselves that such tint shall be reproduced in permanent colour.

There is one more point on the practice of pigment printing to which I would allude. After obtaining permanent prints with alizarine, it was found that they were affected by immersion in the alum solution, which, as I have already stated, is a solvent of alizarine; hence, when the finished prints were allowed to remain some time in the alum bath, both a sensible amount of the red colour was dissolved out and an appreciable effect upon the tint produced.

It is a curious fact that while the true alums, the double sulphates of alumina and potash or ammonia, possess this solvent action upon alizarine, the simple sulphate of alumina is quite inert, yet apparently equally efficacious in fixing the gelatine print, so that the latter may with great advantage be substituted for the former wherever alizarine prints are produced. The only drawback I know of to the use of alizarine pigment prints is thus effectually removed, as Mr. Sarony has proved by several months' experience.

J. R. Johnson.

VIGNETTES IN CARBON FOR COLOURING UPON.

The professional photographer has few commissions so difficult to execute or so remunerative when finished as water-colour vignettes with a carbon basis. For very good reasons vignettes have never been popular among carbon workers, and there are very few establishments in the range of my acquaintance where such pictures are ever attempted. It is not that they are not beautiful, nor that the general public do not "take" to them, for they are good in style, and, as far as my own experience goes, they are liked by the public. The fact is they are difficult to execute, from the general want of any detailed instructions such as would enable anyone having a practical knowledge of carbon to produce one without first spoiling a dozen or two as trial pieces, as was my own experience when first I essayed carbon vignettes for painting upon. I did not put the failures down to want of skill, for, having had on one occasion (before I had perfected my manner of working) to get one of the pictures I am speaking of executed by a professional carbon enlarger of the highest standing, I was much disgusted to find my own rejected things actually superior. The margin, instead of being white, was a dull, ashy grey—not the result of purposed tinting, but caused simply by bad workmanship.

This is, as a rule, the cardinal defect of carbon vignettes, though it is not by any means a necessary concomitant of the process. It is to be guarded against by scrupulous attention to cleanliness in all the stages from beginning to end. Filtered water should be invariably used both for mounting and developing. Paper of perfect surface and colour is absolutely necessary. During the printing the utmost care must be used in shielding the tissue from light, and in this connection it will be well to bear in mind the effects of the so-called "continuating action" of light, as a piece of tissue exposed to light for only a few seconds and then kept a day or two before use will print with a sufficiently pronounced tint to spoil any print of the kind about which I am writing.

The next point to consider is the description of paper to select as the support for the picture, and it is here where the photographer generally fails. (It is to be understood that I invariably use the single transfer process for enlarged pictures, as it is no extra trouble to take the negatives reversed, and it saves all the annoyance of double transfer—the bugbear of the occasional worker.) I do not, on any account, recommend the single transfer paper of the Company. It is not artistic to have a smooth surface for large work, and it is most difficult to paint upon, anything approaching to a work of colour being next to impossible. The smooth paper has another disadvantage. Any slight irregularity in the coating of gelatine—such as a slight excess in one part—produces an effect resembling a dirty smear; and, as I have laid so much stress upon the integrity of the whites, it will be seen that this is a very grave fault.

Whenever the picture is to be more than a few inches in size my prints are always done on paper prepared by myself, and with results with which I am quite satisfied. I select a good, hard, handmade paper, and coat it with gelatine and chrome alum, the solution containing about one per cent. of the latter in proportion to the gelatine. As to the amount of gelatine to be dissolved in making the solution for coating the paper it is not possible to give an exact formula, so much depending on the quality of the particular sample in use. The solution should be of such a consistency that it would easily set when cold. It must be most carefully prepared, filtered, and kept free from dust. I need scarcely say that it will be necessary to keep it hot while the paper is being floated upon it, or it will gelatinise and become useless, a further application of heat not being found to answer when once the mass has solidified—a fact well known to experienced workers, but which I may again mention here, my notes being intended more for the tyro than the experienced worker.

A number of sheets of paper should be prepared at once, hung up to dry in a place quite free from dust, and carefully stored away as soon as dry. The surface, then, of the paper is apparently not at all interfered with; and yet, instead of a semi-porous, useless sheet, we have a paper quite impervious, upon which the print can be developed, and which can be selected of any sort most to the fancy of the artist who is going to work upon it. Harding's, Whatman's, Creswick's, or any other paper can be used, so that the finished picture resemble a real water-colour in every way, and does not show its origin by a paper with a smoothness of surface never seen outside the walls of a photographer's studio. I may say that I have found Whatman's paper very difficult to work with, owing to its porosity and tenderness after prolonged soaking in hot water. I have had many pictures spoiled by dropping away from the clips they were suspended by owing to the pulpy state to which they had been reduced.

I must call attention to the fact that the quality of the tissue itself is a prime factor in the case. With a gelatinous support which holds the tissue the whole of the time, and where there is anything in the tissue to stain, such support will absorb it. This quality of tissue, too, can only be ascertained by testing; but it must be remembered that a tissue that may answer admirably for double transfer off a metallic surface, and give no stain, may, in single transfer, stain sufficiently to ruin everything. The Autotype Company's No. 100 is a good tissue; but their engraving black, through having no red or lake tone about it, is less liable than all the papers to the well-known and objectionable pink hue.

I may conclude by saying that when I wish to have plenty of margin I do not use a piece of tissue the whole size of the sheet, but cut a piece of a size somewhat larger than the vignette required, round the corners, and develope in the middle of the sheet. If the above instructions have been attended to the margins of unexposed tissue will be next to invisible, and a little application of a camel's-hair pencil while they are still wet will entirely destroy any trace of tinted film. G. Watmough Webster, F.C.S.

THE ALLEGED FADING OF CARBON PRINTS.

[A communication to the Photographic Society of Great Britain.]

Those practising the so-called carbon process have been from time to time reminded that the use of fugitive pigments will lead to the production of fading prints; and, at the present time, this fact is sufficiently recognised by all concerned.

Dr. Monckhoven now strikes at the foundation of the process, and his remarks would lead us to believe that carbon prints, as at present made, are essentially alterable by the action of light, and he appears to found his case principally on two bases, viz.:—

"Many photographers have already noticed the alteration which takes place when carbon prints have been exposed for a few weeks to the influence of the solar rays. These prints lose their beautiful colour, and become yellowish or of a dingy green.

"A sheet of paper is immersed in bichromate of potash and dried. It is then exposed for an hour to daylight; next washed for an entire hour in boiling water, to be afterwards immersed in an alum solution for several hours; afterwards washed in cold water, and finally hung up to dry.

"According to the before-mentioned theory [that usually received], this paper should contain nothing more than a salt of sesquioxide of chromium, absolutely unalterable by the action of light. But the paper is *yellow*, while the salts of sesquioxide of chromium are *green*. But, moreover, if this paper be exposed to light, a part being covered by a mask of black paper, it undergoes alteration in the course of a few weeks, and a sharp, distinct impression of the mask is brought to view. Now, where the light has acted, the paper is *green*, like all the salts of chromium."

Dr. Monckhoven next sums up his conclusions as follows:—

"This experiment, and many others which we have made in this direction, prove, to our thinking, that neither hot water nor alum *fix* carbon prints. It is true the excess of bichromate is removed by these means; but the chromic salt which has rendered the gelatine insoluble not only *remains*, but this salt itself *undergoes a change by exposure to daylight.*"

With regard to the first statement the general feeling in this country was surprise, as I think very few have noticed the phenomenon alluded to by Dr. Monckhoven, and then only in cases where fugitive pigments have been employed. I can say quite confidently, that a print made with permanent colours, and treated in the usual way, does not undergo the change described by Dr. Monckhoven, as I have frequently had occasion to compare the colours of prints, not only when new, but also after partial masking and exposure to light. This holds good whether the prints have been treated with alum solution or not.

With regard to Dr. Monckhoven's experiment on simply bichromated paper, I can merely say that I have repeated it several times, and find that no yellow colour remains after washing, the washed paper being no longer sensitive to light; and the same holds good in the case of simply gelatinised paper. In order to ensure the absence of mineral impurities, which might vitiate the result, I prepared paper myself, using in some cases cotton and in other cases linen fibre.

The editor of the *Photographic News*, in a leader under date April 5th, points out a possible and, I am inclined to think, a probable clue to the change of tint noticed by Dr. Monckhoven. In this article the writer assumes that Dr. Monckhoven used a single transfer paper containing barium sulphate, and under these circumstances barium chromate* would be formed, giving a light yellow tint to the groundwork under the print, and when this is exposed to light it will naturally change colour, and this despite of long washing or treatment with alum.

I prepared samples of single transfer paper with various proportions of barium sulphate, and found the sensitive yellow tint to be proportionate to the amount of barium sulphate present and to the time the bichromated tissue is allowed to remain on the transfer paper before development. A few hours' exposure to sunlight is sufficient to change this yellow colour to a very light green.

I believe that single transfer paper containing barium sulphate has never been manufactured in this country, the English single transfer paper being merely coated with a thin layer of gelatine made insoluble, and any yellow tint this may take, from the diffusion into it of potassium bichromate, can easily be removed by soaking in cold water.

The thanks of British carbon printers are due to Dr. Monckhoven for having raised a discussion which has opened their eyes to the danger of using single transfer paper from unknown sources, it being obvious that the sending out of expensive enlargements so sensitive to light as to show a change after a few hours' exposure would tend to bring the carbon process into disrepute. Thanks are also due to Mr. Simpson for having indicated the nature of the danger.

As soon as I have time to make the necessary series of experimental tissues, I hope to present to the Society some remarks on that part of Dr. Monckhoven's paper in which he discusses the pigment question in relation to the gelatino-pigment process.

Addendum.

Since the above communication was sent to the Photographic Society of Great Britain, Dr. Monckhoven has published further particulars which necessitate a few remarks.

As a transfer paper containing barium sulphate was not used in Dr. Monckhoven's experiments, it is clear that the yellow colour observed by him does not arise from the presence of this salt in the paper; and the fact that he regards the formation of barium chro-

* Chemists are familiar with many cases in which physical condition and mass determine a reaction, or the reversal of a previous reaction. As an example may be mentioned the well-known lecture experiment in which water and metallic iron are obtained by passing hydrogen over heated oxide of iron, and the inverse phase in which oxide of iron and hydrogen are obtained by passing water vapour over heated metallic iron.

mate, by the action of potassium dichromate on gelatine containing barium sulphate, as "*contrary to the most elementary ideas of chemistry*," indicates that he is not deeply impressed with the dangers attending the use of certain pigments for giving opacity to single transfer paper.

The term "fading," as used in Dr. Monckhoven's original paper, is, according to his last communication, to be read as "change;" but he practically retains his old position by stating that "simple washing of a carbon print, even though it be prolonged for hours, will not eliminate the chromate nor fix the image." This is just the point which is contrary to the experience of others.

In Dr. Monckhoven's last communication he recommends the use of alum, which he repudiated two months ago, and, instead of dipping his prints in a solution of sodium bisulphite, he now adds an insignificantly small quantity of this salt to the alum bath.

Since Dr. Monckhoven's original paper was published several notices have appeared, showing that workers in this country find a moderately long immersion in water, or in water followed by alum solution, to be quite sufficient to fix carbon prints, provided that obvious sources of mischief are avoided.

Thomas Bolas, F.C.S.

NOTES FROM AMERICA.

Prizes for Photographic Results.—The "Lightning Process."—The "Poetry" of Photography.—Retouching.

From the American journals we learn that Mr. H. J. Newton, President of the Photographic Section of the American Institute, has offered six premiums for the best photographs classified as follows:—

First and second premium for portrait negatives of adults, first and second premium for portrait negatives of children, and first and second premiums for landscape and outdoor work. The first premiums will be $30, and the second premiums $20 each. The negatives in all cases are to be untouched. Two prints and the negative are to be enclosed in a sealed package and directed to the Secretary of the Photographic Section of the American Institute, on or before September 5th, 1878. No mention of the name of the competitor is to be contained in the package (or otherwise) with the negatives and prints; but the descriptions of the offerings, with a private mark indicating the names of the competitors, must be enclosed in a sealed envelope and directed to the judges. The premium negatives and prints from them are to become the property of the Section. No prints, however, will be made from the negatives without the consent of the competitor. The premium pictures, with the certificate of the judges, will be exhibited in the art gallery of the fair of the American Institute at the annual exhibition during the coming fall. This competition is restricted to those who reside within twenty-five miles of the city of New York.

The "lightning process," which has of late months been causing much sensation, is now being spoken of rather disparagingly by some who have given it a trial. Among these is a correspondent of the *Philadelphia Photographer*, Mr. I. B. Webster, who, alluding to *three* such rapid processes now being presented to American photographers for a consideration, speaks of one of them in the following manner:—

It is now five weeks since "the license to use" came to hand, which was followed in a very few days by the three bottles, in which was said to be "lightning." And lightning it was, sure enough, for every experiment took the patience out of a man quicker than lightning could begin to do it. As we went along I dotted down results, and up to this week only discouragements prevailed. Do not imagine that efforts were not put forth to make it a success, for I can assure you that the license was obtained and the compounds were purchased in good faith, with an eye singly to business; for photographers need not be told that he who can produce good results with very short exposure has largely the advantage over the one who requires a long one, and to cut a fifteen-second sitting down to one of five seconds, gives opportunities for catching frisky children and nervous adults not to be slighted. Hence the animus for securing this immense accelerator. And that is why there was so great a disappointment during the four weeks' experimenting. I send you two cards taken of the same sitter, without allowing him time to change his position or for the light to change—one taken with the regular formula of the gallery and the other with the "lightning" process; *both were given the same time.* The result shows the "lightning" undertimed.

Mr. Webster followed up these remarks by an *addendum*, in which he describes the contents of the three bottles containing the chemicals upon which the lightning process depends. He says:—

I made mention of the secrets being in bottles, and gave the number of bottles as three, but I failed to give the contents of the bottles. I write now to give that information, hoping I may be in time to have it inserted in the same number as the other. The three bottles contained silver solution forty grains strong, for bath, in one of them; collodion in another; and developer, double strength, in the third. The silver was simply a neutral mixture. The collodion could not have differed much from ours in regular use, as appeared upon trial; but the developer gave every indication of being different from any that we had ever used before. The deposit, however, was of a coarse, sandy nature, which gave to the background anything but a pleasing effect. Take it all in all, from what I have seen of the "lightning negative process," I would not give it house-room, let alone paying twenty dollars for the privilege of using it.

On the other hand, we find in *Anthony's Bulletin* and elsewhere statements made to the effect that certain photographers have found great advantage in using the lightning process, in the bath for which *fused* nitrate of silver is said to be employed. The editor of the *Philadelphia Photographer*, summing up a mass of correspondence upon the subject, says:—

One thing the "lightning" has done that is good, and we give it free credit for it. It has led photographers to try comparatively with it how quickly they can work their own preparations, and to their great surprise they can excel its results in the same time! *Moral:* save your money, and try to develope the full capabilities of what you have by intelligent and diligent experiment, and then, although you won't do it, you will have knowledge and power sufficient to prosecute the regular photographic tramp-process business.

America has produced several poets whose names will never die. Whittier, Dana, Poe, Bryant, Longfellow, and others are among her gifted sons. So, we take the liberty of modestly asserting, is "Hamilton Gordon Wemyss, of S. A.," who in the pages of the *Practical Photographer*, and as "A Tribute to Old Daguerre," pours out his poetic soul in the following lines:—

How dear it is in cranny nook,
Where dust and cobwebs cover,
To study works of sages deep
With ardour of a lover.

In scenes like this old Daguerre
Studied in light and shade
With camera and chemicals;
A tribute shall be paid.

Now raised by a fleeting joy,
Now dashed in deep despair,
Now thrown aside as useless,
Now tried again with care.

Never on earth's philosopher
Did the Fates more darkly frown;
But perseverance and constancy
And Daguerre won renown.

The diamond dug from darkest cave
To blaze in regal crown,
So works of art from one deep thought
Reward and honour found.

He is the father of our art,
So faithful and sublime,
And many sons and relatives
Are following in his line.

Farewell! old Daguerre, farewell
To all his sons of care!
Be constant, just, and true.
Remember the old philosopher, and art will follow you.

It is not for prosaic individuals like ourselves to challenge the lyric utterances of such gifted mortals as the author of the foregoing; our functions as journalists are fulfilled by reproducing this choice *morceau* for the benefit and edification of our readers.

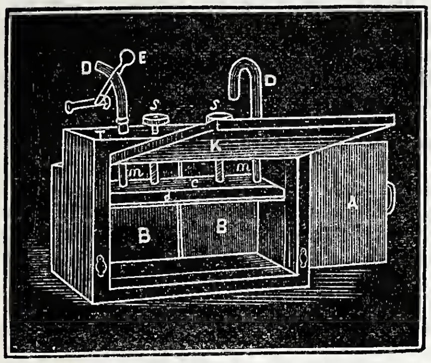
In a more matter of fact style are some observations on retouching, in the same journal, by Mr. J. Leon Pease:—

Much is said of this branch, but not to the point, or so as beginners readily see what is meant. If the following remarks will benefit any one I shall be fully repaid for my trouble in penning them. In the first place, do not go too near the negative; do not go so close as to see each minute spot, but so far away from it that you see the patches these small spots (taken collectively) make. Next have your pencil not very sharp and the point rounded off, so as to give a dull mark, not a sharp one like a scratch. Now commence on the high lights, and work it clean as you go. Work all the high lights first, and by so doing you will keep the modelling of the face perfect. If you are too close to the negative you will lose all this in a short time; practice only will help you to determine when you are at the right distance. Next work the shadows clean, and be very careful not to fill them up entirely—a very common occurrence with retouchers. See that the lights do not stop abruptly, but "blind" into the shadow. Now you must touch lightly. Do not try to fill a spot with one touch, but touch so lightly as to be unable to see each separate mark, but still to see the spot gradually fill up. You must think of what you are doing. No retoucher can do as nice work and think of anything but the face before, as he can by applying himself closely to his work, and knows before he puts his pencil down just what effect the mark will have on the finished print. Just as soon as you try to think of your girl, for instance, and try to retouch at the same time, just so sure will you begin to lose the modelling of the face and leave it only half done. It is this modelling that forms a nice photograph, and the lights and shades that form the expression and likeness. I like to grind my negatives, if I can get a fine surface and not too gritty. Pulverised resin is good for grinding. Do not grind any part but the face, and do not let it overrun on to the background. Experience will teach you how hard a pencil to use, how far away from the negative to get, how hard to touch and when to stop. Most persons do not learn this latter part, but touch till the face is spoiled for a person of any artistic taste. Practice and accustom yourself to study faces and find out the different muscles that form the modelling, and, by so doing, you will aid yourself in keeping the shape of each negative you work on.

ON A PIECE OF APPARATUS EMPLOYED IN RESEARCHES IN PHOTOGRAPHING SPECTRA.

[A communication to the Photographic Society of Great Britain.]

It will be in the recollection of the Society I expressed a hope that I might be able to perform some experiments in atmospheres free from oxygen, and thus to offer a confirmation of the theory I had propounded. There were certain mechanical difficulties in the way which required a little consideration, particularly when, for economy's sake, it was desired to use the same apparatus to experiment with oxidising as well as deoxidising agencies. At last I devised a dark slide which seemed to fulfil the part I required, and got Mr. Meagher to carry out my design. The accompanying sketch shows it:—



The slide is increased in thickness in order that it may be wide enough to hold a glass cell of half-inch width, in which the plate can be placed in solutions, or exposed in an atmosphere as required. A is the front of the slide, which is shown half drawn out, and B is the place in which the cell is placed. C is a wooden slab, on which a layer of india-rubber *d* is placed, as in the ordinary travelling bath tops. Through this top pass two glass tubes *m m*, passing also through the top of the slide T. On to these tubes are fixed india-rubber tubes, D D, which can be closed by clips such as E. The back of the slide is closed by the flap K, to which the usual spring is attached. At each end of the front of the glass cell are glued two little strips of glass, against which the sensitive plate rests, and the latter is pressed against them by means of a platinum or silver spring inserted between the back of the cell and the back of the plate. If a solution is to be experimented with, the solution is first placed in the cell and the plate dropped into position, and the spring inserted. The cell is then placed in the space prepared for it at B, beneath the top *c*, which is carefully screwed down by means of the screws *s s*. The back is then closed, and the slide is ready to place in the camera.

When using gases the plate is placed in position, the top is screwed down, and one of the india-rubber tubes placed in connection with the gas holder or gas generator. For example: in filling the cell with hydrogen one of the india-rubber tubes is connected with a long glass tube filled with calcium chloride, and through this the hydrogen passes after bubbling through a solution of silver nitrate direct from the generator. By keeping up a quick flow of hydrogen the cell is filled in a very short time, and after ten minutes any oxygen remaining must be immeasurable and not enough to vitiate the experiments. In the case of nitrogen the cell is first filled with hydrogen, and then this displaced by the heavier gas.

A very fair vacuum can also be made by attaching one of the tubes to the air-pump or sprengel pump, after stopping the access of air through the other tube by means of a clip. When the vacuum is nearly complete this tube may be connected with a vessel holding the gas; and when the clip is opened it will rush in and fire the cell. After exhausting once more, and refilling the cell with the required gas, exposure may be made in an atmosphere *very* nearly free from oxygen.

The sides and the cell can be cemented with marine glue, in which case a plate may be exposed in any atmosphere or in any solution which is unaffected by marine glue. By cementing the sides with common glue and treacle an arrangement is made by which exposure may be made in such liquids as naphtha, alcohol, &c.

I have communicated the results of experiments already made with this arrangement of slide to the Royal Society, and I was in hopes that I might have been able to have given this Society a fuller description of them than I have in the paper sent to Burlington House; but unfortunately, owing to circumstances, my communication will not be read till the 14th instant. Owing to this my mouth is closed till after that time, and I can only say that the theories which I have ventured to promulgate seem to be fully confirmed, and that the experiments point to conclusions which, if correct, cannot fail to be valuable to the practical as well as to the theoretical photographer.

In the interval which will elapse between this last meeting of this session and the first of our next, I hope, if nothing unforeseen occur, to be able to give the results of new explorations in fields akin to that I have already travelled over.

W. de W. Abney, F.R.S.,
Capt. R.E.

FOREIGN NOTES AND NEWS.

Sigson on Companion Pictures.—The *Wochenblatt* on Obernetter's Reversed Negative Process.

In the *Mittheilungen* Herr Sigson says that, being only able to take portraits at one end of his studio, he used to feel annoyed at not being able to get proper companion pictures to hang (say) on each side of the fireplace, as both pictures would look the same way. He, however, got over the difficulty by stripping off one of the negatives and printing it with the wrong side uppermost. His *modus operandi* is as follows:—The negative to be drawn off is retouched and varnished (Herr Sigson uses Schering's varnish much diluted with alcohol), and is then laid in water. As soon as the edges of the film begin to soften the negative should be taken out of the water and left to drip, and a piece of common writing paper, which had previously been floated upon water, should be laid upon the negative and the superfluous water pressed out. The corner of the film should then be raised from the glass with a knife and drawn off along with the paper. If on raising up the corner the film should crackle, that is a proof that it is not sufficiently softened, and the whole, including the paper, should be returned to the vessel of water for a short time. Herr Sigson found that with the varnish he used the time the negative required to soak in the water varied from one and two hours with a thin varnish and clean plate to a whole day when the varnish was extremely thin, and sometimes it was even necessary to revarnish. When the varnish is glassy half an hour is generally sufficient to soften it, and care must be taken not to let it soak too long, or it will cause rents in the film. When the film has been drawn off another piece of writing paper is moistened and laid upon a piece of glass, and the film is then laid upon it with the first paper uppermost; the whole is then pressed together and the first paper removed. A thin solution of gum arabic is now carried over a clean plate, and the same is passed over the upper side of the film, which is then laid upon the plate. The excess of gum is discharged by pressure and the paper removed, leaving a reversed negative. The rest of Herr Sigson's paper is occupied with directions for combination printing.

With regard to Obernetter's reversed negative process the *Photographisches Wochenblatt* says:—

"Repeated careful experiments have convinced us that the prescribed proportion of silver (namely, five grammes to 400 c. c. raw collodion) is insufficient. The film got with it is too thin. We added eight grammes of nitrate of silver and were not then satisfied, and only when we used ten grammes could we get a film with any body. Further: it is important to keep this silver collodion in the dark, as the light affects it. Then it seemed that the nitrate of silver was far from being as equally distributed in the collodion as the bromine and iodine salts, the first plates being really cloud negatives with more or less opaque spots. We have, therefore, tried shaking up the silver collodion when preparing it with our whole strength, and then letting it stand to settle. This operation repeated for several days at length produced the desired result.

"According to our observations the potassic bromide bath is the one best suited for dry plates. We take—

Raw collodion	1 pound,
Nitrate of silver	10 to 12 grammes,

and sensitise in a bath of—

Distilled water	1 kilogramme.
Bromide of potassium	120 grammes.

Then we rinse both sides of the plate carefully with common water, let it drip, and then coat it twice with a ten-per-cent. tannin solution. In spite of the comparative insensibility of bromide of silver films coated with bromide of potassium solution we should by no means advise anyone to wash them by ordinary daylight, as that tends to render them insensitive and foggy.

"We develope as follows:—When the plate has been exposed we pour over it the ordinary mixture of water and alcohol and then wash on the tannin solution, though it should be said that Obernetter's way of first coating the plate with a weak solution of nitrate of silver gives still better results. We coat the plate then with a three-per-cent. silver solution, followed by a one to fifty solution of pyrogallic acid in water with a small addition of alcohol as developer, and get the best results. We also tried the alkaline developer and found it possessed no advantage; it was also very disagreeable to work with. Damry's developer also gave very good plates, and the developer he recommends proved usable.

"We found Obernetter's dry plates (developed with pyrogallic acid) specially worthy of recommendation for enlargements, as they reproduced all the details even in the shadows, without being too dense for artificial light—that of the sciopticon, for instance—to pass through them."

PARIS EXHIBITION.

COMPLETION OF THE LIST OF JURORS IN CLASS XII.

UNITED STATES.—Henry C. White, Esq., Honorary Commissioner, U.S., to the Paris Exposition.

Great Britain and Ireland.—William England, Esq., 7, St. James's-square, Notting-hill, London, W.

By the above appointments the International Jury for Class XII. is thus complete.

M. Davanne was elected President by all the members except one, who voted for M. Adolphe Martin.

M. Levitsky, the juror for Russia, was unanimously elected Vice-President.

M. Adolphe Martin was elected Honorary Secretary, but owing to his numerous engagements he requested that he should be excused, which was agreed to with regret. A further election was then proceeded with. Herr Luckhardt, Austrian juror, received four votes and the Comte d'Heliand three votes; consequently Herr Luckhardt was named Honorary Secretary.

The above elections were adjourned for a day in the hope of the English juror being able to arrive, to whom the Prince of Wales paid the signal honour of himself commanding his personal attendance in Paris, the telegram notifying Mr. England's appointment.

The jury is in active operation. W. HARRISON.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
June 27	Liverpool Amateur	Free Library, William Brown-st.
,, 27	Oldham	Hare and Hounds, Yorkshire-st.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

WE now give the conclusion of the report of the meeting of the above Society, a portion of which was given at page 283 in our last number. The papers read will be found in other pages of the current issue. We are again indebted to the Society's official organ for the report of the observations made by Mr. J. R. Sawyer, Mr. W. S. Bird, Mr. J. R. Johnson, and others, on the papers read at the recent meeting.

Mr. T. J. PEARSALL said there was one remark he wished to make in regard to Mr. Bolas's paper. Mr. Bolas spoke as if the whole question turned upon the presence of the baryta salt, and, though chromate of lime was mentioned, not one word was said as to its probable influence. Some years ago, in the course of some experiments in connection with chromic acid, he had had this substance before him; and though he did not pay much attention to the colours, which were neither beautiful nor interesting, he yet thought it was possible that the "greening" or changing of the tint might be due to the combination of the common salts of lime with chromic acid as well as to the salts of baryta.

The PRESIDENT asked whether Mr. Sawyer would say a few words on the subject of the paper.

Mr. J. R. SAWYER: We have had this evening a somewhat exhaustive paper upon the subject of alizarine, interesting to some extent, although not, I fear, practically interesting in a photographic point of view. I take it the addresses that are delivered here, as a rule, have been such as would lead to some possible modification or improvement in the practice of photography. Mr. Johnson has given us a history of alizarine, an account of its uses in dyeing, of certain modes of preparation, but he has at the same time taken the opportunity of reflecting somewhat severely upon the company of which I am a member, and also upon the learned doctor whose address the Society heard read some little time since. I must say, sir, I feel somewhat diffident in approaching this matter, because I feel it is difficult for me to make the few remarks I should like to make without drawing upon myself the imputation of speaking in a "shoppy" or personal sense.

The PRESIDENT: I will stop you, Mr. Sawyer, when you are approaching that ground.

Mr. SAWYER: I hope that no charge of that kind will be laid against me; but when, in the paper just read to us tonight, it is recommended that we should go for our pigments to a certain individual who will undertake to make them of any shade we may require, I venture to say——

The PRESIDENT: Is there such a recommendation in the paper?

Mr. SAWYER: Certainly; that portion relative to Mr. Sarony.

Mr. J. R. JOHNSON: I simply mentioned that as a proof of the facts I had stated.

The PRESIDENT: The paper says—"If such a tint be sent to Mr. Sarony we pledge ourselves such tint shall be reproduced in permanent colours."

Mr. SAWYER: That is the part to which I refer. Sir, I shall not venture to suggest any proceeding of the kind with regard to ourselves. Well, Mr. Johnson has made something like a complaint against us that we have allowed the perfect process of Mr. Swan to become, in the hands of the Autotype Company, deteriorated. I understood Mr. Johnson to say that Mr. Swan left his process perfect, and that afterwards we——

Mr. JOHNSON: No; that is not so.

Mr. SAWYER: You say that there is now a stigma upon the permanency of carbon prints.

Mr. JOHNSON: I said that Mr. Swan produced no fugitive prints. No fugitive pictures were ever prepared by Mr. Swan; that is all I wish to place upon record. My point, if I am not out of order——

The PRESIDENT: I think you are a little out of order. I must ask Mr. Sawyer to go on, if you please.

Mr. SAWYER: What Mr. Johnson said bore this reference to my mind—that Mr. Swan left this pigment process perfect, and that by our *Manual* of 1876 we confessed to the use, in certain cases, of what has been styled fugitive pigments. I will not discuss what are fugitive pigments. It may be, that because you have a modicum of cochineal a print may be called fugitive, but not in any case such as to be absolutely discernible. As I have before said, what is there on earth that is *not* fugitive? The water colours which are now hanging on those walls in ten years' time will be changed and faded in their tints. I do not say that this change is a change for the worse, as they will have but got mellowed by time, and have got the impress which time alone can give. I do not, of course, compare photography to water colours, but I wish to point out that a great deal has been made, for certain purposes, of this term "fugitive," when in no sense has the term been applicable to carbon prints. But I will let that pass. We said, in the *Manual* of 1876, that in order to obtain brilliant tones it had been necessary to employ certain colours which were not absolutely permanent. Mr. Johnson wishes you to infer that during the time he was with the Autotype Company he used a solution or a preparation of alizarine which was perfectly suitable for double transfer prints.

Mr. JOHNSON: I said in 1872.

Mr. SAWYER: And the gist of his remarks is that from 1872 to 1876 we had ignored this valuable discovery—had put it on one side—and, for certain purposes, had taken and used fugitive colours.

The PRESIDENT remarked that rather dangerous ground was being approached.

Mr. SAWYER: I will endeavour to avoid it. It is said that this preparation of alizarine was not suitable for single transfers because it stained the transfer paper. As most of the work done by the company, both in Mr. Johnson's time and since, is single transfer, it is absolutely necessary that the colour employed should not stain the single transfer paper. But the allegation is that colour was prepared as to be so suitable. There are two double transfer processes—that of Mr. Johnson and that of M. Lambert. Mr. Johnson's did not find favour because it did not give that brilliancy of surface desired by photographers, and the transfer was replaced by development upon wet collodion. But up to 1876 it was not possible to develope prints containing this preparation of alizarine in combination upon collodion, because it stained the latter to such an extent that it was absolutely useless. As photographers must have this brilliancy it was to meet this difficulty that we introduced a small quantity of what has been called fugitive colour; whether it is fugitive or not the results must show. All that I can say is that we have had pictures hanging for a lengthened period in our rooms exposed to a strong light. There are pictures in every part of England; the Society have had a number in this room, and none have ever shown signs of fading. He (Mr. Sawyer) then referred to the history of the discovery of the new forms of suitable alizarine colouring matter for introduction into the carbon tissue, and continued:—Our efforts, as members of the company, have always been most earnestly in the direction of permanency. Thousands of experiments have been made, we have got together the best chemical assistance we could procure, and when a paper is read before you containing the matter which the latter part of this one contains, I felt that, at the risk of being a little out of order, I had a right to defend the course of action which has been rather severely commented upon by the author. Mr. Johnson, in the process which he has patented, makes a point of using a salt of lime in conjunction with alizarine; but in my practice (carried out with very great care) this salt has not had the slightest effect one way or the other, except to increase the bulk of the alizarine. We keep our preparation of alizarine a secret, and we honestly say that we do not come here to reveal what is a source of commercial profit, and by which we live. Mr. Johnson says that in his experience alizarine prints are affected by immersion in the alum solution. My experience does not bear this out. We have used alizarine for single transfer without any stain, and we have found it to mix perfectly. I am sorry to come before the Society in this light, and I think it would have been better if Mr. Johnson had confined himself to the history of his own invention, and to have left Dr. Monckhoven and the Autotype Company to that oblivion which would have suited them.

Mr. S. FRY thought that any fears that might be entertained as to the permanency of carbon prints were quite unfounded. He (Mr. Fry) could not help thinking, however, that Dr. Monckhoven's paper was very injudicious; at the same time he did not believe he intended to fix anything like a stigma on the carbon process as it is worked in the tissue supplied to the whole world. The statements he made were not such as could be fully borne out by the facts.

Mr. W. S. BIRD: I am sorry a discussion on carbon printing has taken a form which is scarcely suitable for a learned society. Mr. Johnson's paper is a clever and interesting one; but certainly he has indulged in reflections of a more or less personal character. I may, perhaps, be allowed to correct Mr. Johnson in a matter of history. He says that in 1872 he succeeded in producing alizarine suitable for use in pigment prints which, with double transfer, answered perfectly. I think that here Mr. Johnson must be slightly in error. Mr. J. A. Spencer was associated with Mr. Johnson in these experiments, and Mr. Spencer—an able and careful chemist—did not know that alizarine could be so used. The staining of the tissue was a difficulty not then overcome. Mr. Johnson was associated with us at that time as one of the company, and he never said to me that he had a method by which alizarine could be used. There is, therefore, in his mind a little error as to dates. We had tried alizarine without effect, and it is only under new combinations that it has become at all practicable. Dr. Monckhoven suspected its permanency, and, as it is a matter of great importance that carbon prints should be without the slightest suspicion of change, any communication which could assist that result should be thoroughly welcome. At the same time I must say, with regard to Dr. Monckhoven's statements, that we deny that his experiments were made with the Autotype Company's tissue. Here are specimens said to be on this tissue which, I am absolutely certain, were never made on our tissue at all. We deny the fact, and it is unfair to publish experiments which are of a one-sided character. I believe Dr. Monckhoven to be under a mistake with regard to his paper, and to be very rash in regard to his facts.

The President observed that, without entering into the merits of the controversy, he might point out that when Mr. Johnson said that in 1870 the Autotype Company produced prints which did not fade, and that now a certain stigma rested upon their work, a disagreeable inference could not fail to be drawn. He was sorry the statement had been read, but having been read he was obliged, as a matter of justice, to allow Mr. Sawyer an opportunity to reply. It was well known what the Autotype Company had done. Not very long since a large number of prints were exhibited by the Society which had been produced some six or seven, or fewer, years since, and, to his mind, there were no signs of fading. Dr. Monckhoven stated that he had made experiments with the company's tissue, but that had been denied by Mr. Bird. It was painful to him (the President) that a difference of this kind had arisen, but he trusted that it would be the last time, and that all would endeavour to work for one common object—the improvement and development of photography.

Mr. Johnson, in reply, said: As regards the importance of the subject I need simply refer you to Mr. Sawyer's remarks. He tells you he has made thousands of experiments upon colouring matters to arrive at a permanent compound. At the same time, having myself, I believe, succeeded in forming such a compound, I think it is my duty to call your attention to the result. It is true that the matter has been put on record as a patent, but that patent will be manufactured and supplied at a reasonable price to the public; and, as every one can now make the tissue for himself, the question of permanent colour comes home to every individual present. As to the question raised by Mr. Sawyer in respect to the double transfer, it is a matter which can be very easily tried. I pledge myself to show him—if Mr. Sawyer will allow me to state what it is. May I say what is the formula?

Mr. Sawyer: Mr. Johnson is perfectly at liberty to state what the formula is, for up to this time it has not come down to the company.

Mr. Johnson: On the contrary, you have the solution.

Mr. Sawyer: It is simply called the red solution, and nothing more.

Mr. Johnson, in reply, was understood to say that by using tartrate of potash the ordinary effect of the insolubility of gelatine of alumina was no longer obtained. With madder red in combination with alumina for a basis he pledged himself to produce perfectly permanent pigments, only he admitted that they could not be used with single transfer. It also stained collodion, but in certain methods this might be obviated. In conclusion Mr. Johnson said he considered he was justified in claiming that he had settled the formula for double transfer in 1872, and that, having seen in the fifth edition of the Autotype Company's *Manual* a statement that fugitive materials were employed, he thought it was his duty to place on record his share in the matter.

The President, in closing the discussion, alluded to a promise made by Mr. Sawyer, that a print, one-half of which was to be covered, should be exposed for some time to light, and hoped that the promise would be fulfilled.

Correspondence.

SENSITISED GELATINE SUBSTRATUM.

To the Editors.

Gentlemen,—I will add another idea to that thrown out last week in regard to a gelatine substratum—an idea which occurred to me some three years ago, when considering by what means great intensity could be secured in the negative, more especially in reference to dry plates and to the gelatine film, which was scarcely so well known then as now for its capabilities in the direction of intensity. The idea may have occurred to me, as many others do now, from something I had read in The British Journal of Photography. At anyrate, it has been treated in the Journal since that time by other correspondents, and, as usual, ably experimented and commented upon by the Editors. Still the experiment, as far as I recollect, was not made in the precise form in which I had proposed it to myself. I have made many experiments in the intervals I have since been able to devote to such subjects; but this has been kept in reserve, and, as some time may elapse before I can return to the matter, I venture to suggest it now in case anyone else should think it worth while to repeat my experiment.

My idea, then, was to coat the plate first with sensitive gelatine emulsion and afterwards with a washed collodion emulsion. I forget now whether, in the experiments afterwards recorded, this was done in a reverse order, or whether only collodion films were used; but the impression remained on my mind that my own experiment was left untouched. The importance of placing the sensitised gelatine film first arose in my mind from the following considerations:—The rays of light having to traverse the upper film, in which they would be to a considerable extent absorbed before reaching the under one, could only act more feebly there; but the greater readiness with which the more sensitive gelatine film would respond to this more feeble action might permit an effect to be produced as great as that in the upper film, and thus the image developed right through both films might become very intense.

For my own part I prefer to print, not from a *dense*, but from an *intense*, negative. The relative sensitiveness of the two films as I proposed to use them would have been as seven or even as ten to one. The collodion film, therefore, even if equally exposed, could only receive the very faintest impression by the time the gelatine would be fully impressed; and, if placed underneath, would absolutely have no chance. On the other hand, with the gelatine film underneath, even if it should, owing to its much greater sensitiveness, be impressed in a greater ratio than the other, would only come under the action of the developer after it had penetrated the collodion film, and thus something more like a simultaneous development would be effected.

One more consideration may be added here—although that could not enter into my speculations at the time, having been only revealed at a later period through the able researches of Captain Abney—namely, that the impressed film underneath would aid the development of an image in that above, although the latter had not been previously impressed. I am not sure how far the same fact was established with regard to an impressed film underneath. But there is still one point with reference to a gelatine film above instead of below:—The developing fluid, having to penetrate the gelatine completely before it could reach the other, and to be kept on still some time, I should fear a solution of the gelatine would have begun before the action could be complete beneath.

I do not know how far the experiment—which I still hope some day to make—would, if successful, be available for any particular purpose; but I may remark that, having made recently, at Gibraltar, somewhat systematic experiments with various kinds of dry plates—gelatine emulsion and collodion washed and unwashed emulsions—I found no difficulty in getting a large amount of intensity. Only one kind—a commercial sample—failed me, but I think there was something else wrong with them.

It may, perhaps, be interesting, in regard to the question of dry plates *versus* wet, to notice that I was wishing to do something towards the solution of this question; but was not quite able to work both together as I intended. The wet-plate work was done a year earlier, under as nearly as possible the same conditions. I believe both may be taken as a fair average of what wet- and dry-plate work are each capable of producing. I submitted the whole of the negatives to a more experienced photographer, who pronounced, without hesitation, in favour of the wet plates. The gelatine plates, he thought, came nearer to the wet than the others. The wet plates were not intensified with pyro. and silver, but for some of them silver was added to the iron developer. The commercial samples of dry plates, except the one (which also promised admirably at first), were all of great excellence. When not experimenting, I would undertake to make from every one of them a good negative. An unwashed emulsion, which I prepared from known formulæ, gave me negatives equal to any of the former; but I could not equally rely on these, owing to a want of convenience for properly preparing them.—I am, yours, &c., Wm. Washam.

Eastbourne, June 17, 1878.

A PERVERSE PRINTING BATH.

To the Editors.

Gentlemen,—We are all pretty familiar with the vagaries of the negative bath, and I have hitherto considered myself fortunate in being spared much of the trouble of which I hear others complain in that direction. I have recently, however, had to confess myself beaten by my printing bath, which is usually supposed to be so easily managed and kept in order.

This is how it occurred, and perhaps you may be able to assist me to a solution of the mystery:—A few months ago I came across a formula in one of your Almanacs for the preparation of paper that would keep. I have not the exact formula at hand now, but it consisted in acidifying the bath with citric acid and subsequently neutralising with ammonia. I don't know what went wrong exactly, but, after "dodging" it alter.

nately with acid and ammonia, I found that to obtain a clear solution it must be either very acid or very alkaline, neither of which conditions appears to me desirable. At length in disgust I threw it down with carbonate of soda, and, after washing, proceeded to redissolve the carbonate in dilute nitric acid. I have always been under the impression (and the idea has been fostered by what you yourselves, as well as others, have written on the subject) that carbonate of silver and free nitric acid cannot possibly exist together—that one, at least, must disappear. Imagine my surprise, then, upon testing the solution, which still contained some undissolved carbonate, to find it extremely acid. I boiled it to drive off any traces of carbonic acid gas which *might* possibly remain, but the corrosive fumes bore ample testimony to the presence, in large quantity, of free nitric acid.

I have that bath yet, and calculate that I should have saved by the transaction if I had sent it down the sink before I commenced messing with it. If anybody else tries to persuade you or your readers to go in for citrate of ammonia, take my advice, and—don't. In future, the reply received by all such advisers will be from—Yours, &c.,

June 18, 1878. "NOT GOOD ENOUGH."

[The precipitate which remained after the solution had acquired acid properties was not carbonate, but *citrate*, of silver. The latter appears to be somewhat erratic in its behaviour; it is more or less soluble in neutral or alkaline solutions of silver, but neither in nitric acid itself or in solutions containing it.—EDS.]

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

EXCHANGES.—In our next.

CONGRESS.—It is worth trying, but we have some doubt of the result.

F. R. J.—It is the *back lenses* of the portrait combination that determine the flatness of the field.

DELTA.—Collodion emulsion may be applied to paper; but, in developing an image obtained upon this basis, care must be taken that no stains are formed.

LANCASTERIAN.—The colour of the paper is decidedly bad. Let it either possess a delicate rose tint or, otherwise, be of a deep cream colour. The mount may with advantage be a deep drab.

ALEX. THOMSON.—The finest collection of photographs of wild animals of which we are aware is that of Mr. F. York, of Lancaster-road, Notting-hill, W. We presume that you can obtain a list of the subjects on application.

J. A. (Beverley).—There is no difficulty in procuring formic acid—at least in London. Perhaps the true cause of its not having been "universally adopted" is that the claims made in its favour have yet to be established.

THOS. FOWLER.—The mottled appearance of the prints is due to the weakness of the hypo. fixing bath. The yellow stains are sulphide of silver. By employing a fixing bath of a sufficient degree of strength both of these annoyances will be got rid of.

J. H. P.—The *Silver Sunbeam* was published by Messrs. Longmans and Co., but it will be almost impossible for you to obtain a copy now. By calling at our office, about a week hence, you may have the privilege of examining the most perfect copy of the work that we have seen.

W. H. R.—Although lampblack and vegetable black are so nearly similar in colour when mixed up with varnish, there is a great difference between them when dry. If the proportions of black and of varnish have been properly adjusted both will dry quite dead, but one will be grey in comparison with the other.

G. B. SANDS.—A stage micrometer may be made very easily by means of photography; but it is absolutely necessary that it be used only with the lowest powers. If a high power be employed it will show the lines in a very blurred condition, and the atoms of silver which compose such lines will also be plainly visible.

T. T. S.—We have never disputed the admirable quality of the results obtained by the collodio-albumen process; but you are surely not prepared to place it in competition with some of the modern processes as regards convenience and ease of manipulation. After all has been said, too, in favour of its results, the very finest dry plate pictures we ever saw were produced by an emulsion process.

BOWSCAR.—1. Of the three lenses mentioned in your list for the purposes of enlarging, the half-plate will be found most suitable, the length of exposure increasing with the length of focus.—2. Our correspondent asks where he can find M. Poitevin's formula for the perchloride of iron and tartaric mixture mentioned by him for the equalising of intensity in negatives. Perhaps some reader will be able to supply the information.

AMATEUR.—Teak has been preferred for cameras by some experts in wood, but mahogany must be considered as holding the sway; we therefore advise you to make use of this kind of wood for your camera. Mahogany also answers well for making baths; but in this latter application the pores of the wood must be filled by either paraffine or wax, or by a mixture of both. It has been proved that a bath-holder so prepared exercises no injurious action upon the nitrate of silver solution.

C. B. A.—The nine-inch lens will give a picture of *Arthur's Seat* which will convey to the spectator a truer idea of this towering eminence than the six-inch lens. The reason of this is, that the lens having the shorter focus introduces into the picture objects in the immediate foreground which, from their comparative magnitude, dwarf the larger object. When a wide-angle lens is employed for landscape work it is a safe expedient to remove a large portion of the foreground.

W. L. A.—Bromide of potassium is not sufficiently soluble for the purpose, though admirably adapted to gelatine emulsion. Unlike the ammonium salt, its solubility in alcohol is not increased in the presence of cadmium bromide. Your supposition that the increased sensitiveness of gelatine emulsion "may be" due to the employment of potassium bromide will scarcely hold good when some of the most rapid formulæ published contain the cadmium and ammonium salts.

NOIRCEAU.—Drop-black is superior to lampblack, *i.e*, the ordinary lampblack of the oil-shops, which appears to consist of little else but ordinary soot. Moisten the black with methylated spirit, having previously rubbed it down to a fine powder in a mortar, and then stir in gradually ordinary spirit varnish until, when dried by heat upon a piece of brass, the powder will bear moderate friction with the finger. The secret lies in the wetting with alcohol previous to the addition of the varnish.

GEO. C. COOKE.—In the photographing of granulated paper, so as to obtain a negative that will print the granulations properly, the whole secret consists in directing a very oblique light upon the paper. The more oblique and intense the light the more decided will be the definition of these granules; and, on the other hand, the more directly the light falls upon the paper the less will its surface texture show in the negative. For this reason, when copying a paper photograph it should be illuminated by a diffused front light, this being the condition under which the finest copy will be obtained.

J. H. L.—Of the two forms of lime light burner of which you have sent diagrams (both of which are defective), that containing the wire gauze is the better one; but it will require more pressure on the bags to overcome the resistance caused by the wire gauze in the burners.—2. Yes.—3. Water-colour flat tints can be laid evenly if you first coat the glass with weak albumen, and dry. To lay oil colour requires nothing but practice. We published, in our columns, a few months back, a very exhaustive treatise, by Mr. Ross, on the painting of magic lantern slides, to which we must refer our correspondent for full information on this subject.

OBLIGED READER.—By dabbing the prints with a large sponge and lukewarm water the hyposulphite of soda may be thoroughly removed from them in a quarter of an hour. We have seen an apparatus, whose construction was based upon the knowledge of this fact, by which long washing of prints was obviated, the whole operation being completed in less than the time we have mentioned; but in a large establishment in which several hundreds, if not thousands, of prints have to be washed at a time the most practicable way of proceeding is to place them in a trough through which a stream of water flows in such a manner as to keep the prints in a state of constant, although gentle, agitation.

FERRUM.—1. We have been unable to recognise any of the advantages claimed for salicylic acid in connection with iron. Theoretically, it would appear strange that a substance itself possessing reducing powers should act as a restrainer or retarder of reduction, and practically salicylic acid is found wholly incapable, *per se*, of exercising this function. Its extremely feeble solubility in water—at least at ordinary temperatures—limits its application; and by no variation in the proportions of iron and acid have we been able to secure a solution which does not rapidly "fog" an unexposed plate.—2. Both the acetate and nitrate of iron have given good results in the development of wet plates; but there can be no doubt that, for general purposes, ferrous sulphate is *the* best of all the iron salts.

RECEIVED.—J. Solomon; S. Rouch; G. Mason; J. Nicol, Ph.D.; and *Autotype Notes.*

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. STEWARD, Optician.

For the two Weeks ending June 19, 1878.

THESE OBSERVATIONS ARE TAKEN AT 8.30 A.M.

TRANSPARENCIES FOR WINDOW ORNAMENTATION.

Photographers being sometimes called upon to provide transparencies for the ornamentation of glass doors or windows in domestic architecture, a few remarks on this application of the results of our art-science may be useful; but such observations as we have to make must be considered as merely suggestive, and not by any means as exhaustive.

There are certain principles which we would lay down as a basis for this application of our art, the first of these being that the window or door pane to be ornamented must have its transparency destroyed, by which is meant that it must be so treated as to render it impossible to be seen through. The general function of an ornamented window is to prevent an unpleasant or inartistic scene outside from being perceived by those inside; and it is well known to some of our readers that one of the largest and finest windows of the kind we are describing intercepts and blocks out by such artistic means the view of a coachhouse and stable with their accompanying stable-yard. Those whom we have captivated by this choice specimen of the united work of the photographer and the painter had no conception of the fact that as a background to this work of art, although unseen by the spectator, the unpleasant erections named stand at a distance of thirty feet. A second principle that should be recognised is that of having the picture of a vignetted, sketchy character. The tone, unless when the nature of the subject otherwise demands it, should be warm and "sunshiny."

There are three mediums which may be made use of as the bases upon which to print the transparency, namely, paper, opal, and ground glass. It is very fortunate that the first is at once the best, the easiest, the cheapest, and most convenient of these various bases. But if the image is to be formed upon it by silver printing a method quite different from that employed in ordinary practice must be made use of; for, whereas in an ordinary photograph it is essential that the image be on the surface, it is here one of the conditions of success that it be sunk into and distributed through the entire substance of the paper. The difference between these two conditions may be easily exemplified by dividing a sensitive sheet of albumenised paper into two, and printing one of them with the albumen surface, and the other with the back of the paper, next to the negative, the printing being carried out in the second case until the image is clearly visible upon the albumen. Now examine the two prints as transparencies, and it will be seen how much more vigorous is the one than the other. To prepare paper for transparency printing it should be immersed in and not merely floated upon the silver bath. Several very fine window transparencies we have seen are made upon plain salted paper.

There does not appear to be any special condition required in the selection of paper for this purpose beyond this—that it must be wove and not wire-laid paper. Plain, unalbumenised Saxe or Rives papers answer admirably, and the only preparation required is a primary immersion in a ten-grain solution of chloride of sodium, followed, after drying, by immersion in a thirty- or forty-grain solution of nitrate of silver. The printing must be carried to a great degree of depth to allow of the reduction that will ensue upon the fixing; for the gold toning will be so slight as not to interpose any great obstacle to the solvent action of the hyposulphite of soda upon the silver of which the print is composed. It will be borne in mind that what we are now aiming at is the production of a very deep, warm-coloured transparency.

This having been obtained, the next step is to render it transparent and attach it to the window pane. It will be understood that the degree of transparency to which the print will be amenable falls far short of that by which objects at a distance can be perceived through the pictorially-ornamented glass; in short, it is the transparence or, more correctly, the *translucence* of ground glass or of pot-opal that is required. To such end provide a rather weak solution of Canada balsam in benzole, and apply this repeatedly to the picture until the transparency acquired by the first touch of the varnish brush, and which disappears upon the evaporation of the benzole, becomes permanent. Three or four applications of the varnish may be required ere this be attained.

The glass plate, having been cleaned, is coated with the same varnish, which, for this purpose, should be strengthened by the addition of more balsam; and a similar coating having been given to that side of the print that is to be placed in contact with it, an attachment is made commencing at the foot, and keeping the upper portion of the print curved outwards so as to admit of a continuous layer of the liquid varnish remaining at the point of junction between the paper and the glass, until the two are brought into contact up to the top. This ensures the avoidance of air-bubbles, which, although they may be rubbed out, are yet better avoided. When the whole has become thoroughly dry the services of the artist may be utilised to examine the whole critically, and complete the effect by imparting a little more depth here and there as may appear necessary. In the manner now described have been produced a series of the finest window transparencies we have yet seen.

A friend of ours, having a cultivated photographic taste, became the fortunate possessor of a yacht in which were a pair of folding doors with ground plate-glass panes of large dimensions, having a very handsome border, embodying a floral design surrounding each. The centre was adorned with the arms of a previous possessor, for whom the vessel had been constructed. Both the ornate border and the arms were deeply engraved by means of fluoric acid, which, when applied as a fluid, causes the surface acted upon to be of a glossy, smooth texture compared with the matt surface that results from effecting the etching or engraving by fluoric acid *gas*. What was required was the means of removing the arms, leaving the *entourage* intact. This has been effectively accomplished by covering the former with a photographic paper transparency prepared as we have described, with the additional element of colours, the transparent oil colours employed having been those found most effective in the colouring of lantern slides, namely, Prussian blue, gamboge, burnt and raw sienna, with madder and carmine for the reds. By means of these colours every combination of tint may be made. The pictures prepared in this manner possess a very fine appearance, no trace of the still existing arms being visible. It will be understood that although we have described in detail the method of printing by silver, pigmented tissue may be made use of with equal facility and with the further advantage of permanence.

ON THE EFFECT OF PRECIPITATION UPON COLLODION AND EMULSIONS.

In the communication of M. Ch. Audra, read before the last meeting of the Photographic Society of France, and in the discussion which ensued, we notice one or two points in connection with the properties of washed emulsions which do not coincide with our own or the general experience of emulsion workers on this side of the channel. We allude, of course, to the want of keeping qualities observed by M. Audra in connection with the finished emulsion—not as an accidental or occasional circumstance, but as the general characteristic of the emulsions he employs. In so short a time as six weeks after re-solution he finds the preparation completely useless; but the exceptional case of an emulsion retaining its working properties for twelve months has excited his astonishment, and has caused him to draw the valuable deduction that a washed emulsion may be made to keep indefinitely.

As regards the latter term its vagueness prevents our fully endorsing M. Audra's deduction, but this much we can with safety assert—that for one, two, or three years, or even longer, it is not only possible but easy to keep an emulsion in the state of solution and in full working order; indeed in this country the exceptional cases are those in which an originally good emulsion fails to retain its working qualities (to use the common expression) "indefinitely." Where, then, is the cause of this difference in behaviour?

Our reply to this question will, we fear, cause a shock to M. Audra, and, indeed, to all his French *confrères*, for it amounts to nothing less than an impeachment of the process almost universally adopted in France for the preparation of emulsions, and which is little, if at all, employed elsewhere. The very fact that our Gallic neighbours, who employ a process of their own, are those only who complain of a certain defect in emulsion working is in itself a strong argument in favour of the supposition that the defect is one of detail rather than of *principle* in washed emulsions, and the experiments we shall mention in the course of this article leave little doubt that such is the case.

It will be within the recollection of most of our readers that in the early part of last year the prize, offered jointly by the French Photographic Society and the Minister of Public Instruction, for the best dry process was awarded to M. Chardon by the commission appointed for that purpose. The Chardon process may be said to have been, if not the first introduction of emulsion photography into France, at least the first step towards its popularisation in that country, and still forms the basis of French emulsion work. Like the majority of new processes of the present day it consists of a grouping together of the best points of already-existing methods, the only really novel feature it possessed being the employment of precipitated pyroxyline, *i.e.*, pyroxyline thrown down from its solution in ether and alcohol by the addition of water. As we pointed out at the time, the effect of this modification was to render the subsequent precipitation of the emulsion in a fit state for re-solution a matter of certainty rather than of speculation, as it had hitherto been, and, in fact, the process greatly facilitated the preparation of an uniform and workable emulsion.

It will be remembered that at the time of its publication we devoted considerable attention to the new process, and spoke highly of the quality of the results obtained by its means. Up to the present time we have had no reason to alter the opinion then expressed with regard to the properties of the *freshly-prepared* emulsion; but, viewed from another point—its keeping power—we are compelled to acknowledge that it falls far short of other processes in vogue in this country. Our experience with the Chardon process, in its integrity, has not been sufficiently systematic to enable us to form an accurate opinion as to the limit of time the emulsion will keep good; but when, a few months ago, the results of some experiments made by MM. Chardon and Audra, on the keeping properties of the plates and emulsion, were communicated to the French Society, we were reminded that a bottle of the Chardon emulsion still remained on our shelves, and we at once proceeded to test it.

The results of the French experiments proved that, when properly packed, the dried emulsion as well as the prepared plates were unaffected by a sea voyage of three months, during which they were exposed to great heat, but that the dissolved emulsion under similar circumstances had much deteriorated. Our own experiments with the emulsion prepared eight or nine months previously showed that it had become utterly useless; it still retained its power of producing an image, but the film was of such a thin and granular nature that it was quite impossible to develope a satisfactory picture.

It was evident, from the appearance of the film and the thinness of the emulsion, that the cause of deterioration lay in the collodion rather than in the sensitive material of the emulsion. The suspended bromide certainly had lost much of the peculiar richness of colour by transmitted light for which the Chardon emulsion is remarkable, but that we attributed to decomposition of the collodion and consequent diminution of its power of holding the bromide in suspension, and our subsequent experiments tended to support this belief.

We had on hand several samples of precipitated cotton, including the remains of two of M. Chardon's own preparation, forwarded by Mr. W. R. Harrison, our Paris correspondent. With these we made five separate emulsions, employing the same proportions of bromide of silver in each case, the former being slightly in excess. A sample of ordinary commercial cotton was emulsified at the same time, the object being to ascertain which would remain in working condition for the longest period in the unwashed state. The different emulsions made from precipitated cotton assumed a deep ruby colour almost immediately after the addition of the silver, and within half-an-hour gave rich "creamy" films; the sample made from ordinary pyroxyline at the end of half-an-hour gave, however, a very thin and transparent film, and after twelve hours was still apparently far behind the others. But trying plates at that stage there appeared little difference in sensitiveness, though, as might be expected from the difference in the samples of cotton, the character of the development as well as the resulting image varied much with the different emulsions. Those from precipitated cotton developed quickly, and intensified readily with alkali, the deposit being opaque; with the ordinary pyroxyline the development was more gradual and intensification comparatively difficult, and the deposit more translucent in character, as if composed of finer particles.

Not to prolong the description unnecessarily, we may say that within four days from sensitising the whole of the five samples from precipitated cotton were quite useless. After about thirty-six hours the turning point seemed to be reached; the emulsions commenced to lose their richness of colour, and the development became more and more feeble and uncertain, until at last nothing but a faint, fogged image could be obtained. The remaining sample retained its good qualities for about a fortnight; it was difficult to tell exactly when it commenced to deteriorate, the changes taking place more slowly than in the other cases.

This experiment showed clearly that in the unwashed emulsion—that is to say, in the presence of soluble salts, which might possibly exercise an important influence on the result—the precipitated pyroxyline is far inferior in stability to that ordinarily employed; it remained now to try how far this instability extended to the washed or precipitated emulsion. The following experiments were unfortunately not performed contemporaneously; but, as far as possible, the same conditions were observed throughout, in order to preserve the comparative character of the results. It is impossible to follow minutely the individual experiments, so we shall briefly summarise the principal facts noticed. Adhering to the same formula, several emulsions were prepared from cotton precipitated by ourselves with both hot and cold water, or, as M. Chardon designates the two sorts, *pulverulent* and *resistant*. These were allowed to ripen for periods varying from six to thirty-six hours, and were then precipitated, some with hot and some with cold water. Two samples were treated by pouring out, and washing one with hot, and the other with cold, water.

Upon re-emulsifying the results varied very considerably. Samples allowed to "ripen" for thirty-six hours produced very inferior films, even when newly dissolved; but when the "ripening" was not prolonged beyond half that period the new emulsions were all that could be desired. The difference in their keeping powers was, however, very remarkable, some appearing to deteriorate steadily from the commencement, others successfully resisting the test for several weeks. With one or two exceptions, caused, no doubt, by slight accidental variations from the general conditions, the following facts were observed:—The "*coton pulverulent*" was subject to more rapid deterioration than the "*coton resistant;*" precipitation with hot water led to a similar result, though when newly dissolved the emulsion from hot water gave, perhaps, a better film than that from cold. The pulverulent cotton, as also a precipitation of the emulsion with hot water, gave a more porous, "dusty" film than was obtained under reverse conditions; the development was more rapid (in many cases high lights and details appearing simultaneously) but less vigorous, and density very difficult to obtain. The best results as regards keeping properties were obtained with the two samples which were "washed." The deterioration was in some cases so gradual that it was almost impossible to say exactly when it commenced or when the emulsion became unworkable; in fact, at the present time, after the lapse of four or five months, some of the samples have not altogether lost their working qualities, though they are by no means perfect.

In conclusion: we must express a very strong opinion that it is to the employment of precipitated cotton that we must look for an explanation of the want of keeping properties observed by M. Audra. That gentleman's remarks upon the change which occurs in the character of the film by keeping the collodion for some months previous to sensitising prove that it is more unstable than pyroxyline which has not previously undergone the ordeal of precipitation, and it is only reasonable to suppose that a repetition of that treatment must lead to a further development of the defect. The employment of hot water, too, appears to exert an injurious effect both on the stability of the cotton and on the character of the developed image. The general experience of washed emulsions in this country is that, provided the newly-dissolved preparation be in good condition, it will remain so for many months or even years, and that the whole secret lies in the capacity of the pyroxyline to resist decomposition, in which respect precipitated cotton appears to be deficient.

Since writing the above we have received a communication from Mr. W. B. Bolton upon the same subject, which will be found in another column. Although the writer views the question from a somewhat different standpoint, the general result of his experience appears to coincide with our own. It is important that the question of the stability of emulsions prepared by precipitation be settled as early as possible; and we therefore press the subject upon those of our readers who are interested in this branch of photography.

RETOUCHING.

In our last we left this subject at what may be termed the first stage—the preparation of the surface of the varnished negative so as to cause the pencil to "bite" or "take"—that state, brought about by the use of the turpentine and dammar medium, being the one we most recommended.

Keeping to the mechanical aspect of the subject, we may now describe the pencils to be used—the great desideratum being one with a tough texture, and capable of taking a fine, hard point. It is contrary to the usual plan we adopt to mention the name of the maker of any article of common use; but in the case of pencils we are justified in breaking it, for we may say that some little time ago we instituted trials of nearly every make of pencils we could obtain, and one pencil has come out conspicuously the best in every desirable quality to the retoucher. We allude to the best octagonal blacklead pencils of Faber, which in contrast with many we have tried are, as a retoucher once observed to us, "almost capable of doing the retouching themselves." We have also more recently been shown some very excellent pencils with the black lead in long sticks capable of being inserted in the pencils or pencil cases, and secured in their place by a simple arrangement, the whole being very light—a most important consideration. For retouching upon the matt varnish we described last week, the gentleman alluded to informed us that he could not, with comfort, use any pencil but the pure Cumberland lead as obtained from one of the Keswick manufacturers. Our readers may be aware that blacklead pencils are now made by compressing finely-levigated plumbago into a mass, and this, even in the best, is liable to contain gritty particles, which break through the matt surface.

It is desirable to have three or four different degrees of hardness of pencil so as to suit every class of work, the HH, H, F, and HB being the most suitable. The H is for general work; the HH (the hardest of the four) for very fine and delicate execution and where little labour is required. The F and HB are suitable for heavier pencilling when the shadows are heavy and considerable opacity is needed. It is customary to point them in a manner quite different from what one is usually accustomed to do. The lead is laid bare to the extent of almost an inch, and a more or less fine point given to it according to the negative under treatment.

Having now arrived at our surface for pencilling upon and our pencils for working with, it is time to describe the stand for holding the negative, usually called a "retouching easel." Some very useful and elaborate easels are described in our advertising columns; but, as they will be much more expensive than many of those for whom we write would require, we may say that, primarily, all that is needed is a sloping board with a central aperture, and sustained at a proper angle by a leg or strut. From this, as a beginning, are built with greater or less convenience and variety of adjustments all the more expensive and elaborate stands. Some contrivance is required to keep negatives of various sizes in their places, which is often done by a series of frames fitting one into the other. The simplest and, we think, the best arrangement of the kind we are acquainted with is formed by means of a slight bar placed across the whole width of the stand, with grooved side pieces attached to clip the stand and retain the bar in its place. The bar is thus movable upwards and downwards, and clamped by the simple act of drawing one end a little downwards, and so tightening its hold upon the stand by means of the groove. It is also necessary to prevent the negative from receiving any light upon its upper (the prepared) surface; and this may be done by suspending a piece of black velvet, or even brown paper, over a wire or other support fastened to the stand. It will be found much better not to make this easel too diminutive, as it is apt to cramp the hands if sufficient room be not allowed.

The light is to be thrown upon the negative from below, and upon its due modulation depends much of the success with which the negative may be finished. There is much discrepancy of opinion among retouchers as to the kind of light to be employed, some preferring artificial, and others not caring to work at all if they cannot have daylight. Very possibly the preference for artificial light may be due to the fact that so many photographers find it easier to work at their negatives when their day's work of negative producing, &c., is over, and they can keep to their pencil without interference, there being nothing so conducive to bad and uneven work as frequent interruption. When daylight is to be used the easel must be placed in front of a window commanding a view of the sky, and under the aperture should be placed a small mirror so arranged by means of a little packing that the retoucher, looking through the aperture, can see reflected in the mirror the sky in front of him.

For some negatives it is sufficient to place a piece of white paper in place of the mirror, while most others will require a piece of obscured glass, placed either between the mirror and the sky or between the negative and the mirror as may be found most convenient—taking care, if the latter method be adopted, not to place the glass too close behind the negative or the grained surface will interfere with nicety of touch.

Those who employ artificial light generally prefer to have a slight blue tinge imparted to it, to soften the heating and irritating effect which accompanies the flame of gas, &c. An ordinary paraffine lamp is preferred by many, but we find a good fishtail gas burner, fastened to a small stand, to be much more handy and equally useful—the former, of course, being preferred by those who have not gas connections at hand. The blue tinge may be produced by procuring an ordinary plain bedroom water bottle and filling it with water, and throwing into it a brushful of indigo colour. This, placed in front of the light, softens and cools it in a most pleasant manner.

In our correspondence column we publish this week a letter from Mr. W. B. Woodbury, narrating his experience with the ferrous oxalate developer, on which we may make a few remarks supplementing what we have previously written upon the same subject. A few weeks ago we described the anomalous behaviour of a quantity of the ferrous oxalate solution, which a few days after preparation had become totally deficient in developing power, though another portion of the same solution had worked well to the last drop. We have since submitted this enfeebled solution to the action of metallic iron, as proposed by Mr. J. W. Swan, with but partially successful results. After remaining in contact with a quantity of iron wire for several days it was found to have acquired the power of developing a feeble image, whereas before that treatment it exhibited no developing power whatever. The development, however, was of no practical utility, being of such an inferior character as to possess no interest even from an experimental point of view. As in Mr. Woodbury's case, the addition of a very small quantity of ferrous oxalate restored it to something like its original state; but the improvement was only temporary, as after a few hours' lapse it again became inert. The very small quantity of fresh oxalate which is requisite to restore the developing action at first puzzled us, as we were unable to comprehend its action upon the portion already in solution. Subsequent experiments have led us to the belief that the restored action is due entirely to the fresh oxalate, and not to any "revivification" of the old solution; in fact, we find that a solution many times weaker than that usually recommended is capable of giving a satisfactory development, though it is much slower and more under control than when employed stronger. Until the uncertainty which attaches to the keeping powers of the ferrous oxalate solution is removed it will be advisable, as Mr. Woodbury suggests, to mix only such a quantity as may be required for immediate use. We have found that by keeping the solution in contact with metallic iron it appears to retain its powers for a longer time, though in view of the eccentric manner in which different solutions behave it is quite possible this improvement may be only accidental.

ON THE CONTINUATING ACTION OF LIGHT, AND THE THEORY OF ALKALINE DEVELOPMENT.

I am much obliged to Captain Abney for the kind manner in which he discusses my criticisms of his important and scientifically-carried-out experiments; and it is with pleasure that I now reply to his last communication.

It is quite possible that I may be mistaken to some extent in my ideas of the nature of the "continuating action of light," and I must say that I thought the term applied to the effect on the *developable* image as well as to the visible image produced by the prolonged action of light. By this I mean that what may be called a "deoxidation" (de-chlorisation, &c.) of the silver haloid *continued*, not that an "oxidation" commenced—this latter action being a destroying action so far as the *developable* image is concerned.

So far as I can make out, I believe that Captain Abney is right in saying that the action of the red rays is, what we will take for granted to be, an oxidising action; but, on the other hand, I cannot find any evidence that the "oxidised" image was, in Becquerel's experience, a visible one, as Captain Abney infers. Claudet and Becquerel found that the "latent image" on the daguerreotype plate was destroyed by the action of the red rays, and that (presumably) the surface was restored to its original state. Those interested in this subject will find Claudet's and Becquerel's experiments quoted in an extract from a paper by Dr. Frankland, included in a communication from the late Mr. Sutton, at page 38 of The British Journal of Photography for 1872.

I may be wrong, but I do not think this action there referred to is the "continuating action" to which I refer; but I am doubtful whether I shall be able to adduce the evidence which I believe exists. I may, however, quote a passage from Mr. Sutton's paper which bears upon the action—whatever it should be called—to which I refer. He says:—

"These same experiments have been made the basis of a physical theory of the latent image in the collodion process; but has anyone ever observed the effacement of a latent image by the exposure of a plate to the yellow light of a dark room? I fancy not; on the contrary, we heard not long ago of a plan for reducing exposure by admitting red light into the camera through a hole in the front fitted with a trough filled with a red liquid. How could this be if red light effaces the image and undoes the work of the actinic rays?"

With regard to the non-effacement of the "latent image" by the yellow light of the ordinary dark room referred to by Mr. Sutton, it may be that the actinic and "destroying" rays for a particular class of sensitive film about balance each other in effect, so that the action is *nil*. Here, at any rate, we have a reference to the kind of "continuating action" to which I refer, whoever may be the discoverer, or alleged discoverer, of the "process" in question.

I have a distinct recollection of having, in the days of my earlier experience, exposed a piece of ordinary sensitised chlorised paper for a short time under a negative, and then of having transferred it to another frame, where the negative was replaced by a piece of ruby glass, in the more or less (probably less) faith of obtaining an intensified visible image. I have, moreover, a distinct recollection that I *failed* in what will appear to many to be a scientific adventure worthy of a Don Quixote; nevertheless, as my ideas at that date were not generally evolved from an inner consciousness, it seems to me highly probable that my experiment was initiated by those of others in a similar direction.

I intended to have made it plain in my last communication that the experiment with the three films, referred to by Captain Abney, was a purely imaginary one—at least so far as my own actual experiment is concerned. But I certainly believed that with Captain Abney the hypothesis there brought forward was an accomplished fact. Did not Captain Abney find that an exposed or developed film, coated with another bromide film, and then developed by the alkaline developer (the latter film not being exposed to the "actinic rays") produced this effect?—that the film acted on by the actinic rays developed (say) half through the thickness of the film, this under portion developing first, and that in a more or less short space of time the whole of the upper film was reduced without reference to the extent of the reduced silver underneath; that is to say, that wherever the upper film was underlaid by reduced silver reduction took place, this reduction proceeding upwards? I am uncertain, however, whether the reduction proceeded at the same rate in those parts over the half tones as in those parts over the high lights. I had certainly intended to have stated as clearly as possible Captain Abney's own experiment. I may state that, in order that my theory (or Captain Abney's, whichever it may be) should hold good, it should be possible, by exposing a bromised plate with the back to the lens, to develop an image *all through* the film, because the first reduced bromide, or sub-bromide, would underlie the surface of the film.

I had looked upon my version of Captain Abney's experiment as a statement of fact—a fact which I never thought it worth while to question. Of course, if what I have stated be only an imaginary fact, the *raison d'être* of my argument—that the particles of bromide in a film have the same relative position both before and after reversion—ceases to be.

When Captain Abney first published his experiment I inquired of him, by letter, whether he could account for the reason why the effect was not to be obtained with certain double films with which I was then experimenting. The films were composed of a sub-film of sensitive collodion emulsion, covered by a thin film of gelatine emulsion. I understood that his opinion was that the upper film being most affected by light the developing action did not proceed downwards. He also added that he had found that gelatine emulsion did not answer when used in the same manner as collodion emulsion; that is, when an exposed or developed film was coated with gelatine emulsion and then acted on by the alkaline developer, the impermeability of the gelatine being the probable cause.

Captain Abney states that he intends to repeat some of his former experiments. I, too, will make some trials when I can conveniently do so.

I have been testing volumetrically some solutions of zinc bromide and chloride with silver nitrate solution, and the following question has again occurred to me:—If to a solution of silver nitrate in water acidified with nitric acid a solution of a soluble bromide be added, the silver nitrate being in excess, and the whole be exposed to light, the silver bromide darkens, or becomes of a dirty yellow. Bromine is ejected—it is said as hypobromous acid. From what I can gather from Watts' *Dictionary* the action may be thus: that the nascent bromine acts upon the silver nitrate, half the bromine being precipitated as bromide, and half remaining in solution as hypobromous acid. If this be so, it is not scientifically correct to test a solution of a bromide with a standard solution of silver nitrate (the latter being in excess), unless the operation be conducted in the dark room; for some bromine would do work more than once—first, by precipitating $Ag_2\ Br_2$, and then, after leaving $Ag_2\ Br$, by combining with more $Ag\ NO_3$.

The actions may be thus expressed, zinc bromide being used:—

$$2\ Ag\ NO_3 + Zn\ Br_2 = Ag_2\ Br_2 + Zn\ N_2\ O_6.$$

Then, by the action of light—

$$2\ Ag_2\ Br_2 = 2\ Ag_2\ Br + Br_2.$$

Lastly, by the action of the nascent bromine on silver nitrate and water—

$$2\ Ag\ NO_3 + 2\ Br_2 + 2\ OH_2 = Ag_2\ Br_2 + 2\ Br\ HO + 2\ H\ NO_3.$$

By dividing the last equation by two we have an atom of bromine from every two molecules of silver bromide acted on by light going to form more silver bromide. To this extent, then, extra work is performed by the same atoms of bromine. The consequence would be that less soluble bromide would appear to be required. It, moreover, will not do to go on adding soluble bromide till the normal colour of the bromide has returned, even if this part of the operation be performed in the dark room ($2\ Ag_2\ Br + 2\ Zn\ Br_2 = 2\ Ag_2\ Br_2 + 2\ Zn\ Br$), as half of the bromine is present as hypobromous acid, and has not precipitated silver. HERBERT B. BERKELEY.

A WET-PLATE DEVELOPER.

AN interesting article by your able correspondent, Mr. M. Carey Lea, in a recent number of your Journal, directs attention to the action of cupric salts, combined with gallic acid, in the development of dry plates. Some years ago I was desirous of obtaining a developer to be used in a tent of small area for wet-plate landscape delineation that would give, without prolonging the exposure, sufficient printing density at one operation. Amongst other researches I experimented with the then suggested additions of copper salts to the ordinary ferrous sulphate developer, but without gaining any noteworthy advantage. I find, however, upon an incidental reference to my notebook, suggested by the above-mentioned article, under date April 23rd, 1872, the following formulæ, and remarks reserved for further consideration in connection with wet-plate photography in the field:—

"A.

Cupric sulphate	1 ounce.
Water	3 ounces.

"B.

Pyrogallic acid	10 grains.
Water	1 ounce.

"The saturated filtrate from the former is to be mixed with an equal volume of the latter. The mixture affords a solution equal in power with the ordinary iron developer, and gives sufficient intensity without subsequent treatment with pyro. and silver. The details in the shadows are as well rendered as when using protosulphate of iron followed by intensification. The addition of acetic acid to the extent of ten minims to each fluid ounce of the mixture renders the action of the developer slower without otherwise modifying its general efficiency."

I have recently re-tested the developer, using an old bath and collodion made according to my lately-published formula, and not only find the correctness of my former deductions fully confirmed, but notice an additional advantage. Negatives can be obtained with full printing density, and good rendering of the parts in shadow, with a *shorter* exposure than is requisite with the ordinary ferrous developer and subsequent intensification.

A convenient practical formula I herewith annex:—

A.

Cupric sulphate	1 ounce.
Acetic acid	15 minims.
Water	5 ounces.

B.

Pyrogallol	96 grains.
Alcohol	1 fluid ounce.

To each fluid ounce of the filtrate from A add forty minims of B, being equivalent to the addition of one grain of pyrogallol to each fluid drachm of the cupric solution. The mixture may either be made immediately before or within twenty-four hours of its application to the film.

Under many circumstances, especially when working in the photographic laboratory, the ordinary method of keeping the development apart from intensification is highly advantageous. When manipulating, however, in a tent of limited area the use of a developer capable of giving full detail and sufficient density simultaneously becomes of great advantage, and possibly the balance in favour of wet plates over dry depends on the issue. However this may be, I introduce the above developer, not as a substitute for existing ones, but as an additional power vested in the hands of the practical photographer. T. SEBASTIAN DAVIS, F.C.S.

PRACTICAL NOTES ON CARBON PRINTING IN HOT WEATHER.

ALTHOUGH *summer* weather has not made its appearance amongst us until within the last few days, yet short as has been its duration many young beginners in the carbon process have had to undergo some little difficulties which older and more experienced workers have been prepared for, and thus avoided. To novitiates in the process I think a few hints at this season may be of some service, even at the risk of being charged with telling a twice- or even thrice-told tale.

Mr. Blank writes to me saying that upon sensitising his tissue (a new supply) he found that its pigmented surface dissolved off in the bath, although it was the same one he had used with perfect success for the previous batch; so he says that, of course, it is the tissue that is at fault. More experienced hands would have at once known that it was the increased temperature that had brought about this result. The temperature of the sensitising bath should never *exceed* 60°, but the old bath my friend was using had been kept in an ordinary room, and so had become heated to something over 70°. It should be borne in mind that carbon tissue is more soluble in a solution of bichromate of potash at a given temperature than it is in plain water.

Now, as I have said that the bath, for successful working, should not exceed 60°, this temperature may easily be secured, even in the hottest weather, by substituting a pound or so of ice for an equivalent of the water used in making the bath, or by making it with freshly-drawn spring water, which rarely in summer exceeds 50° or 55°. The precaution should also be taken, in sensitising the tissue, not to place the hands in the solution more than can be avoided, as their heat will soon raise its temperature 20° or even 30°.

After removing the tissue—which should only have been allowed to remain in the bath until it has become thoroughly limp—it must be placed on a sheet of glass, or, if very large, on a sheet of zinc, face downwards of course, and a squeegee passed over the back so as to remove a large proportion of the solution. After this treatment there will be little danger of the gelatinous coating running off in the drying, even if the temperature should be somewhat high.

It should be remembered that if the tissue be squeegeed off a large proportion of the bichromate of potash solution is removed, and allowance must be made for this in the strength of the bath. Thus, a bath of three and a-half per cent. will give quite as strong a sensitised tissue, when not squeegeed, as will a five-per-cent. bath when so treated.

The drying of the tissue requires quite as much attention in a very dry season as in a very moist one, for many tissues, if dried too quickly, will reticulate, and also wash up in the high lights; although some are not subject to this evil, however quickly the drying may be effected, but all may be made to work satisfactorily by slow drying. If, however, a batch of tissue should be found to reticulate owing to proper precaution not having been taken, it need not be wasted, for if after (or before) printing it is coated with collodion and allowed to dry it will be found to work quite satisfactorily. A wet and dry bulb thermometer should always be suspended in the drying-room, so that the operator may see at a glance the state of the atmosphere, and so secure any length of time in drying, either by lighting a fire in the grate or stove should the room be too damp, or by watering the floor with a watering-pot should it appear too dry.

I prefer that tissue for chromotype work should be dried at a temperature of about 60° or 70°, and when the difference between the wet and dry bulbs is about 5° or 6°. Should the high lights of the picture be found to wash out—a no very uncommon occurrence when the temperature is very high—it may be remedied by keeping the tissue for a day or two before using it, or by giving it a very brief exposure to light after removing it from the printing-frame—of course not sufficient to tint the whites of the picture.

There is another matter that requires attention during this season, namely, the temperature of the water used to soak the tissue in previous to mounting it on the support upon which it is to be developed. This water should never exceed 55° or at most 60°, or breaking up of the picture may happen. This temperature is likewise secured by the use of a little ice or, more economically, by the use of freshly-drawn spring water. This will also greatly tend to prevent the washing up of the high lights of the pictures.

In the foregoing remarks I have had in view more especially the development of prints on glass (chromotypes) or other rigid support, although they apply equally to single transfer or to Sawyer's flexible support, except that in these two latter processes the reticulation so frequently met with in the former are seldom seen.

During the last few weeks the atmosphere has been very highly charged with electricity, and great care has been required to prevent the finished picture developed on glass being covered with innumerable small specks of dust, owing to the highly-electrical condition of the plate when freshly waxed. A few days back a plate of this kind attracted and supported a good-sized piece of tissue paper. Such a plate would, of course, soon be covered with dust should any by chance be in its neighbourhood, and which could not be easily removed by brushing while in this condition. The plates must not be used for ten or fifteen minutes after waxing, when any dust that may have been attracted by these can easily be removed by passing a broad camel's-hair brush *lightly* over its surface. E. W. Foxlee.

ON THE KEEPING QUALITIES OF WASHED EMULSION.

The almost universal experience of those who have worked much with washed emulsions goes to prove that for some imperfectly-explained reason the plates prepared by that process are much more liable to spots and blemishes than those which have to undergo washing and organifying previous to drying. But, though all attempts to provide a sure remedy for this fault have so far proved at best but partially successful, the simplicity of the process and the uniformity of its results combine to retain for washed emulsion a high position in popular favour. At the last meeting of the Photographic Society of France, however, M. Audra read a paper in which he lays a charge against the process which, if well founded, removes at once its chief recommendation, and leaves no counterbalancing gain to recompense us for the trouble and extra expense of washing the emulsion. In short, M. Audra states that the emulsion becomes useless within six weeks of solution—a period during which it is no uncommon thing to find an ordinary unwashed collodio-bromide emulsion retain its working properties. This experience of M. Audra is, however, so contrary to my own observations, and those of many others who have worked the process for the last four years, that I think we may safely conclude it to be an isolated case, or, at least, that the result springs from some special detail connected with that gentleman's mode of working. Such is my own view, and I shall endeavour to point out where and how M. Audra fails in securing a keeping emulsion.

From a perusal of the paper read before the French society it will be seen that M. Audra works the Chardon process—if not in its most minute details, at least with sufficient closeness to render his method virtually identical with that of M. Chardon; consequently my remarks may be taken as bearing upon the Chardon process generally, and not upon the particular formula stated by M. Audra. There are two, or I may say three, points in that process which I believe from experience to be conducive to the unfavourable result recorded in the paper to which I have alluded—precipitation of the emulsion in place of simple washing; the employment of pyroxyline which has already undergone precipitation; and the addition of an organifier to the final emulsion.

The first two of these conditions may, perhaps, be considered merely as variations of the same inducing cause; but I prefer to treat them separately, as the ultimate effect differs in the two cases. My readers—who I presume are emulsion workers—will scarcely require to be reminded of the different results given by the same emulsion when unwashed, washed, and precipitated respectively. An emulsion which previous to washing gives a clear, dense picture is frequently found after the performance of that operation to produce results quite the reverse; while others, though capable of resisting the washing, break down entirely under precipitation. These differences have been ascribed—and no doubt rightly—to the solvent action of the diluted ether and alcohol, which are present in larger quantity in a thick layer of emulsion than in the extremely thin film extended upon a sheet of glass.

This action, whatever it may be, is evident in the physical character of the final emulsion when newly dissolved, and I wish to suggest a possible explanation of the deterioration that takes place in an emulsion which upon re-solution is in good working condition. The properties and reactions of pyroxyline have formed the subject of a great amount of research, and one important observation—made, I believe, by M. Camuset—seems to bear directly upon the present question. It is that pyroxyline precipitated from its solution in ether and alcohol becomes altered in its chemical composition, combining *chemically* with a large proportion of water, one equivalent of the cotton taking up (I speak from memory) six equivalents of water. If such a change occur in the precipitation of an emulsion—and presuming, for the sake of clearness, that the sensitive silver compounds are not altered thereby—there must still be a vast alteration in the physical character of the pyroxyline, upon which the keeping properties of the emulsion largely depend.

I may not be correct, but I have always considered the keeping qualities of a washed emulsion to be limited only by the stability of the pyroxyline. All pyroxylines, when kept in solution as plain collodion, become gradually changed, until at last a dusty, opaque film is given when the collodion is poured upon glass. This is the only change which *ought* to take place in a properly-washed emulsion, for we can scarcely imagine that the insoluble particles of silver bromide can exert any chemical action upon the collodion. When the finely-divided bromide becomes granular or altered in character I should attribute it to this decomposition, which deprives the collodion of its power of retaining the bromide in the state of fine division which is necessary, and not to any reaction between the organic and inorganic constituents of the emulsion. I speak now, of course, of an emulsion of pure bromide of silver.

I have so far attempted to show theoretically the manner in which I believe precipitation may affect an emulsion. Practically I have found the results obtained with different forms of emulsion to accord closely with this theory. There can be no doubt that the method of precipitation is a great improvement upon the older and more cumbrous plan of washing, at least as regards convenience; but the question is—Does it affect the permanency of the emulsion? I reply distinctly that I think it does. There is certainly a great temptation to adopt the simplified method; and I, along with many others, have for some time done so, but somehow I fail to produce emulsions of the same quality I used to get. They may be all right at first, but after standing for a few days there is a noticeable though indescribable difference in their working; and, though I cannot give so unfavourable an account of my experience as M. Audra does, I should certainly, for any particular work, prefer to use a newly-dissolved emulsion rather than rely upon an old one. I have the remains of several samples of emulsion prepared by washing, from twelve to eighteen months ago, which remain in much better condition than more recent samples obtained by precipitation. Indeed, except for their having become thick from use, I can see no deterioration at all.

There is one very striking difference between emulsions prepared by the two methods. If set aside for several days to allow the bromide to subside it will be found upon reversing the bottle that in the case of the washed emulsion the deposited bromide runs down the sides of the bottle in oily lines or streaks, and that comparatively little shaking is necessary to thoroughly re-emulsify it. With the precipitated emulsion, on the contrary, there is an even wave of extremely minute particles, not individually distinguishable, but conveying an impression of granularity, and a very considerable amount of shaking is necessary to get the whole into suspension. The deposit detaches itself in hard "caky" pieces, and seems to have thoroughly dissociated itself from the fluid portion of the emulsion.

Before concluding I wish to say a few words on the employment of organifiers in the final emulsion. In my earlier experiments I recommended this plan, as from insufficient knowledge of the requirements of the process I was unable otherwise to obtain a film sufficiently permeable to the developer. Among the substances thus employed were soap, tannin, gallic acid, tolu balsam, and quinine—all of which I found in course of time to produce a peculiar sort of reticulation upon the dried film. The structural markings were quite invisible on the moist film; but when dry the surface was found to be covered with irregular streaks and waves of an extremely fine transparent network. Quinine either pure or in the state of sulphate produced this effect in a very short time, and had, besides, a very injurious action upon the keeping qualities of the plates after exposure.

I will mention one more cause of the gradual deterioration of emulsions, namely, the employment of weak solvents. The best emulsions, both as regards quality of film and keeping qualities, are those made with solvents as free from water as possible. The presence of the latter in any considerable quantity not only renders the film repellent and lumpy, but after a few weeks causes the bromide to become coarse and granular. The film acquires a harsh, dusty appearance when dry, and frequently splits away in shreds. If M. Camuset's observation of the hydration of the precipitated cotton be correct, the introduction into the emulsion in this manner of a considerable quantity of water would no doubt conduce to a similar result.

I have dealt with this subject from a purely physical point of view, because, as I have stated, I believe the keeping qualities of the emulsion to depend entirely upon the stability of the cotton, provided all soluble matter be eliminated. Anything which tends chemically or otherwise to alter the physical character of the collodion, and to render it liable to decomposition, is to be avoided; hence precipitation is, I think, open to considerable suspicion, as also the addition of organic substances to the final emulsion and the use of weak solvents.

W. B. Bolton.

ON THINGS IN GENERAL.

Tehre has recently been quite a little buzz of excitement, raised through causes photographic, in the columns of several periodicals. Some members of the fair sex, whose vanity is said by their detractors to be their most prominent mental development, have been—"by permission," of course—exhibited in photographic "counterfeit presentment" in nearly every shop window in the kingdom, and a torrent of abuse has been heaped upon them. Why should they not be exhibited and sold?

"An honest man's the noblest work of God,"

and a handsome woman the most beautiful; and why, I repeat, should she not, by means of photography, be exhibited to an admiring world? The fact of vanity being at the bottom of the show does not matter one jot. There is an old Indian tradition that in the early days of the world there were no women, but only men, who were possessed of tails upon which they lavished all sorts of caresses and dressed up and trimmed with all beautiful things. Their only trouble was that they were not loose, and that they thus could not carry them about as they wished. Prayers to their gods resulted in success, and their tails were loosed and converted into women. They had not had them long before they wished from the bottom of their hearts that their tails were in their old places; but that was never granted again, and their vanity is reflected in the sex to this day, as any portrait photographer could readily tell. I wonder what tradition the natives will invent after a few hundred years' familiarity with the camera and its product—possibly they will evolve a woman out of a *carte-de-visite*.

I read somewhere in these pages that the grand "all-round" discussion at the Photographic Society of Great Britain should lead to discoveries about pigments for carbon printing. We want them, for there is still a void to fill in the production of pigment papers—permanent, rich, and beautiful. What I like about this Society is its perfect freedom. It is so nice to go and hear read a really good paper, yet full of spicy personalities, and followed by a discussion of an entirely commercial nature—one of your useful nights, devoid of those wretched scientific discussions that everyone yawns at and would like to cut at once if it were not for the look of the thing. But what did the President mean by saying he hoped Mr. Sawyer would fulfil his promise. He promised us a photograph of parallel lines some time since. Hasn't he sent it in yet? I wonder.

I saw, too, another promise made through The British Journal of Photography. Mr. Washam had invented a new process of considerable interest and spent a good share of an hour in writing about it, but yet could not find time to get a print from his negative showing results. Fie! Mr. W., you are not serving us right!—we are anxiously awaiting the Editors' verdict on your print.

Wet *versus* dry is still as lively as ever. The most interesting phase has occurred in America, the President of the Photographic Section of the American Institute having undertaken to do anything with his emulsion process that could be done with wet, and in one-third the time. Mr. Bierstadt accepted his challenge, and I hope something definite may come of it; for really the outer public are kept in a state of constant expectation in the matter. I am, however, afraid of the President's arithmetic, for he is reported as saying—"That with a process in which eight seconds is necessary, to give it twelve increases the time thirty-three and one-third per cent.!"

Another American gentleman advises us, when taking a sitter who cannot do without his spectacles, to avoid getting his "features refracted" through the glass, which would be as likely to succeed as the caudal chloride of sodium process for stocking aviaries. I must, in concluding, express my admiration for a new word in our vocabulary: for "head-rest" in future *read* "guide." Thank you, Mons. Villecholles!

Free Lance.

TRANSATLANTIC NOTES.

From the United States to Canada, across one or other of the suspension bridges that span the Niagara, is but a short distance, yet the difference between the two countries is, in some things at least, very great. Wisdom is said to come by experience, but it sometimes has to be paid for in hard cash. Here is a little that I paid sweetly for, and which intending travellers in those parts would do well to note. Before leaving New York, Boston, or Philadelphia see that you have a sufficient supply of English gold or silver for use in Canada. Being unacquainted with that simple "wrinkle," I applied to one of the banks in Niagara village, and readily got sovereigns in exchange for American "green backs," but had to pay about twenty per cent. for the accommodation!

I should have liked to have seen Mr. Notman and Mr. Henderson, of Montreal; but as that city lay far out of our route my first stay was made at Hamilton. London, Paris, &c., &c., were subsequently visited; but I feel bound to admit that neither in beauty, order, regularity, or apparently in business enterprise, are the towns in Canada equal to those in the States. It may be that there is as much business done, and that the business men amongst the Canadians are as wealthy as their American brethren; but there is certainly no visible evidence of it in their homes, either externally or internally, or in the dash and "go" everywhere seen in the States.

Hamilton is prettily situated on the banks of Lake Ontario, and consists of one principal business street, in which are some really fine public buildings, several large hotels, and numerous capacious and well-filled shops or stores—at least every third or fourth of which is a chemist's. Crossing at right angles in the ordinary way, as in the States, are a number of streets of lesser importance, but sadly deficient in the beauty everywhere so visible in towns of similar size in America. The city is, to a large extent, peopled with immigrants, the great majority of whom are from Scotland; and, as amongst these, home ties are proverbially strong, the demand for photographs is, as might be expected, very considerable, children of very tender age forming probably a large majority of the candidates for camera favours. The cause of this peculiarity, as explained to me by one of the photographers, would seem to be the desire of the young mothers to delight the eyes of the grandpapas and grandmammas in the old country with a look at each young "hopeful" as soon as possible after he or she makes an appearance in the new country; and, judging from the specimens everywhere visible, neither mothers or grandmothers are difficult to please. In this class of work ferrotypes are much run after—partly, in all probability, because they require but a short exposure, partly because they can be finished and delivered within a few minutes after the time of sitting, and partly, also, on economical principles, the usual price being a shilling for one, which in most cases is all that is required. I do think, however, that our Canadian brethren should try to give something better for that small sum, as, even after making due allowance for the fact that the many years which have elapsed since I had a personal interest in babies may have dulled my power to appreciate their beauties, peculiarities, and individualities, I do confidently assert that each is so like all the rest that an exchange might be effected without anyone being the wiser. They simply look like badly-stuffed pillows with much too long slips, and a bullet at one end, with several indentations, which convey about as clear an indication of the human countenance as do the markings on the moon of the man who is popularly supposed to reside there.

Of course the ever and everywhere popular *carte de visite* is also produced here in great numbers; but with one or two exceptions it is but little better than the ferrotype or tintype, as the Americans are pleased to call them. The prices are, on the whole, lower than in the States, being from six to eight shillings per dozen, and very dear at that. But the one or two exceptions are really first-class, and such as would do credit to any European photographer; and it was pleasant to find that here as elsewhere good work was both appreciated and paid for, two at least of the best houses getting some twenty-five shillings per dozen for their *cartes*.

The Canadians, more perhaps than any other people, "go in" enthusiastically for winter sports, and as they differ much from those in more temperate climates they never seem weary of getting themselves portrayed as if in their fullest enjoyment. In the show-cases of, perhaps, the most successful worker in this department—Mr. Fenwick—I was particularly struck with some beautiful examples of groups engaged in skating, snow-shoe walking, sleigh riding, and "tobogganing." I do not know if this last be correctly spelt, but the amusement consists in several people seating themselves on a plank, turned up at one end like the iron of a skate, which has been drawn to the top of a hill, and sliding down on the hard frozen snow with, to the eye of the uninitiated, dangerous velocity. The "toboggan" is guided in its descent by an iron-shod pole or stick, and, so far as my recollection serves me, much of the fun lies in the way in which a "spill" is brought about at the proper place and suitable time. The whole series was so well managed that, but for the announcement that character pictures were taken by arrangement, I should have thought they had really been photographed on the hills, rivers, or in the woods.

Of course I was anxious to see the actual production of such beautiful effects, and as usual received a hearty welcome from the proprietor. His establishment occupied the three stories of which the building consisted, the ground floor being a compound of reception room and picture gallery. Here there were shown some fine enlargements, made in New York and painted on the premises. They were quite equal to the average work in Scotland, and varied in price from four to twenty guineas. The first floor was devoted to beautifully-furnished dressing-rooms, painting room, and rooms for retouching, mounting, finishing, &c., &c. The third storey contained two large studios of the usual American construction—a large top light at a very gentle angle; with what little side light there was altogether shut out. In one of these an operator was busy with the ordinary kind of work, and that of a very high class, although there was not a single curtain to soften or direct the glaring light of a sunny Canadian day. The lack of curtains was amply compensated for by the use of movable screens of various shapes and sizes, all fixed to stands like head-rests; and for those who know how to use them they seem much better and more manageable than the usual method of curtaining.

This operator stated that he had made pictures for over twenty-five years in almost every town of importance both in the Dominion and in the Union, and that he would never use curtains again where he could have his own way. "You see," he continued, "it's light as makes the picture, and darkness ain't no good at all; so it stands to reason that the more light you have the better. I like to have it all round when I can get it, and when a sitter comes in I look at him well and make up my mind in what way he will look best. I then seat him on the platform, and wherever I want a shadow I hoist a screen, and move it backwards and forwards till the effect is produced." "A long time?" "Why, bless you! no; it is done in less time than it usually takes to pull up one curtain and pull it down again when you do not find it answer." The other studio had the side lights uncovered, and as it received the benefit of the full noonday sun it presented a sight not easily forgotten. The whole of the wall which did duty as a background was frescoed into a hazy wintry landscape, and executed in such a masterly way that the clouds and distant hills were represented in the photograph truer to nature than anything of the kind I had before seen. There was, however, but little of the background seen, as it was to a large extent covered by a very natural arrangement of leafless but finely-branching trees, masses of rock, both natural and artificial, and inclined planes of various degrees of angle, the whole, wherever it would lie, being covered with a liberal supply of salt mixed with minute pieces of crystal which shone and sparkled in the brilliant sunlight, producing a most charming and realistic appearance of a Canadian winter scene.

At the other end of the studio, hanging on the wall and piled on the floor, was a collection of the *matériel* for the amusements—sufficient, apparently, to start an enterprising caterer as a supplier of everything necessary for the winter sports. There were skates, sleighs, taboggans, snow shoes, and fur dresses, including the universally-worn fur cap, and those of all sizes and shapes to suite the tastes and ages of the patrons of the establishment. At the first glance one was apt to suppose that the whole secret of how the beautiful specimens I had seen below were produced was laid bare; but a careful examination of them showed that there was still something wanting in the visible arrangement.

Those who are acquainted with the introduction of groups in landscape work—especially where the figures are intended to play the principal part—know how difficult it is to get anything like a fine play of light and shade just where it is most to be desired, and that was just where the figures in Mr. Fenwick's winter scenes showed to the best advantage. The explanation lay in the use of movable screens, screens fixed to branches, screens on stands, and hand-screens—screens, in fact, that could be placed anywhere and everywhere, and which would either make or remove a shadow. Although the mention of so many screens may be apt to make the hair of some of the old curtain-loving operators stand erect, I can assure them that I here saw the most exquisite effects produced by such an arrangement in little more time than it takes me to write about them. Of course to do this requires artistic knowledge and genius too; but *pictures* cannot be produced without a combination of these rare qualities, and wherever they are found they will, if properly applied, always command a fair remuneration. I was, therefore, quite prepared for the information that for such photographs of about 8×6 inches Mr. Fenwick readily gets about fifty shillings per dozen, and an equally liberal remuneration for smaller sizes.

From Hamilton to Detroit is a long stride, but the art in the smaller Canadian towns is so much like that in the American towns already mentioned, only hardly so good, that I follow our route, and in my progress westward once more cross into American territory.

Detroit is, probably, one of the very best examples of the rapidity of the growth of American cities. Originally—and that but a short time ago—a small village on the west bank of the strait which joins Lake St. Clare to Lake Erie, it now extends in beautiful tree-lined streets as far as the eye can reach, the longer ones averaging from ten to fourteen miles. Its city hall, theatres, and other public buildings equal, if not rival, those to be found in any city in America, and its trade enables it to rank as the fourth or fifth city in the Union. Here, as elsewhere, photography receives a fair share of attention, but different from most other places, the average quality being decidedly high. Of course where professional photographers are numbered not by tens but by hundreds, there are some whose work will not stand inspection; but in no place where I have yet been is there so little that is bad and so much really good. As a natural consequence prices are, on the whole, better than even in New York and Philadelphia, *cartes de visite* bringing hardly ever less than four, and in many cases as much as six, dollars—twenty-five shillings.

Where all, or nearly all, are so good it is somewhat invidious to mention any one in particular; yet I cannot refrain from saying that I was much pleased with the exquisite work I saw in progress in the establishment of Mr. Bigelow. He, unfortunately for me, was in Europe when I called; but his obliging assistants were very polite and attentive, and afforded me an opportunity of inspecting the whole of the very complete arrangements, about which, however, there was nothing out of the ordinary run. Here, as elsewhere, wherever high-class pictures are produced they are the result of artistic culture and patient striving after perfection rather than of any pecularity in mode or material.

Before leaving Detroit I may remark that, in the arrangement of its streets, it is different from any city I have seen either in the old world or the new. Standing on the top of the city hall tower the visitor finds himself in the centre of a system of streets which branch off like the spokes of a wheel, some of them being so long that they are lost in the horizon, and all, or nearly all, so beautifully lined with trees that, after the distance of a mile or so, they look like a systematic arrangement of green avenues, the beauty of which must be seen to be understood.

From Detroit we passed on to Flint, through what had been a short time ago primeval forest; but now, thanks to the demand for pine lumber, a rich agricultural country, well supplied with rude but comfortable-looking farm houses. Flint—once the flourishing centre of a grand lumber district—is now apparently on the wane, although I think its present state of inertia is only temporary. It consists, like almost all its class, of a series of streets crossing each other at right angles; but except in Saginaw-street—and even there, too, to a certain extent—there is a general appearance of its having seen better days. There are many fine and comfortable-looking houses—the homes of families who have amassed wealth in the lumber trade—but the axe of the lumberer has long since ceased to be heard within a radius of many miles, and with its departure has gone the trade which made Flint what it is. There are, it is true, several saw mills still at work, but the logs are floated down the river from a considerable distance, and there is everywhere evidence that the glory of Flint as a lumber mart has departed. By-and-by, however, as roads get into good condition and farms become productive, Flint may experience a return of prosperity by becoming a centre for the supply of the wants of the agriculturist, and the Flintites may take comfort from the thought that, although such prosperity may not be so great, it will be more permanent than that on which it formerly relied.

Photography in Flint is, of course, no exception to the rule, and is in that sleepy state in which good work can hardly be expected. I visited some half-dozen studios, and each has the same story to tell—poor work and equally poor pay is general; although the latter is rather an effect than a cause of the former, as I found in many of the houses I visited beautiful specimens of portraiture, which the sitters had gone to Detroit to secure.

Probably the best work, as certainly the greatest amount of energy, was shown by a Mr. Thomson. He had been catering for the people of Flint for some years, but without such success as seemed to him satisfactory. He assured me that Flint was "used up," and that the only hope of business lay in getting at the country people; and as they would not come to him he had resolved to go to them. For this purpose he had built a light but convenient caravan, some twenty by nine feet. A portion of the side near one end was a foot broader and glazed, as was also a portion of the roof. It was mounted on wheels, and could easily be drawn by one horse, even on the rough American roads; and he was just about to start and visit all the villages in Michigan, quite sanguine of doing a remunerative trade before the winter snow compelled him to settle down somewhere for the season.

John Nicol, Ph.D.

THE BIG SHOW.

We Start.—Enlarging.—How Can We Get the Negatives?

Early in June I started to pay a visit to the Paris Exhibition. My friends insisted that the heat would be so great in the French capital during this season of the year that I would be sure to get melted, but having all my arrangements made I risked being turned from the solid into solution. Of course it is only little fellows (from a business point of view) in the country, like myself, who can feel of how much moment and consideration taking such a trip means. We who indulge in one or two holidays at a time, and are even then afraid in our absence that a sitter of importance might have been lost, require to screw our "courage to the sticking-place." There is an uneasy beating of the heart when anticipating the length of time that it will take, and the many chances of things going wrong during our absence, which have to be got over; but, having resolved to go, we subdue the twitchings of anxiety, and smile to think of the care we bestow upon so little, trying to forget for the moment that that little is our all. However, we made our arrangements, got our tickets, and started—four as merry fellows as you would meet in a day's march (excuse the egotism)!

On our way to London, to while away the time we had a conversation which, being photographic, might contain a germ of interest for the profession, and hence might be none the worse for being ventilated here. The subject was the enlarging of pictures and the growing demand for the same, and whether an easy method might not be arrived at whereby the exchanging or lending of negatives to each other could not be done in a regular business way, so that the copying of *cartes* would be reduced to a minimum, giving each and all the chance of obtaining the best results, and with a fair show of profits to all concerned.

Jack Smart, who started the subject, said :—"When a client brings me a *carte* and says 'I want a life-size head of this, how much will it cost?' I give him the price, and resolve at the same time to get the negative if I can."

"And if you can't, what then?" I asked.

"Copy the *carte*, of course," he replied. "But mind you this—I am always willing to give ten shillings for the loan of a negative at any time when wanted, and also I am always willing to lend my negatives on the same conditions."

"That's the only fair way," Henry said. "In these days of unions, if we could start a union for the giving and receiving of negatives at a price it would be an ordinary business transaction, and you would be free of the feeling of obligation you place yourself under now when asking a loan; in all cases, however, we would have to keep good faith with each other."

"There's where the shoe pinches," Tom broke in. "I have on several occasions sent for negatives, offering a fair sum for the loan; but no sooner was the photographer aware that enlargements were wanted than he hied away to the party to see if he himself might not be able to secure the order. This has happened so often to me that I really don't care to write for the loan of a negative at all unless I know my man very well—I just content myself with copying the *carte*."

"Yet you know," Jack said, "it does seem 'hard lines' for the original holder of a negative to lose the orders for large work, does'nt it?"

"Yes, but in the usual run of trade it is not a thing that can be obviated; for in many cases the party wishing the large picture only holds a *carte*, is a client of yours, and knows nothing of the original photographer at all, and, even suppose he did know, would not go past you for his work, being pleased with what he has had from you before."

"That's so," I replied. "I have had clients again and again possessing *cartes* only who would not go to the holder of the original negative, and of course I would rather do my best with them, if the negatives were not to be had, than acknowledge that it was out of my power to produce the best results, and so the holder of the original negative does not get benefited in the least; but if this half-sovereign arrangement was entered into he would at least pay himself for the keeping of it on his shelves."

And so we came to the conclusion that it would be well for the trade if a society were started all over the United Kingdom, the aim and object of which would be the giving and receiving negatives on loan when required for enlarging purposes; ten shillings, or any other sum specified by the society, to be be paid for such loan to the party holding the negative. Negatives of celebrities, or for commercial purposes, not to be included—only usual negatives of ordinary customers. It should be understood that the party applied to for the negative would not use any influence to obtain the order for himself. Under these or similar conditions the privilege would be enjoyed by all the members of such society alike, and would wrong no one, but might be the means of returning some little to pay for the keeping of negatives in many cases where there is no return now. It is worth a thought. MARK OUTE.

,, 3	Photographers' Benevolent	160a, Aldersgate Street.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

THE above Society held an ordinary meeting on the 26th April,—Dr. Vogel occupying the chair.

After two new members had been admitted,

The Chairman referred in a few words to the death of Herr von Voigtländer, and the whole assembly rose to its feet to testify its respect for the memory of the deceased.

A communication from Herren Strumper and Co., of Hamburg, on the marks observed by Herr Schahl in drawn off negatives was then read. [See report of meeting of 15th February, page 188.] It ran as follows :—

"As we are in the daily habit of drawing off negatives by means of gelatine, and as we were formerly a good deal troubled by negatives spoilt by the spots spoken of by Herr Schahl, we thought our four years' experience in this matter might have some interest for others.

"In our opinion these spots are induced by unequal drying, or rather by an inequality in the temperature of the drying place. Why an unequal temperature should have such an effect upon the gelatinised negative we have certainly not yet been able to find out; but as we have generally been able to ascertain that a change had taken place in the temperature of the room in question, which cooled down considerably in the course of the night, and as the plates left to dry during the night showed these spots oftenest, and those gelatined in the morning and dried before evening showed them seldom, we thought that the fault must lie in the gelatine, the glycerine, or in the negative itself.

"We then placed the negatives, after coating them with gelatine, in our drying-box, and, keeping the lid open, we raised the temperature by gas to about 30° R., and in this way we have been able to avoid the spots as long as the warmth was equal and sufficient.

"But when the negatives were placed in the drying-box in the evening they were sometimes not quite dry next morning, owing to the pressure of gas being less during the night than in the daytime, and thus allowing the temperature to fall below 30°. In this case spots often made their appearance, as well as in plates which were carried, even for a short time, into another room while still scarcely dry.

"We, therefore, believe that the best way of avoiding these spots is to dry the gelatinised negatives at an equal temperature, and as much as possible in a place free from draughts and changes of air (preferably in a drying-box, with the lid open). Too rapid drying should be avoided, as it makes the gelatine film spring off.

"We shall have much interest in hearing the experience of others in this matter, should our communication lead them to further experiments towards clearing it up."

Herr SCHAHL admitted that his experiments had not been always made at an equal temperature, as he had not thought it of great importance. He therefore admitted the probability of Herren Strumper and Co.'s explanation. He (Herr Schahl), however, remarked that he had got fewer spots when using an inferior sort of gelatine.

The CHAIRMAN recommended Johnson's method of drawing off negatives.

Herr Obernetter stated in a letter to the Society that his method of reversing the negative process had produced good results in the hands of Prince Lobkowitz, but that the latter recommended that the iodide and bromide of potassium baths be slightly acidulated with nitric acid. He had also tried to increase the quantity of silver in the silver collodion, but had found it was easily thrown off on the addition of the ether.

A series of "imperial" pictures by Mr. Rocher, of Chicago, was then laid on the table, along with a novelty in applied photography shown by Herr Prümm. The latter was the *menu* of a marriage feast decorated with the portraits of the bride and bridegroom.

The subject of the Berlin exhibition of 1879 was then introduced, and the CHAIRMAN said he did not know where the photographic apparatus would be placed. The meeting was of opinion that the best plan would be to place the photographs and photographic articles by themselves. As yet twenty firms or individuals connected with the Society have announced their intention of exhibiting.

Herr SCHNEIDER offered to supply the mounts for all the photographs exhibited by members of the Society on condition that his name might be placed in small print on the said mounts.

His offer was gladly accepted, as it would add materially to the uniformity of the whole exhibition.

The CHAIRMAN then showed Volhardt's volumetric method of analysing silver. This process is adapted to the exact determination of the silver contents of photographic baths, and is manipulated like Vogel's silver test. The same burette and pipette are used as with the latter, but sulphocyanide of ammonia is used as the standard solution instead of the potassic iodide solution. The Chairman, in the course of his explanations [*ante*, page 281], said that, as the preparation of the sulphocyanide solution might be found troublesome by those photographers who were not also chemists, it might be as well if a solution of the proper proportions were to be bought already prepared. The great advantage of this process over Vogel's was that only one fluid (the salt of iron oxide) was required as "indicator," while by Vogel's method two fluids (the fresh solution of starch and nitrous acid) were necessary. On the other hand, the blue colour of Vogel's test, being complementary to the yellow of the iodide of silver, was much more distinct than the yellow of the sulphocyanide of iron.

Herr PRÜMM, in moving the thanks of the meeting to the Chairman, said that they all understood the process very much better from having seen the experiments than they had done from the mere reading an account of it.

Herr RICHTER thought Vogel's test with iodide of potassium and starch much the most practical, as the iodide of potassium solution was quite stable, which could not be said of the sulphocyanide of potassium solution. As for the difficulties of the iodide of potassium test, in the hands of a moderately careful worker there were none.

The CHAIRMAN said that certainly iodide of potassium came into the market pure, so that one could easily prepare a solution of any desired strength, while sulphocyanide of potassium was generally impure and required to be tested. Still, he had not as yet observed any decomposition of the testing fluid.

Herr KUNZE wished for some information with respect to the treatment of a collodion which, when poured upon a plate, dries so unequally that it still remains fluid at the side where it was poured off, when the opposite side has already become horn-dry.

Herr Halwas thought the cottonmust be at fault, and no one could suggest any other remedy than using other cotton.

The Secretary then concluded the business of the evening by presenting his annual report, which concluded, by request, with the eight stanzas composed by Herr Linde, and sung by him at the last *conversazione* of the Society in March.

The meeting was shortly afterwards adjourned.

THE PHOTOGRAPHIC SECTION OF THE AMERICAN INSTITUTE.

At the March meeting the President, Mr. H. J. Newton, occupied the chair.

Dr. Higgins said : I have various specimens to present to the Section illustrative of emulsion photography. The photograph now shown is one which I placed upon my easel and have brought with me so that the Section can judge of the negative taken therefrom. It is a photograph of the interior of the Tribunal of Commerce, Paris, and possesses every possible variety, almost, of light and shade. (Exhibiting negatives from photograph.) That is the photograph from which I took this negative. I made use of it by reason of its difficult character. It is a small, quarter-plate negative with moderate development. I pushed that development much farther than necessary to show the intensity which is obtainable in the emulsion process. I then took a large negative for the purpose of obtaining a print therefrom, which I now exhibit. I also exhibit the print obtained from the negative, so that it can be compared with the original. The development in both cases was simple alkaline development—alkaline pyro.—and much weaker than ordinarily used. The President's formula for alkaline development is, I believe, bromide of ammonium, forty grains; sal soda, two ounces; water, one pint. The developer which I use is bromide of ammonium, eighty grains; sal soda, one ounce; water, one pint. I have of late combined with that one drachm of honey to the pint. Such is the developer I use—twice as weak as the President's in alkaline, and twice as strong in the restraining agency of bromide; and this I almost always dilute one-half with water. I exhibit also a second negative taken by the emulsion process, *The Marriage Ceremony*, by Raphael, and the print therefrom. I am not positive whether the print was on toned or white paper. I also exhibit a positive made by the emulsion process upon a preserved plate. The three former negatives were wet plates. This is a preserved dry plate, and the positive was obtained by contact with the negative and placed in opposition to the gas light, an exposure of one second exactly being given. In order to facilitate the matter by counting true seconds I erected a pendulum of a proper length for the latitude of 45°, which is $993\frac{52}{100}$ millimeters, or, in English measurement, $3\frac{2616}{10000}$ feet (approximating very nearly to 40 inches), to oscillate in exactly one second. I also exhibit a second negative taken by contact—a dry preserved plate transparency with ground glass backing—held one foot from an ordinary four-foot gas burner. That is a dry emulsion plate, showing that preserved plates can be made fully equal in rapidity to bath plates. Outdoor photography is another branch. I have no particular specimens to exhibit in that line, except the mere matter of showing the time of emulsion photography as compared with that of bath-plate photography. The negative exhibited is on a preserved dry plate take with a Voigtlander lens of eleven-inch focus; size of aperture in diaphragm, $11\frac{1}{2}$ millimeters, representing $\frac{f}{24}$. There are four different exposures on that plate, each of five seconds; the third, of fifteen seconds, seems evidently to be the full exposure. The next plate was taken with a Morrison lens (which I would take occasion to most highly praise for its very valuable character of depth of focus, which it seems to possess in an extraordinary degree), eight-inch focus, taken with the third opening; size of aperture of diaphragm seven millimetres, representing $\frac{f}{30}$—four equal exposures on same plate, fifteen seconds for each. I have not the negative, but I have the print of an outside view taken with a similar eight-inch Morrison lens in thirty seconds at half-past three o'clock p.m.; size of aperture in diaphragm nine millimetres, representing $\frac{f}{22\frac{1}{4}}$. All the plates had been prepared over three weeks. I am in the habit of using dry plates that have been prepared three or four months with the same certainty. In this case I developed them immediately after exposure; but I have frequently developed them after two weeks.

The President : You stated you use a drachm of honey in a pint of water with your ounce of alkaline or sal soda—that is, in all these, the wet and the dry?

Dr. Higgins : Universally.

The President : What is the immediate effect of the honey?

Dr. Higgins : The reasons for its use are two—one being that I find much greater intensity of result; the other, in cases where a long exposure is required, honey in the developer prevents it drying nearly as readily as without it.

The Secretary : It does not prevent the plate drying, does it? It may prevent it exhibiting traces of the drying on the developed image, as it otherwise might do.

Dr. Higgins : I am glad you corrected me, as it makes me state what I have neglected to do. It is an absolute fact that, in the use of the emulsion wet plate, if previous to exposure you flow that plate with your alkaline developer minus the pyro., which afterwards you put in, that you will accelerate the action of the light upon the plate from one-half to two-thirds. I have tried the experiment over and over again. Our President will, I think, corroborate my statement in so far as it relates to the accelerating influence when applied to the plate previous to exposure. I always flow my alkaline developer containing the honey over the plate *before* exposure in the camera; it both adds to the intensity and prevents the developer flowing unevenly over the surface. I use the same developer immediately after exposure with the pyro. added.

The Secretary : I observe here one feature always noticeable—in making a reduced copy, as Dr. Huggins has of this *Interior of the Tribunal of Commerce*—the shadows, or the dark portions, always appear darker in proportion to the reduced copy than in the large picture, from the fact that in the large picture we have very small points of light in the shaded parts, which give to the shadows transparency. When we reduce those points of light they become so small that we do not see them, and the shadows appear more dense.

Mr. Chapman : I think that that transparency—the one that is mounted without any varnish on it—shows a perfect freedom from granulation, which a silver bath always has; and that was the first thing that attracted my attention, in commencing with the bromide plate, as being of very great importance in transparencies. In using a film composed of iodide of silver there is always a deposit of silver on the surface. No matter how clean the work may be it is impossible to prevent the silver precipitating on the shadows at the same time it is depositing on the high lights of the negative, and the same occurs in making a positive on an iodide of silver film. The only really good way to make transparencies is with bromide plates, and developing them with an alkaline developer; then you will have no deposits.

The President : Dr. Higgins, were the plates merely washed and dried, or was there a preservative or organifier put on them?

Dr. Higgins : The dry plates were, after being flowed, very thoroughly washed through four or five changes of water, and then organified with an ordinary organifier or preservative.

The President : If there is nothing further to communicate on the emulsion question, Mr. Bierstadt has some interesting experiments to relate in reference to the action of light.

Mr. Bierstadt : I have been trying experiments to see what colours I could photograph and what I could not. I prepared a piece of paper with the seven colours of the spectrum, as nearly as I could get them. I photographed that strip over one hundred times, and have made prints from over seventy of these negatives. I wanted to see if I could make any other colours appear white on the print, as well as we do the blue, and I wanted to see if we could make blue black. I succeeded. I succeeded in making green a light, and yellow quite a light, colour. I have not yet made red white. I have here a number of examples (exhibiting). I worked through blue glass—through glass of all colours that I could grind sufficiently true to allow me to bring the image of my object in focus. I had coloured glass ground until I exhausted all the bright colours I could get; then I made a cell of two thicknesses of glass and placed a rubber ring round it, and filled it with different fluids of different colours. The same colours do not always produce the same results; and different kinds of aniline dyes, different kinds of minerals, all seem to produce different results (exhibiting many prints, with number, description, and explanation on each). I was told that I could not photograph anything through a cell of bisulphide of carbon with iodine dissolved in it, as it cuts off all the light and lets through all the heat. I made such a cell, tinted with iodine, until I could not see the image on the focussing glass at all, and yet photographed it perfectly. In fact, I believe, instead of cutting off, it accelerates, because among those trials there was one that required twelve minutes' exposure. It was with a cell containing aldehyde green—an aniline colour. I used a cell of this bisulphide of carbon *with* the cell of aldehyde green, made an exposure in four and a-half minutes, and you here see the result.

The Secretary : Mr. Bierstadt's remarks about the characteristics of bisulphide of carbon call to mind some remarks which may be found in *Tyndall's Excursions in the Alps*. The excursions were made somewhere about twenty-five years ago. In the second part of that work may be found a discussion upon the nature of light, and he speaks of some experiments upon the actinism of light passed through certain media, and also speaks of peculiar action when the light is passed through fluid containing no oxygen. Bisulphide of carbon, of course, contains, if pure, no oxygen; and he mentions that it would be interesting—but he does not say he has tried the experiment—to utilise several other fluids, and one particularly named by him is chloride of phosphorus. This is not a very common chemical, and one somewhat dangerous to handle; but I think if Mr. Bierstadt should continue his experiments it might be worth while to try it.

The President : In this experiment which produced more photographic action upon the green than the blue, what was the appearance of the image on the ground glass?

Mr. Bierstadt : The green appeared much lighter than the blue.

The President : It made it look white?

Mr. Bierstadt : If you take a deep red cell and look through it you will make the blue end of this object sheet very dark, very black; the other end will be quite light. If you look through a blue cell it will be quite the reverse.

The President: In connection with the cell that made the green photograph white, what was the colour of the blue adjoining?

Mr. Bierstadt: The blue was nearly black—a very strong contrast between the two.

The President: Mr. Chapman promulgated a theory, when Mr. Chisholm's blue glass experiments were under discussion, that the light from the object being photographed in passing through a coloured medium did not change in actinic force; the wave length of the light that comes from the object being photographed was not changed. I do not see how they can be reconciled with these experiments.

Mr. Chapman: There is nothing inconsistent with it, I am sure. He stated he made a longer exposure.

Mr. Bierstadt: It would take longer exposure if the light was passed through blue glass than without any glass.

The President: The point is here: is there any gain by the interposition of coloured media through which to pass the light in photographing the green? In all these exposures or in these experiments, where the green shows more actinism than the blue, such seems to be the case.

Mr. Bierstadt: I have not found any increase of actinic force by the use of coloured media.

The proceedings then terminated.

Correspondence.

FERROUS OXALATE DEVELOPER.

To the Editors.

Gentlemen,—Many photographers will be trying this new and simple developer, and any remarks even on what has resulted from failures may prove acceptable.

My first trials were with Swan's new plates, which, for rapidity, cleanliness, freedom from spots or stains, and ease of manipulation, leave little to be desired, and to the inexperienced amateur must prove a great boon.

But the instructions given are, I think, inclined to mislead. I prepared, according to them, a pint of solution, and my first developed negative gave me a very good opinion of the developer; the advantage, however, of occasionally moving the bath was made apparent by the sky being thin, owing, doubtless, to that part having exhausted the power of the solution in its immediate vicinity. The next negative, left in the developer for fifteen minutes, hardly showed a trace of an image; but, after rather more than an hour, a weak picture resulted. This I put down to under-exposure. But my next plate, to which I purposely gave a full exposure, refused to show any trace of an image. After one hour's immersion I took it out and placed it in the sun's rays, and again in the developer. After another hour still the same as when taken from the slide. I thought I must by some blunder have not exposed the plate at all. The next trial gave no formation of an image after two hours' immersion. I then added (not even filtering, as I expected no further result) a pinch of the ferrous powder, and left the plate in the solution for a couple of hours—in fact, I forgot it. My astonishment was great at finding an excellent negative as the result.

From these failures I gather that it is best only to mix what solution you are likely to use in a day, as it loses all its developing powers in a very short time, or to revive it with an occasional pinch of oxalate of iron, this being contrary to what I had learned on the subject.—I am, yours, &c., Walter B. Woodbury.

Manor House, South Norwood, June 24, 1878.

FILTERING SILVER SOLUTIONS.

To the Editors.

Gentlemen,—I was much interested in the description given by the "Peripatetic Photographer" of his method of filtering, and have lost no time in constructing an apparatus of a form similar to the one he described; but, as it differs from his in one or two minor details, permit me to give an account of it.

The glass jar which I have procured for my cistern, if I may so speak of it, is of a square shape, with a wide, round neck, its capacity being six pints. I prefer the square form on account of its occupying the least space; for as the nature of my business avocations leads me to travel a good deal it is of some importance that my camera (18 × 16) and other appliances should be packed in the smallest space convenient. The bung or stopper is made of boxwood, round which is an india-rubber ring half-an-inch in width, which ensures so good a fit that not a drop can leak out, even if the bottle be carried upside down. The funnel, which in the "Peripatetic's" filter is of glass, is in my apparatus made of ebonite, and I have it firmly cemented into the boxwood cover, the hole or nozzle of the funnel being screwed inside, so as to hold a stopper, also of ebonite, which screws in and renders this part quite water-tight.

The filter proper is, like the funnel, formed of ebonite, and consists of a piece not much unlike, both in form and dimensions, the leather cap of a small *carte* lens, there being a hole in the centre into which is fixed the end of a piece of pure, black india-rubber tubing. The mouth of the filter is covered with two thicknesses of white calico of close texture, and it is allowed to hang suspended in the reservoir to within three-quarters of an inch of the bottom. The portion that passes through the hole in the cover of the reservoir is cemented to it, which is very advantageous, inasmuch as it enables me, when I wish to start the action of the syphon, to do so by simply inclining the bottle on its side and pouring out the solution through the rubber tube, and by thus starting the outflow of the silver it will continue to run until all that is required has been removed from the bottle. This entirely supersedes the awkward and somewhat dangerous method of applying suction by the mouth.

From the brief experience I have had of this filter I like it very much, and should be sorry to be deprived of it. I would have preferred the use of felt to calico as a filtering medium, but there was none to be had in the locality in which I had my filter constructed.—I am, yours, &c., Ajax.

June 24, 1878.

NATURE *VERSUS* ART.

To the Editors.

Gentlemen,—Journeying with my camera in the neighbourhood of Killarney, some years ago, I met such a pretty girl—an Irish girl, of course—with unkempt locks, and a costume which had once, perhaps, been a gown, but, owing to the dilapidations wrought by time and weather, now barely afforded a decent covering, and displayed legs which would have startled the Lord Chamberlain. Being then (as now, for "age cannot wither me") extremely susceptible to female loveliness, I was anxious to obtain her for a model, and, with some difficulty, surmounted by the help of the universally-potent talisman, succeeded in persuading her and a younger sister to call at my quarters next morning to be "took;" or, rather, my sister, who accompanied me, persuaded her, which I mention in order that your modest readers may be assured that everything was quite proper. There was a romantic stream of water just behind the house, and I went home rejoicing, and dreamed all night of the charming pictures which could be composed out of such promising materials.

In the morning my models duly made their appearance; but, oh! horror! I beheld two commonplace-looking girls decked out in their "Sunday's best," including shoes and stockings, and in whom I quite failed to recognise my little dilapidated fairies of the day before. What was to be done? I had never thought of such a transformation. It was an early experience of the Irish peasantry, and I could not very well ask two young ladies to modify their costume in accordance with my ideas. All I could do was to get off the shoes and stockings and extemporise some sort of hood for the head. Perhaps you know the pretty way those Irish girls have of turning a shawl, a skirt, or anything into a hood. But, after all, how different from my dreams! What comparatively ugly and ungainly figures, as peasants always are when in their best clothes!

And let my fair readers, if any, take warning and remember that they are not always most attractive when decked out in their "war paint and feathers;" although, on the other hand, they need not (chiefly on account of Mrs. Grundy) attempt to dress with the extreme simplicity of the heroine of my tale.

Moral: "Never put off till tomorrow what can be done today."—I am, yours, &c.. R. S.

June 25, 1878.

[The specimens enclosed with the above letter testify to what can be done by the tourist photographer in the way of "character" pictures, and cause us to regret that "the girl" proved such a failure. —Eds.]

Venus and Adonis.—"Men who suffer their wives' photographs to be exhibited for sale in the shop windows run the risk of being thought to get some profit by so doing, for they otherwise would hardly sanction such publicity."

Where are you going to, my pretty maid?
I'm going to be photographed, sir, she said.

May I go with you, my pretty maid?
Yes, if you like it, she calmly said.

What is your fortune, my pretty maid?
My face is my fortune, sir, she said.

How do you live on't, my pretty maid?
By selling my photos, she promptly said.

Then may I marry you, my pretty maid?
If you've a title, perhaps—she said.

—*Punch.*

EXCHANGE COLUMN.

A strong ash tripod camera-stand with brass top will be given in exchange for a 10 × 8 bath.—Address, H. Buttrum, Wolverton-road, Stony Stratford.

I wish to exchange twenty dozen fine American assorted stereoscopic slides for an equal number of good English ones.—Address, A. Downing, Aldeburgh, Suffolk.

Wanted, a Ross or Dallmeyer *carte-de-visite* lens, in exchange for a burnisher, best albumen paper, printing press and type.—Address, "Photographer," Grove-terrace, Victoria Park, London.

Stereo. camera for plates $6\frac{1}{4} \times 3\frac{1}{4}$, with dark slide, changing-box, lens by Jamin, in good condition, will be exchanged for a portable tripod-stand. Value adjusted in cash.—Address, F. C., 55, Bold-street, Liverpool.

Offers in exchange wanted for a ten-inch square Kinnear's camera, by Meagher, with Dallmeyer's No. 3. triplet lens; all equal to new. Also, a No. 5 Dallmeyer's triplet and a No. 1 triplet.—Address, Arthur Maddison, artist, Huntingdon.

Wanted to exchange, an improved burnisher, fitted with gas burner, for *carte* or cabinet pictures (quite new), for camera with bellows body and several dark slides. Particulars per post.—Address, G. A. Hayward, St. Giles'-street, Northampton.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

J. Houghton (Leeds).—Received. A private reply will be sent in a few days.

N. V. S.—Thanks; but at present we cannot avail ourselves of your offer. In a few months hence we may.

F. Sinclair.—A plano-*concave*, not a plano-convex, is required. You must have misunderstood the optician.

Jacopo.—In papering the walls of your new studio avoid paper of a dark colour. A light grey is best, but there should be no decided pattern impressed upon it.

S. O. J.—We quite well recollect the statement, which was controverted at the time, and very properly so, for ferns *do* grow close up to the margin of the sea. The other matter was quite correctly stated.

G. Allen.—The only work on the subject which we can at present call to mind is published by Mr. J. Newman, of Soho-square. An application to that gentleman will, no doubt, ensure your requirements being satisfied.

D. W. H.—Notwithstanding the number and variety of the methods of preparing oxygen that have been proposed there is no method which, for small consumers, is so good as that by means of chlorate of potash and peroxide of manganese.

A Brixtonian.—In several shop windows you will see Japanese trays of fanciful designs. Select one of the plainest that is nearly of the dimensions of your plates, and try it. We have succeeded when using them, and there is no reason why you should fail.

Tyro.—There is no discrepancy. The temperature given is evidently that indicated by the Celsius or centigrade scale, and hence the hundred degrees of temperature mentioned is in reality equal to that at which water boils, or 212° Fahrenheit—the scale made use of in this country.

W. Weston.—Thanks for the specimens of "self-developed" plates; though not technically perfect they bear evidence to the practical nature of the process. The remaining specimens are creditable as instances of photography under difficulties, but would scarcely rank as first-class work.

B. Esselment.—Although we have never seen a portable tent formed of bamboo, we have heard of several instances in which bamboo canes have been utilised for that purpose, and it is said that, owing to their lightness and rigidity, they answer most admirably as the framework of a tent.

Two Occasional Readers.—Seeing that the plates were prepared with a view to their being utilised within one or, at most, two months afterwards, it is not matter for surprise that you should not get an image after keeping them for three years. Read the articles on this subject which have recently appeared in this Journal.

Geo. Lindsay.—We do not know by what formula the maker named prepares his retouching varnish, nor would it be greatly for the benefit of our readers to learn; because the manufacture of varnish, like that of collodion, is best conducted on a large scale, and by a person who has acquired experience in that branch of manufacture.

B. W.—1. A plano-convex achromatic lens of the kind specified may be purchased for twelve shillings. We do not think it will answer the intended purpose as well as one of a more meniscus form.—2. The lens mentioned is a triple cemented compound, and is much superior to that composed of two elements. This matter we have determined from actual comparative tests.

Jacques.—To obtain opal glass plates two by two and a-half feet it will, we imagine, be necessary that you have it made expressly, as we are not aware of its being sold in plates of such dimensions. Any dealer in photographic materials will, however, be able to answer the question. In reply to the other query: we are rather averse to entertaining the proposal.

J. P.—It is, as we have frequently stated, contrary to our custom to recommend any particular form or make of lens as better than another. The reason for our taking such course you will readily comprehend. You will be perfectly safe in applying to any one of our first-class opticians and abiding by his advice. The same remarks apply to your second query. You will have no difficulty in finding what you want in our advertising columns.

R. C.—You do not rightly apprehend the function of the microscope, for it is quite indispensable to the student of science. But you also make a mistake in associating a microscope with considerable pecuniary expenditure, whereas—although it is quite true that some instruments of this kind are very costly—the cost of one that will quite satisfy all the requirements of that branch of study upon which you have entered will not exceed twelve or fifteen shillings. A compound microscope is not required.

Photolitho.—Intensify either by the chloride of copper or the bromide of copper process. In this way you will be able to obtain density of the greatest degree without any danger of the fine lines becoming filled up.

O.—We should be very happy, did our arrangements permit, to undertake the task of testing the plates as you suggest; but, for some time to come at least, we shall be unable to do so. Our experience with that particular class of plate, moreover, is comparatively limited, and we should scarcely consider the result of our trials as conclusive in the event of their proving no more successful than your own. From your description of the development we should be inclined to lay the blame upon an over-dose of ammonia.

Tourist.—The plans you propose adopting are excellent, and with your companion, whom we know to be one of the most genial of men, you cannot fail to have an exceedingly enjoyable trip. You do not seem to be aware that much of the ground you intend to cover has been gone over by Mr. O. R. Green, who, in our Almanac for 1876, and subsequently in an article entitled *A Run for Sunshine*, described his adventures with a camera in Egypt, Rome, and other localities. We strongly advise you to peruse the articles to which we have referred previous to taking your departure from home.

F. R. S.—We are only too well aware of the fact that the stains on the hands, arising from the use of alkaline pyro., are far more difficult to remove than those caused by the use of acid pyro. and silver. It has been recommended to employ a solution of bichloride of mercury, to which have been added a few drops of hydrochloric acid and a little common salt. It is scarcely necessary to say that, after the application of this mixture, it will be requisite to wash the hands thoroughly. We find that friction with a piece of pumice stone, using hot water and soap, removes the stains in an effectual manner.

Geo. Wingate.—We cannot offer any advice under such circumstances. The name of a certain manufacturer of collodion upon one or more bottles does not necessarily prove the collodion to have been manufactured by such maker any more than the fact of his label being on the bottle would do so. It is easy for an unscrupulous individual to fill a number of empty collodion bottles with a sample different in quality from their original contents, and then to sell them as genuine; but to *prove* the accomplishment of such a fraud would be an exceedingly difficult matter. You had better submit a sample to the reputed maker, who will, at any rate, offer an opinion as to its genuineness.

Rev. J. Scott.—The French chalk best adapted for causing the collodion film to adhere to glass plates is that which is made use of so extensively by bootmakers and glovers for dusting the insides of their respective productions in order to make them slip on with facility. By inquiring for "powdered French chalk" no difficulty in obtaining a large supply will be experienced. The method of using it is, first of all, to clean the plate, and then to sprinkle on the surface a little of the powder, making use of a rubber to spread it. The superfluous powder must then be removed by *lightly* rubbing with a wash-leather. In most cases this renders quite unnecessary the employment of a substratum, especially with plates of small dimensions, by which we here mean those of 8 × 5 and under.

George S. Haley.—If you are "handy with the tools" it will not cause a great deal of trouble to fit your lens with Waterhouse diaphragms. First of all mark on the jacket the portion it is desirable to cut out, and then by means of a circular saw of very small diameter let the piece be cut out as far as that can be done by such an instrument. It will not, perhaps, be sawn up to the corners, but this can be effected by means of a small straight saw. If you have not a lathe drill a row of holes all round the portion marked on the jacket, and then break out the piece. Finish the edges with a file and emery paper, and then cut the slit in the tube, using for that purpose a rigid saw. Two annular pieces of brass inserted in the tube, one at each side of the slit, complete the operation. Do not cumber yourself by making too many diaphragms.

X. Y. Z.—Make use of a large wooden tray coated inside, first, with lac varnish, and then with a mixture of wax and paraffine. The dimensions of the tray may be about four feet by three feet. It must be fitted to a table-stand in such a manner as to be suspended on stout pivots projecting from the sides, and a heavy pendulum must be attached it so as to impart an oscillating motion. To use the tray fill it half-full of water, and, having coated the plates one after the other, lay them down in order, in the tray, which will hold two dozen of the size you indicate, and when all have been properly placed impart a slight degree of motion to the pendulum. By doing this a gentle tilting to and fro will be given to the tray, which may be continued, with several changes of water, until the whole of the soluble bromide has been removed. There are numerous details connected with this which will suggest themselves.

Received.—E. Dunmore; J. Nicol, Ph.D.; "Gloaming Time;" E. O. P.; "Medicus;" and W. S. Hay.

JOURNAL OF PHOTOGRAPHY.

No. 948. Vol. XXV.—JULY 5, 1878.

ON THE DETERMINATION OF SPECIFIC GRAVITY.

A knowledge of the "strength" of various liquids and solutions employed in different branches of photography is frequently of the greatest importance, and a ready means of acquiring the needful information should be at hand in every photographic studio as it is in the laboratory of the chemist. But too many of the followers of our art are content, if they give a thought to the matter at all, to accept as correct the *reputed* strength of the materials obtained commercially, and in the matter of solutions in constant use (the negative and printing baths, for instance) they work a "rule of thumb" mode of calculating or guessing at the extent to which the solutions are deteriorated by use.

Under such circumstances it is not surprising that serious difficulties not unfrequently arise, and in the latter case the photographer has no one but himself to blame; but in the case of liquids such as alcohol, ether, nitric or sulphuric acids, which for certain purposes require that the strength or specific gravity be accurately known, the chemist is oftentimes unjustly blamed when it is accidentally discovered that the quality is not such as had been supposed. The whole of these substances are liable to rapid deterioration if badly or carelessly stored; indeed, even when the utmost precautions are adopted, it is almost impossible to preserve anhydrous alcohol and ether or the most concentrated acids in the same state as when freshly prepared. The photographer, then, is almost equally blameworthy if, by neglecting to examine his materials, he incur failure from this cause.

The methods by which the strength or quality of different liquids may be arrived at vary according to the nature of the substance to be examined. In the case of saline solutions the most convenient method is to proceed by quantitative analysis, though if a table of densities can be procured the determination of the specific gravity is sufficient, provided the solution is known to be pure. But, as has often been pointed out, the application of the specific gravity test to such solutions as a negative bath which has been much worked is worse than useless, as the salts introduced into it by the decomposition of the soluble haloids in the collodion entirely upset the calculation; hence the "argentometer" is to be avoided. In estimating the strength of acids the chemist usually adopts the process known as *acidimetry*, in which the result is obtained by ascertaining the number of measures of a standard solution of alkali a given quantity of the acid is capable of neutralising. For nitric and sulphuric acids, however, which are the only ones that require to be estimated to a nicety, the determination of the specific gravity answers equally as well, and the operation is much more easily performed. For ether and alcohol the specific gravity test is the only one available.

Very few of our readers, we imagine, require to be told that the specific gravity of a substance is the weight of a given bulk of it at 62° Fahrenheit as compared with an equal bulk of some other substance which is reckoned as unity. Distilled water is universally adopted as the standard for liquids and solids, merely on account of its uniform composition and the fact that it is always at hand or readily obtainable. At present we are not concerned in the specific gravity of solids, and shall, therefore, confine ourselves to a description of the various methods in vogue for determining the density of liquids such as fall within the experience of photographers, though it may be remarked that the same means are equally available to every description of liquid, whether it be a simple substance or a solution, and either heavier or lighter than water.

For many purposes connected with the arts and manufactures the result is attained by means of an instrument commonly known as the hydrometer, of which there are several forms, differing slightly in construction but identical in principle, which will be familiar to most of our readers in the "argentometer." These are chiefly useful in testing spirits, oils, saccharine solutions, and other liquids, the commercial value of which depends to a great extent upon their specific gravity, but are not so well adapted to the purposes of the chemist. The latter proceeds by ascertaining the actual weight of a known volume of the substance to be examined, from which the specific gravity is obtained by simply dividing the result by the weight of the same bulk of distilled water, each of the liquids being weighed at the standard temperature of 62°.

The instrument employed for this purpose is called a "specific gravity bottle," and consists in its simplest form of a thin glass bottle or flask with a somewhat long and narrow neck, and of such capacity that when filled to a point in the neck (at which a scratch is made with a diamond or fine file) it shall contain a known weight of distilled water at the standard temperature. More delicate instruments are provided with an accurately-fitting glass stopper, through which is drilled a small hole, so that when the bottle is filled with liquid and the stopper inserted any excess will escape by the perforation, and the contents be always invariable in volume. A further refinement consists in the addition of a small thermometer, forming part of the stopper, for the purpose of noting variations in temperature in cases where the liquid cannot be conveniently raised or lowered to the standard of 62°. In very delicate experiments the chemist is frequently obliged to resort to special means which need not be described here.

The capacity of the specific gravity bottle is a matter of no importance, provided it be accurately determined, but, for the sake of convenience in saving subsequent calculation, one containing 1,000 grains is to be preferred. All that is necessary in that case after weighing the liquid is to point off three figures of the result as decimals, and the number thus obtained is the specific gravity required. Thus we find the weight of a sample of sulphuric acid to be 1845 grains; we mark off the last three figures, and we have s.g. 1·845. Or a sample of ether is found to weigh 720 grains; we place the decimal point before the first figure, thus—s.g. ·720. If a bottle of half the capacity be employed the final result is the same, but we have to divide the result by 500 (the weight of the same volume of water), or, which amounts to the same thing, consider the weight as a decimal number, and multiply by 2. So, with the same examples given above, we find the weights to be 922·5 grains and 360 grains respectively, and dividing by 500 we get s.g. 1·845 and s.g. ·720.

But even with the most perfect apparatus obtainable the result will be far from accurate if the item of temperature be disregarded, and it is here where we should expect those inexperienced in chemical manipulations to be most likely to fail. However, by adopting a slightly modified course, a result, which though perhaps not strictly accurate is sufficiently near for all photographic purposes, may be easily obtained. It consists in weighing the liquid to be examined and also the water at the same temperature (the normal temperature of the atmosphere, regardless of the standard), and working out the calculation with the figures thus obtained. It will be found very much easier to proceed in this manner than to produce the standard temperature and retain it throughout the operation, either in the cold of winter or in the tropical heat of last week.

In order to obtain as clearly as possible this assimilation of temperature, the specific gravity bottle should be filled with the liquid under examination, and plunged up to the neck in a vessel of rain water previously boiled and allowed to cool. After remaining a quarter of an hour or so the stopper is inserted, the surplus expelled, and the bottle carefully wiped and weighed. The s.g. bottle is then emptied of its contents, thoroughly rinsed at the tap, and refilled from the vessel in which it was previously immersed, and the second weight taken. Theoretically this plan is open to the objection that, as different liquids do not expand equally under variations of temperature, different results would be obtained in summer and winter with the same substance; but practically the error is so slight that for photographic purposes it may be wholly disregarded. An actual experiment performed during the recent very hot weather will demonstrate this.

We operated upon a sample of sulphuric ether, employing a specific gravity bottle of fifty grammes' capacity. The particular sample of ether we found by a recent trial, carefully conducted, at the standard temperature to register s.g. 725 (strictly speaking, a little more, perhaps ·7252). Under the conditions described above the weight of the ether was found to be 555 grains, and of the water 767 grains. Dividing the weight of the ether by that of water, we have $\frac{555}{767}$ = ·7236, or ·0016 below the true result—a difference which could scarcely be expected to cause any serious injury if totally disregarded. In like manner we found that a sample of so-called absolute alcohol showed a specific gravity of ·812, the real figures being a little higher. To show the result of disregarding the temperature—at least so far as concerns the ether—it may be noticed that the actual weight of water contained by the bottle at 62° is 771 7 grains, and adopting these figures the ether would show a s.g. of ·719.

In conclusion: those of our readers who wish to avoid the expense of a specific gravity bottle may construct a very efficient substitute at a small cost. Procure a narrow-necked, one-ounce, stoppered bottle (the "squat" shape will be the more convenient), and file a groove down one side of the stopper, so as to provide a means of escape for the surplus liquid. This may be filled with distilled water and weighed at 62°, or the absolute weight may be taken at each experiment as we have described. A counterpoise is easily made from a piece of lead or brass carefully filed down to the exact balance. In emulsion experiments, or in the manufacture of pyroxyline such an adjunct to the laboratory will be found of very great use, but especially so in the latter case. We recently had occasion to doubt the strength of some acids we had been using for that purpose, when we found the nitric to be s.g. 1·36 and the sulphuric s.g. 1·67, instead of, as reputed, 1·42 and 1·85 respectively—a sufficient difference to entirely alter the character of the pyroxyline made with them.

EXAGGERATION OF RELIEF.

A PERSON possessing only one eye has no adequate idea of the effect or value of distance. The faculty of estimating the nearness of one object compared with another situated in the same direction depends mainly upon a system of triangulation, in which both eyes of the observer form the base of a triangle the apex of which is the point under observation, the convergence or the parallelism of the optic axes serving as an insensible means of appreciating the relative distances of the objects observed. The longer the base of this triangle the more delicate will be the appreciation of these measurements; from which fact it will be correctly deduced that while a one-eyed person cannot estimate distances unless by the aid of aërial perspective, a person whose eyes are separated by a greater width than usual will have a more delicate perception of relative distances.

Before proceeding to speak of a certain photographic application of this principle we shall describe a little instrument by which the effect of distance is greatly increased and intensified, owing to its being the means of effecting a virtual separation of the eyes of the spectator. The construction of this instrument, we may premise, is within the reach of every reader who possesses a modicum of mechanical ability, while its utility for purposes of observation is undoubted.

It consists of a light piece of tube of a moderate degree of width, say two inches, the length being considerably in excess of the distance the eyes are situated apart. That with which we have experimented exceeds six inches in length. In one side of this tube are cut two round apertures equidistant from the centre, their diameters being a little under an inch; another pair of holes are cut on the opposite side of the tube, but one of each of them being situated as near to the end as possible, their diameters also being as large as the tube will admit of. If, while in this state, the eyes be directed to the eye-holes, nothing but the opposite interior of the tube would be seen; but, by means of a pair of small silvered-glass mirrors placed at an angle of forty-five degrees directly opposite the holes, the eyes become cognisant of such scenes or objects as happen to be situated at right angles to each of them, causing a confused appearance by the blending of the dissimilar scenes. But by means of a small mirror placed in each end of the tube opposite the outer aperture in the side, and having its plane quite parallel to that of the eyepiece mirrors, the view of nature that is presented by looking into the eye-apertures is precisely similar to what is seen by the unassisted eyes, subject, however, to this difference—that moderately near objects appear closer at hand, and distant objects more distant; in short, that the relative distances of objects from each other have become intensified or magnified. We have described the instrument in its simplest form, but it will be seen that by adopting a telescopic construction of the tube any desired degree of intensity or exaggeration may be imparted to the distances in the scene under examination.

Every photographer conversant with the use of the binocular camera knows that the wider apart the lenses are mounted on the camera the more pronounced will be the stereoscopic effect of the pictures taken under such conditions. There are certain subjects, however, which from their nature are not amenable to being taken with stereoscopic effect at all, unless under circumstances in which a departure from ordinary usage has taken place. Of this kind is the photographing of a coast line from the sea.

A few days ago it was our good fortune to be on board a quick-sailing yacht when, under a fair wind, she was making rapid progress within a mile of the coast of the island of Hoy, one of the Orkney group. To the eye the coast appeared uniformly even and monotonous; but from previous acquaintance with the scene we knew that this uniformity was only apparent, as the coast in reality was indented with creeks. To render apparent in a photograph these creeks with the accompanying headlands a stereoscopic camera seemed altogether inadequate; for, as no stereoscopic relief was visible to the eye, so neither would there be any in a binocular transcript of the scene. We, therefore, seized the opportunity of putting into practice something respecting which we have already thrown out a hint in these pages. Accordingly, having adapted to the camera a pair of quick-acting lenses fitted with shutters capable of rendering it easy to give an exposure the fractional part of a second, we placed an exceedingly-sensitive dry plate in the slide, directed the camera towards the coast, and exposed one half of the plate only. Having allowed the yacht to proceed several hundred yards, we exposed the second half. In accordance with the principle laid down in the former part of this article, the picture, when developed and examined in the stereoscope, showed ravines of great depth, the jutting headlands projecting forward with singular boldness, and the creeks retiring away inland. In short, we obtained not merely a relief which was altogether invisible to the eye, but which could not under any other circumstances than those described have been rendered visible. The value of this method of acquiring a knowledge of the contour of an unknown coast must be apparent.

By making use of the highly-sensitive emulsions now so easily made, or of the plates so readily procured, no difficulty will be experienced in the practice of photography aboard ship. If a rapidly-acting shutter be employed it will be found that, even when the vessel is subjected to sensible motion other than that of the smooth, onward, gliding motion of progress, a picture may be obtained satisfying all the requirements of, at least, artistic sharpness. We do not now allude to the facility of taking groups or scenes *on board of* the same ship on the deck of which the camera is planted, because in this latter case a prolonged exposure may be given without jeopardising the sharpness, seeing that both the subjects and the camera partake of the same kind of motion in common. The highly-sensitive gelatine plates, on the preparation of which such plain directions have recently appeared in the Journal, will prove exceedingly useful for such flying shots as we have here indicated.

RETOUCHING.

This article is intended to complete the short series on this important part of the production of a modern negative. The previous articles having treated of the materials to be made use of and the mode of obtaining a proper surface, we now describe the best method of setting to work.

The negative being placed on the frame, as described, the light should be regulated according to its density—the greater the density of the negative the stronger the light required—taking care always to use the lowest degree of illumination consistent with complete visibility of all detail and half-tone. If too strong a light be used the retouching will show more forcibly than appears in the negative, and would ruin its delicacy. The aperture in the retouching easel should not be too large, or there will be a flood of light running into the eyes that it will not only dazzle and tire them, but render the lighter and more delicate tones invisible. The plan we adopt is to have a sufficiently large aperture to see the greater part of a *carte* negative, for instance, and to diminish it while working by placing on the negative a piece of black cardboard in which a hole about an inch in diameter has been cut out. The pencil is to be pointed in the manner described, the final "sharpening" being best given by a piece of emery paper or cloth not too fine, a little care being necessary to avoid breaking the long and fine point. The easiest and surest mode is to work the point by repeated strokes away from the body, and not to rub it sideways or backwards and forwards. This hint will be found very useful, as the breaking of half-an-inch of point is very irritating. We have not had much experience with the "ever-pointed" leads we have alluded to, our preference being for the ordinary make of blacklead.

Our mode of practice is to take out of faces all freckles and marks, blotches of unequal colour, &c., first, and then very carefully to make the smallest possible amount of alteration in what is usually termed the "modelling"—that is, softening very heavy shadows and increasing the prominence of some of the leading lights. This is done by delicate "dabs," or dots, so to speak, with the point of the pencil, which must be made of the right intensity at once, as the depth cannot be increased by successive washes of colour, as in painting, though if the retouching be done in very fine dotting or stippling extra depth may be got by carefully filling in between the first pencillings.

The terms "stippling" and "hatching," as they are often employed, may be briefly described as dotting and lining respectively. When there are transparent parts requiring a considerable amount of intensity given to them it will be found next to impossible to do it at once, and then the only plan is to make the first retouching upon the *roughened varnish* as deep as possible, to soften by the aid of alcohol vapour, and then to heat strongly. This will fasten the retouching, and allow another coat of varnish, quickly applied, to be given. After the spots are all taken out by stippling the modelling may be done by hatching, making small lines only as regular in size and distance apart as possible, and as much as can be done causing them to follow the lines or contours of the features, or those particular facial developments that are being worked upon. It is important that the hatching should be done in a regular manner, or a very scratchy and uneven effect will be produced. Great care must be taken to avoid crossing the lines, or making two strokes touching one another, this being a fertile source of "lumpy" or "scratchy" work, as it is forcibly called.

It will be found of great use, if not an actual necessity, to have a magnifier for especially delicate work—not to be made use of from beginning to end, but merely for particular portions of the work, and to aid a general scanning of the whole when completed, so as to pick out any unevenness or roughness. If used all through it causes the work, strange as it may appear, to be less real and flesh-like and, we might almost say, less delicate. The glass should be of good width, so that both eyes can be used, and it is better if it can be affixed to a permanent support which will hold it at one distance from the negative; and this will materially lessen the fatigue of the eyes in using it.

The hatching may be suitably begun at the forehead and finished at the lower part of the face, working from the highest lights to the shadows, and not *vice versâ*. We do not intend to enter into a description of the anatomical development of the face, but, instead, we say go to nature. Every face will impart hints as to the leading lights and shadows under varying modes of illumination. A gentleman who was one of the earliest of retouchers in this country used to make a point of scrutinising his own face in a mirror, observing the disposition of high lights and shadows under every possible variety of illumination, and he recommends the method still as being better than all the books in the world. To the younger members of the profession we, apart from its entire desirability from other points of view, strongly recommend a study of drawing; the benefit would be great in many ways.

We conclude by pointing out some alterations which may be made or avoided with advantage. One of the commonest faults of a photograph is the stern or "cross" expression so frequently seen, which is caused by a too strong light, or it is the natural expression of a face at rest. One of the chief seats of this expression is between the eyebrows. It is not caused by the perpendicular line or lines, more or less pronounced, always seen there in persons somewhat advanced in life, but is produced by the contraction of the eyebrow, which at the end nearest the nose will be found, when under this expression, to have taken an angular form, and produced a decidedly darker shadow underneath in the orbit. If the corner of this angle be taken off, and the heavy, dark shadow be slightly lessened, the effect is at times almost magical; and yet any one can see, by looking at a retouched negative, that very few retouchers are aware of this simple expedient, it being generally thought that the upright furrows cause the frown.

It is generally advised to heighten the toning of the eyelids. We can only say, except to such experienced artists as need no advice from us, "do not touch them," for in ninety-nine cases out of a hundred the face gets spoiled by such work. That portion of the cheek nearest the nose should be most carefully and thoughtfully done; there is often a delicate shadow which is liable to be taken out by the unskilled retoucher with the effect of producing a swelled cheek. The line often found running down from the wings of the nostrils should be carefully lightened with the aid of the knowledge which would be obtained by a slight study of the artist's own face in a mirror. The difference between a smile and a sneer is caused by an almost imperceptible difference in the shading of this furrow that cannot be conveyed in words.

Finally: there is the corner of the mouth, where much may often be done if it be borne in mind that in a smile the corner of the lip is slightly turned up, and with a serious, grave, or crying expression it takes an opposite direction. The hands may often be improved by taking out the swollen veins they frequently present in the photograph, though often it happens that this can only be done on each individual print.

We think our instructions if attended to will be found to present nearly all it is necessary to learn—beyond what experience alone will teach—to enable any person to become a proficient retoucher.

A QUERY which we have answered this week in the proper column brings into prominence the fact that some considerable misconception exists in certain quarters upon the subject of filtration as applied to emulsions. Our readers are all aware of the care bestowed upon the filtration of collodion, and that special apparatus is necessary in order to avoid the evaporation of the volatile liquid during the tardy operation; but some, at least, among them err in supposing that an emulsion requires to be treated in the same manner as collodion. The nature of the two liquids is entirely different, collodion being a perfect solution, and emulsion, as its name implies, holding insoluble matter in suspension. Collodion, therefore, may be filtered through the closest material obtainable without suffering injury, whereas if an emulsion underwent the same treatment the result would be that a very small quantity of *pure collodion* would pass through the filter, the pores of which would soon become blocked by the minute particles of solid matter extracted from the collodion. The requirement in filtering an emulsion is entirely different from collodion; in the latter case, when we resort to such close filtration, we desire to remove the extremely minute particles of undissolved pyroxyline which rob the solution of its brightness. In the case of an emulsion, on the contrary, the object is merely to remove any accidental fragments of matter of comparatively large size which it may have acquired during the operation of sensitising, any closer filtration being performed previously. To effect this it suffices to run the emulsion rapidly through a plug of cotton or of sponge—an operation which, if applied to a dull collodion, would have not the slightest effect. A large plug loosely packed, it should be remembered, answers far better than a small one packed tightly, as the latter soon becomes choked with particles of bromide. For the same reason felt, unless very thin, is not to be recommended, except when employed in connection with an apparatus in which pressure is employed to force the particles of bromide through the fibres of the felt.

FURTHER NOTES ON THE WASHING OF EMULSIONS.

SINCE I wrote last week I have successfully carried out an experiment which has long occupied my mind, and which, by its result, seems to confirm my previous theory as to the cause of difference in the emulsion before and after washing. This difference lies chiefly in the varying degree of density obtainable under the two conditions, the image produced by the washed emulsion being generally, I may indeed say invariably, inferior in this respect to that given by the same emulsion unwashed. The inferiority I speak of is not always sufficiently marked to prove objectionable, but I have proved again and again that a washed emulsion capable of rendering a dense image without forcing has given still greater density previous to the performance of that operation.

The cause of this difference, which at first puzzled many of us, is now generally attributed to the removal of some important constituent of the emulsion simultaneously with the unevaporated solvents contained in the pellicle when first submitted to washing; and, in further explanation of the discrepancy between the effect of washing upon the film of a prepared plate and upon the mass of emulsion, it has been pointed out that in the latter case a much larger proportion of the solvents remain in the pores of the pellicle than is possible with an extremely thin film.

Accepting this theory as correct, the direct inference to be drawn from it is that by thoroughly removing the whole of the solvents before commencing to wash the cause of diminished density would be entirely removed. It will be remembered that my earliest instructions in washing the pellicle were to allow it to set very firmly before washing; while Mr. M. Carey Lea, on the other hand, recommended the water to be poured on as soon as the skin formed upon the surface of the layer of emulsion, and while the portion underneath was still fluid. These diametrically opposed plans are not necessarily anomalous if we take into consideration the great difference existing in pyroxyline and its capability of resisting washing, and I have more than once obtained by Mr. Lea's plan an emulsion giving any desired degree of density.

The objections raised against my own plan were that the pellicle became leathery and impermeable to the action of the washing water, that the soluble salts were imperfectly removed, and that the dried pellicle became very difficult of re-solution. These objections have been, however, I think, exaggerated; certainly the pellicle, if very thick, becomes "leathery," and requires a long washing to thoroughly remove the soluble matter, but that it becomes impermeable is with equal certainty incorrect. So long as the mass contains soluble matter diffused evenly throughout its bulk the water is bound sooner or later to remove it by a species of dialysis. It is a different affair altogether when a film of collodion containing no soluble matter whatever is allowed to dry; the pores of the film then contract and close, and the subsequent moistening with water fails to restore them to their original open state. Even then absolute impermeability does not result, as is abundantly shown by the possibility of developing an image by means of an aqueous developer.

Turning to the question of completely drying the pellicle previous to the application of water, the difficulty of removing the soluble salts would appear to be greatly increased; my readers will perhaps be surprised to hear that the direct reverse occurs (I am speaking now of a moderately thick layer—say the thickness of a piece of stout cardboard *when dry*). It must be borne in mind that the dried pellicle contains a large proportion of soluble matter in its pores, and that the retarding action brought about by the repulsion of the washing water by the ether and alcohol is entirely removed. The water, in fact, has nothing to do but enter the pores of the film by dissolving the crystallisable matter contained therein.

How little difficulty is likely to be met with in this direction is, I think, plainly shown by a simple experiment. Let two plates be coated, one with a washed and the other with an unwashed emulsion, and both thoroughly dried by the application of considerable heat. If these two films be now exposed for some time—say an hour—to a moderately damp atmosphere a great difference will be discovered in their appearance. Whereas the washed emulsion will have undergone no change, the other will be found to be covered with a dewy moisture, as of condensed steam, and varying in intensity in proportion to the length of time allowed to lapse after drying. This arises from the deliquescent nature of the decomposition salts (the nitrates of cadmium, ammonium, zinc, &c.) contained in the film, and surely if they *attract* moisture from the atmosphere there is not likely to be much difficulty on the part of the water in getting at them when they are immersed therein.

Such were the views I had long since formed, but until last week I never put the experiment into actual practice. Now, however, I am in a position to report upon the success of the trial, not only as it affects the possibility of removing the soluble matter under those conditions, but also in its bearing upon the density of the resulting emulsion. I may briefly recapitulate my experiment. Twelve ounces of collodion (bromised with cadmium and ammonium bromides in equivalent proportions) were sensitised so as to leave a very small excess of soluble bromide—in fact it was nearly neutral. The emulsion was allowed forty hours to "ripen" and was then divided into three equal portions, one of which was precipitated, a second washed in the usual moist or leathery state, and the third completely dried by heat before applying the water. These I will designate Nos. 1, 2, and 3 in the order I have mentioned them.

The free bromide, and with it we may presume the rest of the soluble salts were, of course, removed from No. 1 in the shortest time, but the smell of methyl remained with this as with No. 2 for a considerable time; indeed, it scarcely disappears entirely until drying is effected. Nos. 2 and 3 were washed simultaneously in equal quantities of water, and were allowed to soak for the same length of time in each change. Three changes completely removed the bromide from No. 3, while five were required to effect the same end with No. 2. The washing was continued until No. 2, by its general appearance and smell, appeared to be freed from soluble matter and solvents as far as it was possible to do it. So much for the possibility of washing the pellicle after total desiccation.

The three products were then dried by heat and redissolved in similar quantities of solvents. No. 1 dissolved almost instantly; Nos. 2 and 3 required several hours, with shaking at intervals. No. 1 was less rich in colour and gave a thinner film than the other two, between which, as regards appearance, there was little to choose. The dried film obtained with No. 3, however, appeared to be harder and more glass-like than No. 2, and, possibly (though it may be fancy), a little finer "in grain."

The photographic properties may be very briefly stated:—No. 1 gave a clean but feeble image with alkali and required silver intensification; No. 2 gave density with alkali alone without trouble, but no pushing would produce the almost complete opacity obtained with a sample plate tried before washing the emulsion. No. 3 *developed* in exactly the same manner as No. 2, but when the solution was strengthened the density "jumped up" with great rapidity, and the image obtained was, in every respect, as dense as the unwashed sample, though different in colour.

So far the results appear to be strongly in favour of washing in preference to precipitation, but more especially in favour of complete desiccation of the emulsion before washing. The addition of a little glycerine or soap, as recommended by me on the first introduction of the washed emulsion, may possibly aid in the rapid washing of the pellicle, but, as shown above, is not necessary.

In conclusion: I may be allowed to express an opinion that most of the objections raised against washing the pellicle are to be traced to a habit of pouring it out in too thick a layer. I have seen it cut into "blocks" half an inch each way whilst moist. I formerly recommended an area of eight square inches for each ounce of emulsion to be poured out, but this may be considerably increased. A good plan I once adopted is to take a number of clean plates—size and number depending upon the quantity of emulsion to be washed—and to coat and recoat them in turn three, four, or five times, until the whole quantity of emulsion is used up. The washing is then conducted in the ordinary way, and a considerable saving of time, both in setting and washing, secured. The thick films split off the glass when dried; hence the plan is perhaps not so well adapted to the system of drying before washing. W. B. Bolton.

INTENSIFICATION.

In giving expression to a few thoughts suggested by photographs exhibited for sale the intensity of the negatives from which they were printed seemed to be a most important consideration, both from an artistic and a commercial point of view.

Opinions have differed, and in all probability will always continue to differ, as to the proper strength of a negative, each operator having his own ideas on the matter; for much, in reality, depends upon the printing afterwards. A thoroughly good negative will print well under almost any conditions; all the processes of getting the print will seem to work smoothly and pleasantly when such negatives have to be dealt with. The smooth and pleasant working seems to depend, in a great measure, upon the intensity of the image. To take a negative wet from the hands of the operator and give a decided opinion upon its sufficient or insufficient strength, unless one or the other quality is very decidedly pronounced, is impossible, unless to some one accustomed to the particular method employed for its production. "It will be right when it becomes dry" is the almost unanswerable assertion, and one that is constantly made. Whether it *is* right when it is dry is another matter.

Intensification is of two kinds—one requisite for preserving half-tones and modelling, and the other for producing perfect opacity with no regard whatever to gradations. The first kind is constantly in use in almost all studios, applying, as it does, to most classes of work—portraiture, landscapes, and reproductions generally; in fact, to all except designs and drawings or subjects that consist of series of lines or dots in pure colour, that give the idea of half-tone by their nearness or separation, and represented on the negative by perfect transparency and opacity.

Intensifying being the proper strengthening of the image—such that will enable the more dense portions to resist the passage of light sufficiently long for the image to be thoroughly impressed on the sensitive paper through the less dense portions, and for permanent and brilliant results—a tolerably strong image seems absolutely necessary, whatever may be the means adopted to obtain it. The thin and delicate images now so popular require the most careful printing in the shade to produce good results, and cannot, in the nature of things, produce such permanent results as those of a stronger character. Occasionally we see negatives full of detail both in lights and shadows and with strong printing powers—in fact, perfect negatives; but where we see one like this we see hundreds of an inferior kind. Perfect negatives, in a chemical and optical sense, ought to be the rule not the exception in the present advanced state of photography; and this consideration brings me to the point that has instigated these remarks—are *perfect* negatives requisite, or proofs from them more pleasing and saleable, than those from inferior *clichés?*

I am inclined to think they are not. That the most perfect negative as a negative will not produce an artistic picture more pleasing or more saleable than one of inferior quality, is a disappointing admission, but fully borne out by a visit to the shops where photographs are sold. So long as the composition and lighting is good the manipulative excellence is quite a secondary consideration. Artistic qualities are the *only* qualities appreciated by the public in their judgment of a photograph. It is remarkable how the most experienced photographers are influenced and biassed in favour of an artistic and pleasing subject; the beauty of the design really prevents a fair criticism of the quality of the photograph irrespective of it, and will pass off in the first ranks as second-rate manipulative work. In portraiture—to which these remarks principally apply—a clever composition of a pleasing subject, well lighted, will, providing the the flesh is retouched with ability, pass off a vilely-manipulated negative in the first class with others of undoubted excellence—at least in the estimation of the purchasing public. Photographers may, however, take heart, for a thoroughly good negative produces a richness and quality in the prints unattainable by any other method; and this richness and quality depends very much on its intensity, other things being as they ought.

That in the most perfect negatives the deepest shadows are represented by points of clear glass and the highest lights by points of absolute opacity is an axiom I cannot altogether agree with. It sounds theoretically correct, but in practice and on ordinary subjects is not right; for to obtain absolute opacity in any portion of a picture (I am alluding to portraiture) over-intensification will result, and to get clear glass in the shadows simultaneously under-exposure is necessary; either one or the other result is sure to take place. The best negatives by the best photographers I have ever seen have had not a vestige of *clear* glass about them; and, whether in portraiture or landscape work, clear glass should, it seems to me, be absent. If it be present it is a sign either of under-exposure or under-development unless in very exceptional cases. Perfect opacity means considerable intensification, and considerable intensification means harshness. This retouching attempts to remedy, and does so to some extent; but, as the retouching is mainly confined to the lighter portions of the pictures, the principal part is left cruder and harsher than it ought to be, and this effect passes under the name of "brilliancy"—another name for under-exposed photographic pictures of all sorts. Yes! brilliant at the sacrifice of many other good qualites.

By want of intensity we rush at once to the other extreme—too much half-tone or too little separation of delicate shades and gradations. The negative may look nice—in fact, a negative slightly deficient in this respect is the nicest looking of all negatives—but, in printing, to obtain a bright result several of these half-tones merge into one and result in flatness, and do not print nearly so well as expected. Another drawback to insufficiently-intensified negatives is the readiness with which all defects on the albumenised paper show up. Paper considered excellent by a printer of strong negatives would be quite unsatisfactory when printing thin ones. There is no pure white in pictures from such negatives unles sintroduced by retouching, and, generally speaking, the colour is not good.

The intensification of the other class of negatives alluded to is, of course, different, as different results are aimed at, and is carried on until the deposit is perfectly opaque. At the same time a negative through the dense parts of which the flame of a candle can be seen will print equally well, and sometimes even better, than one more intensified. In all cases I believe the less intensification the better, so long as sufficient is done to produce a bright result in the print.

In landscape work, in addition to composition and lighting, perfect manipulation is a *sine quâ non*. The retoucher can lend but partial aid. Shadows massed artistically *must* be full of detail. Lights without detail are designated "chalky;" and unless a landscape negative have all the good qualities a negative should possess it is at once condemned both by photographer and public as inferior work. Intensification, therefore—whether in portraiture, reproductions, or landscape work—plays a significant, if not the most important, part. Edward Dunmore.

NOTES ON PASSING EVENTS.

By a Peripatetic Photographer.

This being the tourist season, I have read with a more than usual degree of interest an editorial article in this Journal given under the heading *General Arrangements for Field Work*. Having in my capacity of a peripatetic photographer enacted the *rôle* of the nomad many a time, I have acquired so much experience as to know at least what are my own requirements when "out and about," camera in hand. The difficulty of providing mats to place between the faces of the plates, so as to keep them separate, is not so great as may be imagined. Each photographer may construct them for himself by procuring sheets of very thin cardboard the exact size of his plates, and then, by means of a straight-edge and a knife, cutting out the middle so as to leave a border of any desired width. I adopt a still simpler method than this. Having procured a number of slips of thin cardboard I fasten them together at the corners by means of glue. The most expeditious manner of doing this is to lay down upon a table a glass plate the correct size, then place upon it one of the slips of cardboard, making its outer edge correspond with that of the plate. This is retained *in situ* by means of a small pill-box full of shot, several of which should have been prepared, or provided, before commencing operations. A little glue having been dabbed upon the end, at the corner of the glass, a second slip is placed upon it, and, like the former, retained in its place by means of the shot-box. After becoming quite dry the corners are trimmed, if necessary, by a knife, the services of a file being had recourse to in order to smooth excrescences and thin the inner edge of the mat, which it is better to have bevelled a little to the inside. One dozen of these mats answer for two dozen plates, and no one who has used them once for packing plates would willingly employ any other means for effecting such end. *Apropos* of numbering the back of the plate so as to correspond with the entry in the note-book, without which no photographer must betake himself to the field: if the plate be backed it can be written on with a common blacklead pencil, but if there be no backing a small bit of very hard soap forms an excellent writing medium. Some years ago I made a special preparation with which to write upon the backs of plates. It consisted of a quantity of lampblack incorporated with soap by melting the latter. This answered admirably, but I found latterly that the colouring matter was not at all requisite. For this purpose the soap should be very old and hard.

I observe that in the various formulæ given for alkaline development bromide of *potassium* is usually recommended as the restraining agent. One day last month, when paying a visit to a clerical friend, I found him in quite a "state" on account of his having just made the discovery that his stock of bromide of potassium was exhausted; and how then was he to develope the plates, upon which exercise we had both set our minds as the preliminary to an evening's enjoyment of a different kind, in which the "feast of reason and the flow of soul" would be permitted full play without the presence of any restraining agent, however potent might be the developing agents that were to be employed in stimulating our social feelings? "But," I observed, glancing towards his shelves, "you have other bromides there; why not make use of those of ammonium or cadmium?" He appeared surprised at being informed that the base of the bromide was of little consequence when making use of it in alkaline development; and we obtained several fine negatives by the aid of bromide of cadmium. A white precipitate of carbonate or oxide of cadmium is formed according as the carbonate or liquor ammonia may be used, but it has no effect upon the resulting development. As there may be others among my readers who, like my genial clerical friend (at whose suggestion I write this note), pay a too close attention to the letter rather than to the spirit of a formula, I would have them to know that bromide of potassium is preferred to other bromides mainly on account of its cheapness. Other bromides will answer the purpose equally well.

There is an expression in a report of a recent meeting of the Edinburgh Photographic Society that is not quite clear to my apprehension. Enumerating a list of members that were "unanimously elected," I find among them "Mr. Peter Ferguson *by* Mr. Tod; Mr. James Abbot *by* Mr. Matheson; Mr. Ross *by* Mr. Young," and so on. Does this mean that the latter-named gentleman in the names thus coupled together is the sire of the newly-elected member, as when in race-horse phraseology we speak of Flying Charlie *by* Blue Peter, or *out of* Forest Nymph? or, to put it in a more national manner, is the "by" the synonym for Mac (son of) Donald or anybody else? If I am correct in this surmise, I may observe that although it may not appear to be of much interest to the present-day reader to know from whom a member of the Edinburgh Photographic Society is descended, yet in future times, when fame and honours sit worthily upon the brow of any such member, it will really prove interesting to know, from referring to the pages of THE BRITISH JOURNAL OF PHOTOGRAPHY, that such a member had a father who was not ashamed to own his offspring. The idea is an excellent one, and should be generally adopted. Seeing, however, that "he is a wise son who knows his own father," all existing doubt relative to this may be got rid of by giving the name of the *mater* for that of the sire. The statement that the members were *unanimously* elected precludes the idea that one gentlemen was *elected* "by" the other, and equally impossible is it to entertain the thought of one having been *proposed* by the other, as the act recorded refers to election. Anyhow, this Society must be in a very healthy condition, for not only can they afford to give a presentation print, which is more than the chief London society can do, but can also organise and enjoy a trip to the country, and, in addition, "bag" a large number of new members at their indoor meetings. Happy fellows!

(To be continued.)

A QUESTION OF TIME.

"LET well alone" is, no doubt, under certain circumstances, an admirable motto, but its application is sometimes overdone, especially when it is made to cover a disinclination to get out of the beaten path, and an apology for continuing in "the good old way" long after a shorter and better road has been opened up. An examination of the work of our best photographers during the last half-dozen years —and by "best photographers" I mean those who have by diligent study mastered the principles of art and attained something like perfection in the technicalities of manipulation—will show that, as far as finished results are concerned, there is little room left for improvement, and that little, we shall be told, is, first, a shortening of the time of exposure so as to enable them to catch a fleeting expression; and, secondly, a getting rid of the bath and all the vexatious troubles connected with it.

Shortly after the introducton of the emulsion process, now a good many years ago—or, rather, after its revival, as, like most other good things in photography, it lay dormant for a considerable time—the most advanced thinkers on photographic subjects predicted the speedy dissolution of the bath with all its attendant troubles. But, although vast improvements have been made in the process since then, including a rapidity greater than wet collodion had, with few exceptions, ever shown, and a certainty almost mathematical in its exactness, I doubt whether there are half-a-dozen true professional photographers who have availed themselves of its advantages, and I suppose there are hardly a dozen who have really given the process a thorough trial.

Professional photographers have, of course, some excuse for this unsatisfactory state of matters in the frequency with which their attention has been called (and in not a few cases their pockets lightened) to processes that have promised much but yielded little. Although, however, there has doubtless been much "blarney" written on emulsions, the reliable information contributed by thoroughly trustworthy writers ought to have been sufficient long ago to convince the greatest sceptic that in neglecting the process he was overlooking his own interests.

While urging this fact on the consideration of those with whom I frequently come in contact, I have occasionally been told that it really had been tried, but that from want of time or other cause the trials had been made with plates or emulsion supplied by the manufacturer, and that while some plates or one sample of emulsion worked satisfactorily, the next batch from the same source did not. There may be truth in this, but *was* the fault in the material or in the method of using it? There is no royal road to the emulsion more than any other process, and I hesitate not to say that, with all the available information on the subject, one-tenth of the study given to the management of emulsion that has been bestowed on the ordinary wet collodion method would banish all the doubts and difficulties that have hitherto prevented its general adoption.

Although I am aware that already much published formulæ, and many commercial preparations, by any of which the most rapid and highest class work may be done, are in existence, I fear that the subject will for some time require to be pressed on the attention of photographers before they will be induced to "take kindly" to it, and so think I may help on the good work by giving some details of what I have seen and done in the matter.

Foremost amongst those who have done much good, practical work in emulsions stands Mr. H. J. Newton, the President of the Photographic Section of the American Institute. Having recently had an opportunity of spending some time with that gentleman, this process was naturally the subject of conversation; and as he is an enthusiastic experimentalist, and ever ready to give his co-workers the benefit of his experience, I learned a good deal of what he is doing, and what he yet expects to accomplish.

In the first place, Mr. Newton directed my attention to a number of about 12 × 10 landscapes from his emulsion negatives; and, most certainly, no one who sees them, and compares them with even the best results from wet collodion, will ever again say that a dry plate cannot give a perfect negative. The prints were toned a rich, warm, purple brown, and, while perfect in breadth and fine contrast, were full of most charming detail; in fact, they were a set of the most perfectly beautiful photographs I have ever seen. In portraiture, also, he showed some hardly less fine specimens. Most of them had been taken in his own studio, which is lighted by a window in the roof of about four feet square, and with an exposure of only six seconds. Anxious to compare the emulsion with wet collodion as worked in an ordinary studio, it was tried by one of his friends, and the result is before me now in a portrait of himself, fully exposed and technically perfect, with an exposure of only two seconds—less than one-third of what would have been required to produce the same result on a wet collodion plate.

Mr. Newton's formula for emulsion has been repeatedly published, and differs little from that originally used in this country, the principal requirement being that of perfect neutrality, or with only the faintest trace of free bromide. Since then I have repeated the experiments, using an ordinary emulsion made, in the first instance, with six grains of cadmium bromide, three grains of ammonium bromide, and fifteen grains of silver nitrate. I ascertained at the end of six hours the exact quantity of ammonium bromide required to neutralise the excess of silver, adding just a trace more, and using it after standing forty-eight hours. I may add that I know by experience that this emulsion will keep in perfect working order for at least ten weeks, and probably for as many months.

The great sensitiveness and other good qualities of Mr. Newton's plates are due to a large extent, in his opinion, to the preservative he uses, which is as follows:—

Japan tea	¾ ounce.
Alcohol	6 ounces.

Boil for a short time.

The preservative is made by adding half-an-ounce of the alcoholic solution of tea to sixteen ounces of water, and used in the ordinary way after the plates have been well washed. I am not aware whether "Japan tea" is known in England; but as Mr. Newton assured me he had not succeeded so well with the product of either China or India, I got some in New York, which has been used in my experiments. Of course this is only to be used when the emulsion is to be worked dry; and, as Mr. Newton is evidently aware of the prejudice still felt by many against dry plates, he has energetically endeavoured to perfect a method of working the emulsion wet, and with such success that, without difficulty, practically instantaneous work may readily be done with it. In this case the plate is coated with emulsion and washed till greasiness disappears; then coated or flooded with an accelerator, and exposed while wet. In either case the development is carried on with soda carbonate instead of ammonia, as generally used in England; and Mr. Newton expressed surprise that any one who had tried both could ever give a preference to the volatile salt.

In reply to my statement that I had known several operators who had tried the soda formula as published by him, Mr. Newton said that he could quite understand that, as the developer must be modified to suit various conditions. He never meant the public to understand that as the formula he generally used, but merely intended it as an outline, to be varied as occasion required and experience dictated.

The accelerator referred to is made as follows:—

Water	12 ounces.
Carbonate of soda (washing soda)	180 grains.
Bromide of ammonium	2 ,,

This may be made in any quantity, and used in a dish or bath, as it will keep indefinitely, and may be used as long as it lasts.

Knowing what I do respecting emulsions, and after repeating over and over again Mr. Newton's experiments, I am more than ever convinced that already we have, both in gelatine and collodion emulsions, the power of making dry films as sensitive as, and far more certain than, wet collodion, and that they will be found better suited for studio work than it. It is, therefore, but "a question of time" when the bath shall for ever be laid aside; but till that time comes photographers will do well to turn their attention to working emulsions wet, and if they adopt Mr. Newton's plan they can hardly miss securing success. JOHN NICOL, Ph.D.

ON THE INTENSIFICATION OF NEGATIVES.

PHOTOGRAPHERS who only require to finish negatives for one purpose—as, for example, for silver printing—pay little attention to intensification. But it is quite different when the negative is also used for the purposes of enlarging and for carbon printing and lichtdruck, or for photolithography and photozincography. One soon comes to see that one negative cannot be used for all these purposes; that the requirements of a good negative for enlarging on the one hand, and for photolithography on the other, are quite opposed to each other. In the former case is required a fully-exposed, well-developed, and unintensified negative; while in the latter, on the contrary, a negative which has had but a short exposure and has then been intensified until the blacks are perfectly opaque is the most suitable. For lichtdruck and carbon printing those negatives are best suited which are almost too delicate and too slightly intensified for silver printing; but they must always be perfectly exposed and rich in half-tones.

Then, again, the age and composition of the various preparations—such as the iodo-collodion, the silver bath, and the developer—all play an important part in the attainment of the desired result; so that while a thin, delicate negative requires *freshly*-prepared chemicals and a *slightly*-acidulated developer, on the other hand negatives for photolithographic purposes require an old iodo-collodion, which has become red, and an acid developer, and, besides, it requires a special intensification after all. Indeed, as long as one keeps in view the fact that the lights of the negative should always remain clear, in this last and most extreme case it is scarcely possible to over-intensify.

Thus, when one has decided on this method of intensification, which is not merely a continuation of the development, no great stress is laid upon the composition of the original developer if only the lights of the negative remain perfectly clear under its influence. In such a case it is best to develope either with pyrogallic acid alone, leaving out the iron, or else to use only an old, already yellow, and strongly-acidified solution of the latter. On the other hand, again, if a negative pretty rich in half-tones be required to be either more or less thin and delicate, everything depends on the composition of the developer. If one require only a slight intensification, as if for silver printing, it must be done with great caution, and must partake more of the character of a continuation of the development.

According to Heighway this latter source of intensification is based upon alternate applications, *before* fixing, either of silver and iron solutions (after each of which the plate is well washed) or of pyrogallic acid and silver, the object being not to injure the details but rather to increase them; while true intensification of the already present blacks takes place *after* fixing, when, the iodide of silver being already removed, it cannot bring out any further details.

For very delicate negatives the following developer with formic acid is worthy of commendation:—

Sulphate of iron	12·5	grammes.
Distilled water	540	c.c.
Sulphuric acid	2	drops.
Formic acid	26	grammes.

Formic acid is best kept in narrow, graduated phials, and a sufficient quantity should be measured out and added to the iron solution very shortly before use. The development will proceed very rapidly.

In the case before us also the developer with succinic acid which I used at first is also very good:—

Concentrated iron solution	4 parts by bulk.
Concentrated solution of succinic acid	4 ,, ,,
Distilled water	16 ,, ,,
Alcohol	1 part ,,

When acetic acid, formic acid, or succinic acid in the iron solution is replaced by citric acid a far more powerful negative will be got. A solution of citrate of silver in as little as possible dilute nitric acid, afterwards diluted further by the addition of distilled water, is a very energetic intensifying medium. The above solution is poured upon the washed plate, and after it the ordinary iron developer.

The silver solution may be more easily prepared by dissolving—

Nitrate of silver	4 grammes.
Citric acid	6 ,,
In distilled water	100 c.c.

According to J. C. Browne, however, the plates intensified with citrate of silver possess the unpleasant property of always becoming darker, so that after having been kept for a few years they are useless to print from. When examined under the microscope the change that has taken place in the silver deposit is distinctly recognisable.

Though not distinctly coming under the head of negative intensification, a method of development may be mentioned here which has done me good service in cases where there is a question of taking small portraits rapidly—above all, those of children *carte* size. I used an iodo-collodion intended for direct positives upon glass (being that of Le Grice, namely, bromide of potassium, iodide of zinc, iodide of iron, and a trace of etherial oil), and after a very short exposure I developed by dipping into a concentrated solution of sulphate of iron *without either acetic acid or alcohol!* The image appears instantaneously, and is so powerful that no intensification is required. The dipping-in must be very dexterously done. The bath may be used repeatedly.

But to return to the proper theme of this article. I shall, in conclusion, describe the peculiar action of the several intensifiers.

Amongst these the compounds of mercury play an important part. The use of chloride of mercury itself has been almost wholly given up, because it is too unequal in its action. A not too concentrated solution, which is only poured on after the negative has been fixed and very carefully washed, acts slowly enough to allow of the intensification being watched. When the plates are large, however, there will almost always be some places that become white, especially when the coating with collodion succeeds and the picture film is therefore thinner. According to many formulæ the plate which has been treated in this way and has become almost white is well washed, and then coated with dilute (1:8) ammonia.

A solution of the red iodide of mercury in iodide of potassium is certainly better than the sublimate solution, as the former does not bleach the negative and acts much more equally. It is prepared very simply by dropping a sublimate solution into a strong solution of iodide of potassium, stirring all the while, until the red precipitate, which at first forms and then redissolves in the excess of iodide of potassium, no longer dissolves. One then dilutes with five or six parts of water and filters. The chloride of potassium which is thus formed as a by-product is not injurious. The supplementary treatment with ammonia is done away with.

As a general rule a negative intensified with a salt of mercury possesses the unpleasant property of darkening when repeatedly printed from. I have also frequently observed that the silvered albumenised paper printed upon becomes greenish in hue through contact with the mercuric film, and this is more particularly the case when the printing occupies a long time owing to the badness of the light. It is, therefore, advisable to confine the use of such mercuric salts to negatives which are only to be printed from once or twice, and even then only to be used with chromated paper, as for photolithography or zincography.

The old style of intensifying with sulphurous alkalies is not commendable, on account of the very unhealthy, and to photographic operators very injurious, development of sulphuretted hydrogen.

Eder and Tôth's lead intensifier—of which a great deal has been said in the photographic journals—requires, in order to be successful, the observance of many precautionary measures, and will on that account be less adopted in practice than it deserves, and than the intensification with iodine or one of the many other methods of intensifying. It is as follows :—The negative should only be developed with iron, fixed with soda, and very well washed, the last washing being with *distilled* water. The intensifying bath, in which the plates, while still wet, are laid for a few minutes, consists of—

Ferricyanide of potassium	6 grammes.
Plumbic nitrate	4 ,,
Distilled water	100 c.c.

When taken out the negative is washed thoroughly with distilled water until a drop of the washing water ceases to colour a solution of ferrous sulphate blue. We shall pass over the various precautions required by this method of intensification, as they have been so fully described in the *Photographisches Correspondenz.*

The very commendable intensifying process with iodine may be done in two ways, which should be chosen depending upon whether the negative is already varnished or not. In the first case one takes a solution of one part of iodine in 150 parts of alcohol of 90°, and removes the varnish by pouring hot alcohol of the same strength (without the addition of iodine) repeatedly over the negative before pouring on the iodised solution. This process may be repeated. The plate becomes very dark, therefore one should proceed with caution. When the alcoholic solution of iodine has been allowed to run off the negative is again varnished. According to the degree of intensification required a weaker or a stronger iodine solution may be used.

If the negative has not yet been varnished of course an alcoholic solution cannot be used; so six parts of iodide of potassium are first dissolved in one hundred parts of water, and then three parts of iodine are dissolved in that solution. An old solution works better than a new one. When the image has been sufficiently developed with the iron solution, and then with the iron solution to which a little silver solution is added, it should be *well* washed, fixed with a dilute solution of cyanide of potassium, and again washed *very carefully*. The plate is now coated with a sufficient quantity of the above solution of iodine in iodide of potassium, which is allowed to act until the negative has become yellow even when looked at from the glass side. The plate is then repeatedly washed, after which it is intensified, while daylight falls upon it, with the ordinary citric acid and pyrogallic acid solution to which a little silver is added. The plate is then well washed once more.

There are besides these still several very good ways of intensifying, as, for instance, that of Selle, by means of ferricyanide of potassium and nitrate of uranium ; and, further, those by means of the salts of the noble metals—gold, platinum, and palladium. We pass over these, however, as one can have too much even of a good thing, and with the methods already described the desired end can be attained.

—*Photographisches Wochenblatt.* JULIUS SCHNAUSS.

THE BIG SHOW.

SCENES AT CALAIS.—AT PARIS.—THE EXHIBITION.—THE ENGLISH PHOTOGRAPHS.

THE passage from Dover to Calais was short and anything but sweet, for the *swells* were abroad. The heaps on heaps of luggage piled up filled all the fore end of the vessel, whilst we, the poor passengers, hung like fringes round the edges of it. There did not seem to be many passengers for the quantity of boxes piled up on board, and the number of little "Noah's arks" that lay uneasily on the bevelled tops of each other looked mysterious in quantity and capacity. I got to speculating on the quantity of stuff they held, and what, in all the world, the possessors of them could be going to do with it; but making no headway in that speculation I gave it up.

During the two hours of "pitch and toss" we had to endure we did a little balancing performance when trying to walk from one end of the deck to the other. Not being constituted for "a life on the ocean wave," we endeavoured to keep clear, as much as possible, of those peculiar people who would have preferred to walk the journey if they had had the means of doing so. By those who, like us, have never travelled much, if possessed of the faculty of observing, it will be found that the kaleidoscopic changes of scene and form and character will produce an endless round of enjoyment. It is to be supposed that when travelling becomes familiar the novelty gets rubbed out of it, so that our feelings in this respect will have more interest for the untravelled, like ourselves, than for the traveller who looks upon such scenes and sights with a familiar eye, and consequently with a touch of contempt at this enjoyment of ours produced by inexperience.

We were greatly amused by one or two scenes that took place when landing on the shores of France. The gangway by which we left the boat was, to say the least of it, "a caution." It was of considerable length, and it stood as nearly as possible perpendicular from the side of the paddle-box to the quay. An old man in the midst of the crowd said—"It seems like a tempting of Providence to risk climbing up that thing ! It is as dangerous as walking the plank ; and if this is the way the French do things it really doesn't say much for them! I know a country where things are done better than that."

A little boy stood by the side of the ticket collector chattering away to him in his native tongue, when Jack turned to me with a smile on his good-natured face (and I can tell you it was something to get up a smile in that same crowd)—"Look there, Mark," he said, "at that child; do you not hear how he speaks French ! Man, it's wonderful !"

At the upper end of the gangway a man with book and pencil in hand stood and inquired the nationality of each passenger as he or she left the boat. In front of us a bold youth was passing from the gangway to the pier, when he was accosted by the book-holder with—"Wat contrie are you from, sare?"—"Glaiskey," the youth replied loudly, walking on evidently proud of the place of his birth, and doubtless thinking that "Glaskey" was just another name for Scotland.

We got into the train, and they took us up from the quay to the station, where ten minutes were allowed to get some refreshment. The time being short and the demand great, there was a considerable hurry-scurry, in the midst of which an old man lost his wife, which produced a little sympathy and considerable fun. The poor old fellow, when going from the refreshment-room to his carriage, saw with dismay his wife being whisked out of the station on her way to Cologne instead of Paris, having got into that train by mistake when waiting for her husband. The old man was a Scotchman, and the railway official did not seem to understand one single word that he addressed to him, so he stood in bewilderment and shrugged his shoulders, his eyes opening wider and wider as he perceived the canny Scot's increasing excitement. "They tell me she's awa' ta Cologne!" he exclaimed, pointing to the disappearing speck in the distance ; "and, man, she has baith our tickets for Paris, and I canna get on. I ha'e the purse, so she has'na a bawbee o' siller ! What am I tae dae? and what can she dae?" Though he yelled aloud the Frenchman did not understand a word, but a looker-on came forward and explained the old man's position, when he was conducted to the department where English business was transacted, and where he would likely have to wait the return of his "better half."

One thing that attracted our attention on the French railway was the women, with trumpets and flags and glazed hats, dotted all over the line and standing alongside of their sentry-boxes, their duty seeming to be to sound out that the line was clear. It looked very primitive.

We arrived in Paris all right, and first thing next morning we made it our business to visit the Exhibition. We drove to the Trocadero gate, and on entering and looking round our first sensation was that no definite idea could be conveyed of such a place. To stand and look in wonder and astonishment was our first action, feeling quite bewildered at the extent and magnificence of the place. It was like entering into a settlement composed of many nations who, having resolved long years before to build a city and live and intermingle with each other, had set about it then, and now sat enjoying themselves amidst the work accomplished ; for who would believe that so much could have been done in so short a time, if it were not standing there in very substance, produced as if by a wave of the magician's wand ?

Around us stand palaces and cottages, villas, shops, and tents, whilst away over the bridge stands the biggest show, the centre af a thousand other centres of attraction. On the ear sounds the tramp of many feet, the impression of whirl and movement is everywhere around, and the mingling sounds of the languages of many countries float on the air, as, spellbound in our excitement, we feel that surely this is the biggest show the world has ever seen.

After taking a look round we subdued our feelings and arranged our thoughts, naturally turning to our first love—photography. Purchasing a plan we started to study the same ; but even with a plan it seemed the most confusing place in the world to us. With some study and many inquiries we managed to find our way to the English department.

Having seen some of the best exhibitions of photography at home, I, at first sight, was rather inclined to be dissatisfied with the display from England. Even after careful examination the thought has not left me; for, although I believe we could not have shown better work in the various schools than is there exhibited, we certainly could have had many more exhibitors from amongst the first-class men of whom our country can boast. And although the work might be equal in excellence, the variety of styles itself lends a charm to such an exhibition, quite independently of its being an educator to the younger members of the profession.

Mr. Vernon Heath shows some fine pictures quite up to his usual standard, in saying which I can pay him no higher compliment, for they are choice in subject, artistic in feeling, and exquisite in detail.

Messrs. Elliott and Fry's portraits attract general attention, and justly so, for more artistically-finished pictures I did not see in the Exhibition. They are evidently worked up in chalk in the most delicate manner, and being well hung—which is an advantage even to the best work—the effect produced is simply charming.

Mr. Payne Jennings' display of landscapes is very fine. "Liquid pictures" I would call them, they are so clear and bright, and full of sparkle that you do not usually find on other photographs, except, it may be, when they are being washed, but which dies out as soon as they are dry.

Mr. A. L. Henderson's reputation amongst us for enamels is so well known that every visitor to the Exhibition, from a photographic point of view, will wish to see his *burnt-in* pictures. See them—they are beautiful.

Mr. Vanderweyde's pictures, taken by means of the electric light, are so good that you really would not know they were taken by artificial light—if he didn't advertise it.

Mr. D. Hedges' (Lytham) studies of dogs and cattle are fine productions, and of great value to artists as studies. Considerable skill and management are shown here with what we photographers find so difficult to manage—in fact, as difficult to manage as a baby is a dog or a cow; and its more to get a sharp picture than an artistic pose we aim at when we have such subjects to photograph. But Mr. Hedges has managed to make pictures as well as sharp photographs.

Mr. W. England's landscapes are so well known that I need make no comment on them here. But the same gentleman shows some photographs of statuary on glass, backed up with black, and having coloured drapery at the side, which are finely-finished pictures. It is a style of photograph that would make beautiful panel or window decorations.

The composition pictures by Mr. H. P. Robinson and Mr. R. Slingsby are always interesting, no matter how often they are seen; for they are works as artistic as if they had been produced by the brush and palette, and from the hands of a master, rather than by the lens and camera and such mechanical contrivances as printing-frames. MARK OUTE.

Meetings of Societies.

EDINBURGH PHOTOGRAPHIC SOCIETY.

AN outdoor meeting of this Society was held on Tuesday, the 18th ult., the excursion being to the Bridge of Earn, and included the beautiful Moncrieff grounds and the old-fashioned village of Forgandenny. A good deal of rain had fallen during the previous night, and it continued till within half-an-hour of the time of starting; but a number of the more enthusiastic workers had faith in the experience of the poet who wrote

> "I've seen a dark and cloudy morning
> Turn out a braw, sunshiny day,"

and appeared at the Waverley Station by 6.30. During the crossing of the Forth from Granton to Burntisland the sky looked threatening enough; but the party had their confidence considerably strengthened by the assurance of one of the members whom they met on board, and whose experience as a lieutenant in the navy has been considerable, that it would certainly be fine before they reached their destination—an opinion which, with the exception of about two hours, proved to be correct.

A two and a-half hours' journey before breakfast had sharpened the appetites of the party, and, therefore, on arriving at the Bridge of Earn about nine o'clock full justice was done to the substantial breakfast provided by the hostess of the Moncrieff Arms, after which the party put themselves under the direction of Mr. C. Sinclair, as the member best acquainted with the beauties of the locality.

The village itself possesses little interest from a photographic point of view, the only thing worth notice being the remains of an old bridge, at one time the only means of crossing the Earn on the high road from Perth to the south, but long since superseded by the fine modern structure from which we suppose the village takes its name. It is, however, very picturesque, and well worth more time than, according to previous arrangements, the members could devote to it. Originally consisting of five arches, and built much in the style of the fine old bridge at Stirling, only two now remain; but they are so broken up with massive ivy, and stand at a spot where the water is generally as smooth as a mirror, reflecting on its surface both the arches and the beautifully-variegated banks, that very many pictures sufficiently perfect in composition to please the most fastidious taste may be obtained. In fact, from the nature and position of the bridge, and especially in combination with the ruins of a cottage that had at one time guarded its northern approach, the ever-changing position of the sun "from early morn till dewy eve" would afford a succession of pictures well worth the attention of a Wilson or a Bedford.

Perhaps no body of men know better than the members who attend the outdoor meetings of the Edinburgh Photographic Society how absurd it is during such excursions to attempt to visit several places at considerable distances apart, and none have more frequently resolved to limit themselves to one good spot in the future; yet, nevertheless, there have been few such meetings at which much more was undertaken than could be conveniently accomplished. The excursion in question being no exception to the rule, there was only time for the exposure of a few plates on the quaint old bridge before the break was ready to convey the members to Forgandenny. This is an antiquated village composed of a number of thatched houses, each with a pretty and well-kept flower-border in front, which (with the exception of a school-house and perhaps two small dwelling-houses) have remained unaltered for about one hundred and thirty years. Here there is *matériel* for a number of good pictures, and in a short time all the cameras were at work; but by the time two plates had been exposed in each the clouds had gathered and rain was falling heavily, the members gladly taking shelter under trees and in the school-house, and by the time the weather had again cleared up the order to return had to be given.

After a hurried luncheon a visit was made to a lake on the Moncrieff estate, and although some of the party were somewhat reluctant to go, its extreme beauty and suitableness for camera work, as it burst upon their view, elicitated exclamations of surprise and pleasure from all present. It is nearly half-a-mile in length, tortuous and varying in breadth, and in many places completely covered with beautiful vegetation, in which lovely water-lilies abound. The banks are wooded, in most cases, to the edge of the water, and as the foliage is now at its best the effect is simply charming. It being at once agreed that the lake was well worth a whole day, and the resolution taken that one should be given to it at an early date, the party retraced their steps to the high road, where the break had been left, and drove up to Moncrieff house; but neither it nor the beautiful and admirably-kept grounds afford much scope for photography, and so only two plates were exposed, the rest of the members visiting, meanwhile, the fine garden and hot-houses.

From thence the party returned to the old bridge, where a number of plates were exposed from different directions to those selected at an earlier period of the day, and shortly after five o'clock the notice that dinner was ready put an end to further work. After dinner an ordinary meeting was constituted, and Messrs. A. L. Dowie and Alex. Lindsay were elected members.

The return journey commenced at 7 30, and Edinburgh was reached at 9 45, the excursion having, on the whole, been both successful and delightful, while (rather an unusual circumstance where beginners are present) all the plates exposed were fairly successful, and the majority developed into excellent negatives.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE usual meeting of this Association was held on Thursday evening, the 27th ult., at the Free Library, William Brown-street,—Mr. H. A. Wharmby, President, in the chair.

The minutes of the previous meeting were read and confirmed.

Some exceedingly beautiful negatives, taken by the gelatino-bromide process were shown by Mr. H. Houlgrave. These were all the more interesting as they comprised both views and portraits, with their respective prints, so that their printing qualities could be examined. Mr. Houlgrave also exhibited a developing dish with wooden sides and glass bottom. Mr. Houlgrave described his method of working, and said that he had no difficulty in developing up to the edges of his gelatine plates, as he moistened them first in a solution of one ounce of alcohol to ten ounces of water, using a little of the same solution in his developer.

Mr. Ellerbeck exhibited a number of views he had taken during a recent tour in Switzerland.

The presentation prints for the past year were distributed, the print being a fine 24 × 18 view of the *Arch of Constantine*, from a negative by Mr. O. R. Green, enlarged and printed in carbon by the Autotype Company.

The July meeting is intended to be an outdoor one, if arrangements can be made for a suitable locality.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

A MEETING of the above Society took place on the 3rd May,—Dr. Vogel presiding. Two new members having been admitted, Baron des Granges placed on the table a number of landscape photographs, which he presented to the Society. Amongst them were two large panoramic views of Sparta and Athens, and a number of scenes in the South Tyrol. He (Baron des Granges) also made a communication with respect to Durand's new quick printing sensitised paper. When in Italy he had heard of and procured some of the paper in question, and though already six weeks' old he saw a landscape with printed-in clouds fully printed before his eyes in five minutes. The paper would keep perfectly good for three months. He also spoke very favourably of the euryscope No. C, and of Ross's new symmetrical lens, &c.

The meeting requested the Chairman to obtain specimen lenses, and to try them and report.

The Chairman then read the reply of the Imperial Patent Office to a protest which had been lodged against a patent being granted for shutter arrangements for a lens, by which it was claimed that with a single lens *separate* pictures could be produced, which, when combined, would produce a stereoscopic effect. This was to be done by a shutter with two holes.

The Patent Office replied to the protest that if the demand for a patent was made in favour of anything new, the office had nothing whatever to do with its usefulness.

The Chairman remarked that, apart from the question of usefulness, the idea of a shutter having two openings was not even new, as some seven or eight years ago the question was put—"How can a stereoscopic picture be taken with a single lens without moving the camera or lens?" and the following answer was given in the *Mittheilungen:*—"Take a large seven or eight inch lens, and *place in it a slide having two openings.*" Later on the following directions were given:—"Cover three quarters of the left side of a four-inch lens and expose; then cover in the same way the right side, and expose again on a new plate. When combined these pictures will give an excellent stereoscopic effect." He (the Chairman) exhibited a lime light fed with common air heated instead of with oxygen. Similar blasts were constructed some time ago in England by Fletcher, but they had lately been so much improved by Dr. Müncke that platinum melts in the flame, as shown experimentally by the Chairman at the meeting. The lime becomes heated to a white heat; still the chemical effect of the light is so small that, after an exposure to it of twenty-two minutes, at a distance of seven inches, a Vogel's photometer remained unaffected. In England a similar lamp is used with effect in the sciopticon, and in Germany by Warmbrun and Quilitz, of Berlin.

A number of Japanese pictures sent by Dr. Weissenbach, of Nürnberg, were laid upon the table.

Herr Marowsky begged those members who had not yet sent their portraits for insertion in the Society's album to do so at once.

The meeting was immediately afterwards adjourned.

THE PHOTOGRAPHIC SECTION OF THE AMERICAN INSTITUTE.

At the April meeting of this Society the President, Mr. H. J. Newton, occupied the chair.

The President: I understand Mr. Price is writing, in the *Photographic Times*, a continuous article on the practical process of working emulsion, commencing with the first rudiments, so that any one who is not a photographer can learn to work it by this article. The article will be continued through several numbers, as I understand, giving all the *minutiæ* in the working of emulsion. One of the impediments in the way of working emulsion has been the difficulty in making uniform samples. Samples made today and others made tomorrow with the same chemicals and formula may not produce like results. Such variations in photographic processes are not, however, exclusively confined to emulsions. This objectionable feature has been overcome by the peculiar method now adopted in the manufacture of my emulsion. The question has been raised here, and generally assented to, that emulsion or bromide of silver plates are not as sensitive to weak light as bath plates. That is almost the universal experience. Dr. Vogel alluded to this fact in an article which he wrote a year ago, and published in one of the European journals. As I have stated before, in my experiments the bromide, in this respect, differs not a whit from iodide. The first collodions were made with iodide alone, and it was years after the introduction of bromide with the iodide in this country before it was adopted in England. I have experimented with those two salts and their compounds in every conceivable way. I find that bromide and iodide used separately are almost identical in sensitiveness to weak light. Iodide alone is not sensitive to the weaker lights. It works strong in the high lights, similar to bromide; but when a small portion of bromide is added to the iodide the action is entirely different from what it is with either one separately, and the maximum benefit does not depend upon the large quantity of bromide, but the reverse. If you mix them in equal parts you get no benefit from the bromide. With bromide emulsion the same fact is true in reference to the iodide in conjunction. That fact has, perhaps, been elucidated fully here by a committee of this Section, appointed three years ago last fall, to investigate a process brought to this country by a Mr. Hammenstede, who came here from Japan, and who made a bromo-iodide emulsion. The question of the union of these two constituents is not the only important thing for the best results; it is the *way* in which the emulsion containing them is compounded. I claim that my emulsion, as now being made, is as sensitive to weak light as any bath plate that can possibly be made. In making these copies (shown here), being negatives on 8 × 10 plates and prints from the same illustrative of this fact, I took three different kinds of engravings—one that was nearly black, another with very delicate contrasts, and still another with very strong contrasts—to show that emulsion properly compounded would work on all of them, and give all the detail in the shadows or dark places in the engraving that it was possible to get by any process. When it will do that it approaches perfection.

Mr. Chisholm: How does that emulsion seem to keep?

The President: It keeps indefinitely. I exhibit two portrait negatives, the time of exposure being eight seconds. One I arranged so as to have very deep shadows, in which you will find no lack of detail. These negatives are just as they were developed and fixed. With the bath plate I could not have made negatives showing the same exposure in less than twenty-five seconds. With this emulsion I will do anything you can do with the bath plate, and in one-third the time.

Mr. Bierstadt: I accept the challenge, though I have never seen the negatives and prints exhibited here by the President excelled by any photographic process, if equalled.

The Secretary: These pictures are very beautiful; the details in the shadows and high lights are as finely rendered as I ever saw them. I cannot suggest any improvement; they are perfect.

Mr. Chisholm: Are you able to combine the iodide well with this bromide emulsion?

The President: Yes; I have used bromide three parts, and iodide twelve parts, and all the way from that extreme up to the fraction of a grain of iodide to twelve of bromide in almost every conceivable proportion.

Mr. Chisholm: The iodide has a clearing property; it makes a negative very brilliant and clear, and it does not fog.

The Secretary read the following from Mr. Palmer's paper, published in our issue of March 13:—"An experience of several years of this process [the emulsion process] has convinced me [the writer] that the very rapid emulsions which are at present in vogue were steps in the wrong direction, as great rapidity and reliability do not go hand in hand."

The President: In the article which the Secretary has read we find the expression of an idea which has always prevailed among photographers, not only in reference to emulsion processes, but to all photographic processes, viz., as one approximates towards the maximum degree of sensitiveness just in that ratio he would depart from certainty. That idea is not only applicable to emulsion, whether of gelatine or collodion processes, but to all photographic processes.

The Secretary: Probably that idea has originated and been sustained with and by the fact that a departure from the proper time of exposure with a rapid working process, if it be very small, shows more than a very much greater departure would with a slow process. I see no chemical reason why a quick process should not work as certainly as a slow process, provided you can work proportionately close to the *proper* time.

The President: Here is an illustration, being a print from a negative exposed twelve seconds; it is an over-exposure. If I had been working a process which would have required at least twenty-five seconds' exposure, four seconds more or less would not have materially affected the results. Now, with a process in which only eight seconds is necessary, to give it twelve increases the time thirty-three and one-third per cent. That is just where the difficulty, in my estimation, lies in reference to the uncertainty with quick processes; you cannot have the latitude that you have with slow processes.

The Secretary: Our English brethren seem to have given considerable attention to gelatine emulsion. The pictures by the gelatine process—though I have not seen a very large number—have usually shown a grain on the print, as though it was in the negative film.

Mr. Bierstadt: I have seen the plates just as free from grain as I have ever seen with collodion. I have some of Kennett's gelatine pellicle that I think is just about as rapid as Newton's emulsion.

The meeting was then adjourned.

Correspondence.

THE ALUM DEVELOPER.

To the Editors.

Gentlemen,—In your next issue kindly extricate me out of a difficulty which I at present experience with Henderson's new developer. The quantities are carefully measured, but on no account can I pour the developer over the plate without a flocculent precipitate settling all over the film and producing stains; without the alum there is no precipitate. I have tried two different baths. I think there must be two kinds of alum (independent of chrome alum), because I was successful with the developer when Mr. Henderson first published it, using a different sample of common alum; at that time I found it the best developer I had ever tried.—I am, yours, &c., R. D. P.

Edinburgh, June 26, 1878.

[We have never experienced the difficulty described. Perhaps Mr. Henderson can throw some light upon the cause. Our correspondent is correct in surmising that there are different sorts of alum; but we do not think it probable that this is the source of his trouble. Common alum, or potash alum, is a combination of sulphate of alumina with sulphate of potash. Ammonia alum, in which the potash is replaced by ammonia, is sometimes found in commerce; but, even supposing that to have been used, it is so similar in character and general behaviour to potash alum that it is little likely to act in the manner spoken of above.—Eds.]

FILTERING SILVER SOLUTIONS.

To the Editors.

Gentlemen,—Seeing that the subject of filtering silver solutions is on the *tapis*, I crave permission to describe one that I constructed two years ago, which is in use still, and promises to remain good for two more years.

Having obtained an ebonite funnel with a smooth inside, I procured a strip of steel about a sixteenth of an inch in thickness, and fixed it in a handle. Having rounded one edge I toothed it like a saw, and with this I cut a number of small grooves inside the mouth of the funnel from top to bottom, taking care not to cut through the ebonite. I next procured a piece of fine felt from the Wandle Felt Company in Endell-street, and having shaped it properly, I had the two sides sewed together, so as to fit the interior of the funnel, one edge slightly overlapping the other. This is the whole.

The felt allows the liquid to pass rapidly through, and the little channels or grooves which I cut with the saw in the funnel, act as so many gutters to convey the liquid to the nozzle, to which it passes with great freedom.

In connection with this filter I reiterate what "Ajax" in last week's number says of his, namely, "I like it very much, and should be sorry to be deprived of it."—I am, yours, &c., An Old Photo.

July 1, 1878.

Miscellanea.

Whitening Positives.—Bichloride of mercury and other things have been suggested and tried in the process of whitening a dark positive picture, but with no good and satisfactory result. We have found a very simple and pure method by which an ambrotype or ferrotype may be whitened in the shortest time and give excellent results. The first trial was with a much under-exposed picture, which was entirely too dark. After it had been fixed and dried we ran a stream of water over it again, in order to soften the film; we next prepared a mixture from one part of the usual developer (consisting of protosulphate of iron and acetic acid) with half a part of the silver bath, which was entirely neutral. This mixture we flowed over the picture, and after the lapse of four seconds the picture became nicely white; the half-tones appeared white, while the blacks of the darkest shades remained perfectly uninjured. The solution was now thrown off, and as a number of grey, dirty-looking specks appeared on the picture, the usual fixed solution was applied to it again, by which means the picture appeared faultless, the whites being intense and of a brilliant white. Since that time we have made the same trials with a different developer and an acid silver solution, and obtained the same excellent results. We have carried this redeveloping process farther, and in the course of one minute changed a good positive into an excellent negative, which printed very good. We have tried this method with pictures which were more than half under-exposed in the camera, and did not fail in a single instance.—*Practical Photographer.*

Increasing the Sensitiveness of Silvered Paper.—Mr. A. M. De Silva, in *Anthony's Photographic Bulletin*, says:—Some time ago, while making prints from a negative of a most difficult subject, in which from the excessive contrast of light and shade the lights had become too dense to my liking under development, I tinted the paper in the sun previous to printing the picture—a not uncommon practice in the case of "hard" negatives. After the prints were mounted I noticed that those made on the "dashed" paper *had more detail in the lights*—a distinctly different appearance to the toned-down flatness of prints receiving an after-exposure to the light; for, while they were mellow, they were by no means flat. Like very many valuable things, from want of application or want of time to study it was shelved until very recently, when I had occasion to resort to the same method. The grinding of the varnish of a portrait (a most abominable practice, for it takes the juiciness and texture out of the picture) had "hardened up" part of the face. I again "dashed" the paper *previous* to printing. This time, not only had I more detail in the high lights, but an impression printed *through* the yellow oval mask placed on the negative. I again tinted one-half the paper, and again the same result on the side tinted, while the other unexposed part did not print through the mask at all. Using the same mask I printed the portrait in the sun on ordinary paper until it was completely bronzed up without a particle of tint showing under the portions covered by the cut-out, thus conclusively proving that silvered paper which has received a preliminary exposure to the light is *very much more sensitive to a much smaller quantity of actinic rays.*

Hints in Printing.—Messrs. E. and H. T. Anthony and Co., in *Anthony's Photographic Bulletin*, say:—"Invariably with the occurrence of very cold weather commence complaints about the working of albumen paper. Printers, from one year to another, seem to forget all the advice they have received, and take no precautions against the evils they annually have to encounter. The present season has been no exception, and the complaints we have heard remind us that the oft-repeated injunctions must be uttered again. The whole trouble turns upon the point of temperature. To avoid, then, all the varied unsatisfactory results:—1. Use a warm silver solution for your paper—not under 70°. 2. As nitrate of silver does not dissolve as freely in very cold water as it does in tepid, and as it is generally difficult to warm all the washing water, use the acetic acid washing bath; this will convert the free nitrate of silver into an acetate or sub-acetate, and thus get rid of the excess of nitrate of silver, which is so detrimental to toning. 3. Warm your fuming box thoroughly. 4. Make your fixing bath with tepid water. The object of this is to avoid a trouble the cause of which few persons suspect. It is quite common to hear persons complain that the albumen becomes soft and disintegrated and leaves the paper without any gloss. The reason why such occurs is this:—In very cold weather, when the water directly from the pipe is used, the act of the solution of the hypo. frequently reduces the temperature below the freezing point. When the prints are immersed in this extremely cold menstruum the structure of the albumen is completely destroyed; its coagulation by the action of the silver bath completely neutralised, and it becomes like so much mush and is easily detached from the paper. Another effect of a very cold fixing bath is to cause the fine cracks which so frequently occur in prints otherwise unexceptionable. 5. Defective prints are also caused by exposure of the paper, while printing, to a very low temperature. This is indicated by the appearance of the prints. No length of exposure will give depth to the shades, and the prints when put into the toning bath become a sickly, pale red and refuse to tone. We trust that all our readers interested in the use of albumen paper will give proper heed to the above facts, and govern their printing accordingly."

EXCHANGE COLUMN.

No charge is made for inserting these announcements; but in no case do we insert any article merely *offered for sale*, that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a *nom de plume* be thought desirable), otherwise the notice will not appear.

I will exchange anything enumerated in advertisement for a good half-plate camera to take two *carte-de-visites* on a plate. See advertisement.—Address, A. Gosney, Sherburne.

Whole-plate mahogany portable camera, brass bound, screw focussing, central partition for stereos, equal to new; half-plate studio camera, swing back, bellows, and screw focussing; and a first-class double geared cabinet rolling press, steel plate, polished, and iron bed. Any of above will be exchanged for a No. 6 Ross' symmetrical, or a first-class tent for plates 12 × 10.—Address, W. Dakin, Holly Bank, Nether Edge, Sheffield.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

Ch. Audra (Paris).—Your letter received. We are pleased that you appreciate our efforts, and shall reply more fully in a private communication.

Developer.—Are you employing a new sample of any of the ingredients? There appears to us no other solution of the difficulty from the data given. If using fresh ingredients test them individually.

Cymro.—Yes, let it be done inside by all means. This may be effected by erecting outside the window, and on a level with the window-sill, a small platform two and a-half feet wide by six feet in length.

Saml. Bamforth.—We have seen advertised a cheap press suitable for both purpose you mention, but do not remember just now the maker's name. We are not acquainted with any work specially devoted to the subject.

Erratum.—In Mr. T. Sebastian Davis's article, *A Wet-Plate Developer*, in our last number, page 303, first column, formula A, tenth line from foot, for "acetic acid, 15 minims," *read* "acetic acid (glacial), 1½ fluid drachms."

W. S. May.—If you are desirous of producing the large opalotype under conditions which do not admit of the possibility of fading, and are unable to do so by means of the carbon process, it only remains for you to have recourse to the "dusting-on" method, the powder to be employed being lampblack or vegetable black. Fading will not then take place.

Nemo.—Having subjected the figures provided by you to analysis we are enabled to say that the larger object glass will admit two and one-third times more light than the other.

E. O. P.—The failure arises from the use of a developer quite unsuited for the purpose intended. As we know that the maker in question accompanies each packet of plates with printed instructions respecting their development, we have only to refer you to such directions.

W.—The method you propose will answer well if applied in the form of black varnish as used for backing glass positives. Let three or four coats be applied, each being allowed to harden thoroughly for several hours *exposed to daylight*. A better plan would be to coat the bath with melted paraffine wax.

J. P., Jun.—The last traces of nitrate of silver in the film may be got rid of by placing the plate in a weak solution of chloride of sodium after it has been well washed with plain water. Upon removing it from the chloride solution wash first with plain water, and then give it a final rinsing with distilled water.

Auld Reekie.—We are quite familiar with both processes of photolithography named; and, while we admit that Professor Husnik's produces most successful results, we do not think that such results are in any degree superior to those obtained by the older process, while the latter is much the more simple of the two.

W. Washam.—It is just possible the cause may be *over-exposure*. These very rapid plates have a sad habit of losing the distant or well-lighted portions of the picture if the exposure be a little too long, though the foreground and shadows may appear underdone. A shorter exposure would permit the shadows to be pushed a little without endangering the lights.

Chas. B. Bradshaw.—The method of drying a gelatino-bromide negative suggested by Mr. Dudley Radcliffe will prove by far the most expeditious of any. It consists in washing the film thoroughly, allowing it to drain, and then immersing it in methylated alcohol, by which the water in the pores of the film becomes displaced. It will then dry in a few minutes.

Carboniensis.—Cut up a portion of the band of carbon tissue into small pieces, and sensitise each of them in a bichromate solution of different strength, the first being treated with a saturated solution, the next in a similar solution diluted with so many parts of water, and so on, reducing the strength more and more. By this tentative process you will ascertain the strength of bath that is best adapted for sensitising that particular band of tissue.

E. M. B. S.—Certainly the ferrous oxalate developer answers as well with gelatine as with collodion plates, as you would have seen had you paid attention to what has been recently written on the subject. There need be no variation from the formula given; experience alone will tell you what strength answers best. Commence with a saturated solution of ferrous in potassic oxalate, and dilute it gradually till you reach the desired point. See remarks in our last number.

H. H. F.—It is very unwise, unphilosophical, and irreligious for a master to swear at an apprentice; but, while this is the case, it will scarcely be held as warranting you in leaving your duties and running away. Our advice to you is to return voluntarily to work, and tell your master frankly that you are sorry for having so acted. The "accident," as you designate it, which elicited the outburst of temper alluded to may, probably, have been construed by him into an act of carelessness.

One in Doubt.—Try the following:—After sensitising the paper transfer it to a flat vessel containing distilled water, upon which allow it to float for a brief period—say for a quarter of a minute—after which allow the excess of the liquid to drip away and the paper to become dry. In this state the sheets thus prepared will retain their whiteness and purity for a long time. Previous to printing let the pads of the printing-frame be *slightly* sprinkled with ammonia. This paper not only keeps well, but yields vigorous prints.

An Inexperienced Photographer.—In our Almanac for the present year Mr. A. L. Henderson gives the formula of his developer, which we think it will answer your purpose to adopt as well as it has done that of Mr. Henderson and several others who have profited by his experience. In this developer there is present twice as much common alum as there is protosulphate of iron. For the details we refer you to the formula itself, which we need not here reproduce, as we presume you have the Almanac at hand to which to refer.

W. L. R.—1. On no account should paper be used, as in addition to rendering the operation a very protracted one it would deprive the emulsion of the whole of its bromide of silver. The best material is cotton wool or sponge well washed and freed from sand. Moisten with ether before pouring on the emulsion. To prevent evaporation lay a piece of clean paper, and over that a sheet of glass on the top of the funnel; sufficient air will find its way in to permit the operation to proceed.—2. There is no necessity to add fresh acid; the albumen becomes naturally more limpid with age. We prefer ammonia to the acid.—3. Ordinary *methylated spirit* is intended, but be careful you do not obtain "finish," which contains a certain quantity of gum.

Medicus.—The smallest and most portable of all photographic tents is the "Howard tent." It may easily be carried in a capacious pocket in one's coat. It is of a triangular form. In the course of a recent conversation with Mr. Howard he described in what manner he had been able to obtain a greatly-increased area inside without a corresponding increase in the external dimensions. Retaining the principle of making the tripod form the supporting frame-work of the tent, he has adopted a quadrangular form for the cover, by which he is enabled to manipulate plates of larger dimensions than before. Writing this "answer" at a great distance from home we are unable to give more definite particulars at present, or to refer to a drawing made by Mr. Howard when explaining to us the nature of the alterations he has found it expedient to make. On our return we shall probably revert to the subject and furnish details respecting this tent as it *now* exists in the possession of the inventor.

G. P. O.—The photograph of the cathedral is quite accurate so far as we can judge, but the perspective is so exceedingly harsh or violent as to cause an erroneous impression to be conveyed. The only way by which this can be rectified is to select a point of view at a much greater distance from the structure. It is quite a mistake to imagine, as many do, that the use of a lens having too short a focus possesses any influence upon the perspective of an architectural photograph; for no matter what kind of lens be employed, or whether its focus be long or short, so long as the point of sight, or that where the camera is placed, be near to the building the perspective will, of necessity, be violent and unpleasant. It is just the same as if you were taking a portrait of a *sitting* man with a camera placed about four or five feet from his projecting knees; his limbs would appear exceedingly stout in proportion to his body.

G. E. (Rochester, N. Y.)—1. Have you tried the plan, recommended a short time back, of coating the glass with a very porous collodion previous to the application of the gelatine? Apply the collodion and rinse in hot water to remove the ether and alcohol, and then coat with gelatine in the ordinary manner and allow the latter to soak into the collodion film, when the plate may be drained closely and *reared* up to dry. Such, at least, is the advantage claimed for this mode of procedure.—2. How did you treat the emulsion after precipitation? It would almost appear as if you had lost some part of the sensitive gelatine during the operation. The precipitated gelatino-bromide, after precipitation, should be soaked for a short time in water in order to remove a portion of the alcohol, which would otherwise prevent its complete solution.—3. We cannot speak as to the action of chrome alum upon the sensitiveness of the emulsion you name, but for plates of ordinary rapidity it does not appear to exercise any deleterious action when present in small quantity.—4. The question is difficult to answer in the way you put it. The plates are perfectly adapted to studio work and to the production of pictures of the highest class; but the question as to whether they will supersede the wet process is another thing altogether. We have heard them spoken of as "*too rapid* for landscape work," by which, we suppose, is meant *general* landscape work.

Colonel Davey asks us to inform him where he can obtain lenses constructed of glasses of different colours so as to enable him to conduct certain experiments. It would appear that he has become imbued with the idea that a blue glass lens will act more quickly than one formed of glass free from all colour, and also entertains other notions concerning properties believed to be peculiar to yellow and red glass. We beg to inform Colonel Davey, in the frankest possible manner, that he is altogether mistaken both with respect to the superior powers of transmitting actinic light possessed by a blue lens compared with a white one, and also as regards certain properties he imagines to be peculiar to orange glass. However, if he determine still to try the experiments hinted at, we advise him not to incur the needless expense of having lenses ground of coloured glass, but to have several pieces of plain glass, of various colours, fitted into a circular framework in such a manner as to permit of the insertion of one of them in front of the anterior lens of the portrait combination. In this way no light will be admitted through the lens except that which has had its properties altered by the transmission through the coloured glass placed in front. This will answer his purpose quite as well as if a series of lenses of coloured glass were provided, while it will save much trouble and no little expenditure of money. We have also to add that the experiments suggested by Colonel Davey were tried many years ago, and were attended with total failure. "A part is *not* greater than the whole." Let this axiom be thought of in connection with the imagined rapidity of blue glass lenses.

Manchester Photographic Society.—It had been proposed to hold an exhibition in connection with this Society, in Peel Park, next month. We are authorised, however, to state that the idea has been abandoned for the present.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician.

For the Weeks ending July 3, 1878.

These Observations are Taken at 8.30 a.m.

CONTENTS.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 949. Vol. XXV.—JULY 12, 1878.

IS EXTREME RAPIDITY DESIRABLE IN DRY PLATES?

In asking the above question we do not wish our readers to suppose that we intend to advocate a retrograde step in the practice of dry-plate photography. Such a course is far from our thoughts; but, as will be gathered from the succeeding remarks, our aim is rather to draw attention to a growing tendency which promises ere long to bring that branch of the art into disrepute—at least in the minds of a large proportion of the unthinking of its followers. The tendency to which we allude has been aptly termed, by Professor Piazzi Smyth, "rapido-mania," and a more suitable name could scarcely be found for the inconsiderate attempts which are made to promote extreme rapidity at the expense of other and equally valuable properties.

This is undoubtedly strong language, but in using it we speak advisedly, and, moreover, with a full appreciation of the advantages derivable from the quality in question for special purposes. Our object, however, is to raise a note of warning against the too eager pursuit of what may under certain circumstances prove to be a phantom. As we have said, we appreciate to the fullest extent the advantages—nay, the absolute necessity—of rapidity for such purposes as portraiture and for the proper rendering of the class of subjects which come under the heading of "instantaneous;" at the same time we fail to see the necessity, and question the desirability, of the same exalted degree of sensitiveness for the purposes of ordinary landscape work.

It may, and no doubt will, be urged against us that sensitiveness cannot possibly be a detrimental quality; that a plate sufficiently sensitive to enable us to secure objects in motion is equally adapted to the rendering of subjects of any other class. The wet process, which until recently has been the representative of extreme rapidity, will be cited as an instance in which we have, combined with the most exalted sensitiveness, the capability of rendering any and every class of subject it is possible to conceive. We are quite prepared to agree that sensitiveness is not and cannot be in itself an objectionable feature in any process, but circumstances may combine to render it so. Let anyone who doubts this explain the reason why wet-plate work as a rule is superior to dry. It is impossible to claim at the present day that a wet plate is capable of producing a better result than a dry plate under the most favourable conditions. The dry-plate work of some of our best men sufficiently proves that there is no inferiority in the process itself; hence we must look further for an explanation of the difference in the general quality of the two classes of work. There is little difficulty in tracing it to the varied conditions which attend the practice of the rival methods, and we shall endeavour to show that the element of sensitiveness plays a by no means unimportant part in the calculation.

It is usual to speak of the "latitude of exposure" permissible with dry plates as one of the strong points in their favour, removing, as it does, the necessity of judging to an extreme nicety the time of exposure. Certainly, if this latitude did not exist the practice of dry-plate photography would cease to be possible under ordinary conditions, and a reliable means of estimating not only the power of the light but also the actinic value of the subject would become a *sine quâ non*. In what does this latitude consist? And, further, we may ask—Is it peculiar to dry plates? To the latter query we reply distinctly, "No." No matter what the process may be there exist certain limits between which it is possible to curtail or prolong the exposure and still obtain a good but not a *perfect* result. The interval between those limits bears a direct proportion to the sensitiveness, and may amount to minutes with a slow plate while it is reckoned in seconds with a rapid one.

In this matter we agree with the writer who some years ago expressed the opinion that with a given light and subject a certain exposure is necessary to produce a perfect picture, and that any variation from that time, though it may produce a *good* result, does not attain perfection. Most dry-plate workers will have noticed at some time or other that in developing a number of plates one has, perhaps, singled itself out from the rest as being in some indescribable way superior. It is not, perhaps, easy to say in what its superiority consists, but it carries with it a certain "tone" (to quote the writer alluded to) which distinguishes it from its fellows. We should point to such a picture and say—"Here is the result of correct exposure."

At a recent meeting of the Photographic Section of the American Institute the Secretary exactly conveys our own impression when he says, as reported at page 320:—"I see no chemical reason why a quick process should not work as certainly as a slow process, provided you can work proportionately close to the *proper* time." This contains the whole gist of the matter in a nutshell. The remark was made with more special reference to the alleged want of reliability of the more rapid dry plates; but it bears equally, we may say more strongly, upon the quality of the result. It means simply this—that in working a process which necessitates exposures reckoned by minutes a departure of a minute or two more or less from the correct time may possibly not greatly influence the result; whereas, when the exposure is counted by seconds it is necessary to so nicely judge the timing as to be within the limit of a very few seconds.

This, with the wet process, is comparatively easy, as the first plate exposed enables the operator to form a tolerably accurate judgment as to whether the time is correct or not, and hence it is possible, either in the studio or in the field, to expose plate after plate with very little departure from the "proper" exposure. Not so, however, with rapid dry plates. Here everything depends upon judgment; and clever indeed must he be who, even with the aid of an actinometer, succeeds in timing to a second or two the whole of the plates constituting his day's work. With plates of a lower degree of sensitiveness no such necessity for this extreme exactitude exists, and the risk of failure is therefore considerably lessened. The fault, if any, is one of circumstances, and cannot be fairly laid to the account of the plates themselves; but, until some important improvement shall be made in the form and capabilities of our field actinometers, a moderately-rapid plate will continue, we think, to possess an advantage over those of the highest sensitiveness for general out-door work.

That the difficulties attending the working of very rapid plates is not merely imaginary we have had forcibly brought home to us recently. We had been for some time using experimentally two distinct classes of plates, and numerous comparative trials had proved that upon a well- or evenly-lighted open view the relative exposures necessary stood in the proportion of one to five. So long as we adhered to subjects in which no violent contrasts were presented these proportions remained good; and even if the exposure had been a little more or less than it should have been, careful development enabled us to produce at least a passable result. But the weak point of the rapid plates showed itself painfully in subjects comprising widely-different gradations of lighting, as a shaded foreground, with well-lighted distance, and under such circumstances, even with the most accurately-timed exposure, the greatest possible care was necessary in development to avoid spoiling the harmony of the picture. With such a subject as we have instanced it is obviously impossible, without the aid of some special contrivance, such as a sky shutter, to time each portion of the plate correctly; and all we can do is to make a sort of compromise between the two extremes. Plainly, if the foreground necessitate an exposure three or four times as long as that required by the distance the capabilities of any plate will be tried to their utmost, and the difficulty is increased in proportion to the normal sensitiveness of the film.

We have said nothing as to the comparative reliability of quick and slow plates from a purely chemical point of view; but in the main we agree with the opinion expressed by the Secretary of the Society to the report of whose meeting we have already alluded. It is, of course, an undoubted fact that the more sensitive we make our preparations the more delicate become the operations involved—not only in the preparation, but also in the development, of the plates; and that a trivial want of care, which may not affect a slow plate, will be sufficient to entirely ruin one of the ultra-rapid class. We have little doubt that much of the character of unreliability which rapid plates have acquired is to be traced to carelessness, and we therefore refrain from urging this as a further objection against their use.

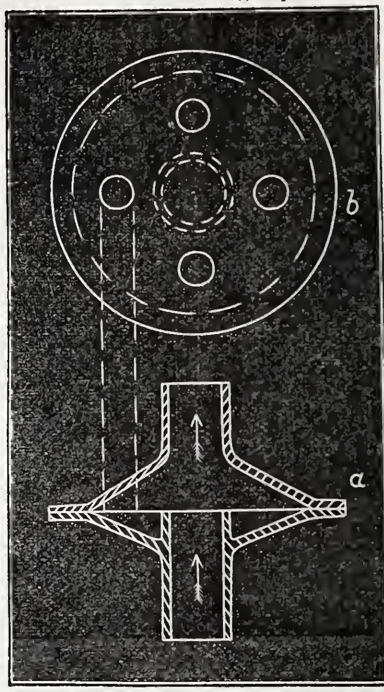
We conclude by repeating that we fully recognise the advantage which extreme rapidity gives for special purposes and under suitable conditions; but in the ordinary practice of out-door photography the conditions are not such as conduce to the production of the best results, either as regards quality or reliability, when very rapid plates are employed. In saying this we do not advocate a return to exposures such as prevailed ten years ago, when plates were in vogue which might receive five minutes or half-an-hour, as might suit the convenience or judgment of the operator. An exposure of from thirty to forty seconds is not an outrageously long one, and plates of that degree of sensitiveness may be easily prepared possessing sufficient "latitude" to remove all difficulties. When, however, the time is reduced to six or seven seconds it becomes "kittle wark."

OXYHYDROGEN EXPLOSIONS.

Several years ago our attention was specially directed to the subject of explosions arising from the intentional or accidental admixture of oxygen and hydrogen gases. One evening, about sixteen years ago, a life very precious to the world of science was nearly sacrificed to such an explosion; and, in consequence, we were requested to devise such means as would effectually prevent the recurrence of an oxyhydrogen explosion, no matter whether originated by accident, carelessness, or design.

This resulted in numerous experiments, the outcome of which was a valve by which safety was ensured to such an extent that the utmost ingenuity of ourselves and friends quite failed in the bringing about of conditions under which an explosion was possible. Among the conditions adopted was one which must be considered as affording a crucial test. It consisted in making use of a small, wedge-shaped gas bag, the top and bottom of which were made of wood, and kept apart by a strong spring, the force of which was entirely overcome by the contrary action of a spring still stronger. This bag, or reservoir, was charged with a mixture of oxygen and hydrogen, the proportions being those which theory and practice had decided would cause, when inflamed, the most violent explosion. One of the safety-valves having been interposed between the bag and the lantern burner, the latter was lighted, and when burning at its best the pressure upon the bag was suddenly removed by the pulling of a string, which also immediately brought into full action the spring inside, causing the flame to be sucked back into the bag, which, owing to the automatic action of the valve, it never reached. As full particulars, with several diagrams of the various forms of valves we adopted, were published a few years ago in one of our Almanacs we shall not here enter into further details in connection with these safeguards.

This subject is revived owing to our having received from Mr. W. J. Chadwick, of Manchester, a "back-pressure valve" he has devised and which he has rightly conceived would interest us. It consists of two obtuse conical discs firmly screwed together, between them being fixed, by the margin, a disc of oiled silk that presses very slightly against the end of the pipe through which the gas is admitted, the pressure of the gas, however, being sufficient to force the silk away from the end of the tube, thus allowing the gas itself to pass onward through several apertures cut between the centre and the margin of the pliable disc. The valve is shown in section at *a*, *b* showing the oiled disc.



Singularly enough an oiled-silk valve was one of the first kind we adopted in the experiments of sixteen years ago; but after a brief trial we abandoned it in favour of those constructed entirely of metal. It is, however, only just to Mr. Chadwick that we should state that his method of utilising the silk is quite different from and, we may add, superior to that which we adopted. We believe it to be a valve that will work with certainty; and we recognise in it an additional aid to those appliances by which an explosion in connection with the exhibition of the lime light will soon become a thing of the past. Even now it is very rarely we hear of such a casualty; with ordinary care, coupled with the use of a safety valve such as that now or formerly described, such explosions will be rendered quite impossible.

ART EDUCATION FOR PHOTOGRAPHERS.

The profession of photography is increasing in importance daily in the estimation of the public, and its ramifications are extending so far beyond what its sanguine professors could have anticipated twenty years ago that it behoves all who practice it to endeavour to preserve and increase the hold it has universally obtained. To attain this object nothing can be more desirable than the sedulous cultivation, in every direction, of the artistic perceptions of all connected with the art, and, above all, to train the mind and, if possible, the hands of those members who may now be said to be graduating—the apprentices and all those younger students of what is already an important profession—who are not too old to take up a systematic course of art training. We would earnestly urge upon every such student the great advantage to him of a few years' attendance at one of the many art schools which, in connection with the South Kensington Museum, are to be found in every town in the kingdom.

The advantages of an early training in drawing, with its natural sequence of advanced study in painting, &c., are conspicuous, and scarcely need to be here enumerated; and there is little doubt—to look upon the question for a moment in a sense outside our present scope—that an assistant so trained would command a far higher salary than one whose abilities had been less cultivated. We suppose we may take it for granted that the bulk of those who take up photography as a means of livelihood have some fondness for art, and nothing is more likely to increase their aptitude for it than the careful training afforded by those "schools of art." Long as they have been established we have had means of observing that they are not, by any means, universally understood nor their advantages known, and we have taken the present opportunity of bringing the great advantages they offer under the more immediate attention of the whole body of photographers. We sincerely and earnestly hope that all employers may point out to the younger members of their staff the efficient and cheap means of education existing close at hand.

These schools, as we have said, are to be found in almost every town of importance in the kingdom. The fees are always very low, something like sixpence a week being a fair average for the public classes, with the advantages of the supervision of a properly-trained and qualified master, the surroundings of artistic accessories, and being in many cases in connection with collections of examples of the highest class of art in painting and sculpture. Not only are the fees low, but there are annual examinations in which all pupils who have passed a certain stage of proficiency, irrespective of there being others still more skilful, obtain prizes of real value.

There are, also, for pupils who have shown application, and who possess sufficient merit, "prize studentships," the holders of which receive tuition for a certain period without payment of any fees. For more advanced students there are in the annual exhibition of their works bronze medals given, obtainable even for work so simple as outline drawing or simple examples of black and white chalk, if of sufficient merit. The recipients of these bronze medals are again eligible for a limited number of gold medals.

Then, again, every year there are a certain number of national scholarships awarded to students who have shown a certain considerable amount of talent. These scholarships include a payment of, we believe, fifty pounds per year and free instruction at the head school at South Kensington. Many of our readers may say—"Oh! we have not time to bestow in order to become so clever as all that." We would, however, point out to them that many of the most successful students at these schools have been working men who have wrought hard at their trade all day, and then received no instruction but such as was imparted at the night classes. There is no reason why any photographer should not attend and do the same, possessing, as he must do, advantages in the shape of association with art of some sort—though often, we confess, of a rather debased type.

A great advantage of these schools is the opportunity they afford for the discovery and education of latent talent. Many a student who had started life in a more humble capacity has, through the instrumentality of their teaching, been able entirely to give up his first trade, and become dependent upon art alone for an income—in many cases, within our own knowledge, a handsome one. Some artists of high eminence, starting life as mere handicraftsmen, have, through these schools, been able to obtain artistic knowledge side by side with the practice of their own bread-winning trade till they could give up the latter entirely. For example: one of the foremost sculptors of the day began life as a working stonemason, and, going to the school of art night classes in his own town, was gradually able to develope the talent he possessed and make it the stepping-stone to eminence and fortune.

With such examples as these before them we urge upon all young photographers to study drawing as much as possible; and, if they cannot attain the eminence we have described, they may yet advance themselves in artistic knowledge, and acquire the ability to show in their photographs the advantage of mental cultivation.

A recent writer in *Anthony's Photographic Bulletin* has revived the old idea of increasing the sensitiveness of silvered paper by treating it to a preliminary exposure sufficient to faintly tint its whole surface. The experience recorded by the writer in question is so decidedly in favour of the alleged accelerating power that, if it be verified by other experimentalists, few, we imagine, will refuse to accept the innovation as a real aid to the printer, especially during the dull winter months. The somewhat common practice of tinting the paper by exposure to light, in order to "soften" harsh prints, is not to be confounded with the accelerating effect obtained from the same cause. The tint thus produced is merely useful in lowering the too-staring brilliancy of the high lights of the picture without materially affecting the half-tones and shadows; and, though wrong in theory, it answers tolerably well in partially hiding a defect which cannot be altogether surmounted. For this purpose, too, it is immaterial whether the tinting be done before or after exposure; but, in order to secure the alleged acceleration, it is imperative that it precede the printing. In this respect it differs from the kindred employment of auxiliary exposure in the camera; for, as is well known, a variety of opinions exist as to whether the best result is obtained when the auxiliary lighting is given before or after or simultaneously with the camera exposure, or, indeed, whether any tangible result is secured at all. Theoretically, we presume, the principle is the same in either case, and is based upon the supposed power of an infinitesimal exposure to set up an altered state of the sensitive surface in which, though the change may be invisible, it is capable of being impressed by rays otherwise too feeble to produce any visible result. It has been argued that the effect thus obtained amounts to nothing more than a general fogging of the picture—to so slight a degree, however, that while noticeable in the weaker details of a negative (or in the lights of a positive) it is indistinguishable where the deposit is denser. But the experience of the writer in the *Bulletin*—that the tinted paper gave an impression through a mask of yellow paper, while the untinted portion, with a similar exposure, remained unchanged—points decidedly to some specific change wrought by the preliminary exposure. We have carefully repeated the experiment described, using a portrait negative and a mask of thin orange paper; but beyond a slight degradation of the whites in the tinted portion we have been unable to detect any difference. In no case did the mask "print through" on the tinted half of the paper until the same occurred upon the shaded portion. A band of the same yellow paper upon which was pasted a narrow strip of opaque cardboard was substituted for the negative, and a piece of partially-tinted paper exposed until the outline of the cardboard became visible, which occurred simultaneously upon the tinted and untinted portions. In its earliest stages the impression was stronger upon the tinted half of the paper, but in no case could we find that it made its appearance sooner on that portion than on the other. Our experiments so far fail completely in corroborating the statements contained in the *Bulletin* article.

DOUBLE FILMS, AND ALKALINE DEVELOPMENT.

I have experimented, as proposed, on the reduction of silver bromide in contact with metallic silver by the alkaline developer, and the theory lately proposed by me has been confirmed to some extent, though not so fully as I could have wished.

It does not appear to be worth while to go into the details of the manipulations, unless Captain Abney should secure other results; it will suffice to say that the exposures were made behind a glass graduated by strips of thin paper, so that the negative contained broad spaces of tones of varying degrees of depth.

When a plate is developed and, after fixing, washing, and drying, coated with a very thin alcoholic solution of gelatine, followed, after drying, by a coating of collodion emulsion, a great accession of density in the high lights is the result of applying the alkaline developer, the reducing action taking place very rapidly in the unexposed bromide. The superposed bromide appears to be reduced in proportion to the reduced silver immediately under it. It does not seem possible to reduce entirely a thick film of bromide lying on a delicate tone, however prolonged, in reason, the process of reduction may be. This is a point which to me seems difficult of explanation.

A plate which has been exposed through the back and then developed from the front in the usual way does not, in my hands, gain in density over a plate exposed in the ordinary way; yet here we should have unaltered bromide superposed upon light-altered bromide, which latter would be reduced to metallic silver by the developer. Why is the unaltered bromide not in the position of that in the first experiment?

It, moreover, appeared difficult to secure reduction in the upper unexposed film when the latter was placed in contact with an exposed, but not developed, film. The development is slower in the lower film, so that there may be less detail. It seems probable that the upper film raises an obstacle to the easy action of the developer on the exposed, but not developed, film; and until this latter has had all its sub-bromide and bromide under the influence of the sub-bromide reduced to the metallic state, reducing action does not commence in the film above.

The following is an extract made from notes jotted down during the course of the experiments, and will introduce the last experiment I shall quote:—

"There seems to be a tendency to *upward* reducing action, as a half-tone does not in ordinary practice continue to be added to by downward reduction after the development proper is finished, though the developer must surely be able to reach the glass. On the other hand, a bromide film superposed on a developed film is reduced considerably. Still it is difficult to say whether, in the case of the ordinary development of a film, an equivalent amount of reduction does not take place in the unaltered bromide. It would be advisable to try the effect of developing and fixing a plate, now coating one half of it with gelatine solution, followed by emulsion, and then transferring the film with gelatinised paper. Then, after drying, to moisten what was the *back* of the developed film with alcohol and apply the alkaline developer, taking care not to wet the back of the paper; then to fix, when any development downwards would be made apparent."

I carried out this experiment, and cut the transferred film in half for comparison. It must be remembered that the tones in each were alike. The developer was allowed to remain for *fifteen minutes* on the film, the sides of the paper being turned up so as to form a dish. At the end of this time the gelatinised paper was stained brown; the developer was washed off, and the film was fixed with hypo. *No gain in intensity was apparent*, yet the developer must have permeated both films in order to stain the paper.

My theory—that the reduction proceeds upwards in unaltered bromide—seems, therefore, to receive some confirmation. I shall, however, await with much interest Captain Abney's further experiments. HERBERT B. BERKELEY.

NOTES ON PASSING EVENTS.*

By a Peripatetic Photographer.

My breath has been well-nigh taken away by the perusal of the five months' collection of applications for new photographic patents which has been published in the pages of The British Journal of Photography. It must be cheerfully admitted that it is of very great interest indeed to the photographic public to be made aware of the new inventions considered worthy of being secured by patent; but the interest would be enhanced if such information were afforded, at a subsequent date, as would throw light upon the future career of each invention whose birth has been thus heralded. Of any of those mentioned the thought will suggest itself—Does it contain the germ of a revolution? Will it be given up by its paternal relative ere it reaches the termination of the six months' probationary period allotted to it by the authorities? or will it enjoy an existence of three, seven, or even of fourteen years, according to the brightness of its prospects or the plethoric contents of the purse of its holder? Now, all these points might be ascertained by each reader for himself if in connection with the list of new patents applied for an addendum were occasionally published in which would be given a statement of those which had "lapsed" at either of the above-mentioned terminable periods, and of those which had been gazetted as having had a further term of existence granted by the payment of one or other of the definite sums of money which are payable as the condition upon which an extension to three, seven, or fourteen years is granted to these inventions. One use of such an intimation would be that many inventions now being paraded in the photographic world having the magic word "patent" attached thereto would be found to have forfeited all claims to patent protection perhaps several years ago. I am aware of one patent which lapsed nearly ten years since, but which is still imagined by many to be existing in full force. Indeed, it was only by accident that I was recently made aware of its demise.

Was Daguerre married? and *did* he leave a widow and "olive branches" to carry on his business? I put these queries *apropos* of the poem in memory of this *savant* which, through the enterprise of the *Practical Photographer* and the genius of one of its poetical contributors, has been allowed to see the light. Permit me to quote—

"He is the father of our art,
So faithful and sublime,
And many sons and relatives
Are following in his line."

Now if our art had only *one* father, was Daguerre that man? "It is a wise child that knows its own father," if we may reverse Shakspere's apothegm; but I don't think "our art" has yet shown any indications of its being the possessor of such discriminative wisdom. Then, as to the sons and relatives who are "following in his line," what line did *he* follow? and who are his sons and relatives? If he be the father of our art, and also of those who follow it, is it not cruel and unfilial in so many of the latter to ignore the existence of their sister? I have been puzzling myself to discover who the foregoing "relatives" are in contradistinction to the "sons," and I now conclude that the former are professional and the latter amateur photographers. But the advice given by the poet in his parting stanza, in which he takes a tender farewell of "Old Daguerre" and all his sons of care, is so excellent that I enforce it:—

"Be constant, just, and true,
Remember the old philosopher,
And art will follow you."

Whether Art is ever to "overtake" the sons of care who remember the old philosopher, and who she is thus guaranteed to follow, the poet sayeth not. On behalf of all lovers of the true and beautiful in poetry I beg to express the hope that we shall hereafter often meet with the effusive heart-utterances of Mr. Hamilton Gordon Wemyss.

I note the conversation between Mr. Mark Oute and his friend respecting the unwillingness of photographers to lend their negatives for the purpose of having enlargements taken. This is scarcely to be wondered at so long as human nature is what it is. Many prefer copying a *carte* portrait to running the risk of a refusal by the holder of the negative to lend it with that object in view. The following is the method adopted by a photographer of my acquaintance, who is very successful in copying paper prints. Having a strong plate of colourless glass a little larger than the *carte* to be copied he applies glycerine to one of its surfaces, also smearing over the face of the print with glycerine. He then brings the two coated surfaces into contact, places a stout plate of glass behind, and inserts the whole in a frame similar to a *carte* printing-frame, a strong pressure being applied to the back by means of screws. By this arrangement the texture of the paper is almost obliterated; and, owing to the print being thus placed in optical contact with the colourless glass in front, it is rendered very soft and delicate, and brought into a condition eminently fitted for copying purposes. The only precaution necessary in making the copy consists in subjecting the *carte* to a front light. In this way may be produced negatives which will bear enlarging very well. I do not say that such negatives would answer quite as well as the originals; but if a good print has been made use of for this purpose the enlargement will be so good as to convey no idea of the method by which it has been produced. I have several magic-lantern transparencies which have been obtained from paper prints by the method described, and they stand being shown upon a twelve-feet screen without the appearance of texture, hardness, or want of sharpness; and what more is required?

* Concluded from page 316.

BABIES AND STUDIOS.

I am very often asked to give some particulars of "how I do it" when the piles of baby pictures which are generally in hand at my studio have been looked over either by admiring mothers or curious photographers. If I were to reply truthfully I should say by the exercise of the utmost patience and the most complete self-control. When once a child enters my studio its fate is sealed—it is bound to give in. My present studio has been built over seven years. During that period I have had only one baby sitter brought into it of whom I did not get a picture before it left. I do not mean to assert that all have been good pictures, nor that I should let an infant be taken into it in a thunderstorm; but I do assert that, with the one exception I name, by dint of patience, tact, judicious selection and arrangement of light, and having my chemicals in the most exalted state of sensitiveness, I have always "hit them off" by one means or another.

Often it takes a long time to get round some particularly beautiful and correspondingly bad-tempered ("high-spirited" the mothers call it) little atoms of humanity; but, as I always arrange for an extra length of sitting for this class of subject, I have not found that difficulty insuperable.

One of the most important points in this sort of work is the treatment of the parents or friends of the tiny sitters, who will insist upon clapping their hands or petting the child at the most inopportune moments; or, if old enough to understand, telling them to sit still, or to be quiet, or be a good child, and so on. Unless under exceptional circumstances the photographer himself should do all that is necessary in the way of attracting, as the action of uncapping is so dependent upon that of amusing the sitter that the two form part of one act, and cannot be separated with advantage. Hence I always gently but firmly insist upon the sitter being left in my hands; if I do want help I ask for it. I further inform the parent, or whoever has the child in charge, that it must not be told to "sit still," "not to move," &c., and I always check any tendency to speak of "taking" or "photographing." These are mysterious words, too suggestive of tooth-drawing, or having about them a gentle adumbration of bunches of birch.

First thing of all the child's confidence must be gained, the general mode of doing which is to chuck it under the chin and say "well, little darling!" this being followed, in nine cases out of ten, by a pout and a shrinking which is never quite got rid of during the sitting, and occasionally it ends the matter at once by the establishment of a series of finely-graduated howls which never cease till the outer door is reached. This is not the way at all. A child's nature is a perfect study, and *it should never be spoken to or looked at* upon its first entry, but its attendant addressed, and perhaps a slight remark made as to the toys in the place. The little ladies or gentlemen generally prick up their ears at that, and if one or two toys be brought out with discretion it is usually only a matter of about five minutes before a friendship is cemented, and the two—that is, the sitter and myself—are either playing on the floor or still more advanced towards the posing. Toys in abundance are a necessity, and the power of mimicking the noises of cats and dogs, &c., is particularly useful. Loud noises, whistles, &c., are vicious in principle; they lead to such open-eyed expressions of fear or wonder that they are utterly objectionable. A musical box I find a very useful aid, some children being quite entranced, as it were, with it; while others, again, do not appear to regard it in the slightest degree. I find a good-sized india-rubber ball will attract oftener than anything, and, owing to some (to me) inexplicable psychological combination, toys thrown in the air will nearly always cause laughter.

Very young babies—and I have taken them from a fortnight old—of course require different treatment. Plenty of life and activity and colour is what they like. A musical box half wrapped in a coloured shawl and waved about, or a twirling feather-fan, &c., &c., I have found very useful. When they are very young, of course, they cannot be attracted by either noises or sights started any distance from them. The plan then is to go close up to them with the bright object and retire quickly; their eye will generally follow the attraction long enough to get an exposure. It is, perhaps, scarcely necessary to say that when two or three children come together they should be introduced into the studio one by one, as otherwise the toys and the little tricks and dodges to attract their attention become stale, and when their turn comes they are "old birds" who are not to be "caught with chaff."

One word about the head-rest. When about to use it take *Punch's* celebrated advice—"Don't"—except in the case of children not too young, such as can thoroughly understand that it is nothing to hurt them; and even then it requires most dexterous handling and delicate adjustment to avoid that unnatural constraint of pose and appearance which, bad enough in an adult, is simply detestable in children, whose posing and arrangement should suggest everything that is light and free.

With regard to the form of studio most adapted for the purpose, it is quite immaterial so long as there is plenty of light; for it can then always be lessened, if required, by curtains, and, above all, so long as there is power to use a south light. The quickest exposure cannot be obtained unless there is an all-round light, one side being the south. It may be softened and diminished as much as is considered necessary; but for exposures such as I give—often less than a quarter of a second—a south light is a *sine quâ non*. Its excessive brilliancy can always be subdued when it is found that the sitter is made to frown and draw up his or her mouth by its too great brilliancy.

With regard to chemicals: I have little to add to what I have written about them in former numbers of this Journal in this connection. The purest materials must be employed. It is, doubtless, an advantage to be able to test everything in one's own laboratory, but it is not a necessity; the dealers supply the best of everything if paid a fair price. A bath made of pure water and silver and a newly-iodised collodion only faintly tinged with colour are necessary (the latter should be tested for cleanness of working and rapidity, there being decided differences in the latter respect among the various commercial collodions); a strong developer—these three things seem to be all that is required with the exercise of tact and skill. But I am bound to confess I find that constant practice in this work seems to give one a power over one's subject which the most skilful beginner does not obtain. No one should attempt this fascinating branch of photography unless he is fond of children and possessed of unbounded patience. G. Watmough Webster, F.C S.

ILLUMINATION BY ELECTRICITY.

[Condensed translation from the *Revue des Deux Mondes* for the *Journal of the Franklin Institute.*]

The Gramme machine, as the electric source, and the Jablochkof candle have made the application of electricity to purposes of illumination a fact beyond doubt.

The intensity of the moon's light is inferior to that of a candle, and incomparably more feeble than that of the sun.

The comparison of the electric arc to the sun, which is our highest conception of brilliancy, may be made in two ways—by the relative times required to produce equal photographic images, or by the direct measure of the illuminating powers. Fizeau and Foueault found by the first process that the power of the sun is only two and a-half times superior to that of the arc; the second method has proved that the carbon points with a powerful machine are equal to the sun in lustre. It is even probable that this limit may be passed, and it is not strange if it be remembered that our sun does not occupy the first position in the universe. It is a star already old, the cooling of which is considerably advanced, and whose yellowish light begins to approach that of terrestrial flames.

In quantity and quality the electric light greatly exceeds all flames, and in brilliancy it approaches or even surpasses the sun. It is precisely this immense profusion of illuminating power that is urged against the electric light. It is said to be exaggerated, to exceed our requirements, and that it ought to be divided, but it is indivisible.

It is true that the electric light is dangerous, like that of the sun; we may be illuminated by it, but we should not look at it. But is it by any means certain that it cannot be divided or so reduced in lustre as to be rendered tolerable?

Nothing is easier than to reduce its lustre to any degree that may be desired; it is only necessary to cover the arc with a large opalescent globe. The latter hides it, and receives all of the rays and dispenses them precisely as if the globe itself were luminous. It replaces the original source, at the same time increasing the dimensions, and if it be ten thousand times larger it reduces the lustre to the ten-thousandth part. It is true this process absorbs and wastes a notable portion of the light emitted, but where the electric light can be adopted this is of but little importance. The division of the arc can easily be accomplished by the use of the alternative currents long since devised by Le Roux; for, when the alternations succeed each other at intervals of one-twenty-fifth of a second, the extinction ceases to be perceptible, and the effect is that of a continuous light. The Jablochkof candle, when the thickness and distance of the two carbons are diminished, permits a still further division, so that each candle may equal but fifty Carcel lamps, and a number of these candles may be placed in the same circuit.

The division may be carried still further, as shown by a new and remarkable experiment by M. Jablochkof. He prepares an immense condenser composed of two tinfoil surfaces, separated by oiled silk, and folded as the condenser of a Ruhmkorff coil. The surfaces are connected with the two rheophores of an alternating current machine, so that a large space is presented on which the electricity may accumulate and condense until, the direction of the current changing, each disappears to be replaced by the opposite electricity, which, in its turn, undergoes the same condensation. It is evident that these conditions should greatly modify the electric circulation in the wires, and experiment confirms the assertion. When the current is broken brilliant sparks are produced, flashing like fire, and enveloped in a very luminous yellow flame, at the same time accompanied by a sonorous humming sound, of the same pitch as the noise of the machine, which proves that the periodic intervals of the production of the sparks are the same as those of the formation of the currents. This experiment leads to one practical result: it is that by introducing a condenser into the circuit the number of candles that the latter is capable of sustaining is doubled, but the light of each candle is, of course, reduced one-half. All is reduced to a greater division of the illumination. It is not desirable to go beyond this point, for the Jablochkof candle, with the condenser, gives a light equal to twenty-five Careel lamps, and, in order that electricity may be adopted as a source of light, its power must be equal to that of at least twenty Carcel lights.

M. Jablochkof made another interesting experiment. He passed the alternating current through the interior wire of a Ruhmkorff coil, producing in the exterior wire induced currents also alternating, but of greater intensity, which are capable of diffusing upon the edge of a thin piece of kaolin, illuminating it, and maintaining the incandescence as long as may be desired. It is a beautiful physical experiment, but its practical application is doubtful.

The light of a gas flame is orange yellow when compared to that of the electric light. That a light may be applicable for purposes of illumination it is necessary that it shall contain the seven primitive colours of the spectrum in certain proportions. All luminous bodies do not contain these colours in the same proportions. The electric arc produced between silver and carbon contains only two green bands, and if the silver be replaced by other metals the spectrum obtained is always formed of brilliant lines separated by wide, dark spaces. These lights are very incomplete, and would not, in any case, be used for illumination.

The spectrum of gas and oil flames are continuous. The red, orange, and yellow are very abundant; there is but little green, almost no blue, and little or no violet. These flames are rich in colours, but slightly refrangible, which gives them their orange tint, poor in highly-refrangible rays, and destitute of indigo and violet. That of which they possess too much, the red, may be removed; but it is impossible to add to them the indigo and violet which they lack, and this is the cause of their inferiority. The electric light is more complex; it proceeds at the same time from the carbons and from the arc, and differs according to the one or the other of the sources. That from the carbons is white; it is absolutely the same as that of the sun, and contains all of the simple rays in the same proportions. It is complete and perfect, and replaces daylight without any modification. It is not the same with the light from the arc itself; it is violet blue, and its spectrum tends altogether towards the most refrangible colours. It is the opposite of gas- or lamp-light; it contains little red, much blue, and a large excess of violet. It is this light of the arc which gives to electric illumination the bluish tint which has been objected to with reason. But it is a fault of excess which can be remedied, for while the missing rays cannot be added to gaslight the superfluous rays can be removed from the electric light. The eye receives the vibrations of the ether which constitute light just as the ear receives sounds transmitted by the air, and ceases to be conscious when the vibrations become so rapid or too slow just as the ear ceases to hear notes too acute or too grave. But such extreme vibrations exist; there are rays below the red and beyond the violet, both of which are imperceptible to our eyes. The first are the heat rays, so abundant in the spectre of flames; the second exist in large proportion in the light of the arc, and are those which it is important to recognise and remove. Their existence may be proved in two ways—first, by receiving the spectrum upon a photographically-sensitive surface. The image formed in the red is very feeble, while those formed as the violet is approached become better and better; but the action does not stop at the violet. The photographic intensity is extended and increases beyond the violet, which proves the existence of ultra-violet rays of rapid vibration which our eyes cannot recognise, but which are eminently fitted for photographic action. The second method is different. If a solution of quinine sulphate be spread with a small brush upon the spectrum from the red to the violet no effect is perceived in the red; but after the blue a whitish tint marks the path of the brush, and this is increased and becomes most brilliant in the rays which are beyond the violet. The quinine sulphate has, therefore, the property of changing the blue, violet, and ultra-violet rays into white light, and, at the same time, it renders visible and useful radiations which the eye could not perceive, and adds them to the available light.

Uranium glass and many other substances act in the same manner, and present the means of suppressing the rays which are objectionable in the electric light. This suppression is necessary in other respects. These rays are said to attack the humours of the eye, and to be the origin of grave diseases.

But the electric light has its faults—one especially, which will exclude it from many places. It produces a grave, continuous note like the buzzing of a swarm of flies or an æolian harp. It is not a disagreeable note, but it becomes monotonous. It is produced by the succession of alternating currents lighting and extinguishing the arc at each change of direction, with a little noise each time. As this noise is produced at equal intervals it becomes a tone, the same as that produced by the machine, and when the candles are placed in globes the latter become resonators, and increase the sound. The Gramme machine is the only one which furnishes a silent light, because its current is continuous in the same direction.* The electric light, however, does not vitiate the atmosphere, and produces very little heat.

In ordinary flames, the production of light is a secondary phenomenon which accompanies the chemical combination of the combustible with the oxygen of the air. This combination is doubly objectionable, removing the oxygen from the air, and replacing it by vapour of water and carbonic acid gas. The latter, although not as dangerous as has been believed, has not a good reputation, and the best that can be said in its favour is that it does not kill. The electric light has the decided advantage of not altering the respirable medium. Chemical combination has still another inconvenience: with the light it developes such an amount of heat as sometimes to render work-rooms almost uninhabitable.

On the contrary, the electric arc does not heat. This appears astonishing at first, for all bodies fuse or volatilise when introduced into this arc. But if a very sensitive thermometer be placed in the spectrum of the electric light it is found that there is no indication of heat in the violet rays; that in the green the thermometer begins to be heated, and that the temperature continues to rise as the red is approached, and attains a maximum in the obscure rays beyond the red. Now these heat-producing rays are by far the more abundant in gas and lamp flames, while the arc, which is the best test of luminous sources, emits the greatest amount of light with the least proportion of heat.

The exact cost of the electric light is yet a matter of question, but the Lontin Company furnish all of the apparatus, wires, lamps, &c., of which it retains the ownership, and demands fifty centimes an hour for the quantity of electricity, equal to 100 gas jets, on the condition of a guarantee of the use of a certain amount of light for a number of years. One of the proprietors of the Magasins du Louvre has authorised the statement that the apparatus of the Denayrouse-Jablochkof Company, in their use, gives more light than gas with thirty per cent. less cost.

* In the experiments made by the Committee of the Franklin Institute, it was found that all of the so-called continuous current machines produced some sound in the arc.

The fault has often been committed of attempting street illumination on the lighthouse system by a beam of light concentrated by reflectors, and thrown along the length of the street. Such experiments have only succeeded in blinding the by-passers and projecting behind them long shadows as black as open precipices. There are cases when such concentration is the only end that is desired. In workshops, it is only necessary that the workman shall have a clear view of the work before him. It is the same in dining-rooms, billiard-halls, reading-rooms, &c., and no one pays attention to the obscurity behind him.

It is different in depôts, theatres, lecture-rooms, and display store-rooms. In these cases a general illumination is required, coming from all directions, and lighting every side of an object.

When several electric lights are placed in a hall illuminated by gas the eye immediately experiences a sort of relief, both by the redoubled brilliancy and by the perception of colours, which were not before suspected; and, on the contrary, if the electric lights be suddenly extinguished the spectators are thrown into the comparative night of the old illumination.

The conditions of good electrical lighting must be determined by a study of the general illumination of objects during the day. When the sky is clouded the sunlight pierces the clouds as through a ground glass, and the whole sky is like an immense illuminated ceiling, radiating light from every point and in all directions. The objects illuminated diffuse in their turn the light which they receive, so that there is an inter-crossing of rays, producing the effect of a mean amount of light everywhere; this is *general illumination*.

Such is the model that must be followed. For this purpose the ceilings, walls, and floors must be illuminated that the diffused light may be radiated into the empty spaces; and, that the quantity may be the same everywhere, it will be necessary to multiply the sources of light. That the direct rays may not painfully affect the retina it will also be necessary to diminish their brilliancy by the interposition of ground glass and some fluorescent substance, such as quinine sulphate, in order to transform the violet and ultra-violet rays into white light. Lastly, and especially, it will be necessary to cover all openings by which the light may escape.

The exterior light enters by the windows during the day, and it is by them that the nocturnal illumination escapes. M. Jablochkof introduced electric lighting into the laboratory of the Sorbonne, and the feeble effect it produced was astonishing. This laboratory is covered with a glass roof, by which it is well lighted during the day, and by which it allowed the loss of at least one-half of the light produced by the electric candles. This wasted light illuminated the high walls of the surrounding buildings, and gave a brilliant but useless illumination in the court. A similar occurrence took place last summer on the occasion of an experiment attempted in the Palais de l'Industrie. All of the light had been concentrated in six lamps, far from each other; this was the first fault, which would have been avoided by distributing a large number of less powerful lamps throughout the immense building. Lastly, all of this light, instead of being directed towards the spectators by a well-combined system of diffusion, escaped through the vast glass roof, to be uselessly lost in the heavens. The experiment would have succeeded had the roof been covered with a thick white covering, destined to reflect back the light so prodigally wasted.

The same thing happens with gas, and will occur with electricity in the illumination of public places. All of the lamps waste half of their light in radiation towards the sky. A simple reflector would return it to the ground and double the illumination. J. Jamin.

THE BIG SHOW.

Boissonnas' Rapid Process. — Photography Used for the Illustration of Subjects.—The American Pictures.

Before leaving home "Boissonnas' extra-rapid process" advertisements had attracted our attention, and on the second morning of our stay in Paris we paid a visit to M. Klary, at 18, Rue Vivienne. We went with very much the same feelings as Charles Dickens stated that he felt on his way to New York. When the Yankee asked him what he was going to do at New York, he replied—"I'm going across to look at it, and if I like it—I'll buy it!" That was just our position with regard to this process; we were going to look at it, and if we liked it we'd buy it. The testimonials were very startling from the shortness-of-exposure point of view—so short, sometimes, that I began to wonder if I would not come across one where the cap had never been removed from the lens at all. When reading them over I was reminded of the Irishman who, when buying the stove that saved half the fuel, thought that he might as well have two of them, and then he would need no fuel at all.

The greatest feat in the published list is that of one gentleman who, when a heavy fog was on and the light so bad that working with ordinary formulæ it would have required an exposure of from twenty to twenty-five seconds to produce a picture, "obtained a perfect negative by opening and shutting the cap of the lens as quickly as possible." Taking a fair average of the list, about one-fifth of the usual exposure is what is claimed for it. Under the conditions in which we saw the experiments, and to the best of our judgment — seeing everything around was strange—the exposure was about half the time the same subject would have taken with us at home and under our own conditions of working.

The light under which M. Klary worked was certainly superior to that which we, as a rule, have the opportunity of enjoying; and this advantage helped him in his exposures. We saw three plates exposed with four *cartes* on each plate (bust heads). The exposure given to each picture was one, two, three, and four seconds respectively on each plate as it was tried, and in each case the three-seconds' exposure was the finest picture. They were taken with a Dallmeyer's lens, three-inch diameter, full aperture. That it is quicker than our ordinary working is certain; for, although the three-seconds' exposure was by far the best, the one-second or two-seconds' pictures might have done good service if one were placed in the position that such were the only things obtainable at the time.

We resolved to wait until the process was tried on our own ground, and under the conditions which we ourselves would have to work it, before purchasing; and if, under these circumstances, it should reduce the exposure to one half the usual time M. Klary will find many purchasers. Should M. Klary think of paying this country a visit I have no doubt he will receive a very hearty reception and a fair field for his demonstrations.

After leaving M. Franck's studio we went on to the Exhibition. The manner in which the photographs were scattered all over the building was, to say the least of it, puzzling. Each set was to be found in its own section or country certainly; but then the distance between each set of pictures was considerable, and in many cases not an easy matter to find out. Suppose you wished to make a comparison of works that you might think similar in value and merit, the chances are that you might have to walk back a mile to do so, and you would fail to be able to judge then as you might have done had you been able to walk out of the one section into the other. But even this evil, if it may be so called, did not exist without a corresponding amount of good to the investigators; for in our hunt for the next section we invariably dropped upon whole sets of photographs, and in many cases fine pictures, illustrative of machinery, mining operations, architecture, furniture, soft goods' productions, views of countries and costumes strange to us—from the apparatus used in preparing the dead bodies for inspection in the Morgue to the newest designs in life-saving apparatus at sea. These collections of pictures speak well for photography being used as the future means to be employed in giving truthful illustrations of all kinds of subjects. To see the thousands on thousands of photographs that are exhibited all through the building for the illustration of subjects simply from a commercial point of view foretells a great future for our baby art, which has yet to spread and flourish to the dimensions of full grown manhood, absorbing as it grows many of the methods now used in the manufacturing of pictures.

The pictures from Canada and the United States are pleasing examples of the general work that comes to us from "over the water," which is, as a rule, far above the average in commercial photography; that is, pictures that are really sent out to clients in contradistinction to those which are neither more nor less than show pictures made for exhibition.

Notman, of Montreal, shows work rich in tone and artistic in manipulation. The snow scenes of Henderson, also of Montreal, look so real they seem to cool you to look at them, and that itself is an advantage with the thermometer standing at a hundred degrees.

Sarony, of New York, from the samples here displayed, stands now, as in the past, unequalled in that style of portraiture which he affects. There is the indefinable feeling of art through all his productions which belongs to the man himself, and which never could be attained by careful manipulation alone.

Weston, of San Francisco, shows some pictures in a cut mount which he calls the "crystal scallop," for which he has taken out a patent. If it be the mount he means—and I could see nothing else about for which he could take out a patent—after inspection I must say I quite failed to see either its beauty or its utility.

Joshia Smith's case of bright-eyed little things—that mutely tell you with the smile of babyhood that they "came all the way from Chicago"—is a perfect poem framed. To stand at that case, letting your eyes wander from the one face to the other, thus studying the differences of expression—the thoughtful, the cheerful, the smiling, the laughing, all happily portrayed—it looks like an index to a hundred volumes of a hundred changeful lives.

I. Landy, of Ohio, has sent seven pictures descriptive of Shakspeare's "Seven Ages." He has, "at first, the infant, mewling and puking in his nurse's arms;"—and "then the whining schoolboy, with his satchel and shining morning face, creeping like snail unwillingly to school;"—"and then the lover, sighing like a furnace, with a woeful ballad made to his mistress' eyebrow;"—"then, a soldier, full of strange oaths, and bearded like the pard;"—"and then, the justice; in fair round belly, with good capon lin'd, with eyes severe, and beard of formal cut;"—"the sixth age shifts into the lean and slipper'd pantaloon, with spectacles on nose and pouch on side;"—"last scene of all is second childishness and mere oblivion, sans teeth, sans eyes, sans taste, sans everything." They form an excellent series of subjects, and are very cleverly treated.

Mark Oute.

FOREIGN NOTES AND NEWS.

Leipzig Training School for Retouchers.—Gilding Solution.—Dr. Liesegang on Mr. Bennett's Emulsion Plates.—A New and Expeditious Mode of Flattening or Retouching the Negative Film.—A Lead-Containing Negative Silver Bath.

A training school for photographic retouchers has just been started at Leipzig. The subjects taught include the following:—Figure drawing (heads), retouching of positives and negatives in oil and in water colours, chromophotography upon paper and convex glass, portrait painting, and, though last not least, the posing and lighting of sitters for photographic portraits. Ever since the practice of retouching negatives was first introduced there has been a never-ceasing wail over the want of skill displayed by retouchers. Their chief aim has seemed to be, not to modify the shadows and lines, which come out with much greater distinctness in the portrait than in the original, and to tone them down only so far as to make them true to nature, but to give to every face a marble-like texture, and to every cheek the roundness and smoothness of a billiard ball. The upholders of the legitimacy of retouching, on the other hand, maintain that retouching would be an unmixed benefit to the photographer in the hands of a properly-trained assistant; but, then, properly-trained assistants are scarce. If the Leipzig experiment be successful they may become more plentiful, though there might be more chance of success if the anatomy of the face were added to the subjects of study.

In the *Chemiker-Zeitung* Dr. E. Ebermeyer gives a formula for gilding metallic articles so as to look like polished gold by simply dipping them into a warm solution. Dissolve ten grammes of gold in forty grammes of hydrochloric acid and fifteen grammes of nitric acid; stew down, letting as much of the acid escape as possible; then throw down the gold as fulminating gold by means of spirit of ammonia; filter, and wash. In the meantime dissolve one hundred grammes of cyanide of potassium in as little water as possible, and then dissolve the gold upon the filter with the cyanide solution. Pour this solution again and again over the filter until all the brown particles are dissolved, when the gilding solution is prepared by the addition of one litre of distilled water. Into this solution, while warm, dip the metallic object to be gilded, and when drawn out it will have all the appearance of polished gold. The formula for silvering is as follows:—Dissolve twenty grammes of silver in sixty grammes of nitric acid, and precipitate with a solution of twenty grammes of caustic potash in water upon a filter, and wash with water; now redissolve upon the filter with a solution of one hundred grammes of cyanide of potassium in water; then dilute the whole to two litres with distilled water, and use like the gilding solution.

In the *Photographisches Archiv* Dr. Liesegang proposes to modify Mr. Bennett's developer for a properly-exposed gelatine emulsion plate thus—

Ammonia of 88°	1 drop,
Pyrogallic acid	1 grain,
Water	1 ounce,

mixing as much in these proportions as will cover the plate in the bath. When the plate is over-exposed take more pyrogallic acid, and when under-exposed less, but more ammonia.

From a series of experiments made with bromide of silver and gelatine, Herr R. Schlegel is of opinion that these plates give a much more correct proportion between the red and green parts than collodion plates, but that the yellow parts have less action on them. Herr Schlegel also found that when the light was dull these plates were of much the same sensibility as collodion emulsion plates, but that in bright light their sensitiveness far exceeded that of the latter.

In the same journal mention is made of a substitute for the retouching pencil when quick work is required, by means of which any given part of the face or hands may be made smooth and flat! M. Ducaisse takes a medium-sized sewing-needle, blunts and polishes the point of it, and then fastens it obliquely into a pencil-holder so as to form an angle with this handle. He then rubs with the side of the needle those parts of the face and hands of the negative which it is desirable to smooth, thus polishing the film and making it more opaque when looked through. The negatives work better gummed than varnished. This is art made easy with a vengeance! It should be said, in justice to the *Archiv*, that it merely mentions this mode of retouching; it by no means recommends it.

In the same journal there is also a formula for a negative silver bath containing lead:—Dissolve in a bottle capable of containing rather more than a litre forty grammes of white nitrate of silver in half a litre of distilled water, and then add carefully twelve drops of plumbic acetate.

On shaking the mixture the silver solution becomes milky. Meantime, in another bottle, dissolve forty grammes more of nitrate of silver in another half-litre of water, and add to the solution twelve drops of pure nitric acid. Pour the contents of the second bottle into the first and mix; the fluid will then become clear again. Then add ten c.c. of iodised collodion, sun the bottle for a few hours, filter, and the bath is ready.

This lead bath, says the *Archiv*, works very rapidly and seldom fogs; but gives very thin, grey negatives, such as are preferred for Rembrandt portraits. It has also the advantage of working well in the dull winter days, giving well-harmonised light and shade. Under ordinary circumstances its negatives may be powerfully intensified with pyrogallic acid.

TRANSATLANTIC NOTES.

Utica, Saratoga, and Albany are the subjects of the present instalment of *Notes*, although, were sufficient space at my command, each would furnish matter enough for several communications.

Utica, intersected by the Erie and Hudson Canal, is really a beautiful place. Free from the geometric regularity of most of the American cities, its tree-lined streets impart to it the truly American sylvan character, while the size and elegance of its suburban residences show that its people are prosperous to a degree unknown in similar cities in the old country. But their commercial prosperity is not the only, or even principal, quality on which the Uticans pride themselves, as they rank only second to Boston in their opinion of their culture and appreciation of science and art; and, so far as I have been able to judge, with quite as much, if not more, reason. Amongst many things of which the Uticans are justly proud not the least remarkable is their cemetery, and especially the fine conservatory connected with it. It stands on a hill about two miles out of the city, from which there is tramway communication every half-hour. The hill was originally covered by a primeval forest, and its principal beauty consists in the way in which considerable numbers of fine trees have been left to line the walks and overshadow the resting-places of the revered dead. The inclemency of the weather during some of the winter months renders the funeral ceremony always uncomfortable and sometimes impossible, and to obviate this inconvenience a beautiful conservatory has been erected near the entrance. Although it is called a conservatory, "crystal palace" would be a more appropriate designation. It is a beautiful, circular-roofed structure of iron and glass, both colourless and stained, fully stocked with the most choice exotics kept in perpetual bloom, and here and there song birds and birds of exquisite plumage disporting amongst the branches and sending forth their songs of gladness, imparting a life and vivacity to the scene that is charming. A large space in the centre is kept clear, in which the coffin, or "casket," as it is more generally called, is placed, with the mourners around it; and there is a gallery at one end for the accommodation of a choir, by which appropriate music is usually sung as a portion of the service. But probably the most interesting feature in this beautiful cemetery is what externally looks like a fine gothic chapel—the gift of one of the wealthy families of the city. The visitor is at first somewhat at a loss to know what purpose it is intended to serve, as although such buildings are to be found in most cemeteries they are always used for the services connected with funerals; but in this case these are amply and much more tastefully provided for in the conservatory. The mystery was, however, solved when the obliging keeper of the cemetery was interrogated; and it turned out to be a receptacle for those who die during the winter months, when the ground is frozen to such a depth or the snow is so thick that graves cannot be opened. Access to the interior is gained by a massive door at the end of the building, and the "dim religious light" passing through the stained glass shows only an empty central aisle with a row of panelled doors on each side. On opening one of these doors the recess is found to be divided by shelves into bins like a wine-cellar, and each bin contains an oblong box of white pine, on the end of which is fastened a card bearing a name and date, and inside of which box is the coffined body of the deceased, awaiting a convenient time for proper interment. The chapel contains altogether four hundred and twenty such bins, and there were at the time of my visit over four hundred bodies awaiting burial, all of which, according to cemetery regulations, must be buried before the first day of June.

Here, as in places nearer home, there seem to be difficulties in the way of insuring negatives and photographic material against fire, and I was surprised to learn that as much as from three to five per cent. was frequently asked by insurance agents. Of course, rather than pay such heavy premiums many do not insure at all, while some only do it for a "quarter," or from three months to three months. Such a method involves frequent omissions, and as a natural consequence, when a fire does occur, it not unfrequently happens just while the stock is uninsured. Why such high premiums should be charged where the arrangements for extinguishing fires are proverbially so perfect I cannot understand, and I am sure that some of our English or Scotch companies might do worse than establish branches here and in other large towns, as, if they would grant policies on anything like the rates charged at home, they would command a large amount of business.

I am not much acquainted with fire-brigade arrangements in the old country, but probably a brief description of what I saw in Utica, Flint, and several other places, and what I know to be general in almost all such towns in the States, may interest the readers of the Journal. The town is divided into districts, in each of which there is a suite of buildings, including a comfortable mess-room for a number of firemen, who live on the premises, and dormitories, with beds, by the side of each of which the fireman's dress is placed ready to be jumped into at any moment. A steam fire-engine is always at hand, with water at the boiling point, and with firewood and coal laid ready for ignition; there is also a stable with a pair of highly-trained horses prepared to draw the engine to any place where its services may be required. Each station is in electrical communication with signal-boxes all over the city, and by the breaking of a pane of glass and the pressing a button at any one of them information is instantly flashed to each of the watchmen on duty. Equally simple and prompt is the result of the action taken by each of such watchmen on the receipt of the electric signals. He pulls a cord which hangs convenient to his hand, and the single pull strikes a powerful gong, the noise of which at once awakens the sleeping firemen and warns the horses that the time for action has come. It at the same time liberates the springs by which the door of the stable is kept shut, and also unhitches the horses. In short, a single application to the bell-pull awakens the men, opens the stable doors, and liberates the horses; and so well trained are both men and animals that within *a few seconds* after the signal of a fire has been received each is at his assigned post, and although the fire may be only in the next street steam at a pressure high enough for effective work is available by the time the engine reaches it.

I regret to say that photography in Utica is not in the position that from the taste and culture of the Uticans we might expect it to be. There are no lack of photographers, but, so far as I could see, there was only one who really did good work, and he certainly had more than a fair share of what was going. His studio was one with the ordinary large top light, and his arrangements generally would not in Europe be considered conducive to the production of high class results; but by the liberal use of hand and other screens he simply and rapidly produced negatives that would do credit to the best artist in any country. Unlike Americans generally, he evidently prefers warm colours, and was toning silver prints a warm brown. He was the only licensee of M. Lambert that I had met in the United States who seemed determined to thoroughly work the process to its entire extent, and his walls bore ample evidence of much patient perseverence, although he had not sufficiently mastered the details to warrant him in abandoning silver printing entirely, though he said that the hoped in a short time to send out nothing but carbon prints. In common with many of his brethren in the profession, he assured me also that he envied photographers in Britain, who could always find reliable collodion and other materials as articles of commerce, while much of his time was consumed in making them; but I strongly suspect that there is a good deal of prejudice in connection with this matter, as since then I have again and again had satisfactory evidence that thoroughly good and perfectly reliable collodion is as easily obtained in the American as in the English market. Far be it from me to do anything that would injure the business of one from whom I received much kindness, yet I cannot avoid saying that I think there is in Utica a good opening for any able photographer who would go in for high class photographic work.

From Utica to Saratoga is a long distance, but after leaving the former the latter was our next resting-place; and probably no two places in this great country are more unlike each other, or, perhaps, it would be more correct to say that Saratoga is unlike any other place in the Union. It is a city of huge hotels, big churches, and a number of shops out of all proportion to the number of its stationary inhabitants, the result being that for at least eight months of the year the principal hotels and most of the shops are shut, while the churches are much more than half empty. Saratoga during the season is, perhaps, one of the gayest towns in the world, and possesses some features that are altogether unique. It owes its origin to its possessing several mineral springs that are neither better nor worse than hundreds of others to be found in this as well as other countries; but a visit to Saratoga has become the fashion, and as Americans do everything on a gigantic scale this their favourite watering-place is no exception to the rule. How gigantic the scale is may be inferred from the fact that at least two of the hotels—the "United States" and the "Union"—can each accommodate something like three thousand guests; and not only are they generally full, but they frequently have to call into requisition private lodging-houses to accommodate their surplus guests. If it be borne in mind that the average charge for board is a guinea a day, it will be seen that these two hotels alone must take considerably over £500,000 during the season. It would be difficult to form anything like a correct estimate of the actual sum expended in Saratoga by the wealthy Americans who year by year spend a portion of their time there; but observation leads me to the belief that these two monstre hotels cannot represent more than a fifth of the boarding-house power in the place, and if that be nearly correct a sum of not less than two millions and a-half sterling is spent in Saratoga alone on seeing and being seen. This is certainly a large sum, but the proprietors in Saratoga make the most of what they have to show in everything except the town itself. The streets are badly paved, or not paved at all, and the buildings, the large hotels excepted, are very deficient in architectural beauty; but this is amply made up for, or supposed to be, by the care lavished on the park, in which the principal springs are situated. Good taste, however, does not always go hand in hand with lavish expenditure. In this case the effect is most wretched, the gaudy decorations in glaring primary colours giving an impression that it is part of a gigantic circus, or other show, and that Barnum—who, by-the-by, is a frequent visitor—had been employed to exercise his genius in making it what it is. Outside the town the roads are kept in first-rate order; and as every American who can afford, and a good many who cannot, drives his *span* or pair of horses, care has been taken to make the most of what is to be seen within the radius of a driving distance.

Of course, as my time was limited, I could not do much in that way, but certainly no one should go to Saratoga without visiting the geyser springs and the very beautiful lake. These really wonderful springs are about two and a-half miles to the south of Saratoga. They are each covered by a neat building, and play continually, each a perpetual fountain of highly-charged mineral and aerated water, which has already become famous all over the United States, and is sent off in thousands of dozens in clear, green glass quart bottles at the rate of about twelve shillings per dozen. It would probably be more correct to say that the jets might play continuously, as in consequence of the great demand for the bottled water the stream is made to flow into the bottling apparatus, and the jet only turned on when visitors arrive.

But probably the most charming and attractive object around Saratoga is the lake, which lies in a basin, about four miles to the east of the town. It is about nine miles long and a mile and a-half broad, and is reached by terraced walks and drives. Two steamers ply on its surface, and afford to the tourist or visitor an opportunity of enjoying a combination of the beauties of Loch Katrine and Windermere. High up on the banks, but level with the road, there is a fine hotel, from the piazza of which a fine view of the lake is obtained, and here during the season may at any time be seen hundreds of visitors absorbed in contemplating its beauties and eating *Saratoga potatoes.'* It is strange how some places obtain a reputation for particular articles. I have said in a former communication that the American tourist does not drink, at least in public. Under such circumstances, in the old country, few guests would be found without the accompaniment of bitter beer or the more potent whisky; but here there is nothing—at least visible—stronger than iced water, but, instead, everyone seems under the impression that the beauties of the scene can only be fully enjoyed while munching the dainty already mentioned, and for the preparation of which this hotel is famous. "Saratoga potato" is prepared by cutting the root into extremely thin slices or ribbons by a suitable machine, and then frying them in lard or other fatty matter. They are supplied to visitors in beautifully-white paper, twisted into the form of a cone or cornucopia; and so delicately is the process carried on, and so thoroughly is the surplus sebaceous matter removed, that the paper cone is not even soiled, and the ribbons may be picked out one by one with the most daintily-gloved hand without the glove being stained.

Of course where so many idle people, or people bent only on the pursuit of pleasure are found, photography is likely to come in for a fair share of patronage. Such photography, however, as is to be found at the average watering-places here as well as in Britain would not be tolerated. Visitors to Saratoga, as a rule, have long purses, and equally as a rule the purse is not without its influence. Although there may be, and undoubtedly is, an absence of a high appreciation of true art, the artist, if he wish to secure a large *clientèle*, must surround himself as much as possible with what is grand and imposing. Of the several establishments I visited the same may be said of each; that is, there is plenty of furniture of the richest description, fine specimens in attractive show-cases outside, and very indifferent work within. The idea conveyed by an examination of the whole seemed to be that the people went to be photographed more as a joke than with any idea of getting pictures for permanent use; or that sitting was more a result of the caprice of the hour, and the portraits intended to be simply amusing reminiscences of temporary acquaintanceships, to be forgotten within a brief period after returning to the sober realities of life. Under such circumstances one could hardly expect to find much striving after high-class work, and if he had he would have been wofully disappointed.

Albany, the picturesque capital of the State of New York, was our next halting-place. It is beautifully situated on the Hudson about a hundred and fifty miles from the city which gives the state its name, and, being built on the face of a hill or rising ground, the streets seem to rise in terraces one above another, with the recently rebuilt capitol as its crown. It is a thriving place as regards business, with a high opinion of itself and of everything belonging to it, and consequently also of its photographers—so far as the latter are concerned not without good reason. It must be true that fashion largely influences photography, otherwise how could we account for the fact that in some cities there is hardly a specimen of landscape or architectural photography to be seen, while in others such specimens are more numerous than portraits in the show-cases of the professional photographer? In Albany the latter is especially the case, and most of the specimens were of a high order of merit. Mr. Notman, of Montreal, who has a branch establishment here, showed a view of the new capitol as perfect in every respect as it is possible for an architectural photograph to be, and a group of the senators hardly less perfect. In the reception-room of Mr. Horton there were also some splendid portraits, from *carte* size up to at least 18 × 24, which in delicate detail and modelling without retouching, were equal to anything I had previously seen. No doubt there were one or two places where the ordinary inferior pictures were turned out, but, on the whole, the observations made regarding photography in Detroit are quite as applicable to that in Albany, and the result, as might be expected, is similar; each artist has as much to do as he can manage, while the prices are far above the average in towns of similar size.

JOHN NICOL, Ph.D.

THE TRUE ACTION OF A HORSE IN TROTTING DETERMINED BY PHOTOGRAPHY.

ONE of the most interesting and successful experiments ever made in connection with electro-photography was witnessed yesterday, at the race track at ex-Governor Stanford's ranch, at Palo Alto. For years past it has been a matter of grave discussion, not only among turfmen, but also with those who take an interest in trotting, as to the true action of a horse when in full stride, both in trotting and running, and the question was never satisfactorily settled until Mr. Muybridge, under the auspices of ex-Governor Stanford, instituted a series of costly experiments that have culminated in a grand success, and will open a new era in the photographic art.

The apparatus is very simple, but yet shows an immense deal of study, ingenuity, and foresight. On one side of the track was a rough shed, in which were the lenses and cameras, twelve in number, and on the opposite side was a huge screen of white canvas, stretched over a scantling fence, some thirty feet long and eight feet high, with a backward declination of some sixty degrees. On the upward edge of this canvas were shown the figures one to twenty consecutively, severed by vertical cords at twenty-one inches distant, and at the bottom of this canvas was a board showing horizontal lines that represented four, eight, and twelve inches above the level of the track. About two feet from the same canvas, but on the track, was a slight wooden ledge, and between the two, at every number between four and sixteen, was stretched a galvanic wire, at about an inch from the ground, each one connecting with its numbered lens on the opposite side, the wires being taken underneath the track. The investigation thus far was very simple, as it was apparent that the inner wheel would pass over the projecting wires, and by a simple arrangement on the other side would close the circuit. But, then, arose the question as to how this could be utilised to take a picture in the estimated incredible fraction of time of the two-thousandth part of a second—in which period the lenses had to be exposed and closed. This was effected by a very ingenious contrivance in the shutters of the camera, to the upper and lower parts of which were adjusted very powerful springs, and when the electric current was perfected they were released, and in crossing they exposed a space of about two inches, and in this space of time, that represented but a flash of lightning, the passing figure was fixed on the highly-sensitised glass even to the minutest details.

The ground over which the experiment was to be made being covered with slack lime, so as to catch even each footstep of the stride, all was duly prepared, and Abe Edgerton, with Charles Marvin holding the reins, appeared on the track to show by twelve almost instantaneous photographs the true story of the stride of the horse. Down the track came the gallant grey at about a 2:20 gait, and, never swerving an inch, despite the glare of the lime that glistened in the sun like a sheet of placid water, he dashed across the lines, the inner wheel touching each of the twelve wires and causing a regular but scarcely distinguishable clatter, and within those twelve cameras each part of his stride was fixed; that would conclusively show that the preconceived ideas of artists and horsemen were all wrong when based on the supposition that in that same stride two feet were never on the ground together. The negatives, as afterwards shown, are far clearer than can possibly be reproduced on paper.

In the first picture the horse's head is under No. 8 on the board, the second under No. 9, the third under No. 10, and so on, each partition of twenty-one inches showing the horse getting forward until the fifth, when he almost exactly reproduces with a change of legs the previous movements, completing the stride in about 18 feet $4\frac{1}{2}$ inches. The first and second positions are pretty natural, one hind foot being on the ground; in the third he has one fore foot planted square in front, while the other is doubled up like the crossing of a letter T; in the fourth position the same leg assumes the form of the loop of the letter P, while the other fore foot and a hind foot are planted straight and square on the ground, producing a most whimsical if not absurd effect, and at the fifth position the half stride is made, and the remainder is but a repetition. Each of the twelve pictures is about half-an-inch in height and three-quarters in length, and so minutely is each delicate line shown that not only are the spokes of the wheel distinct in form and shape, but even the whip in the driver's hand takes shape, and the horse's mane changes also at each part of the tail.

On examining carefully the footprints it is shown that the fore legs are used mainly as props, the imprint being clearly defined, while those of the hind legs, both at the front and rear of the foot, are so vague and enlarged as to show clearly where the propulsive power mostly lay.

It is impossible to state the astonishment that this most successful experiment caused in the minds of the spectators; but there was yet another surprise for them in the shape of photographing a horse at full gallop. To compass this there was necessarily a change in the proceedings, thread being stretched across the track connecting with each lens, through an ingenious contrivance that prevented any strain on the instruments. Then the noted mare, Sallie Gardiner, was sent at full gallop against the frail obstructions; but dazed by the glare of the white lines she hesitated a moment, then dashed on and made a bound again at the finish, thus presenting far from a perfect stride. But still she went fast, and her stride, eighteen and a-half inches, was but little beneath her normal action. The negatives, however, presented the most incongruous attitudes that ever could be conceived by a disjointed imagination, and they are as unlike that fine flowing stride we usually see depicted in our racehorses as are the movements of a dilapidated marionnette.

And here again are the preconceived ideas at fault that the horse bounded, landing his feet in regular succession. But it will be well to reserve an opinion on this subject until further experiments are made. In any case the result was most successful, and it is difficult to state to whom were addressed the heartiest congratulations—to ex-Governor Stanford for initiating the possibility of achieving this unexampled feat, and for the liberality with which he furnished the means for such costly experiments, or to Mr. Muybridge for the patience, skill, and perseverance with which he brought the affair to so happy a consummation.—*San Francisco Chronicle, June* 16.

Our Editorial Table.

PORTRAITS. By G. WATMOUGH WEBSTER, F.C.S.

ON opening a packet of portraits received for review from Mr. G. W. Webster, of Chester, we immediately recognised in these pictures the highest artistic qualities. Mr. Webster, as most photographers are aware, is a gentleman who has often contributed to the literature of our art-science, his literary and scientific essays never descending to the level of commonplace, but invariably being of an advanced and suggestive character. Mr. Webster not only "knows what is right" in the science and practice of photography, but, judging from these examples of his work, he has carried to a very high practical development his knowledge of art principles. It is seldom we find in a photographer a combination of scientific knowledge, artistic feeling, and practical, manipulative ability; but in this artist we have these qualities happily blended.

There are certain specimens from which we infer that Mr. Webster's method of working secures a degree of rapidity much greater than is usually met with. In proof of this we find among many charming portraits of children several which bear evidence of having been taken in a fractional part of a second. Others, in which dogs are introduced, testify to the same fact. Among the latter, one of the finest is a portrait of the Marchioness of Ormonde and three of her canine favourites, two of which are reposing respectively on the floor at her ladyship's feet and upon the chair, over which she leans snapping her fingers at the third, who is "reared" on his hind legs in response to the call of his noble mistress. It forms a very pretty picture, being replete with life and action. In a second picture of the same group the arrangements are different. Here we have a large retriever, his paws upon the back of the chair, "assisting" Lady Ormonde in inspecting a canine pet who has posed himself upon the seat of the chair.

Equally successful in pose and expression are portraits of Viscount Southwell, Lord Gerald Grosvenor, and the youthful Lady Margaret Grosvenor. Several of the portraits of children remind us of the happiest efforts of Faulkner and Boisonnas—names associated with graceful posing and that wonderful expression which in a photograph is so mainly dependent upon extreme rapidity of exposure.

The disposition of light and shadow in these portraits—which include several charming full-length cabinets—indicates a well-arranged studio; for, while the lights are pure and bright, the shadows are neither heavy or smudgy.

We hope to find Mr. Webster contributing some of these pictorial gems to the next London Photographic Exhibition, for we are certain that his metropolitan brethren will not be slow in recognising and appreciating their admirable qualities.

We are pleased to be able to add that Mr. Webster has, at our request, contributed to our present number an interesting article on the photographing of babies, to which we invite attention.

CLOUD NEGATIVES. By W. PERRY, Hythe, Kent.

SINCE we last acknowledged the receipt of a sample of cloud negatives by Mr. Perry, this artist has introduced further improvements, lying in the direction of getting rid of the texture or grain of the paper in a manner more thorough than heretofore, and also in imparting to the paper a greater degree of transparency.

We are not aware of the means employed by Mr. Perry to secure this increased transparency; but, by comparing those by his "new method" with some waxed-paper ones, we find that a decided step in advance has been made. With regard to the great utility of cloud negatives we need scarcely add to what we have already frequently said. The pure white skies, once the pride of the landscape photographer, cannot now be tolerated—thanks to the cultivation of a better taste among both photographers and the public; but, on the other hand, the difficulties of obtaining negatives of a high class in which the sky and clouds shall be rendered as perfectly as the landscape are well-nigh insuperable. In nine-tenths of the landscape negatives taken the sky presents an unbroken, monotonous tint, which in the print is both unnatural and inartistic. It is here that the cloud negative, by being judiciously introduced, imparts value to the photograph.

Meetings of Societies.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

THE half-yearly meeting of this Association was held on Wednesday evening, the 3rd instant, at 160a, Aldersgate-street.

The minutes of the previous meeting having been read and confirmed, the half-yearly statement was submitted to the Board by the Secretary and compared with the corresponding half-year of 1877. By this it was seen that the Association was making steady progress.

Miss M. C. Coates and Mr. R. E. Wilkinson were elected ordinary members of the Association.

Other minor affairs having baen dealt with, the meeting was then adjourned.

THE PHOTOGRAPHIC SECTION OF THE AMERICAN INSTITUTE.

AT the May meeting of this Society Mr. H. J. Newton presided. He said: I stated at the last meeting that I would show some emulsion portrait work at this meeting. I intended to have gone into some portrait galleries where I could have an opportunity of seeing the work done under a different light from my own; but I only had one—that of Mr. S. A. Thomas, forty-first street and sixth avenue—and I here exhibit a print from a negative there made by an exposure of two seconds. You will see that ample time was given. I also exhibit negatives made at my own gallery, with exposures of six and eight seconds—not more than one-fourth the time required by the bath process—and prints from the same.

The negatives and prints were very fine, and elicited much praise from those present.

The PRESIDENT, continuing, said: I have here a 4-4 negative, in the making of which I used Mr. Willis's oxalate of potash and ferrous oxalate developer; also prints from the negative. I experimented a very little with it through the last summer and fall. I also experimented with the oxalate of ammonia and soda, and got pictures with all of them, but much the best with the oxalate of potash. Until recently I had not given much attention to it, being engaged in other experiments; but within the last few months I have simplified it very much. That is what I try to do with every process, so as to make it generally practicable. Now with my emulsion I have aimed, after producing satisfactory results, to simplify it down to a point which makes it practicable and accessible to anybody in the business. This plate (exhibiting) was developed with the neutral oxalate of potash and ferrous oxalate, acidified with citric acid just sufficient to turn litmus paper red. The neutral oxalate was nearly a saturated solution. To that I added fifteen grains to the ounce of pulverised protosulphate of iron. My object was to get rid of that part of the process which required the manufacture of the ferrous oxalate as a separate salt. In these experiments I varied the quantity of iron from five to thirty-five grains to the ounce; but you gain nothing beyond saturation, as the ferrous oxalate precipitates after the solution is saturated. I found that fifteen grains would readily dissolve in the oxalate solution of the strength given. Such was the developer with which this negative was made, and it speaks for itself. It was slightly strengthened with the ordinary acid pyro. and silver, and a more perfect negative is rarely seen.

Mr. Duchochois: Do you find any difference in the time of exposure between the soda and ferrous oxalate developer?

Mr. Newton: I found that with the solution prepared in that way no longer exposure was necessary than with my carbonate of soda developer.

Mr. Chapman: Did you find any advantage in using that instead of the soda?

Mr. Newton: I was trying it, as I try any new thing, to see what there was in it. After I had satisfied my mind that it was a good developer or might be made so, or that it promised to be something of value to photographers, then I went to work to see how far it could be simplified and made more efficient. It is better than I have before made with any modification of this developer. As to the advantages, if any: in the first place this developer can be used over and over again with the same effect until it is considerably weakened; add a little more iron to it and its vigour is restored. A plate cannot be fogged with it if the solution is acid. That is my experience. It promises fair to be the developer of the future for this class of work. After making it in various ways, I find that that stated at a prior meeting was the most simple and attended with much the least trouble, which was to make a saturated solution of carbonate of potash in water (take what is called salts of tartar), and to that add oxalic acid in crystals. Of course, as soon as the oxalic acid comes into contact with the potash solution carbonic acid is evolved so rapidly that it keeps the crystals afloat on the surface; they are soon dissipated—all dissolved. When it becomes saturated some of the oxalate of potash is precipitated, and the natant liquor is a saturated solution which may be diluted as required. This developer was acidified with citric acid. I found by further experiment, however, that this extra trouble of acidifying at this point of the process could be avoided by making the oxalate of potash, when compounded, slightly acid with oxalic acid.

Dr. Nicol, of Edinburgh, was introduced to the Section by the President, with appropriate remarks in reference to his connection with the photographic press.

Mr. Gardner: I have had some little curiosity to know whether Mr. Newton's process was all that it purported to be. I visited his gallery for that purpose, and saw some of his pictures that we have been looking at here this evening. Several negatives were made while I was there—one of myself. As he has stated, his skylight is very small, and, at the same time, the sun was coming in on one portion of it; consequently I had to sit in the back part of the room, where to my eye it looked as though it might require thirty or forty seconds, at least, by any wet process any way, to get pictures. Mr. Newton made a picture in about six seconds. I also examined a number of negatives and saw they were remarkably smooth—that is not apparent in bath plates; and, I must say, I was somewhat converted to the emulsion process. So this evening I wrote this paper with the intention and purpose that, if I am mistaken in my judgment, if I overrate the thing or make any mistakes, it may be stated here and I may be corrected. I say that the specimens of emulsion pictures here exhibited are, in my judgment, conclusive proof that this method of working will produce as good results as any of the processes now in use where negatives are made by means of the silver bath. And it has a number of advantages over any of the bath processes. In the first place it is less expensive, for it does away with the use of about four-fifths of the nitrate of silver commonly used in photographic galleries. In the next place, it is not so liable to fluctuations—for every plate used in a negative bath reduces its strength, modifies its working condition—and the constant tendency is to uniform results. Besides, the bath, to keep it in anything like working order, has to be frequently clarified and strengthened; and to do this successfully no small amount of time and expert practice is required. Another advantage is that it does away with the retouching of negatives, and this is one of the most expensive items of negative making. Another advantage is its sensitiveness to light. With the emulsion process more negatives can be made in a day than can possibly be made by the old methods of working, for the time of exposure is reduced from one-third to one-half of the time necessary for bath plates. For out-door work it requires less luggage, and it is more certain in its results, as it admits of a greater latitude in the exposures, and is more under control in the development of the negative. Now, with all these advantages, viz., its less expensiveness, its greater certainty and uniformity of results, its saving of time and labour, its shortness of exposure, and the small amount of luggage required in practising outdoor photography — with all these advantages, I say, you would naturally think that every photographer would at once sell his bath to the silver refiner, and abandon for ever his old method of working. But you make a great mistake if you think so; and for the reasons, perhaps, that you do not take into account the power of habit, the influence of prejudice, the disposition to scepticism, and the dread and labour of learning anything new that requires an outlay of both time and money. The great advantage, therefore, to be derived from the emulsion process will, no doubt, be reaped by those who are yet to learn photography, and who can learn the use of emulsions quite as easily as that of the silver bath. The emulsion process has no doubt a long lease to run, and in the end will come out the victor; and if spirits be permitted to see the progress of mortals, our President will, no doubt, behold with delight in the vista of the future the fruits of his persevering and eminently philanthropic labours.

Mr. Chapman: You might say that it does away in a great measure with the retouching, but not entirely.

Dr. Nicol addressed some remarks to the Section, in the course of which he said: There is no doubt that the most of us workers have derived a great deal of benefit from Mr. Newton's emulsion. I have tried almost every modification, and my opinion is, at the present moment, that it is the best emulsion—you can get the most reliable plates. I speak of dry plates only, because I have never exposed an emulsion plate wet—mine is always dry work. The best emulsion is one containing just the merest trace of a free bromide—not with free silver, but with bromide. I have had no difficulty in getting density on very sensitive plates. I can usually guarantee a dozen good negatives from a dozen plates.

Mr. Newton: My experiments led me to adopt a chloride instead of a bromide for removing the free silver from emulsions. I use chloride instead of bromide on account of the retarding influence of bromide in excess. There is no retarding effect in chloride.

The proceedings shortly afterwards terminated.

Correspondence.

"TRANSATLANTIC NOTES."

To the Editors.

Gentlemen,—On reading the *Transatlantic Notes*, by Dr. Nicol, in your issue of the 28th ult., I was surprised to read the following:—"I feel bound to admit that neither in beauty, order, regularity, or apparently in business enterprise, are the towns in Canada equal to those of the States."

Now I think it rather unfair of Dr. Nicol to make such a sweeping assertion in contrasting the little town of Hamilton, which is scarcely sixty years old, and whose population is only 27,000, with the monster cities of the Union. If he had gone as far as Toronto or Montreal, I think he would have altered his opinion, and would have found something worthy of his approbation. The latter city is especially worth a visit, and is generally admitted to be one of the finest cities in the western continent. The site of Montreal—as you approach by steam boat, after passing under the Victoria Bridge with Mount Royal for a background, with its beautiful villas, interspersed here and there with tall spires and cupola towers, whose metal coverings glitter in the sun—is majestic, and for beauty almost unrivalled.

Here may be seen abundant evidences of business enterprise and energy—well-built streets, squares, good shops, and, in fact, all that you might expect to find in a place where a very large proportion of the inhabitants are Scotch. Dr. Nicol would have found himself at home there. Mr. Notman, the well-known photographer, would have given him a hearty welcome, and shown him work, perhaps, second to none in the States. I believe he employs upwards of fifty artists and assistants; so we may easily imagine the amount of business done in this one establishment. If my pen were as facile as Dr. Nicol's I might give you a glowing description of what I saw there, but I will not attempt it. Perhaps on his next visit to America he may be able to go as far as Montreal, when, I trust, he will qualify the remarks which have led me to trouble you with this communication.

Dr. Nicol also states:—"It may be that there is as much business done, and that the business men among the Canadians are as wealthy as their American brethren; but there is certainly no visible evidence of it in their homes, either externally or internally, or in the 'dash' and 'go' everywhere seen in the States." That is just the difference, and I admit the "dash" and "go," swagger, bounce, and ostentation which is so conspicuous in the Yankee "boss" is absent in the Canadian; the latter are more thoroughly English in their style. I was frequently asked in the States if I did not think the "old country" was nearly "played out;" perhaps they thought so.

Having visited some of the largest cities in the United States and Canada, I trust I may be excused for giving my views in opposition to those of Dr. Nicol.—I am, yours, &c., T. Protheroe.

Bristol, July 3, 1878.

The Forthcoming Eclipse of the Sun.—The White Star steamer "Germanic" sailed from Liverpool on Thursday, the 4th inst., for New York. Amongst her passengers were Mr. A. Cowper Ranyard, Fellow and Hon. Secretary of the Royal Astronomical Society; Mr. F. C. Penrose, F.R.A.S.; Mr. Giles Loder, Mr. Arthur Schuster, and Mr. T. E. Thorpe. All these gentlemen are *en route* for Denver, Colorado, to witness and take observations of the total eclipse of the sun, which takes place next month. The eclipse is invisible in England, but is visible in its totality at Denver, which is in the centre of the line of observation. Mr. Ranyard, the senior member of the astronomical party, has the special object in view of photographing the corona, and for that purpose takes out an instrument which is exciting much interest amongst astronomers on account of its unusual size and power, viz., a thirteen-inch refractor.

EXCHANGE COLUMN.

We will exchange a Ross's seven-inch focus portrait lens, in perfect condition, for a rectilinear (rapid) of similar value.—Address, Ross and Paton, Hamilton, N.B.

Wanted, an alpinestock camera-stand and quarter-plate or 5 × 4 camera, with two single and double slides, in exchange for any of the following:—Studio camera-stand, box tent for 10 × 8 plates, Chadwick's oxygen retort, or whole-plate camera, with one double slide only.—Address, E. J. Chesterman, 12, Chipping-house-road, Sharron, Sheffield.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

To Correspondents.—Several letters which have been received during a brief absence from home, and to which *private* replies have been requested or are necessary, are receiving due attention. All such communications will be speedily answered.

Electro (Paisley).—We have received the shutter, and will give it a trial.

Geo. Smith, Jun.—A solution of caustic potash will precipitate the oxide of silver from the nitrate.

J. Barclay.—The fact of plates having been developed by tannin, coffee, and tea has long been known.

E. W. P.—Carbon pictures may be intensified by a variety of agents, such as iron, manganese, lead, and silver.

W. R. P.—The degree of heat at present is not so great as to interfere seriously with the preparation of gelatino-bromide plates.

Vox Humana.—A tolerably safe estimate of the quantity of chloride of gold required will be one grain for each sheet of paper.

B. B. B.—No photographic directory has hitherto been published; and it is not at all probable that such a work will ever be issued.

J. P.—We have an impression that the patent is still in force; if this impression be correct it will be more than a year ere the patent expires.

G. B. L.—We are much pleased to learn that you followed our advice, and that by doing so everything was arranged in such a satisfactory manner.

Old Sub.—Try the following:—Iodide of potassium, six grains; bromide of potassium and chloride of soda, of each five grains; water, two ounces.

Alfred.—Chlorise the image by applying to the surface of the plate a solution of bichromate of potash to which a few drops of hydrochloric acid have been added.

F. J. O'B.—The signatures will not be required. Supply such other particulars as you are able to do, numbering each figure for convenience of reference.

Geo. Spence.—If you call at our Publishing Office you will have an opportunity of looking through the file of the Journal and selecting such numbers as are required.

Largo.—Obtain a larger condenser. That which you now make use of is too small. It ought to be ten or twelve inches in diameter at least—if twenty inches so much the better.

E. Grant.—The matter is, we think, one for a solicitor. If you have *not* paid, the affair is exceedingly simple; you have merely to state the grounds upon which you refuse to do so.

M. D. H.—Not so; read the article again, and you will find that precisely the opposite to what you quote is stated. You have mistaken convexity for concavity—that is all; but it is much.

G. M.—The signature is merely a *nom de plume*, as surmised by you. It would be contrary to journalistic etiquette to divulge the name of the writer so long as he does not wish this to be done.

Geo. Richardson.—If you mix a little albumen with the gelatine the desired property will be secured. The albumen must be beaten up and poured slowly into the liquefied gelatine, which must be well stirred all the time.

P. T. A.—We, too, have felt the want of such a piece of apparatus as that at which you hint; but we must continue to wait patiently until some mechanician or maker of apparatus will devote his inventive faculties to the subject.

V. H. Z.—On referring to our volume for 1875 you will find a brief series of articles on polarised light, and in one a full account of the Nicol prism is given, illustrated by a diagram in which its influence upon a ray of light is shown.

Harding.—Without examining the lens it is scarcely possible to pronounce who was the maker, but we think it probable that it was manufactured by the late J. T. Goddard—that is, if your description be correct. The lenses of this optician enjoyed a high reputation.

T. J. P.—The markings on the Fothergill plates are caused by inequalities of temperature during drying. This is so certainly the case that we will undertake to produce a drying-mark by merely lifting up the cover of the drying-box for a few seconds and then replacing it.

H. F. Kay.—If the transfer has been allowed to become quite dry previous to being removed the surface will be glossy, receiving the pigment with facility and without any preparation. Numerous articles have been published on the transfer process, but no work has been exclusively devoted to it.

W. D. H.—A dry plate will not be required for your purpose, seeing that a wet collodion plate will retain its good properties unimpaired for all the time—an hour—you wish to keep it. Let the plate be sensitised for nearly the full time, then remove it and immerse in a silver bath of the strength of twelve grains to the ounce. Drain thoroughly and place behind it in the dark slide a sheet of moist blotting-paper. The slide should then be wrapped up in india-rubber cloth.

L. S. D.—1. The name of the photographer and also the title of the picture will this year be permitted to be exhibited upon the frames of the pictures at the forthcoming photographic exhibition.—2. Yes; the charge will be a shilling per square foot for wall space. This, it will be found upon reflection, is only fair and reasonable.

Cygnus.—In sliding the lens towards the top of the camera let its parallelism to the base be carefully preserved. We are assuming that the back of the camera cannot swing. In the case of a swing-back the lens may, with advantage, be moved so as to have its axis at a right angle to the plane of the ground glass, but this will not always prove advantageous.

E. E. B.—The collodion employed has not been one quite suited for the purpose. Let it be somewhat old, and such as will yield a soft, thin picture full of detail. The tone of the three-quarter figure is excellent; but, owing to the obliteration of detail in the shadows, it presents a harsh appearance. Try the effect of thinning the collodion by the addition of nearly its own volume of ether and alcohol.

P. T. Richardson.—We advise you not to allow anything to be done with the lens. A small chip at the margin, although it might interfere with the saleableness of the lens, will not interfere with its working, except in so far as it reflects light upon the plate. But this it will not do if the fractured patch be painted over with opaque black varnish, which may be applied by means of a camel's-hair brush.

A. C. (Morpeth.)—1. A collodion positive upon glass cannot be fitted into a locket by the method you propose, as the edges would be sure to present a broken and rugged appearance. By employing a pair of sharp cutting-pliers, guided by such skill as can only be acquired by practice, a smooth and unbroken-looking edge can be obtained. So smooth will it be as to render quite unnecessary the employment of a mat.—2. Any jewellery "factor" in Birmingham will be able to obtain, and supply you with, an assortment of oval mats for brooches and lockets.

Received.—John J. Atkinson; J. W. Gough (Durbhanga); W. Washam.

The Jurors at the French Exhibition.—If the Paris correspondent of the *Leeds Mercury* be correctly informed, the jury work at the French exhibition is understood to promise much greater thoroughness of performance than at some previous exhibitions. Members are informed, he observes, they must be prepared for a month's hard work. This, in the case of unpaid gentlemen whose services are often required for their own business, is rather hard. Great courtesy is shown by the French in nominating foreigners, and especially Englishman, to posts of distinction. Thus Mr. John Berger Spence, the well-known chemical manufacturer, was offered the vice-presidency of that section, but he felt himself obliged to decline it, owing to his engagements at home preventing his being always on the spot to replace the president if necessary. The jurors in some cases appear to hold a sort of clinical lecture, each one expressing his views as to the object of examination, and giving rise to a short discussion. This was done in the photographic class, where the members present spent a long time over a collection of specimens of sun pictures, from the earliest attempts of Daguerre and his predecessors down to the most finished modern results. If this workmanlike procedure is kept up, we shall not see any of the scandals of Vienna repeated, where three gold medals were awarded to names in the catalogue whose goods never figured in the exhibition, and where a lawn mower obtained a prize for "sweetness of tone" through its proximity to a stand of organs!—This will be suggestive of the labours of a jury at the North London Exhibition several years ago—a body which awarded medals for the excellence of lenses the show cases containing which had never been unlocked by these *examiners!*

JOURNAL OF PHOTOGRAPHY.

No. 950. Vol. XXV.—JULY 19, 1878.

WINDOW PORTRAITURE.

It is by no means an uncommon statement, and one which has almost come to be accepted as an axiom, that an amateur cannot hope to aspire to the same degree of excellence in portraiture as the professional; and the comparatively limited extent to which that branch of photography is worked by the former class, and the general quality of the results produced, tend to prove at least the prevalence of the idea if not its truth. In landscape work amateur and professional meet upon equal ground in all respects but one, *i.e.*, the relative amount of time which each is able to devote to the practice of the art—a condition which must plainly have a more or less important bearing upon the degree of skill acquired by the operator and upon the quality of his results. But in portraiture the amateur is placed at a still greater disadvantage, inasmuch as but few of them can afford or find it worth their while to maintain a properly-arranged studio for the special purpose. Even if the photographer be the fortunate possessor of a greenhouse or conservatory he is little better placed in this respect, as the arrangements necessary for the practice of portraiture go far to unfit it for its legitimate use.

We have, however, on several occasions pointed out that a glass-room, such as is employed by the professional portraitist, is by no means an absolute necessity in the limited practice of an amateur; and, though the system of lighting adopted in ordinary apartments would prove wholly inadequate to the requirements of the former, the latter—if he be not too ambitious—may under such conditions produce work of a certain class possessing the highest degree of artistic as well as technical excellence. We are aware of many attempts to practice what we have termed "window portraiture," some of which have been entirely successful—others, and perhaps the majority, have proved partial or total failures; and, as there appears to be a growing fancy for portraiture amongst amateurs, it may not be out of place on our part to add to what has been already written upon the subject, and to point out the probable causes of many of the failures.

In the first place, then, perhaps the chief cause of failure arises from the attempt to do too much. It is obviously useless to expect an ordinary apartment, however much be-windowed it may be, to enter into competition upon equal terms with a properly-constructed studio, either as regards the amount of light available or the effects of lighting obtainable. It is a tolerably self-evident fact that the amount of light admitted will depend upon the size of the window; but an equally important element is frequently overlooked—the shape and position of the window. We need not enter into a dissertation on the construction of a studio or of the best form of roof or window; but merely allude to the principle it involves, in order to show in what manner the form of the window, independent of its size, may modify the quantity of available light admitted.

The source of illumination is, of course, the reflection from the sky (direct sunlight, for obvious reasons, we omit from the calculation). With a given size of skylight, in order to admit the greatest amount of light, it is necessary that it be placed at such an angle that an imaginary straight line, drawn from the sitter to the most highly-illuminated portion of the sky, shall fall perpendicularly upon the centre of its plane. This secures the largest possible angle of illumination. But to construct a roof strictly on this principle would be impossible, since its "pitch" would require to vary continually with the seasons and with the time of day; hence it is necessary to select a fixed angle which shall be most generally useful, and this is found to be from 35° to 45°.

A simple diagram will show that in proportion to the vertical measurement of the opening an ordinary window transmits considerably less direct light from the sky than a pitched roof, but that it also admits a large quantity of diffused light reflected from local terrestrial objects, which the latter does not. It will also be seen that the higher the window is placed from the floor the greater will be the distance at which the sitter may be placed, in order to secure the greatest amount of direct light, and that in any case a point is reached at which the illumination depends entirely upon the feeble reflection from local objects. It is needless to say that the actinic value of the two descriptions of light is very great; but the eye being accustomed to the ordinary illumination of an interior fails to take cognisance of this difference as the camera does, hence the cause of many failures. We have two conflicting interests to study: the optical arrangements require a certain distance between the camera and the sitter, to secure which, in combination with an even illumination, the latter must be placed at a considerable distance from the window; on the other hand, in order that the exposure may be brought within reasonable limits it is absolutely necessary that the sitter be placed in close proximity to the window, which entails the removal of the camera to such a position that the greater portion of the figure is in deep shadow.

To reconcile these conflicting conditions, then, is the object we must have in view, and the first thing to be observed is that we do not attempt more than the circumstances permit us to perform. Thus the proper illumination of a full length figure is obviously more difficult of attainment with our limited supply of light than a bust or vignette, and indeed, save under very exceptional conditions, is almost an impossibility. We therefore advise, as the first step towards success, that this style of portraiture be confined to the production of busts or, at the most, half lengths. This not only reduces the area to be illuminated, but permits the sitter to be placed within two or three feet of the window, and, at the same time, enables us to bring a reflector into operation on the shaded side of the figure without its interfering with the picture, which, in the case of a full length, is extremely difficult, if not impossible.

In order to obtain a well-lighted face it will be necessary to devote a little study to the peculiarities of this style of illumination, and to bear well in mind the fact that the shadows will appear much darker in the photograph than to the eye; indeed, the chief difficulty rests in trusting too much to the appearance of the sitter without considering the low actinic power of the light reflected from the walls of the apartment. The first mistake which will be made is in placing the sitter *facing* the light; this not only tries the eyes and produces an unnatural and constrained expression, but it necessitates placing the camera in such a position that the greater portion of the face is in shadow, or the lines and hollows of the features are intensified to an unpleasant extent.

It is, of course, impossible to lay down any fixed rule for posing the sitter without knowing the conditions under which the operation is to be performed, but in a general way the following remarks will be found useful:—Let the relative positions of the camera and sitter be such that a line drawn from one to the other will run parallel with the window. If the latter be of such proportions that the sitter can be placed four or five feet distant from it it will be possible to place the camera much nearer the wall and thus get on the lighted side of the figure, which should be almost but not quite clear of the window on the side most distant from the camera. By this means we secure more of a front light, and the shadows on the far side of the face are softened down. The eyes of the sitter should be directed *into* the room so as to present the lighted side of the face to the camera; it is not well to carry this too far, however, or a shadow will be cast by the line of the cheek, especially if prominent. Finally, a reflector of some sort will be absolutely necessary to the production of a harmonius result; for this purpose we have used a variety of materials, but nothing answers better, or is easier of management, than a sheet hung upon a light framework, and placed as close to the figure as circumstances will permit.

Of course, as the operator becomes familiar with the light numerous effects will suggest themselves; indeed, there is scarcely any sort of lighting which cannot be produced by a judicious use of screens and reflectors. In the matter of exposure very much will, of course, depend upon individual circumstances; but, while not nearly so rapid as in a properly-constructed studio, the time will not be found too prolonged for sitters of ordinary steadiness. We have seen a fully-exposed and well-modelled picture the result of ten seconds' exposure upon a rapid dry collodion plate; and with films of only moderate sensitiveness, used dry, twenty-five to thirty seconds' exposure proved ample. With gelatine plates or wet emulsion the time would be considerably reduced.

So far our remarks have referred entirely to indoor photography, but it is possible to work in a slightly modified manner. We have seen some very charming results produced by placing the sitter in a room on the ground floor and the camera in the garden, the exposure being made through the open window; and where circumstances permit this is, perhaps, the easiest plan of operation. We have said nothing of the employment of a mirror interposed between the sitter and the lens; but in some cases—as, for instance, when space is limited or where reversed negatives are required — this method will recommend itself, and presents no special peculiarity in manipulation.

THE CONSTRUCTION OF WATER TANKS.

The making and maintenance in proper condition of the various tanks, troughs, and sinks required in establishments of even the smallest pretensions is always a matter of considerable importance; and, now that carbon printing is becoming so much more general, the occasions are many in which professional photographers find that an entirely new series of troughs has to be constructed. We have, therefore, thought it would be useful to some of our readers to lay before them for their consideration a few details of various plans adopted, together with some *data* to work from with regard to their comparative cost and the wear and tear they will sustain.

For general dark-room work nothing, perhaps, is more common than wooden trays or troughs kept well painted. They are pretty efficient if properly made in the first instance, the joints being secured, if possible, by white lead, and a good number of coats of paint laid on afterwards. They are, however, liable to separate at the joints, or otherwise to leak rather badly; but to some extent this can be remedied by using the best and driest timber of which to construct the troughs, and instead of painting them to coat them with some kind of bituminous varnish, such as the best "Brunswick black" (not "black Japan"), which forms a very tenacious and useful surface, there being some troughs so made which are, to our own knowledge, seven or eight years' old, and still apparently as good as when new.

Gutta-percha has been used for this purpose, but it is apt to get hard and brittle in time, and is besides not by any means an inexpensive material. A former well-known contributor to these pages described a sink of his own contrivance which answered very satisfactorily. It was primarily a wooden trough of the usual kind, made water-tight by stretching over it a sheet of the thin india-rubber that can be purchased from almost any shop where india-rubber goods are sold.

But the most efficient, substantial, and enduring tanks are those made of slate slabs, or wood lined with metal—zinc or lead. We confess to a predilection for slate tanks. They are so easily cleaned, will withstand all chemicals, and are, generally, so pleasant to work with that we think everyone will endorse our opinion who has had opportunities of giving them a trial. But their great weight and want of portability is a serious drawback. When premises are to be altered or a change is contemplated in the internal arrangement of the laboratory or dark room, these immovable articles, when of considerable size, are too frequently in the way, and often prevent the carrying out of many of those little details of working that go to make a perfect whole.

Zinc or lead-covered wooden structures, therefore, remain to be discussed, and there is not much doubt that the former, from its greater cheapness—that is, for a given amount of superficies—is preferable. But we would here point out that, though cheaper, it is possible for zinc to be less economical; for it is always used so much thinner than its rival, lead, that it will not stand much wear and tear, and it is quite out of the question to use it for holding or carrying off chemicals. Acetic acid, citric acid, and hydrochloric acid—all of common use in wet-plate work—will dissolve it with the greatest ease, and if not rigidly excluded (a difficult matter in studios where many hands are employed) they would cause holes to be formed in a very short time. Another objection to zinc is the difficulty there is in making it lie flat and even. Owing to its rigidity, compared with lead, it is next to impossible to make, for instance, the bottom of a washing tank quite flat and level. The effect of this drawback is to increase the quantity of fluid which is required to be put in the tank before a plate of glass or a sheet of paper could be entirely covered by the contained liquid—a consideration of some importance in developing carbon prints with a limited supply of hot water.

We have had an opportunity of comparing notes with a photographer who three years ago had fitted up an extensive series of zinc troughs for carbon work. He informs us that the strictest orders were given to keep out all chemicals, and yet he discovered the junior hands in more instances than one pouring acid water from plate cleaning into one of the less-used troughs. The result of that and other causes has been that on the prominences caused by the "buckling" of the zinc a number of minute holes were formed, and made their existence evident by the water finding its way through them and leaking out of another part of the wood casing, thus rendering it most difficult to find the source of the leaks in the metal. It was only after a considerable time that he discovered the true state of the case, the presence of the holes not being anticipated, search thus being made in the wrong direction.

It is evident, therefore, that lead—whose good chemical resisting properties and power of standing rough usage are well known—must form the most suitable material for all such purposes, and to any photographer who contemplates fitting up tank work for carbon printing we strongly advise its use in preference to zinc.

It is, of course, very much more expensive, comparatively, at first; but in case of alteration it can always be disposed of for almost its original cost, while, again, it is made up more cheaply than zinc. We have instituted some inquiries as to the relative expense of the two kinds of sheets respectively, from which our readers can make their own calculations. Both materials are sold by weight. Sheet lead suitable for such troughs is sold at about threepence per pound, a suitable thickness weighing three pounds for every foot, thus making the cost one shilling per foot. Sheet zinc costs about fivepence per pound, but, when of common thickness, weighs only three-quarters of a pound to the foot, the cost being under fourpence per foot. The thickness known as "number twenty-five gauge" is what would be usually supplied by the zinc worker, and this, being nearly ·02 foot in thickness, its easy penetrability with the slightest rough usage could be predicted safely.

We think our readers have here sufficient *data* to form their own conclusions; and we hope to hear that the desire to introduce carbon working may cause the erection of many more lead troughs before the year expires.

There are many amongst our readers who follow not only the chemical and artistic branches of photography, but also find pleasure and occupation during the winter months in the various mechanical departments connected with the art, and not a few have proved themselves no mean adepts in the planning and construction of the various pieces of apparatus in general use. We had an opportunity recently of examining a camera of amateur construction, which, in addition to the ordinary arrangements combined in such instruments, presented one or two novelties worthy of adoption by those who delight in the construction of their own apparatus, as well as by the professional manufacturer of such articles. The first was a novel method of hinging the shutters of the dark slide, or, more correctly speaking, a substitute for hinges. Everyone who is acquainted with the operation is aware that a very great amount of care is necessary in making the hinged joint, in order to combine neatness of appearance and a total exclusion of light; while those who have worked much in the field know how easily the hinges become strained and the joints leaky, especially when using large sizes or in windy weather. The adoption of the novelty we are about to describe causes all these troubles to disappear, without in the slightest degree interfering with the convenience and utility of the slide. The shutter when closed presents no difference in appearance, except that the two hinges are replaced by a pair of plain brass plates of similar or slightly smaller size. Upon drawing out the shutter, however, to its full extent, the larger portion (which usually folds to the side of the camera) becomes wholly detached, leaving the shorter piece remaining in the slot to prevent the access of light to the plate during exposure. Upon examining the detached portion it is found that the under sides of the brass plates (which now project over the woodwork) are furnished with a short pin each, the pins fitting into corresponding holes in the shorter part of the shutter. In this manner they act as clamps to keep the two portions of the shutter in close contact until the longer one is drawn clear of the grooves in which it works, when it may be "unhooked," and all danger of tremor in the camera or of injury to the shutter itself by the wind or accidents is removed. The exposure completed the pins are re-inserted in their sockets and the slide pushed home, when the two portions are again as firmly held together as if attached by hinges. The second novelty consists in the arrangement of the swing back. In ordinary landscape work the swing back is rarely required, but cases do present themselves occasionally where it is useful, while for architectural subjects it is a necessity; for which reason many operators are loath to dispense with it although deploring the increase of bulk it gives to the camera. This difficulty is surmounted in the following manner:—The ordinary fixed centres upon which the body swings are replaced by a couple of milled-headed screws working in corresponding nuts attached to the back of the camera. The screws when loosened slide in horizontal slots in the side plates connecting the back part of the camera to the central body, and at each end of the slots there is a depression into which the shanks of the screws drop when pushed to either end. The edges of the two portions of the body are cut square so as to fit closely together when closed, and thus the space usually cut away to allow the swing is saved. When thus packed the camera is virtually without a swing back, but by loosening the binding screws and changing their position to the opposite end of the slots the swing comes into operation, the back being retained in any desired position by again tightening the screws. As a swing back the arrangement is neater than, and equally as efficient as, the ordinary system, while it has the advantage of the decreased bulk of the non-swing-back camera. We have pleasure in recommending these two "innovations" to the notice of those interested.

A PLEA FOR EXTRA SENSITIVENESS.

The article in last week's issue questioning the desirability of great sensitiveness in dry plates will, I think, be challenged by many in spirit if not in writing. I know of many who are not likely to go back to plates requiring long exposures.

The drawback in quick plates which you appear to lay most stress on—namely, the difficulty in giving correct exposures—I fail to see. If a tannin plate require (say) five *minutes* and a gelatine five *seconds* for correct exposures, why should it be more easy to expose the former correctly than the latter? You say (if you will excuse my quoting) that a minute or two more or less may possibly not greatly influence the result in a slow plate; but I conceive that it influences it *precisely* in the same proportion as in the more rapid one, let the exposure be hours, minutes, or seconds. If two plates require respectively five minutes and five seconds for correct exposures they will be equally over-exposed if they receive respectively six minutes and six seconds. The same difficulty lies with each—the quick *and* the slow—properly to judge the time required for them; and when that is arrived at the rest is a mechanical arrangement of uncapping and capping the lens common to both. I could refer to several professional and amateur photographers who can expose gelatine, washed collodion, or tannin plates almost to a certainty and with *equal exactness*, whether it be they have to count minutes or seconds.

The quality of the negative is another matter—I presume you allude to the printing qualities; but as you say "the quality of the result," it may refer simply to the prettiness of the negative, in which case, perhaps, collodio-albumen might hold the palm against any other process. As regards printing qualities, however, I always reckon that the more sensitive the plate the softer the print, and the greater amount of detail in the shadows—details which are altogether omitted in the slower plates. Suppose that you expose a tannin or any other kind of plate that requires a matter of minutes for exposure—subject: looking down a stream, heavy foliage on both sides and depicted on each side of the focussing-glass, and say the correct time is two minutes for exposure—now, I have had enough experience with these slow plates to say that if you left the plate exposed twenty minutes you would not get the trace on your negative of a piece of dark rock which, we will say, you can just see *ought* to be in the negative on one of the margins of the plate. It ought to be there, because, although the rock is shaded by the trees, it is visible to the unassisted eye, and is within the field of the lens. You might expose the plate until the sky and water were completely solarised, but those very shaded details do not appear on the negative. Apply now a gelatino- or even a good washed collodio-emulsion, such as are now advertised as "quicker than wet," and in either case you get the detail. The more sensitive the plate the more *equally* do all the different gradations of light act upon the plate.

Take another subject—say a man twenty yards off, who happens to be standing in your field of view with his hat on, illumined by direct sunlight: the forehead, with tannin or collodio-albumen, is not represented; it is a black shadow and nothing more. With a wet plate you may get slight detail, but most probably still a blank; with a good washed collodio-emulsion you get a little detail; but with a gelatino-bromide plate it is represented as in nature. You say—"Let anyone who doubts this explain why wet-plate work, as a rule, is superior to dry." I think the passage might have read why a wet plate is superior in some respects to a dry one—the "some respects" referring to regularity of appearance and *regularity* of printing qualities, because with a wet plate and a gelatine one no one can well deny that, supposing they have both been properly exposed for the high lights, the latter has infinitely more detail in the shadows than the former.

Many of your readers, I think, will now only allow the precedence as regards regularity, and the reason to me is obvious: the operator has his tent, and his first exposure, if incorrect, can be rectified in the next. Should a plate be faulty he can try again, and he leaves the spot only when he has secured a good negative. The inferior ones (supposing him to have perpetrated a bad one) are not brought home. But this does not occur with the much-to-be-pitied dry-plate worker; this unfortunate man, whether he be "slow" or "quick," carries them all home faithfully in his changing-box, right or wrong. Give him the same facilities the wet-plate worker has, viz., a tent, &c., and there is no reason why after once having tested his plate he should not work with the same regularity with regard to the appearance of his plates as the happy wet-plate worker. The reason in my mind why so much irregularity appears in a batch of exposed dry plates—the result of a day's photographing—is that, in consequence of the difficulty of hitting the right exposures without first having had the advantage of being able to test a plate on the spot, the operator, by using more or less pyro. or ammonia or silver in order to thereby correct in his operating-room the faulty exposures made in the field, alters and makes irregular the tones of his negative—a fault which is common to *both* quick and slow plates. With those, however, who are most apt, and those who have the most experience in the field, this fault is reduced to a minimum, and the working is now brought by some to a certainty perhaps greater than can be obtained with the wet process. C. BENNETT.

DEVELOPMENT AND RAPIDITY.

WITH respect to the letter of "R. D. P.," which appeared in THE BRITISH JOURNAL OF PHOTOGRAPHY of the 5th instant, I have first of all to offer as an explanation of my not having sooner alluded to it the fact of my having been on the continent visiting, among other scenes, the great international exhibition in Paris, from whence I have only just returned.

While I quite agree with all that the Editors have said respecting the action of the various kinds of alum, I think that the Edinburgh correspondent who makes use of the above initials will, upon investigation, find a clue to all his troubles by detecting that his sample of alum contains a chloride. This he can easily ascertain by making a solution of the alum in distilled water and adding to it a solution of nitrate of silver. The formation of a white, flocculent precipitate (chloride of silver) will determine this point. Should such a precipitate be formed the probability is that the alum contains a chloride.

I have now to direct attention to another matter. It is still fresh in the recollection of the readers of this Journal that M. Boissonnas, of Geneva, exhibited in London last year a number of portraits of children and groups taken with extreme rapidity; and it is almost equally well known that M. Klary is giving demonstrations of the rapidity of this process to those visitors to the French exhibition who choose to call for that purpose at the studio of M. Franck, of Paris. Being desirous of ascertaining for myself the precise ratio of the sensitiveness said to be obtained by the Boissonnas' method, I took to Paris with me a portion of my own collodion, bath, and developer such as are in regular use in my studio in King William-street, and by the courtesy of MM. Boissonnas and Klary was permitted on more than one occasion to try my chemicals and method of working against theirs. Seeing that I was successful in this competition the result could not be otherwise than gratifying to me, and both of the gentlemen named did me the honour of asserting their belief that I worked with a briefer exposure than any other photographer whom they had met. I explained to them that I made use of a process in which there was little, if anything, that could be termed new, and that the great rapidity was mainly due to the wonderful clearness of the Paris light, which I found to be greatly superior in actinism to that of London.

Having been informed by M. Klary that he intends visiting London in a few days to demonstrate the Boisonnais' process, I have offered him the use of one of my studios provided he can satisfy me that there is something really novel or good in his method of working. In the meantime I shall, in a short time, have great pleasure in sending to this Journal for publication the fullest details, including formulæ, &c., of the method I adopted on the competitive occasion referred to. A. L. HENDERSON.

PHOTO-ENGRAVING.

THE above heading, properly speaking, would include a great deal more than could possibly be embraced in a magazine article, even in the most condensed form. I therefore intend to treat only of the method practised in obtaining relief plates in metal from line or stipple pictures, of which the illustration in this number is a sample. This picture is a reproduction of a steel-plate engraving published in the London *Art Journal*, by the process invented by Mr. L. E. Levy and myself, and which we patented in 1875. Of the merits of the picture I will leave the intelligent reader to judge. I believe, however, that it is as close a reproduction of the original as could be obtained *in a relief plate*, as it must be borne in mind that these prints are made by the ordinary printing press, and are not like the *intaglio prints* from the original plate, but, as compared to those, very cheap productions.

Of the influence exerted by the various and steady improvements in photo-mechanical processes within the last fifteen years on the profession it is almost impossible to form an estimate. It has placed photography in the front rank of the graphic arts. Who that has seen the productions of the Albertype, Woodburytype, heliotype, and other similar processes for half-tone work, and the reproductions by photolithography, photogravure, and last, but not least, the multitude of newspaper and book illustrations by photo-relief plates, such as the illustration in this number, has not felt on beholding them that photography, as a profession, was worthy of the greatest effort and the most subtle skill, and that its practical application extended to almost boundless limits! And all these are produced by the direct agency of the camera.

Since the first rough proofs by Paul Pretsch, of Vienna, were exhibited, the progress in this branch of the art has exceeded the most extravagant anticipations. Very few can appreciate the patience and effort of the comparatively few workers in this direction—the difficulties, disappointments, and repeated failures that had to be overcome by them before success had crowned their efforts; as it must be remembered that all these inventors had to treat with a very peculiar and (until recently) unreliable agent—gelatine rendered sensitive to light by the chrome salts.

The following is the method employed for obtaining relief plates in metal from line and stipple work and engravings, as practised by the Bachrach Photo-Engraving Company, of Baltimore, and the Levytype Company, of Philadelphia.

First, as to the original. When it is a print of any kind, it should be in pure black on a white surface to produce the best results. When it is a drawing or original design, it should be made with a pen in thick black India ink or colour, every line clear and distinct, on white paper, or, still better, enamelled cardboard, as the enamel can be easily scratched away for an erasure, or when a line is too thick, &c. The best results are obtained when the drawing is two or three times as large as desired, and the lines made in proportion, so as not to be too close or too wide apart for the proper effect.

The next, and almost the most important, part of the process (and this applies to photolithography as well), is the making of the negative. First, it must be extremely sharp to the edge, the lines being absolutely rectilinear, and only the best lenses can be used for this purpose. The sensitive plate must be absolutely plumb with the picture on the copying-board, and the exposure must only be just sufficient to give absolutely clear glass in the lines. The opacity must be as great as possible in the lights, and for this purpose I will give a special method of intensifying. I will here remark that unless the negative comes up to these requirements all subsequent steps will result in failure. The best collodion for the purpose is that containing very little of the bromide and a large proportion of the iodide salts. I prefer a bath made in the usual way, and then fused to the "oily" state, with which method, no doubt, all are familiar. It should be neutral, or very slightly acid. It must be remembered that the result aimed at is the very opposite of what we strive for in our usual work—that is, we want absolute blacks and whites. The double sulphate of iron and ammonia is the best developer when used with a large proportion of acid, it having the least liability to deposit on the blacks. I use glycerine with my acetic acid No. 8 in the proportion of one ounce to one pound of the acid. It is also a help in this direction. The fixing must be done with cyanide of potassium, and the plate then thoroughly washed. I next flow over a solution composed of one ounce of sulphate of copper, two drachms of bromide of potassium, and twenty ounces of water, till the negative has assumed a white appearance all through, and then wash again thoroughly. I next *immerse* it in a dish containing a twenty-grain silver solution, slightly alkaline, till it is completely blackened, and then wash it again. If it is not intense enough yet, the last two operations must be repeated until it is. If there is any dirt on the glass (to avoid which use albumenised glass), or it has been over-exposed in the camera, the lines are liable to be covered more or less; and in this case it is worthless, as in such places the lines do not come up to the same plane as the rest of the picture, on account of receiving a much less exposure to the light in the next operation, for it should be remembered that every line on the printing block must come up to the same plane.

Next comes the preparation of the gelatine plates. Dissolve one ounce of Cox's or Nelson's gelatine in eight ounces of water, in a small portion of which one drachm of bichromate of potassium has been previously dissolved in a separate vial. After the gelatine has been dissolved by heat in the usual way this should be added, and the whole carefully strained. Put carefully-cleaned glass plates on levelling shelves in a dark room free from dust, and level each plate with a spirit-level. Then pour the gelatine solution upon the plates to the proper thickness—this depending on the class of work desired—and keep the room at a uniform temperature until the plates are entirely dry. This is a very important operation, as the nature of the lines will be governed in great measure by the temperature used, as well as the exact amount of the chrome salt in the solution.

We can obtain lines varying from being round at the bottom to perfectly flat ones (the kind usually desired), and even to *cup*-shaped lines. This can be learned only by actual practice. After the plates are dried they should be wrapped up carefully and excluded from light and air. They will keep in this condition for two or three weeks, and sometimes even longer. The exposure under a negative must be conducted in such a manner that the rays of light fall constantly at right angles to the plate, for which purpose a long box arranged so as to have a parallactic motion similar to a telescope, and denominated a "heliostat," is used. In sunlight the exposure averages about ten minutes. On dark days we use a large condensing lens, under which we expose usually from four to six times as long as in the sun's rays. There must be absolute contact between negative and plate, consequently perfectly flat glass should always be used. After exposure the plate is immersed in cold water, and at once a curious phenomenon occurs. Those parts of the plate not exposed to the light *swell* by the absorption of water, while those exposed remain unaffected. This, it will be seen, forms the relief. As soon as this action has begun all over the plate, we plunge it into a twenty-grain silver solution till the relief is high enough, *but not a minute longer;* for if the action is carried too far the lines become rounded at the bottom, and sharpness is lost, This part of the process is very important, and is our original invention. We have patented this step particularly, as it is peculiar to our process alone. The advantage of this operation lies in the fact that it sharpens the lines, and allows of greater relief being obtained without injury—very important for practical printing qualities—which advantage is recognised by printers using our cuts, which they prefer on this account over those made by other processes. The film, becoming full of bichromate of silver by this step, obtains greater consistency and solidity, and is capable of standing more handling in the subsequent steps. We have thus far found nothing that could equal this method in the results obtained. In our original invention we now proceeded to prepare the plate for direct action in the electrotype battery; but we have abandoned this for a more practical method, the copper facing of the cut not allowing of such easy retouching and finishing.

After the plate is properly swollen it should be rinsed with water, and a saturated solution of the sub-sulphate of iron poured over it. At the same time plaster of Paris must be mixed to a proper consistency, the plate put upon a level surface, the casting irons adjusted, and the plaster then poured into the mould thus formed. This should be mixed very thin, like cream, and only enough to cover the surface poured on and air-bubbles removed, when the balance must be added and allowed to set till sufficiently hard, which will require from fifteen to thirty minutes. The irons may then be removed and the cast separated, which will generally come off perfect. If not, another must be made at once. Those lines that were sunk in the plate will be raised in the cast, which is then right, or, as we term it, a negative. From this we take another mould, by first covering it with a solution of one part of silicate of potash to three parts of water, pouring off the excess and allowing the surface to dry somewhat, and then making the mould by again placing the casting irons around it and repeating the former operation.

This second cast is then put in the stereotyping pan, and a metal plate cast therein. It is not within the province of this article to give a description of this process, it being really another business entirely. After the metal cast is completed it is routed in the wide spaces where the relief is not sufficient to prevent the roller from touching while being inked in the press, defects are corrected, and the plate improved wherever possible with the graver. It is then mounted on a level block of hard wood, type high, and is now ready for the printing-press.

The entire operation I have described, from the making of the negative to the completion of the engraving, is often done in our establishment in four to six hours, when specially hurried; but we usually deliver work in three to four days from the time of receiving the order.

By the various processes of this kind, in the United States alone, there is probably produced as much work *as a thousand wood engravers could do if constantly employed,* and some of the work, such as very small reductions, &c., could not possibly be done by any other means. This has all been accomplished within the last ten years, and the field is constantly enlarging, more especially in the reproductions of foreign works.

I have endeavoured in this article to give a brief history as well as description of the processes employed in this important branch of our art, and hope that more of those who have had experience in this line will give us the benefit of their knowledge.

—*Photographic Rays of Light.* DAVID BACHRACH, JUN.

CARBONATE OF SODA.

As this preparation is frequently used by the photographer, more especially since the introduction of alkaline development, the ability to distinguish good from inferior samples is a matter of some importance, as the success or failure of a troublesome experiment may and does, in a great measure, depend upon the quality of the chemicals used. The failures we see recorded from time to time in our photographic literature would probably be explained if the quality of the chemicals was rigidly examined.

The purity of carbonate of soda, being an article of everyday use, is, as a rule, taken for granted, its comparatively small cost being considered sufficient warranty for its unsophistication. Carbonate of soda at a penny an ounce, or two ounces for three-halfpence, should be avoided by the photographer as utterly unsuitable for his work, and likely to lead him into difficulties. I had occasion during this summer to purchase a packet neatly done up, sealed, and labelled "best carbonate of soda;" but, to my surprise, litmus paper placed in a solution of it was changed bright pink. How such an impure sample would influence the delicate reactions that take place in the development of a dry plate the reader must determine. I merely call attention to the fact.

Carbonate of soda is the usual designation of bicarbonate, sesquicarbonate, or carbonate—each preparation differing from the other, sometimes considerably, so that a loose nomenclature of this kind is apt to mislead and is much to be deprecated. The differences in these soda preparations are these:—Washing soda is a very impure carbonate, containing about twenty-two per cent. of real alkali; pure carbonate of soda is the same, *minus* impurities; bicarbonate or sesquicarbonate—an appellation used indiscriminately—contains about forty per cent. of real alkali, being, therefore, much stronger than the carbonate. It is the kind usually prescribed, and for general purposes is the best preparation.

In purchasing, "Howard's" best bicarbonate of soda should be asked for. It is usually kept by all respectable chemists, and is acknowledged to be the purest make and a thoroughly reliable article. The price is rather higher than that sold in packets, but the little difference is unworthy of notice. Unless, therefore, "carbonate" is expressly prescribed, Howard's bicarbonate may be safely used for all purposes that carbonate of soda is generally used for, especially for those purposes for which the photographer is likely to require it. EDWARD DUNMORE.

TRANSATLANTIC NOTES.

NEW YORK.

BEFORE speaking of this great city, as this will for the present wind up my series of *Transatlantic Notes,* I had better, as my note-book has come to hand, redeem my promise to give the formula by which Mr. Davis, of Niagara, gets very rapid results. He is evidently a disciple of Mr. Black, of Boston, so far as the bath is concerned, as he works it in a very acid state, and of a strength of forty-five grains to the ounce. To a hundred and forty ounces of this he adds sixteen ounces of nitric acid, and should it not work to his satisfaction he continues to add more and more till it does. His collodion, of which the ether and alcohol are in the proportion of twenty of the former to sixteen of the latter by weight, is—

Ether and alcohol	1 ounce.
Iodide of lithium	5 grains.
Bromide of lithium	$3\frac{1}{2}$,,
Anthony's soluble cotton, No. 1	*q. s.*

Bromide of ammonium may be substituted for the bromide of lithium, but he considers the lithium base essential in the case of the iodine. The developer is made as follows:—four ounces of refined sugar, and twenty ounces of iron and ammonia sulphate are dissolved in a sufficient quantity of hot water and boiled, with constant stirring, quite dry. This is dissolved in water in the proportion of one ounce to four, and just sufficient acetic acid added to prevent fog. Mr. Davis claims, on behalf of this solution, that development may be pushed to any extent, and protracted to almost any length of time, without producing fog or getting muddy from reduction; and that, consequently, an image may be developed to printing density with a shorter exposure than by any other solution that has hitherto been proposed.

Anyone attempting to "do" New York, or even to examine any one of its many industries, in a few days, will certainly fail, and therefore I contented myself with brief visits to a few of the better-known establishments connected with photography, and with such opportunities of acquiring a knowledge of the position of the art in that city as was afforded by the show-cases in the various streets through which I passed.

Probably one of the most interesting places to a photographer is the immense establishment of Messrs. E. and H. T. Anthony and Co., which occupies an entire block of building in a central position in Broadway. I got a cordial reception from two members of the firm, and my request for permission to make a general inspection was heartily complied with, Mr. H. T. Anthony himself offering to be my guide. The firm of E. and H. T. Anthony and Co. is one of the oldest and best known in the United States, and there is hardly a photographer from Philadelphia to California who has not dealings with the house, either directly or indirectly, as there is not an article in any degree connected with photography that they do not either manufacture or supply. From the first floor to the attic the establishment is like a busy hive, and contains probably the most complete and the largest stock of photographic material to be found under one roof in any part of the world.

One floor is devoted almost exclusively to posing and studio apparatus, including cameras and lenses of every description; another to albums, velvet, and other ornamental frames, the former varying in price from eightpence to as many pounds; another to chemicals and chemical apparatus, including enormous quantities of collodion of various kinds, a favourite variety being partially sensitive to light even before immersion in the nitrate bath. In connection with this department I noticed a habit which might be adopted with advantage by chemists in the old country, namely, the almost universal use of square instead of round bottles—a form which economises room, and admits of much easier and firmer packing.

Here I saw large quantities of the bath and developing solutions used in what the Americans, with their usual aptitude in selecting names, call the "lightning process," but which in more prosaic England is announced simply as Boisonnas' "extra rapid." I could, however, get no information regarding the nature of the solutions, neither have I met anybody who has given them a trial; but I heartily wish the inventor all success, as, if there be really anything in it, it comes just in the nick of time to enable wet collodion to hold its ground against the numerous extra-rapid emulsions that at present threaten to supersede it for quick work.

Messrs. Anthony and Co. are extensive and enterprising publishers of photographic pictures, being ready to purchase suitable negatives whenever they are offered, and also sending out their own *employés* to produce whatever is likely to become in demand. In this department I saw what is, perhaps, one of the largest stocks in the world of prints ready for the market, varying in size from stereo. up to 14 × 11, the latter size including some fine transparencies on glass, printed in carbon. Of those I was particularly charmed with some statuary in exquisitely delicate detail and perfect in the rendering of light and shade. They were evidently copied from fine statuettes, and with a perfectly black background; after development they are transferred to the glass in such a way as to leave a broad margin of clear or obscured glass. Running along this margin there was executed with much taste a border, either floral or geometric, and polished in the obscure, or obscured in the polished, glass. The picture was, as usual, protected by a second plate of glass, the two being bound together by a neat nickel-plated frame, and formed as beautiful a window ornament as one could wish to see. The only drawback to their general introduction will, perhaps, be the cost—forty-two dollars per dozen, or fourteen shillings and ninepence each, wholesale; but I think I could make a good thing out of them at less than half a guinea.

To keep their stock up Messrs. Anthony and Co. have three manufactories constantly going—two in New York and one on the Jersey side of the river. The latter is the chemical laboratory; but as it was pretty fully described in this Journal some time since, I shall only say that in it is made almost every compound used in the art, including eleven varieties of soluble cotton, and that every article produced is as nearly pure as it can be made—a matter of even greater importance here than in the old country, from the fact that the great majority of American photographers still continue to make their own preparations.

In one of this firm's New York factories I found several floors of a large building devoted to the manufacture of albums and ornamental frames, and as for the successful pushing of this branch of trade new styles must be constantly produced, the variety of designs is immense, and the range of prices very great. This latter may be judged of from the fact that the work actually in hand varied from twenty-four shillings to fifty-eight pounds, six shillings, and eightpence per dozen.

The manufacture of albumenised paper was also at one time a large item in their work of production; but, so far as I could learn, the continental makers have gained a good footing in the States. Messrs. Anthony and Co., however, make an excellent article, and the few girls I saw employed manage to turn out from twelve to fifteen reams a day, consuming in the process about fifteen barrels of eggs.

Notwithstanding the fact that some of the English camera-makers send out the most perfect work, both as regards finish and design, to be found in any part of the world, cameras of American manufacture have been for some time finding their way both into England and Scotland. Most that I had seen had been the work of the Scovill Manufacturing Company, and so I thought it advisable to have a look over their store when in New York. I had expected to find them makers of photographic apparatus only; but in this I was much mistaken, as they show quite a bewildering assortment of almost every little appliance in iron and brass that is in general use. The photographic department, however, was the only one that had a special interest for me, and the examination of the various items amply repaid me for the time it occupied. The space at my disposal will not permit of anything more than a general description of the stock as a whole, and therefore I may just say that its characteristic is great strength, excellent fitting in all its movable parts, nickel-plated metal instead of brass or iron wherever possible, and considerable disregard to the element of weight, even in folding landscape cameras, or "view boxes," as the Americans persist in styling them. The studio cameras, with their various movements, are decidedly superior to anything usually made in England; but English makers have nothing to fear from American competition in those intended for landscape work, as, in addition to the clumsier appearance of the American article, it is generally much heavier than it need be, and has nothing approaching the perfect finish of the English work.

Much the same may be said of the camera-stands. Those for use in the studio are very perfect in their movements, and their unusually-great size is a real advantage; but the tripods, with unseemly wooden tops, instead of the light ring or triangle usually seen at home, are not more rigid, though much heavier, than we are accustomed to see. Of course this applies only to the tripods of ordinary size; the extraordinary ones—and there were some nine feet high—needed all the strength they had to support the cameras for which they were intended.

I suppose the beautifully-artistic studies of Sarony are as well known all over Europe as they are in New York, being highly appreciated wherever they are seen. No doubt most people have an excusable curiosity to see the man who produces anything they very much admire, and I willingly plead guilty to that in the case of Mr. Sarony, although the curiosity was somewhat damped by the assurance of one of his intimate friends that, if busy, he would hardly take time to exchange the ordinary courtesies of life with the President of the United States were he to call. Trusting to the chance of finding him at leisure I went to Union-square pretty early in the forenoon, and had no difficulty in recognising the block of building occupied by this artist—which is five stories in height—by an enlarged copy in gold of his well-known signature by way of sign, which, however, is the only indication of his whereabouts, as there is neither show-case or specimen of any kind outside the building.

In common with the proprietors of most large business establishments in New York, Mr. Sarony gives his customers the choice of walking upstairs or going up in a hoist. My guide, choosing the latter, made the necessary signal, and in a few seconds we were landed on a level with the reception-room. This is a magnificent apartment of the dimensions of eighty-five by thirty feet, and covered with a rich Turkey carpet. In a recess at one side is a desk and small counter at which appointments are made and business transactions conducted, and every portion of the walls and much of the floor space is occupied by a fine collection of pictures, objects of art and of *virtu* generally, in bronze, terra-cotta, ivory, iron, wood, &c., &c., gathered, I understood, mainly by Mr. Sarony himself, from almost every quarter of the globe. Many of the pictures, including life-size drawings of Wilkie Collins and Mrs. Scott Siddons, are the work of Mr. Sarony, and bear ample evidence that his ability as an artist is not a whit behind his power as a photographer.

The floor above the saloon is mainly used as a workshop and store-room. Here the odds and ends of repairing, fitting, and altering, so essential to the apparatus and properties of a studio where the peculiar kind of work which has made Sarony famous, are done, and which is thus much better executed, while at the same time it is done under the artist's eye.

Still higher up we find a series of rooms shelved all round, in which are stored such quantities of negatives as one might suppose to have been the work of a whole lifetime, and amongst them, doubtless, many of those from which have been printed the artistic gems that ought to be in the possession of every photographer, if for no other purpose than to show of what the art is capable. Higher still, on the fourth floor, and in what at first seems a confused jumble of articles of every conceivable kind, will be found a seeming chaos of old furniture, armour, stoves, musical instruments, skulls—a place in fact like nothing on earth but the property-room of a large theatre during the run of a successful pantomine. Opposite the property-room are dressing-rooms, and beyond them is the studio, the place for which all the others exist, and where the principal artistic work that keeps this great establishment going is done.

We may not enter now, as the artist is engaged with a sitter, and so in hope that he may have a few minutes to spare shortly, we pass still higher up—to the roof, in fact—and see the printing operations. Here I found some half-dozen hands working under the superindence of the head printer—a gentlemen who has been in Mr. Sarony's employment for many years, and whose services are highly appreciated. The paper is fumed with ammonia—a practice almost universal in America—and the printing is all done in the open air. At the time of my visit there were nearly three hundred negatives in use, one hundred and seventy-five of which were being vignetted; and all, or nearly all, were printing under tissue-paper. The vignetting is done through masks of orange-coloured paper, each negative having one suitable to itself cut out and pasted on the outside of the frame, and over it the tissue paper. An examination of the negatives showed that retouching was not resorted to to any extent; in fact, the removal of an accidental blemish, or the softening of a too dark shadow, is all that is permitted or required.

By the time the printing had been examined Mr. Sarony was disengaged, and on presenting myself in the studio I got a hearty but characteristic reception. I handed him my card and was about to say something in the usual style, when he shook hands warmly, and thus expressed himself, without a pause, or giving me the chance to say a word till he had taken a good negative of me. "I'm very glad to see you," wheeling me into a corner; "beautiful lines! ah! that's just the style! oh! you need'nt look at the place; I like to have everything rough and ready, and the light is quite good enough. A man's not worth much if he can't get a picture under almost any light." Throwing an old blanket over one of my shoulders, he exclaimed—"There! that's it now! true art! never touch a bit of drapery; if it don't fall right throw it again—it's sure to fall better than you can make it!" He then said to his assistant—"All right!" and then to me, waving a card in his hand a little above the level of my eye, and about eight feet off—"Look this way, and let your eye follow the card." "Go!" and after an exposure of about thirty seconds, at the end of which the lens was capped and the assistant disappeared, he resumed—"Stand where you are for a few seconds; I don't often go twice, but sometimes have to do so. Very picturesque! charming! Nothing like a loose, flowing robe to work with—the dress of the nineteenth century is a vile abomination!" A whistle was heard from the adjacent dark room. "You're all right. Where are you to be found? and when do you go? I can send you a proof tonight, and, if you like, will also send a bundle of my best studies." I told him, and, hardly giving me time for thanks, he again shook hands in the unmistakable way which says it is time to go. I may add that I received at my hotel that same night the promised proof, and two dozen of the most perfect gems of photographic art he has ever produced, and since then a number of prints from the negative of myself, which, as an art study, is almost perfect. Mr. Sarony's light is like that very common in American studios—a low top; and he makes but little use of screens, trusting for the desired effects to the position, relative to the glass, in which he places the sitter.

There are several other noted photographers that I would fain have visited, but time would not permit, and a hurried look at their show-cases was all that I could accomplish. From this I am satisfied that New York is no exception to the general rule prevailing in all, or nearly all, large cities, viz., with a very little of the finest of the wheat there is a large proportion of chaff—a few good men and true, who aim high and succeed in doing really excellent work, and a large number who would seem to regard their work as mere matter of routine, seeking nothing higher than what may be required by the uncultivated tastes of their *clientèle*, and aiming at no higher reward than the *quid pro quo* which such work brings.

While in New York I had the privilege of attending a meeting of the Photographic Section of the American Institute, under the presidency of Mr. H. J. Newton; but as I see a report of that meeting in a recent number of the Journal I need not say anything further regarding it, except that the pictures shown by the President, most of which are now before me, were, notwithstanding the short exposures, admirably lighted and really excellent, and that the members present showed a zeal and energy that should secure for the Society a useful future.

Now here must for the present end my *Transatlantic Notes*. The gathering of them has been a pleasant occupation, and I most heartily recommend a similar trip to all who may have the opportunity of visiting America. JOHN NICOL, Ph.D.

THE BIG SHOW.

OUR EVENINGS.—PARIS SHOW-CASES.

UNDER the influence of a broiling sun we find it weary work this all-day-search after improvement combined with pleasure; and so, with the conscious feeling of fatigue, to be forgotten amidst the courses—not of nature, but of a good dinner—we made for the principal entrance to the Exhibition, to be whirled home in the first swift conveyance that could be had for hiring. This, however, is no easy matter to obtain, for many visitors with the same intent as ourselves are there before us; and in the midst of the demand for *voitures* the *cochers* forget all rules and regulations, and make it their business to take the lightest weight the shortest distance for the most money. So cheap has money got amongst the *cochers* that a half-franc piece cannot even secure politeness from them. With the exercise of considerable force, and the expenditure of a fair quantity of bad French mixed with hard English, we manage to obtain a *voiture* and get home in time for dinner.

By way of amusement after dinner we saunter round the Palais Royal, feasting our eyes on the never-ending display of jewellery, and then take a walk along the principal boulevards; but it is wonderful how soon a little of that sort of thing satiates one. It is new to see the crowds of people sitting round the doors of the *cafés* under the shadows of the trees enjoying their cigars and *café-au-lait;* but, as it repeats itself again and again, the novelty soon wears off, and so we sit down amongst the crowd in front of one of the *cafés* to enjoy a view from the other side, and have a look at the passers-by.

But sitting outside at little white tables on cane-bottomed chairs, and drinking coffee mixed with water grew tiresome, and we resolved to try the theatre. That was not much of a success either; for, what with the heat of a summer night and being packed into a crowded house, backed up by the fact that we did not understand a single word of the performance, the whole arrangements act as a soporific, and we go to sleep.

We tried to obtain admittance into the New Opera House, but not having applied in time for tickets we failed. So should any of the readers of the Journal who intend visiting Paris wish particularly to see the New Opera House, it would be advisable to apply for tickets on their arrival in Paris, by which means they will have a fair chance of getting them during their stay. We tried to get in without tickets for the sake of getting a glance at the house, but we had to stand in the *queue*—an arrangement which we, in our own country, would do well to imitate, so as to save many of the abominable crushes and crowds that occur at the doors of places of amusement previous to the doors being opened. In Paris they do these things differently. On reaching a place of amusement previous to the doors being opened all comers stand two and two behind each other, and, no matter what be the length of the line, they preserve this form until the doors are opened, patiently waiting without crowd or bustle, first come being first served, and when the place becomes full those whose turn to enter has not come walk quietly away, which was precisely our case on this occasion. The justice of this sensible arrangement of the French people is this—the weak have an equal chance with the strong.

The photographic cases and show-frames exhibited in connection with the places of business in Paris are in many instances different from, and an improvement on, those usually shown by us. Some photographers have the whole entrance way or passage to the stair-case glazed in the form of a window about two feet wide, and running all the length of the passage both sides. These windows are usually draped with maroon-coloured cloth, and filled in with framed enlargements, plain and coloured. At night the effect is striking; for these windows are all lighted up, and the pictures thus show with even more effect than during the daytime, and is a means of causing many of the passers-by to stay and inspect the work.

In one instance I saw a very pretty effect produced by showing one single enlargement, framed and beautifully finished, placed on an easel in the centre of a window, and draped all round with folds of maroon cloth. When looking at this picture and its arrangement I thought that the effect produced by this one specimen in the position in which it was placed, and its subdued, artistic surroundings, would do more as an advertising medium for the photographer than if he had had twenty samples crowded into the same space.

We saw a moving advertisement in the shape of a little square van drawn by a pony, the back and each side of the van being squares filled in with samples of the artist's work. It had the advantage of bringing the quality of the production under the notice of many who might never have the opportunity of seeing the specimens at the entrance to the photographer's studio. MARK OUTE.

FOREIGN NOTES AND NEWS.

GRANULAR PHOTOLITHOGRAPHS.—WOOL AS A FILTER.—HÄRTWIG'S COLLODION.—SIEMENS' PRESSURE-HARDENED GLASS.

DR. SCHNAUSS has been authorised by Professor Husnik to publish the following account of a method for obtaining granular pictures on stone by means of the photolithographic transfer paper of the latter:—Take a finely-ground plate and rub it, as for a copperplate, with weak, fatty printing ink, and then with a coarse, but not thready, well-washed cloth, rub until the ink only remains in the hollows. Then place the plate in a horizontal position and coat it with a mixture of a one-to-ten gelatine solution containing three parts of spirits of wine and one-sixth of glycerine; make perfectly dry, and then draw off the skin of gelatine. The latter now possesses a very beautiful granularity, and should be kept between the leaves of a book, as it is easily injured. In printing with the chromated photolithographic transfer-paper lay the smooth side of the skin upon the negative and the paper upon the granular side, and print four times as long as usual. In washing off the ink a fine, soft, wet sponge must be used with great precaution, for fear of injuring the granulation; and the paper should be allowed to soak rather longer than usual in cold water previous to development, so that the slightest pressure may suffice to remove the ink from the unlighted parts. The shadows must be developed by a somewhat stronger pressure with a pointed piece of sponge, care being taken not to disturb the lights. This process is suitable for large pictures.

In the *Photographisches Wochenblatt* Herr Wilde says that he finds unspun, well-washed sheep's wool the best thing for filtering collodion or emulsion. It is superior to cotton wool, and when placed in the neck of the filter, owing to the greater elasticity of its fibres, it does not get matted, and the filtration goes on smoothly. The filtrate is very clear and free from all threads, dust, or other insoluble substances.

In the same journal Herr Härtwig, of Magdeburg, gives the following formula for a chloride of silver collodion, which is said to work well.

Prepare the following solutions:—

(1) 8 grammes of nitrate of silver in 8 c. c. of distilled water.
(2) 1 gramme of chloride of calcium in 20 c.c. of alcohol.
(3) 1 gramme of citric acid in 20 c.c. of alcohol.

Heat in a beaker 180 c.c. of alcohol, and add the silver solution drop by drop, stirring all the time. Now add eight grammes of collodion cotton (the solution can most easily be kept hot in the sand bath); then add, little by little, still stirring constantly, 150 c.c. of ether. Now take the twenty c.c. of chloride of calcium solution, which has been kept protected from daylight, and add it, finally adding the twenty c.c. of citric acid solution. The collodion has now got all its ingredients, and after standing a few hours is ready for use, upon gelatine paper, chalk paper, or direct upon glass. When used upon gelatine paper the toning is done in a soda bath containing gold.

In the *Mittheilungen* Herr Herrmann (of Siemens', Dresden) has a long article giving an account of Siemens' pressure-hardened glass. As *verre trempé*, he says, is best adapted for hollow articles, such as drinking cups and glasses, so is pressure-hardened glass best for flat sheets of glass, such as are used for windows and for *clichés*, both for ordinary photographic and lichtdruck purposes. For some time past Herren Römler and Jonas have tried pressure-hardened glass printing plates for lichtdruck both in hand and in Schnell presses, and are so well satisfied with the result that they have ordered a large quantity of all sizes. One printing-plate, eight millimetres in thickness and 45 × 32 centimetres in size, was laid directly upon the iron underlayer of the Schnell press and drawn fourteen times through the press, under the strongest cylindrical pressure, without breaking. Another plate, measuring also 45 × 32 centimetres, and five millimetres in thickness, also passed the ordeal triumphantly. The gelatine film adheres to the pressure-hardened glass much the same as to ordinary glass.

The Siemens' glass is also said to be suitable for ordinary photographic negatives or transparencies, being as level and transparent and not so liable to break. The hardened glass will be about thirty per cent. dearer than ordinary glass, and unfortunately it cannot be cut down to the desired size with a diamond, though it may be ground, polished, or bored. It is said, also, to stand sudden changes of temperature remarkably well. Rumours are afloat to the effect that the newest thing in furniture is glass frames for chairs, &c., toughened either by De la Bastie's or by Siemens' process; but that report is probably only one of the numerous *canards* that are always rife on subjects upon which nothing is positively known.

Contemporary Press.

NICÉPHORE NIEPCE.

[Daily News.]

Nicéphore Niepce, according to a recent biography, "never ceased being unknown till the seventh year after the end of his laborious life." As Niepce's laborious life ended about fifty years ago, it is certainly high time that "his posthumous notoriousness overpassed the bounds of a strait circle." This is the opinion of the brave people of Chalon-sur-Saône, whose fellow-townsman Niepce was, and who now assert his merits in a pamphlet written in the English language. We have already quoted two brief passages from the courageous work of the linguists of Chalon-sur-Saône, and they are enough perhaps to awaken some interest in the career of an ingenious man, "whose apotheosis was retarded owing to public error originating from an intrigue." "The very rare person hereby alluded to," as his biographer says, was born at Chalon-sur-Saône in 1765, and, in the opinion of the people of Chalon, was the father of photography. Up to the present moment no monument has been erected to the honour of Niepce, and the citizens of Chalon think it high time that his statue should decorate the market-place of his natal city. They point out the wonderful character of his invention. "It was not irrational to prejudge against the future inventor of photography that he had undertaken a run after a chimæra." This sentence illustrates a very common confusion of thought which may as well be cleared up before we pursue the history of M. Niepce any further. The chimæra was a fabulous animal, partly serpent, partly goat, and partly lion. It was excessively destructive in Lycia and the neighbouring district, and its appearance was dreaded by the surrounding peoples. No one would ever have dreamed of "undertaking a run after a chimæra," for the very good reason that the most reckless hunter would have been too much afraid to do so. In spite of these facts, not only English but French people, like the historian of Niepce, constantly talk of "pleasing chimæras," of "pursuing vain chimæras," and even of taking a run after the creature. To return to the early history of photography. The enemies of an inventor would have said, "Light is aught incoercible; there is no hold on it, and lo! you presume to enslave it?" People actually did speak thus to Niepce, who, in spite of the laughter and suspicion of his fellows, managed, with wretched materials, and "drugs of questionable genuineness," to make the sun "impress a neat and permanent image of the objects disclosed to view by its irradiation." So at least says the apologist of Niepce, and goes on to tell the old and trite story of inventive genius repressed and robbed by men of the world.

Niepce, it seems, was not satisfied with this first partial success. No one who remembers the early daguerreotypes, those hideous representations of the human features which had to be held on one side and squinted at, will wonder that Niepce was not satisfied. Mr. Leech's caricature, representing a happy family group before being "taken," and as they later appeared on the plate, was no exaggeration. The poem of "Hiawatha's Photographing" by the author of "Alice in Wonderland," is another monument of the old and evil days of the process. The bard tells how the baby "came out" so very badly that—

> In comparison the others
> Might be thought to have succeeded—
> To have partially succeeded.

Such partial success was not enough for Niepce, who knew that the public, like the "fools and bairns" of the Scotch proverb, "should not be allowed to see half-done work." In addition to his sensitiveness, Niepce's want of money prevented him from pushing his invention. Niepce had, however, a partner, M. Daguerre, if we rightly interpret the somewhat confused language of his biographer. A "painter and manager of the diorama," according to the biographer, got a hint of what Niepce was working at, and "drew out of his candour the secret of the proceeding." He then entered into formal partnership with the original inventor in December, 1829, and the act of partnership has been published. From this document, we are told, it appears that Niepce "had already found the fundamental means of rendering permanent the images received in the camera obscura." The great difficulty was thus overcome, and there only remained the task of improving the details. The partner "had lent cunningly to this second-rate task the seemingness of a mysterious indagation, tending to a personal discovery." Here the biographer has the advantage of his English readers. They cannot easily discover the mystery of this "mysterious indagation," and can only suppose that the partner improved the unpublished invention. Niepce died as unknown as he had lived, and his son, it seems, neither understood nor valued his discovery. The partner stood to Niepce as the inventor of a more or less indifferent modification of the boiler would have stood to the inventor of the steam-engine. In 1827 it is said that Niepce exhibited in England several heliographic drawings of his own, and some even earlier attempts are preserved in the Museum at Chalon-sur-Saône; "contrarily to which," says the biographer, "for the whole lapse of nine years, extending from the date of the contract to the divulgation of the proceedings, his partner never did show a single pattern of his own making, nay, to his surest friends." It is added that in 1839 Mr. Bauer, a member of the Royal Society, declared that the specimens of Niepce, exhibited in 1827, were as perfect as those of Daguerre, "described in the French papers of 1839." We do not gather from this statement that Mr. Bauer had seen the examples of M. Daguerre.

Sic vos non vobis might be the motto and device of inventors. If Niepce did and suffered all that is described, he was only suffering the usual fate of minds in which originality is stronger than self-assertion. Photography has been brought to considerable technical perfection; it is a useful (if not exactly ornamental) craft, and the people of Chalon-sur-Saône think Niepce should have his statue, like another. They ground his claims to this honour on the merits of the process he "invented;" but perhaps his modesty and perseverance are in themselves things more honourable than his disputed and doubtful success. Certainly the services of photography are many and meritorious, even if we do not actually think it "a condition of the spiritual life of all nations." The committee who ask for subscriptions for the monument point out that microscopic photography was of great service to Paris during the siege, as messages could be reduced in size, and sent out under the wings of carrier pigeons. Again: "with the photographist's assistance, the investigations for Verity cease being hard and liable to error; oftentimes he removes the doubts of justice," though not often, we presume, by the simple process of photographing the eyes of a murdered person, so as to get a portrait of the assassin. "Physic resorts to him as an infallible demonstrator;" and, in short, photography reproduces with mechanical exactness all objects in nature or art. Deductions have to be made, of course, from the value of the representation, which must always be more or less inadequate, and which has never the spirit, the life, the satisfying human qualities of the work of the artists' hands. It may be true that "photographic miniatures on enamel, set in rich medallions, are ranked among the accessories of an elegant dress;" but the value of Niepce's invention is rather diminished than increased by the coloured perversions of his process. In bad hands, and when set before dull eyes, photography is actually the rival and foe of art. Its real uses are ancillary and scientific; though, after all, the cheap portraits which photography makes possible are really valuable additions to the sum of human happiness. So hideous and vulgar are some popular photographs of eminent or notorious persons of both sexes that one is sometimes tempted to wish Niepce, Daguerre, and the others had exercised their inventiveness on some other material. The treasured photographs of the poor, the cheap comfort of the widow, or wife, or mother, atone for the monstrosities of popular photography, for the postures and attitudes of fashionable notorieties, and for the finery and flowers out of which women lift coquettish eyes to every owner of sixpence.

Our Editorial Table.

Catalogue of Photographic Specialities.

Liverpool: J. J. Atkinson, Manchester-street.

Mr. Atkinson's new catalogue has attained the goodly dimensions of 104 pages, every one of which bristles with information of a nature calculated to interest all who are connected with photography. One feature distinguishes this catalogue from many others: it is the number and variety of articles of American manufacture which are supplied by Mr. Atkinson, in addition to articles of home production. We find that several pages have been devoted to descriptions of lenses alone; some more to cameras, printing-frames, stands, and other accessories. The department of frames, cases, and mounts appears to be quite filled up, several illustrations being devoted to the elucidation of this part of the work. What with these, and with chemicals, batteries, colour boxes, posing chairs, and the numerous *etceteras* required in the business or practice of photography, Mr. Atkinson's catalogue is a work of a most comprehensive kind.

The Autotype Manual.—Popular Edition.

London: The Autotype Company.

This Manual differs from all former editions, inasmuch as it is issued at a lower price and in a different size, viz., *octavo*. Notwithstanding its being prepared for "popular" use, we are unable to discover anything, except in external appearance, in which it is inferior to its more elegant-looking predecessors. Mr. J. R. Sawyer, its astute editor, has in this popular edition availed himself of the hints and items of experience of the most advanced carbon printers, which, from his position as director of the Autotype Works, he is so favourably situated for receiving. The work is one which every experimentalist in carbon printing will find it advantageous to study carefully.

Samples of Photographic Chemicals.

London: Burgoyne, Burbidges and Co., Coleman-street.

Among the above samples, one of collodion, although rather too small to enable us to subject it to the test of preparing a few plates by its means, is yet amply sufficient for us to have ascertained its flowing properties and the excellent physical qualities of the film obtained by its means. It is clear and free from structure. Of the other samples, the pyrogallic acid is a fine one. Having tested it in actual practice we can speak confidently of its excellent developing properties. The bichromate of potassium is a vêry fine sample; and of the bichromate of ammonium the same may be said in the most absolute sense.

There are no fewer than five samples of albumenised paper, included among these being the kinds most in everyday use. We observe that these samples are all of a pink tint, from which we infer that there is an increased demand for paper having a tone of a more or less rosy hue.

The reputation of this well-known firm stands too high to render it necessary to speak of the qualities of the goods supplied by them, which, from a perusal of their monthly catalogue, we know to be very varied and extensive.

The University Magazine.

London: Hurst and Blackett.

The portrait of Mr. E. J. Poynter, R.A., from a negative by Messrs. Elliott and Fry, is one which shows better than many we have seen the admirable capabilities of the Woodbury process for book illustration. We had long observed that those negatives which were taken by Messrs. Lock and Whitfield, who have made the requirements of the Woodburytype a special study, gave much finer prints than those by other artists. A few days ago, when in conversation with Mr. Geo. Whitfield, we alluded to this and inquired the cause. It arose, he informed us, from their taking all the negatives intended for Woodburytype purposes in a very soft light, and developing the image in such a manner as not to have great intensity in the details. A negative which prints well on albumenised paper is not necessarily well adapted for Woodburytype. The portrait of Mr. Poynter is much better than many of those which have appeared in the pages of the *University Magazine*, always excepting those by the firm we have just named.

The subject of the portrait in the present number of the *University Magazine* has for a considerable period been recognised as an apt teacher of art. When the professorship of the new schools of art established in connection with University College, in 1870, was offered to Mr. Poynter he accepted it and held the post for six years, after which he received the appointment of Director for Art and Principal of the Government Training Schools at South Kensington.

Among the various articles in the current number of the magazine the *Notes and Reminiscences*, by the late W. H. Harrison, possess an interest for photographers in connection with several reminiscences relating to Sir Frederick Pollock, Lord Chief Baron, and former president of the Photographic Society. The other contents of this popular serial are as varied and excellent as usual.

Light. By Alfred M. Mayer and Charles Barnard.

London: Macmillan and Co.

This forms one of the *Nature Series* of scientific manuals. In it we find a number of easy experiments in the phenomena of light which can be performed with materials that may either be found in every dwelling-house or can be purchased for a small sum in any town.

In order to conduct experiments with light it is necessary that a beam of sunlight be admitted into the room through an aperture in the window shutter. Now, it will be in the recollection of our readers that only a few months since the subject of the *heliostat* was brought prominently before them in these pages. The authors of this treatise (which, we may premise, is a reprint of certain articles that appeared in our contemporary, *Nature)* tell in a few words the whole story of the necessity for a heliostat. We quote as follows:—

"In studying light we do not wish a great quantity. We want only a slender beam, and we must bring it into a dark room, where we can see it and walk about it and examine it on every side, bend it, split it up into several beams, make it pass through glass or water, and do anything else that will illustrate the laws that govern it.

"Choose a bright, sunny day, and go into a room having shutters through which the sun shines. Close the shutters, curtains, and blinds at all the windows save one. At this window draw the curtain down till it nearly closes the window, and then cover this open space with a strip of thick wrapping-paper, cut a hole in this paper about the size of a halfpenny, and at once you will have a slender beam of sunlight entering the hole in the paper and falling on the floor. Close the upper part of the window with a thick shawl or blanket, and when the room is perfectly dark, our slender beam of light will stand out clear, sharp, and bright.

"As soon as we begin to study this beam of light we find two little matters that may give us trouble. The sun does not stand still in the sky, and our beam of light keeps moving. Besides this, the beam is not level and it is not in a convenient place. We want a horizontal beam of light, and some means of keeping it in one place all day. An instrument that will enable us to do this, and that can be adjusted to the position of the sun in the sky at all seasons of the year and every hour of the day, may be readily made and will cost only a small sum of money."

The *brochure* contains several illustrations, and is written in a plain and simple style. The nature of light itself has not been touched upon; this, together with the phenomena of interference and polarisation, is intended to be explained in another book. We may also add that the chemical action of light is not here introduced.

The Psychological Review.

London: E. W. Allen.

For the benefit of a large number of our readers, whom we know to be keen students of psychological phenomena, we may state that the second number of this quarterly more than bears out the high promise of the first. It is ably conducted, and the various articles are of a high class.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
July 25	Oldham	Hare and Hounds, Yorkshire-st.

AMATEUR PHOTOGRAPHIC ASSOCIATION.

The annual meeting of this Association was held on Monday, the 8th inst.,—The Right Hon. Lord de Ros in the chair.

The minutes of the last meeting having been read and confirmed, the following were elected members:—W. E. Gibb, Esq., F. A. W. Whitmore, Esq., H. T. Simmons, Esq., E. Dubois, Esq., and Mrs. Mansel Lewis.

The Secretary having laid before the Council the pictures for the current year, Mr. Glaisher read his report, of which the following is an abstract:—

Class I. contains 73 pictures, contributed as follows:—R. O. Milne, Esq., 19; T. R. Shervington, Esq., 11; W. S. Hobson, Esq., 8; J. W.

Leigh, Esq., 6; T. Brownrigg, Esq., 5; F. Beasley, Esq., 3; Sir George Prescott, 3; Major Chadwick, 2; Major Allen, 2; Mrs. Gulston, 2; W. H. Kirkby, Esq., 2; W. Vanner, Esq., 2; R. Murray, Esq., 2; Rev. W. H. Palmer, 1; J. C. Stenning, Esq., 1; J. E. Thornburn, Esq., 1; Lieut. S. G. Fairtlough, 1; R. Leventhorpe, Esq., 1; Rev. W. Hancock, 1.

Class II. contains 94 pictures, contributed as follows:—The Right Hon. the Earl of Caithness, 3; the Right Hon. Lord de Ros, 2; R. O. Milne, Esq., 12; Rev. W. Hancock, 8; J. C. Stenning, Esq., 6; J. W. Leigh, Esq., 5; R. Murray, Esq., 5; W. S. Hobson, Esq., 5; F. Beasley, Esq., 4; Rev. H. Palmer, 4; Major Chadwick, 4; Major Allen, 3; P. Gunyon, Esq., 3; W. Vanner, Esq., 3; Mrs. Deeble, 3; R. Leventhorpe, Esq., 3; C. Stephens, Esq., 2; G. W. D. Green, Esq., 2; T. R. Shervington, Esq., 2; Capt. Fox, 2; Mrs. Gulston, 2; J. E. Thornburn, Esq., 2; Lieut. S. G. Fairtlough, 2; T. Brownrigg, Esq., 1; E. Milsom, Esq., 1; W. H. Kirkby, Esq., 1; Miss Coxe, 1; Sir George Prescott, 1; A. Watkins, Esq., 1; H. T. Simmons, Esq., 1.

Class III. contains 100 pictures, contributed as follows:—The Right Hon. Lord de Ros, 2; Rev. W. Hancock, 10; W. Muller, Esq., 8; the Right Hon. the Earl of Caithness, 2; G. W. D. Green, Esq., 6; W. Vanner, Esq., 6; C. Stephens, Esq., 5; E. Milsom, Esq., 5; Rev. H. Palmer, 5; Mrs. Deeble, 4; Mrs. Evans, 4; F. Beasley, Esq., 3; W. S. Hobson, Esq., 3; Major Allen, 3; Capt. Fox, 3; J. C. Stenning, Esq., 3; W. H. Kirkby, Esq., 3; Major Chadwick, 3; G. W. Keeling, Esq., 2; R. O. Milne, Esq., 2; P. Gunyon, Esq., 2; Lieut. S. G. Fairtlough, 2; J. W. Leigh, Esq., 2; R. Murray, Esq., 1; Mrs. Gulston, 5; J. E. Thornburn, Esq., 1; A. Watkins, Esq., 1; H. T. Simmons, Esq., 1.

The remainder of the pictures are comprised in Classes IV., V., and VI.

Mr. Glaisher, after mentioning the assistance rendered by his colleague, Mr. Sopwith, in the classification of the pictures, remarked that the large number of fine 12 × 10 pictures sent by Mr. Milne merited the highest commendation, and called special attention to the numerous beautiful Chinese pictures contributed by Mr. Shervington. Mr. Glaisher then referred to some excellent work forwarded by Mr. Hobson and Mr. Brownrigg, and also to two remarkably soft and well-chosen views by Sir George Prescott, and a most interesting series of views, recalling Cooke's well-known pictures of shipping, by the Rev. W. Hancock.

The following prizes were then awarded:—

First prize, R. O. Milne, Esq., for pictures Nos. 76 and 82—a large silver goblet. *Second prize*, T. R. Shervington, Esq., for Nos. 2 and 10—a silver goblet. R. O. Milne, Esq., for Nos. 70 and 87—an oil painting in gilt frame. J. W. Leigh, Esq., for Nos. 1 and 4—an oil painting in gilt frame. W. S. Hobson, Esq., for Nos. 158 and 159—a graphoscope. Sir George Prescott, for Nos. 1 and 4—a large album elegantly bound in morocco. Rev. W. Hancock, for No. 13—an oil painting in gilt frame. F. Beasley, Esq., for Nos. 277 and 279—an oil painting in gilt frame. T. Brownrigg, Esq., for No. 36—an album elegantly bound in morocco. Major Allen, for Nos. 102 and 103—an oil painting in gilt frame. R. Leventhorpe, Esq., for No. 4—an album elegantly bound in morocco.

Certificates of honourable mention were awarded to Mrs. Gulston, Major Chadwick, W. Vanner, Esq., Lieut. Fairtlough, W. H. Kirkby, Esq., J. C. Stenning, Esq., R. Murray, Esq., and Rev. H. Palmer.

A vote of thanks to the Chairman was proposed by Mr. Glaisher, seconded by Mr. Gooch, and carried unanimously; and a vote of thanks was also passed to the referees, for the time and attention they had given to the arrangement and classification of the pictures. The latter resolution was proposed by Sir Antonio Brady, and seconded by Mr. Howard. A. J. Melhuish, *Hon. Sec.*

Correspondence.

Death of M. Fordos.—Solid Oxgall.—Carbon Printing.—M. Janssen on Solar Photography.

The usual monthly meeting of the Photographic Society of France was held on Friday, the 5th instant,—M. Davanne, President of the Committee, in the chair. The attendance of members was small in consequence of the heat, which rendered outdoor amusements and the cooler breezes on the Terrace de l'Orangerie, overlooking the river Seine, and in the Champs Elysées, irresistibly attractive.

Herr Luckhardt, of Vienna, Secretary of the International Jury of Class 12 (photography), being present, was invited by the Chairman to occupy a place amongst the committee, and also his colleagues of the jury.

On behalf of the President, and of himself, the Vice-President, of the Photographic Society of Vienna, he (Herr Luckhardt) expressed himself as highly flattered by the reception they had received from the Photographic Society of France and all connected with the Exhibition.

Mr. A. L. Henderson, of London, was also introduced to the Chairman.

The Chairman announced the death of M. Fordos, the chemist—a member of the Society, an operator in the days of Daguerre, and who, as the partner of M. Gelis, first introduced the *sel d'or* of Fordos and Gelis for the toning and fixing of silver proofs, and also, for the more permanent toning of prints, the double salt of chloride of gold and potassium. The Society decided that its regrets and condolence should be presented to the family of the late M. Fordos.

M. Lamy sent a communication on a new solid coating of oxgall. He has for some time substituted for the liquid coating of oxgall a solid one, having for its base the fatty acids of gall. This simplifies the preparation of glass plates to serve as supports for the development of carbon paper, and which he prepares in the following manner:—The oxgall of one animal is kept in a covered vessel until completely putrified, which requires from eight to ten days at this season of the year. From the time the oxgall is considered sufficiently decomposed the fatty acids it contains are precipitated by the aid of about 25 c. c. of glacial acetic acid, or of 100 c. c. of ordinary vinegar, which is necessary to separate all the fatty matter contained in a large gall of about 500 c. c. The precipitate is left to deposit itself at the bottom of the vessel, which requires about two days; it is then decanted and the clearest part rejected. The other portion, which still retains the precipitate in suspension, is poured into a funnel, closed with a fine sponge. If there still remain a precipitate adherent to the bottom of the vase it may be removed with a spatula and passed upon the sponge. As soon as all the matter deposited upon the sponge is dry it is washed with water several times and then drained; the sponge should be pressed a little to remove the last portion of the water. When this fatty deposit is well drained it is separated from the sponge and is pounded, together with an equal volume of melted grease. Up to the present time he has only used melted beef grease and fresh butter. To preserve this mixture without deterioration it is necessary to add a gramme of powdered alum to each hundred grammes of grease and remelt the same. Thus is obtained a sort of pomade insoluble in boiling water, which is very slightly applied upon a pledget covered with flannel or wash leather and rubbed over the glass plates, which should have been previously cleaned. The marks of the pledget must not be visible, so that the final image may not bear any traces of it. The plates thus prepared may be used immediately or kept a long time for future use. The exposed carbon paper is attached to these plates in the ordinary way, either in a tray of clean water or upon a pool of water upon the plates laid horizontally on levelling screws. The development of the image and drying, with the application of the transfer paper, is conducted as usual, and the image upon the transfer paper separates from the glass plates with the greatest facility and having all the brilliancy and lustre of the glass surface without the necessity of using collodion.

The preparation of this pomade is tedious, but when once obtained the employment of it is most easy and rapid, and gives results which may be depended upon as constantly good. Its advantages over the liquid coating described by M. Lamy some time ago in The British Journal of Photography are very great. A simple coating of the glass plate suffices; besides, there is no need to attend to the desiccation, nor is it necessary to render insoluble the dried coating on the glass. Any number of plates may be prepared in advance for future use, and in this case, although the coating is dry, it becomes instantly moist and adhesive when it is wetted. The fatty acids of the gall seem to be chemically combined with the grease, because the film does not repel water; on the contrary, it absorbs it.

M. E. Lamy offered the following remarks on the subject of the employment of the precipitation of oxgall unmixed with grease:—Glass plates cannot be easily coated with the pure precipitate of oxgall alone; for in rubbing the glass surface with the pledget the coating becomes at first sticky, then dries quickly, and presents a powdery surface. Notwithstanding, if with a little trouble a plate has, however, been uniformly covered, it will be seen that the carbon paper, when softened and applied under water as usual, adheres so very strongly that, finally, when dry, it cannot be detached therefrom. This strong adhesion may be utilised to produce the proofs destined to remain on glass; but for this purpose it is advantageous to add to the precipitate of gall a product which renders easy the coating of glass plates without diminishing the adhesion after desiccation.

M. Liebert said that the product of M. Lamy took long to prepare, and having much experience with the carbon process he saw no necessity to change his way of preparing the surfaces of the plates for the temporary support during development. He had used for years benzole, to a litre of which he added ten grammes of the common wax that everybody used for waxing the boards of their oak floors.

M. Davanne, in paying a compliment to M. Liebert for his labours, said he must leave M. Lamy to fully reply to his objections, and proposed that the thanks of the Society be presented to that gentleman for his communication.

The reading of the article, by Mr. Henry Cooper, in the British Journal of Photography (page 266), *On a New Substratum*, elicited the remark from M. Davanne that in France talc answered every purpose; it was especially valuable when the collodion image had to be removed, in proof of which he mentioned the valuable reproductions from the MS. in the Hôpital de Meaux, which had been removed from the glass, to serve the purposes of photolithography, by M. Berthaud.

M. Michaud recommended the addition of one-tenth per cent. of chrome alum to the gelatine before pouring it on the collodion image, which rendered the film when detached from the plate more flat and capable of resisting moisture and damp.

M. AUDRA's experience was conclusively in favour of talc, whether for retaining the film of collodion and emulsion on the plate during development or enabling the same to be surely and effectually transferred therefrom with gelatine.

M. Vidal presented to the Society his new work and views of the Universal Exhibition, the plates of which were printed from gelatine images (phototype), and printed by machinery at the rate of one thousand proofs in nine hours' press-work, giving white margins to each, and thus saving the time and expense of mounting on cardboard. The printing, without finished margins, could be executed at the rate of 15,000 per day of the same number of hours. M. Vidal, for some of his views in the Avenue des Nations, complained that there was not sufficient receding space for his French lens.

M. Michaud also made a presentation to the Society of some of his photo-engraved proofs, absolutely untouched, and printed by M. Chardon, one of the first printers in Paris.

M. le Commandant de la Noë showed some new proofs by the orohe-liograph—a camera perfected by Colonel Mangin, which now gives by means of prisms the circular images of the horizon. The former support of the mirror being superseded, there is no longer any want of continuity in the proofs of the whole circular horizon, as in the original instrument, the fundamental principles of which are still under study; further progress is at present in train, and will in due time be communicated through the kindness of Commandant de la Noë.

M. Raoult, of Odessa, forwarded a numerous colleetion of pictures of the people and costumes in the various governments of Russia, and which were of a most interesting character, being also very good specimens of photography.

M. Chauvigné, of Tours, exhibited some perfect proofs in carbon of groups of flowers; these were of great excellence, both as to artistic composition and technical execution.

M. Rothschild, publisher, stated that he employed photographic impressions in printing ink very extensively for the illustration of his publications, and had utilised the services, since 1872, of M. Tessie de Mothay, M. de Gayfier, M. Thiel, M. Meynier, and M. Berthaud. He had for some time given a preference to the excellent mechanical prints executed by the Autotype Company of London, specimens of which he presented to the Society.

The chief interest of the evening centred in the communication of the distinguished *savant*, M. J. Janssen, Member of the Institute of France, Director of the National Observatory of Physical Astronomy of Paris, at Meudon, &c., whose simplicity of manners added grace to his learning, whilst the numerous diagrams he drew on the black board illustrated his ideas and rendered easy the comprehension of the subject. I here personally take the opportunity of thanking M. Janssen for his extreme kindness and courteous attention to myself. To him the numerous readers of THE BRITISH JOURNAL OF PHOTOGRAPHY are indebted for the following remarks:—

M. JANSSEN brought before the Society the continuation of his researches upon solar photography. It is already known how the author has been led to obtain photographic proofs which reveal to us details before unknown as to the constitution of the solar surface. Up to the present time no one has been able to reproduce photographs of the sun containing anything beyond the great and strongly-marked features of the surface of that heavenly body, and more especially the spots *(taches)*. At various times details having relation to its surface granulation have been obtained, but in a slight and very uncertain manner, and which did not permit of any serious and continued study. Now, the solar photographs obtained at the observatory of Meudon show a disc of about $19\frac{5}{8}$ inches in diameter, and giving details of the constitution of the photosphere totally unknown before—notably on the nature of the granulations. Thus, a new method is opened out for the study of the solar orb. It is principally in shortening the luminous action to an extremely short duration of time—about $\frac{1}{3000}$th of a second—and in afterwards enlarging the images, that M. Janssen has been able to obtain this result. It is well understood, however, that the perfection of the photographic process itself is here indispensable in order to obtain the images of great purity. From the commencement these important labours have conducted the learned author to study the constitution of the photographic spectra, when the time of the luminous action is thus reduced to such short exposures. M. Janssen has found that under these conditions the constitution of the spectrum changes considerably, and recently he has studied the constitution of the photographie spectrum with various collodions, having for a base the principal iodides and bromides, employed separately or in combination. Details will be afterwards given upon these results on the spectrum; but the fact to bring into evidence or light is this—the extent to which the photographic spectram diminishes with the time of exposure, and with the duration of some seconds or fractions of seconds, as the case may be, the spectrum is reduced to a band situated very near the line G of the spectrum of Fraunhofer. M. Janssen placed before the members of the Society the spectra of several substances obtained with exposures successively shortened, and where was seen in effect that the length of the spectrum diminished rapidly. This remarkable circumstance showed all the advantages that photographic images could have under these conditions, from the point of view of sharpness, over ocular images. It explains, in a great measure, how the shortened exposures have permitted M. Janssen to obtain and secure solar images more perfect than the ocular images of astronomical telescopes. On this subject M. Janssen desired to state that these experiments have been made with the photographic telescope, of five inches aperture, that M. Prazmowski had constructed in 1874, at his request, for his expedition to Japan. In the construction of this instrument—independently of the optical principles which belong to M. Prazmowski—this eminent optician had taken into account the above remarkable spectral circumstance which M. Janssen had already observed. He (M. Janssen) gave, in continuation, some details in connection with the instrument which, in the photographic telescope, enabled him to reduce the exposure to so small a fraction of a second. This apparatus is formed essentially of a brass plate having a slit of variable opening, this plate being carried by another larger plate, upon which it moves between small wheels. The movement is obtained by spiral springs, *à boudin*, of which the arrangement is such that to produce the exposure they have no further action when the slit passes before the solar image. It is in virtue of the acquired speed that the plate with the slit then moves, and the result is an uniform movement. This apparatus of exposure is placed at the focus of the lens, and at the exact place where the real image is formed. To measure the time of the exposure a pendulum is used, the duration of whose vibrations are known. The vibratory movement is inscribed by a pointed tool upon the plate carrying the slit, allowing of the measurement of its speed, and, in consequence, the appreciation of the duration of the time of exposure according to the degree of the opening of the slit. In these experiments the duration of the action of the light is *en rapport* with that of the direct light of the sun. In summer the solar photographs are obtained by exposures which may vary between $\frac{1}{2000}$th and $\frac{1}{3000}$th part of a second of time. This short exposure is a circumstance of the greatest importance in securing the details of the surface of the sun.

The thanks of the Society were voted by acclamation to M. J. Janssen with great enthusiasm. W. HARRISON.

Asnières (Seine), Paris.

INTENSIFYING GELATINE NEGATIVES.

To the EDITORS.

GENTLEMEN,—Will you kindly inform me of the best means of intensifying gelatine negatives? I have been experimenting with gelatine emulsion made according to Mr. C. Bennett's formula, published in your Journal some little time ago, and have succeeded in obtaining very rapid plates by it, but have failed to get sufficient intensity; in fact, the images produced are so faint that after the plates are fixed they are scarcely discernible, and on attempting to intensify them by the ordinary acid pyro. and silver method the films blister all over and become spoiled completely.

I have modified the developer, using it weak and also strong, and I have also added a small dose of bromide of potassium to prevent it from acting too quickly and to allow it more time to penetrate the film; but still the images are not intense enough for printing.

I have also tried the ferrous oxalate developer, but with no better result. This developer I like very much when freshly made; but I find that it will not keep good long, as it gradually loses its developing power.

I may state that I thoroughly washed the plates between the development and the intensification.—I am, yours, &c., A. J. REILY.

Weston-road, Handsworth, Birmingham,
July 16, 1878.

[We print this letter *in extenso*, because we have heard of others also who, when making use of plates prepared by Mr. Bennett's formulæ, have not got the degree of intensity they wished. In our own practice we have always obtained intensity by first fixing, and then applying pyrogallic acid with citric acid and nitrate of silver. By making use of *hard* water the film will not be disturbed. We shall be glad to learn the experience of others on this subject.—EDS.]

EXTRA SENSITIVENESS OF DRY PLATES.

To the EDITORS.

GENTLEMEN,—Premising that I am an old experimentalist in dry-plate work—as my card enclosed will certify—permit me a few remarks on the subject of your article on sensitiveness in last week's Journal.

Seeing that it is quite impossible to time the exposure of dry plates with absolute accuracy, unless one carries to the field with him a tent by which he will be enabled to ascertain, from the actual development of a plate occasionally, whether he is not under- or over-exposing, the next best thing to do is to adopt a method of developing which shall be tentative to such a degree as to indicate at an early stage of development whether the exposure has been correctly timed, and, if not correct, the remedial measures to be adopted.

Having tried every method of development that has yet been published, the only one which in my experience fulfils the above conditions is that in which the development is commenced with the application of a plain aqueous solution of pyrogallic acid, having such a faintly alkaline reaction as to bring out the feeble traces of an image after it has been acting upon the film for about a minute. A trained eye will be enabled to decide from the appearance of this feeble image whether or not the exposure has been correct; and the subsequent application of a soluble bromide (I make use of bromide of potassium) will prove an equalising agent in case of the correct exposure not having been hit.

To such an extent is this the case that you, Messrs. Editors, will bear me out when I say that a plate to which I gave more than twice the exposure it ought to have received was, by a copious libation of bromide of potassium at the early stage of its development, made to yield a negative quite equal, in respect both of quality and apparent time of exposure, to one exposed for only half the time it received.

I quite agree with you, however, that for the generality of landscape purposes extreme sensitiveness is *not* desirable.—I am, yours, &c.,

Camberwell, July 15, 1878. AJAX.

EXCHANGE COLUMN.

I will exchange my Woodward's solar camera for a good 10 × 8 camera and lens.—Address, A. B., 91, Eastgate, Rochester, Kent.

Wanted to exchange, carpenters' tools (new) for a good dark tent on wheels, to work 12 × 10, or a 12 × 10 Kinnear camera with sliding front.—Address, J. MERRY, High-street, Glossop.

I will exchange three gross of quarter-plate glass, new and perfect (worth 7s. 6d. per gross), for printing-frames or anything useful in photographic goods.—Address, J. W., 5, Keith-terrace, High-road, Lee, London, S.E.

I will exchange a 15 × 12 mahogany bellows camera with double swing back and screw for focussing, with watertight glass bath in mahogany case and plate-box, for a similar set for 12 × 10.—Address, G. HADLEY, 33, Newland, Lincoln.

Wanted, a good portable whole-plate tent, complete, in exchange for value from the following:—Half-plate portrait and view lens, half-plate light bellows camera (three fronts and folding tailboard), strong folding tripod-stand, umbrella-stand, half-plate box tent with tripod, tray, cistern, &c., complete, Howard tent. All the foregoing are in good condition.—Address, F. MOTTERSHAW, 2, Talbot Gardens, Sheffield.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

NOTICE.—Each correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a *nom de plume* as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

J. J. H.—This correspondent wishes to know the address of M. Steinbach, the continental paper-maker.

T. SADDLER.—It is quite easy to understand: the *principal* focus of a lens is the point to which parallel rays are made to converge.

W. R. HARRISON.—Our Paris correspondent's communication received just before going to press. Will appear in our next number.

F. S. GRAY.—Your scheme is scarcely feasible. It is based on the supposition that the light is uniform in strength, which, unfortunately, is not the case.

P. P., PHOTO.—Use the lens without a stop when taking vignettes. For other portraits let the diaphragm be the largest possible consistent with marginal sharpness.

G. W. GREEN.—We have forwarded your letter to the gentleman named, who will, no doubt, reply to it. We imagine that the publication of the work is only being delayed, not given up altogether. Such a work will be gladly welcomed by many, ourselves included.

GEORGE.—The method of producing vitrified enamels by toning a transparency by means of chloride of platinum and then burning it in is at least as old as 1865, in which year we published it. After this information it rests with yourself whether you will proceed with the proposed patent.

B. WALLIS.—Like many other inventions the graphogenic apparatus did not fulfil the promise it once held out, and so it was discarded. We believe it would now be impossible for you to obtain such a piece of apparatus; but there is no harm in making application at the establishments of the various dealers in second-hand appliances.

OBLIGED READER.—One ounce of sandarac to six ounces of shellac will prove to be a very good proportion. Place a quantity of broken glass, or small pebbles well washed previously, in the bottle of alcohol along with the resins, and then place the bottle in an oven where it will be retained at a warm temperature. Shake it at frequent intervals for half-an-hour, after which the varnish will be made. We assume that a quart of spirits of wine (methylated spirits will answer) has been used. It must now be allowed to stand undisturbed for eight or ten days, by which time a mass of white insoluble matter will have been deposited. When filtered the varnish is ready for use. Common filtering-paper may be employed.

JOHN F. STEVENS.—Your friend has been indulging in a quiet bit of fun at your expense. To "crystallise carbon" is simply to make diamonds; and to raise the temperature of "protoxide of hydrogen" to 100 C. is merely to boil plain water, which, of course, is *not* a solvent for the crystallised carbon.

S. Y. B.—Make a weak solution of cyanide of potassium—about four or five grains to the ounce will be strong enough—and pour it, drop by drop, into the silver solution until a permanent milkiness is formed; then filter, and the solution will be ready for use. In reply to the postcript of your letter: we make it a special rule never to recommend the productions of either opticians or camera-makers. This applies also to collodion and other chemicals. Wherever we think there is a necessity for it we, however, freely intimate where certain rare articles are to be obtained.

T. O. B.—has broken off the lower end of his ebonite dipper, and has been trying to repair it by means of marine glue, which has not proved successful. He wants to know by what means the mishap may be remedied.——He must avoid entirely making use of glue or any other kind of cement, and effect the repair by drilling holes in the ebonite and attaching the broken piece by means of silver pins or rivets. If unable to do so himself, let him take it to a working jeweller and instruct him to mend it in the same way as he would a lady's tortoiseshell comb, making use of silver for the purpose.

ONE IN TROUBLE.—It would be quite impossible for us to explain the cause of the long exposures required unless we paid a visit to your studio. It may arise from the colour of the glass having changed or from the erection of some building in the vicinity. On the other hand, it may be owing to the use of unsuitable chemicals, or of a lens which, having been too much exposed to light, has changed colour, and thus become slower. We would not for a moment hint that you may have less experience in manipulating than your predecessor; but would suggest that you secure the professional services of any experienced photographer who is willing to devote a day to the examination, and thus ascertain the cause of what will sooner or later prove a serious drawback to your success.

MEDICUS.—It is not easy to indicate in an off-hand way the amount of nitrate of silver required to sensitise a sheet of albumenised paper, because the proportion of salting material in the albumen varies according to the tastes of the respective makers. Suppose, however, that the albumen contains ten grains of chloride of ammonium per ounce—a proportion which we believe is extensively adopted—it is found that about six and a-half drachms of albumen is taken up by each sheet. This represents a little over eight grains of chloride of ammonium in each sheet, which quantity nearly equals twenty-six grains of nitrate of silver. But the albumen, in addition, takes up a certain quantity of the silver, which may be estimated at four grains more; hence it is practically correct that to excite each sheet of albumenised paper requires thirty grains of nitrate of silver.

"CHLORIDE OF PLATINUM."—A correspondent, who adopts this *nom de plume*, has been trying to tone gelatine transparencies by means of chloride of platinum, but without success. Had his query related to *collodion* transparencies we could have spoken with freedom, having had some experience with this application. As our experience has not extended to gelatine, we reproduce his note in the hope of its eliciting a reply:—"Will you state in the column of 'Answers to Correspondents,' in the earliest number of the Journal possible, how chloride of platinum is to be used for toning lantern slides so as to produce a dense black tone. I have tried the plain solution of various dilutions, but cannot change the colour of the image in the slightest degree. The plates used are *gelatine*, and developed by the alkaline method. I have looked through the last three volumes of the Journal and the last three ALMANACS, but can find no reference to this method of toning."

THOMAS.—This correspondent makes inquiry as follows:—"1. Does Mr. Edwards use any special developer with plates sensitised in the nitrate bath, particulars for making which he gave in a paper read before one of the London societies over a year ago? If so, please give formulæ.—2. What is the cause of a silvery scum appearing almost immediately after pouring on the developer, and at the same time a gradual darkening of the image? I have tried shorter exposures, but the same thing occurs, only that it is not so quick in appearing. I may say the bath has only been lately mixed, as given by Mr. Edwards, and there has not been more than twenty plates sensitised in it (size of bath, quarter-plate). I have used two different developers—one an ordinary iron developer, and the other containing acetate of soda, as given in the pages of the ALMANAC.—3. Please state what other substances or liquids (besides the following) have been used or are capable of preventing the slipping of emulsion films, viz., india-rubber in benzole, albumen, gelatine, cocoa butter, and gelatine rendered insoluble by chrome alum."——In reply: 1. Mr. Edwards recommends a developer composed as follows:—

Protosulphate of iron	1 pound.
Ammonia-sulphate of iron	1 ,,
Sulphate of copper	1 ounce.

Water to make a saturated solution. To use this add *about* thirty drops of it to an ounce of water, to which must also be added about half-a-drachm of glacial acetic acid and a like proportion of alcohol. The proportions may, however, be greatly varied to suit the nature of the work.—2. The silvery scum indicates the presence of organic matter in the bath.—3. Rub the plate with French chalk. This will effectually answer the purpose of a substratum.

RECEIVED.—E. Eccles; X. Y. Z.; J. G. B.; and Geo. B. Sutcliffe.

No. 951. Vol. XXV.—JULY 26, 1878.

THE NITRIC ACID PROCESS FOR PRODUCING REVERSED NEGATIVES.

Some time ago we were called upon to assist a friend in the reproduction of a number of transparencies which were required for a special purpose, and the negatives of which, if indeed in existence, were not immediately accessible. The originals were of the stereoscopic class, whilst the reproductions were required for lantern purposes, and the method adopted consisted in the double operation of printing, by superposition, first a negative, and from it the duplicate transparency. Those who have had any experience in this direction will be aware of the difficulty which attends the "translation" (if we may so term it) of the deep, heavy shadows of an ordinary stereo. transparency into the clear, juicy details requisite in a lantern slide. By the method we adopted this difficulty was brought into even greater prominence, but, unfortunately, it was at the time we speak of the only plan available.

Now, however, there exist at least two processes by which the required end may be attained in a single operation, and, perhaps, in better style than by the old plan; for we must confess that we do not look back upon the results of our labour on that occasion with complete satisfaction. Had we the same task set us again our choice of means would rest between one of the "dusting-on" methods and the negative reversing process with nitric acid, which have only within the last few years acquired any popularity in this country. The "dusting-on" process would, no doubt, carry the palm provided the exposures could be made by daylight, offering, as it does, so many facilities for modifying the character of reproduction and for improving faulty portions of the original. It has its disadvantages, however, especially in the hands of those not thoroughly conversant with its action, and, unless habitually worked, is liable to give irregular results from slight variation in the state of the atmosphere. For transparency work, too, the image is, perhaps, not of the best quality for the purpose, though we have seen "dusted-on" transparencies as fine in grain as the best developed ones.

The nitric acid reversing process, on the other hand, commends itself on the ground of its universal application. It may be used by daylight or by gaslight, and the exposures may be made either in the camera or by superposition, while a further advantage is found in the fact that it introduces no unaccustomed manipulations, unless it be the removal of the image by nitric acid. This process has been successfully applied to the production of transparencies direct in the camera for enlarging purposes, and has deservedly attained a high degree of popularity. It has also been used for the reproduction of negatives; but in this class of work, for some reason or other, it does not appear to have produced so favourable an impression, though, as far as we can see, there is no real reason for the difference. A *practical* reason does, no doubt, exist in the extra amount of skill necessary in the reproduction of a negative where the operator works to a certain extent in the dark, and much is left to his judgment. Still, we repeat, there is no real reason why one operation should be more difficult than the other, if only an equal amount of study be given to the special requirements in either case.

Though, as regards the facilities afforded by the nitric acid process for the alteration or improvement of the character of the negative, it is, from the nature of the operation, inferior to the "dusting-on" method, it is still possible to produce duplicates fully equal to the original, and in certain cases an actual improvement may be effected. As is well known, one of the special features of the latter plan is the power it gives of working upon portions of the picture which may be defective without altering those parts which do not require such treatment; and it is in the absence of this power of local application, in the case of the nitric acid process, that the difference in their application consists. We cannot, for instance, bring into greater prominence the feeble detail in an under-exposed shadow without, at the same time, producing a corresponding effect upon the remaining portions of the picture; in other words, if we attempt to strengthen the feeble portions of the positive image by pushing the development the reducing action is carried on to a proportionate extent over the whole plate, and the result is that, after treatment with nitric acid, the under-exposed portions of the original are rendered even more transparent and devoid of detail. If, on the other hand, the development be arrested at such a point as to prevent over-reduction in the shadows, the high-lights and half-tones of the reproduction are rendered too dense.

These, indeed, are the two extremes which have to be guarded against, and which constitute the chief difficulty in the successful working of the process. The great mistake is made in trusting too much, if not entirely, to the development to produce the desired effect, when in reality the whole matter hinges principally upon the exposure. We know that in developing a negative in the ordinary way we may by modifying the development produce images of very different apparent density irrespective of the actual amount of silver reduced. Thus, rapid development with a full dose of ammonia will give an image in which the bromide is reduced through nearly the whole thickness of the film, whereas a slow and gradual action produces a denser-*looking* image, though a thinner layer of bromide may have been acted upon. The appearance after treatment with nitric acid of two such films would plainly be very different. The secret of success lies in the careful adjustment of the exposure to a fixed strength of developer, and the total relinquishment of all attempts to modify the result by fresh additions of ammonia or bromide.

There is no greater difficulty in thus regulating the exposure than is experienced by the wet-plate photographer who works with a developer of uniform strength. It results simply in the reduction of alkaline development for this purpose, at least, to an unvarying standard to which the exposure should be adjusted, so as to produce the required effect at one operation without subsequent intensification—a matter which does not require a great amount of practice in its attainment. There will, no doubt, be a few failures at first, but where is the process in which such do not occur?

In fixing the strength of the developer we have to consider the practical requirements of the case, and though it is not possible to give a formula equally suitable under all circumstances, we may indicate the conditions to be observed. We have spoken of using a developer of unvarying strength, and we employ the term as meaning its reducing power, *i.e.*, the quantity of pyro. and alkali it contains. The addition of soluble bromide retards, but does not destroy, the developing power, and, as its retarding action is greater upon the more feebly-impressed portions of the image, its use in slightly-varied quantities enables us to modify the exposure to suit different classes of negatives. A certain quantity of pyro. and of ammonia are necessary to the reduction of a given weight of silver bromide; hence we start with a solution containing sufficient of those ingredients to reduce the film, if necessary, through its whole thickness, and, in order to render the operation manageable, and to prevent the slightest suspicion of fog, we add a due proportion of bromide.

The normal developer we have been in the habit of using consists of a three-grain solution of pyro., to each half-ounce of which we add eight drops each of twenty-grain solution of bromide of potassium and of dilute ammonia (one to eight). This is strong enough to produce at one operation the requisite reduction, and the quantity of bromide renders the action sufficiently regular to enable us to stop it as soon as the desired amount of detail makes its appearance. Supposing the plate to have been timed correctly, the action of the solution is continued until the positive picture appears in its correct gradations as regards the finer tints, when upon treatment with nitric acid the deepest shadows should appear as *nearly* bare glass. If the shadows are perfectly transparent, or, on the other hand, present a considerable thickness of unchanged bromide, the exposure has been ill-timed, and the only plan is to try again, reducing or increasing the time according to the result obtained. In this manner, with a little practice, it will be tolerably easy to test the exposure every time; whereas by following the ordinary method of progressive development success is at best but chance work. Fog is to be carefully avoided, as it means a general lowering of the tone of the whole picture; but it is by no means advisable to keep the plate *too* clean—that is to say, presenting too much unchanged bromide, as that leads to hardness in the final negative. It should be remembered that only the very highest lights should remain unchanged in the positive.

The ferrous oxalate developer seems to be peculiarly suited to this purpose, differing, as it does, in its action from alkaline pyro. It is also remarkably free from liability to fog, and, if used in a sufficiently dilute state and in a dish or dipping bath, is very regular in its action. We cannot, however, as yet say that it is preferable to alkali, but many will, no doubt, prefer its greater simplicity.

The redevelopment of the picture after treatment with the nitric acid scarcely requires any remark from us here. We must, however, state that even in this part of the operation the character of the negative may be modified in a variety of ways. The picture may be made thin or dense, flat or harsh, according to the treatment it undergoes after "clearing." Thus, if exposed after merely washing off the acid it will redevelope into a thin, flat negative; if treated with very weak alkali greater strength is obtained, and a wash of tannin gives still greater vigour. The best result, however, is obtained, we think, by flooding it with a ten-grain solution of silver before exposure, and washing again thoroughly before development. The mode of development, too, exercises an important influence on the result; but in all these matters experience alone is to be depended upon for the production of the best work. Finally: we may remind our readers that under no circumstances should silver intensification be resorted to either in the first or second stage of the operation. In the first stage it is simply useless, as the silver laid on to the image is removed by the nitric acid without leaving any effect behind. In the second stage it will develope a positive image in place of the one removed by the acid, and thus produce an even deposit of silver over the whole plate, consisting of a positive and negative image superimposed.

EXPOSING BY ELECTRICITY.

One evening recently, when visiting the studio of Messrs. Hills and Saunders, Porchester-terrace, Bayswater, we were shown by Mr. Cowan, the manager for that firm, the working of an electric shutter for a camera for which a patent has been lately obtained.

The exposure of the plate is effected by slightly pressing a button at the end of a knob which forms the termination of a silken cord covering a wire connected with a galvanic battery. There is nothing to indicate to the sitter that he or she is being photographed, because the cap is so constructed as to cover the posterior end of the lens, which, being inside the camera, is not seen from the outside. As a consequence of this the nervous feeling that frequently affects a sitter at the moment of uncapping the lens is not here elicited, owing to the happy state of ignorance in which the sitter is kept as to the advent of the "inevitable moment."

In order to avoid the slight jar that might be given to a light camera by the too sudden elevation of a flap cap, the cap of the newly-patented arrangement is differently constructed. It forms, as it were, a rotating cap working in a circle, the axis of its rotation being at one side of the lens. It is attached to mechanism placed inside the camera, and is, therefore, unconnected with the lens. By means of a small electro-magnet, controlled by mechanism of which the details will be given when we publish the specification of the patent, the cap is acted upon by the slightest touch upon the button at the end of the exposing cord, the result of the action being the rotation of the cap upon the axis to which it is affixed and the consequent opening of the lens. So long as the finger is kept pressed upon the button the lens remains open; but upon releasing the button the circuit of the galvanic current is interrupted, and the electro-magnet then ceasing to act the shutter is instantly closed by a small spring, the action of which is suspended by the greater power of the electro-magnet.

In a working model shown to us subsequently by Mr. D. H. Cussons—who, with Mr. Cowan, is "interested" in the patent of this invention—the battery (a small "constant" one) was placed inside the camera, so close to the front as not to impede the full transmission of light by the lens. This method will certainly answer quite well—indeed, it *does* answer, as we had ample opportunity of ascertaining when examining the model; but for real efficiency we greatly prefer the arrangement now and for some time in use in the studio of Messrs. Hills and Saunders. It consists in having a constant battery which, in this instance, is placed in the garden, wires from which are brought into the studio and connected with two others that run from end to end of the studio, and are situated at a considerable distance above the camera. One of these wires is connected with the positive pole of the battery and the other with the negative pole. In order to put the camera into circuit with the battery it is only necessary to lay hold of a silk-covered pair of wires which are separated towards the end, the bifurcated branches terminating in hooks which are thrown over the wires that run overhead. No matter how much the camera may be moved to and fro in making the adjustments of the sitter the wires accommodate themselves to any required range of motion, and the continuity of the electric current is always preserved. By means of an elegant silk cord, which disguises the presence of a pair of fine wires inside, the current of electricity is conducted to a knob at its end, and it is by the pressure of a button at the end of this knob that the exposing operations inside the camera are controlled.

It is only a few weeks since we described an ingenious method of capping and uncapping a lens by pneumatic agency. The advantages of the operator being able to uncap the lens when standing at a distance from it are so very obvious that we at first, and naturally, assumed that the electric idea had been suggested by the pneumatic shutter. We were assured, however, that for a period of several months the idea of applying electric force to the exposing of the plate had not merely been in existence but has been actually applied from the commencement of the present year. Up to a very recent period it has been undergoing such a course of experiment that it is only quite lately it could be said of it that it had been perfected.

The action is prompt, and there is no jarring of the camera produced. As there is nothing visible to denote when the exposure is made the closing of the cap is indicated by a slight click audible to the operator, who is thus enabled to intimate that all is over.

BLISTERS IN ALBUMENISED PAPER.

In the whole range of silver printing we doubt if there is any one trouble more annoying and difficult to get rid of, when once it makes its appearance, than the formation of blisters in the process of fixing, or washing after fixing, in the course of printing upon albumenised paper. Yet, paradoxical as it may appear, there are many to whom the very sight of a blister would be an actual novelty; and no one need be surprised that such photographers, when they read or hear of these most annoying appearances, set the cause of their production down to carelessness, bad chemicals, &c. Yet any such opinion would be entirely wrong. Blistering has appeared under the manipulation of the most able printers and of the cleverest operators, and for a long while there was no remedy to be found. Their cause was at first put down to the weather being too hot or too cold, the silver bath being too acid or not acid enough, the toning bath being too weak or too strong, and to a multitude of the most opposite causes; and, as the disappearance of the trouble was frequently coincident with an alteration in one of these directions, it was not unreasonably supposed that the cause was found until, possibly on some very distant occasion, the blisters made their appearance once more.

It is, however, now satisfactorily settled that it is not in any of the causes specified that we must seek for the origin of the evil, though they may modify it in some degree, but to the albumenised paper itself. Some samples may be used for years and not show a blister, while others cannot be used without almost every batch of prints being more or less injured. The annoyance is increased by the fact that it is usually the brighter and more brilliant pictures that suffer most; and this points to the now well-known fact that it is the more highly-glazed paper that is most liable to blister.

Some of our readers may say—"What matters the blisters, seeing they dry down and do not show?" To this we reply that, in the first place, the washing in the blistered part is uneven, and that there is every probability that the hyposulphite with the silver dissolved—that is, the double hyposulphite—will be found to decompose in them and most likely form a deposit which, in course of time, would lead to fading and spottiness. That the blisters may not show for some time after drying down ought not to be sufficient for any photographer of integrity; he ought to feel reasonably certain that they will not show ultimately in his prints, or he ought to reject them. And that there is every probability of their ultimately changing is proved by the fact that when the blistered prints are washed for from twelve to wenty hours there will be a marked difference between their colour when dried down and that of the surrounding parts. If further confirmation were wanted of the actual difference that exists between the two portions—that is, the blistered and the unblistered—we would suggest to our readers that they try a picture that has been blistered and dried down without leaving a stain by passing it through a hot press or a burnisher. They will then see a most startling change—such a difference as might be expected to show sooner or later in the finished picture.

The injurious nature of blisters being taken as proved, it becomes a matter of moment to find a cure for them; for, though some photographers never experience them, there are many who do, and no one can tell how soon he may have a sample of paper that will break out in this least-desired manner.

A host of panaceas have been invented, and a number of theories offered, to explain the cause of the phenomenon fully. The favourite theory is that the separation of the film of albumen from the paper is caused by the ozmotic force exercised between the two liquids—the strong solution of hypo. and the plain water—separating the film in the parts where there is least adhesion to the paper support; and many practical remedies have been suggested founded on that theory. We have a number of experiments on hand in which we are endeavouring to find the true origin of the fault, and the best remedy and prevention, if possible.

It might be imagined, *à priori*, that if the blisters were caused by this action, and not by the products of the special chemical reaction between the hypo. and the chlorides of silver and the albumen, the immersion of a washed print in a solution of any other salt would also produce blisters; but it must be borne in mind that there is a vast difference in the ozmotic action of various salts, and for the experiments to be parallel the other solution must be of a salt whose power in this respect is on a par with that of the hypo. Thus, a dilute solution of chloride of sodium has been recommended as a medium in which to immerse the prints, to halve, as it were, this action, and so prevent the formation of blisters. But we have tried it more than once, and have not been able to find the slightest benefit from its employment. It is certain that, even if the practice were correct here, it would be a right conclusion from wrong premisses; for, as we have before stated, blisters should be able to be produced by a salt which could act as a remedy in this manner. But if anyone immerse a print in a solution of salt of considerably greater specific gravity than the usual solution of hypo., he will fail to obtain a trace of a blister.

To give some idea of the force of osmose of various salts we pick out two extremes. Chloride of sodium is represented by 2, and chloride of aluminium by 540, in a table showing the osmose of substances through membrane, the degree being a rise or fall of one millimetre.

We close the subject for the present by publishing the experience of one of our contributors. Mr. G. Watmough Webster informs us that, having a sample of paper that blistered to an extraordinary degree, he has after a number of experiments found that the blisters were entirely cured by the addition to the hypo. solution of twenty per cent. of methylated spirit. A smaller quantity would not answer at all with this particular sample.

RECENT PATENTS.

No. XI.—PRODUCTION OF PHOTOGRAPHIC PICTURES ON WOVEN FABRICS.

The following application of photography to textile fabrics is by Mr. William Winter, of Prague, Austria:—

The object of this invention is to produce magnified positive photographs on woven fabrics, such as linen, cotton, silk, or wool, and with the use of iodide or chromide of silver.

The process consists essentially in impregnating the woven fabric with iodide or chromide of silver, and thereby making it so sensitive to light that from a negative plate of about eight square inches a magnified positive photograph of up to more than forty square feet may be produced on the said woven fabric.

When electric light is employed the positive photograph may be produced in from one to four minutes.

The iodides and chromides are in general use for producing negatives, but hardly at all for negatives; and, although many attempts have been made to utilise the sensibility of these salts for the purpose of rapidly producing magnified photographs on paper, these experiments have nearly always remained futile.

The proportions of the chemicals to be used vary, not only according to temperature but also according to the density and material of the woven fabric, so that in the case of lower temperatures and denser woven fabrics, which do not so easily absorb fluids, the solutions must be made stronger, and iodides must be used in preference to chromides.

By way of example there shall now be described the proportions that may be used at a temperature of from twenty to twenty-three degrees Centigrade, and with linen or cotton fabrics of average density and fineness. This description will serve as a measure for the possible variations under the previously-mentioned circumstances.

The woven fabrics must be first freed from all chemical impurities, and the subsequent operations may then follow in the manner now to be described.

1. *The Treatment with Chromides.*—The woven fabric is passed through a solution composed of four parts by weight of chromide of potassium, one part of chromide of cadmium, and 240 parts of water, so as to be equally wet on both sides, and is then hung up to dry.

2. *The Treatment with Silver.*—The dried, woven fabric is passed through a solution of four parts by weight of nitrate of silver, one part of citric acid, and 140 parts of water, and again dried.

3. *The Exposure to Light.*—For this purpose it is generally preferable to use electric light, which may be produced by a dynamo-electric apparatus. In all other respects the proceedings are the same as in the production of magnified photographs by means of the solar camera. The sensitised woven fabric is exposed to the light until the positive photograph is distinctly visible thereon. The time necessary for this exposure depends upon the size and strength of

the negative—generally one to four minutes are required; but it may be added that although the use of electric light is generally preferable, other artificial light or the solar rays may be used in the process.

4. *The Development.*—A solution composed of ten parts of pyrogallic acid, forty-five parts of citric acid, and 410 parts of water is put into a large flat pan, and the woven fabric is left in the solution until the photographic picture or print thereon is sufficiently developed.

The remaining proceedings are as usual in photographic processes. The picture is well washed, then toned and fixed, and finally again well washed.

It is evident that, without departing from the substance of this invention, other sources of light and other iodides and chromides may be used for producing magnified photographs on woven fabrics.

Having thus described the nature of this invention, and in what manner the same is to be performed, as communicated to me by my foreign correspondent, I claim—

First. Woven fabrics provided with magnified positive photographs, essentially as described.

Second. The process for producing magnified positive photographs on woven fabrics, essentially as described.

Third. The process for producing magnified positive photographs on woven fabrics by the use of iodide or chromide of silver, essentially as described.

Fourth. The use of electric light for producing magnified positive photographs on woven fabrics when these are impregnated with iodide or chromide of silver, essentially as decribed.

Although we have printed the specification precisely as published, we are tempted to inquire if by the "chromides" spoken of throughout the specification the *bromides* are not really meant?

Want of time and pressure upon our space prevented our replying last week to Mr. Bennett's "plea for extra sensitiveness." We hasten now to say that that gentleman slightly misunderstands the drift of our arguments in the article to which he refers. Our object was not in the slightest degree to detract from the value of extra sensitiveness in dry plates for special purposes, or when used under the same advantageous conditions as wet plates. A more thorough exposition of our views on the question we could scarcely require than the last paragraph in Mr. Bennett's article, in which he shows the cause of the want of regularity of dry plates—a fault which he states to be common to both quick and slow plates. In this we quite agree with him; but we differ in believing that without the wet-plate worker's facilities, the tent, and a "sighting shot" to get the exposure, the quick plate is more liable to error than a comparatively slow one. Mr. Bennett says:—"If two plates require respectively five minutes and five seconds for correct exposures they will be equally over-exposed if they receive respectively six minutes and six seconds." True; but Mr. Bennett overlooks the fact that it is very considerably more difficult to time to within *one second* of the correct exposure than to within a minute. The difficulty lies in our inability to err *proportionately* to the sensitiveness of our plates. In speaking of the "quality of the result" we of course referred to the *printing* quality; the writer's remarks as to the greater softness of negatives produced by means of rapid exposures are perfectly true—at least with the description of subjects he mentions. These, however, are the ones in which rapid plates have the advantage over slow ones, but "general landscape work" includes subjects of a widely different class. Let us suppose an open view, including a not too well-illuminated foreground, and distant mountains in sunshine, perhaps eight or ten miles away; and let us further suppose a rapid gelatine plate to be exposed for a sufficient time to properly impress the foreground—say six seconds—while the distance requires no more than three, or perhaps two, seconds. Where will the distance be upon development? Very far distant, we fancy—out of sight, in fact. Our sole contention is that until the great bulk of photographers are in a position either to judge correctly or to measure the exposure necessary it will be safer to employ plates of moderate sensitiveness, leaving the luxury of extreme rapidity to those happy mortals who have attained the necessary aptitude in outdoor work.

AMATEUR PORTRAITURE.

The editorial article in the last number of The British Journal of Photography on *Window Portraiture* deals with a subject which should have a special interest for a large class of amateurs who, like myself, find but rare opportunities of practising their hobby in the field. One cannot be for ever exposing plates upon the same cut-and-dried subjects near at home, even though "home" be situated in a very paradise; for, no matter how technically perfect the results may be, their sameness soon destroys all interest and enthusiasm in the practice of photography. But where, as in my own case, the prevailing character of the local scenery is bricks and mortar and groves of chimney pots, matters are even worse; and, despite its noted unremunerativeness, the amateur is glad to work off some of his superfluous energies in the practice of portraiture.

But, as the Editors have pointed out, the absence of suitable arrangements for the purpose too often acts as a deterrent, though, as they go on to remark, there is no absolute reason why this should be so if only the amateur be content to confine his efforts within moderate bounds. I have myself for some years dabbled a little in portraiture under almost every possible condition an amateur is likely to encounter, and the result of my experience is that, for quality of results no less than for convenience, I give the palm unhesitatingly to the system of indoor work described in the article to which I refer. Whether this favourable opinion arises from my having recently paid close attention to this branch of photography or to some inherent superiority in the method I do not pretend to say, but I have a strong feeling that the latter is the cause, and if my testimony be of any value in inducing others to take up portraiture I have great pleasure in giving it.

The first great point which will arise for consideration in the minds of intending portraitists will, no doubt, be the process to be employed. Wet plates have hitherto been so inseparably connected with portraiture, both professional and amateur, that they will at once assume the leading position in such mental calculations; but many dry-plate men will, I venture to say, hesitate before committing themselves again to the employment of the bath, though it be only for portrait work. Yet there is no necessity to take the backward step. All recent evidence is strongly in favour of dry plates as compared with wet in point of rapidity; and, as this has been the one feature in which the latter class of plate has previously excelled the former in its suitability to portraiture, there remains no reason why it should not be substituted. Personally I have not "gone in" for the very high degree of sensitiveness which is now obtainable with dry plates; but I have found no difficulty in working with what I may, I suppose, term a "moderately" sensitive emulsion—one, in fact, which with the full aperture of an eight and a-half inch focus rapid symmetrical requires from six to ten seconds for a fairly-lighted, open landscape at this season of the year.

Such an emulsion, when used dry, I have found to require from fifteen to twenty seconds with a half-plate portrait lens and full aperture, the arrangements as to lighting being such as I am about to describe. If, instead of drying the plate, it be washed and organified it follows that the exposure will be still further reduced. Even with an ordinary emulsion, prepared with just a trace of free bromide and exposed before the film has become dry, the exposure under similar conditions does not exceed half-a-minute. This is certainly rather a long sitting for a nervous individual; but it must be remembered that the chemical conditions are not such as to be conducive to rapidity, while it will be seen that my mechanical arrangements are such as to render needful a longer exposure than would be sufficient if special attention were given to the element of rapidity.

I may premise that there is nothing peculiar in the arrangements of the room in which I usually operate, unless it be its apparent unfitness for the purpose. It is long and rather low, and is lighted by two windows placed at such a distance apart that only one can be brought into play at once. The windows, too, are small, measuring only three feet six by two feet nine, the longest dimension running vertically, and the extreme height of the top of the window six feet from the floor. If my readers will compare these figures with the area of glass in an ordinary studio, the length of the exposures I have mentioned will not be difficult of explanation. It is obvious that with a window of larger vertical dimensions a much larger quantity of light would be admitted, and that of better quality, as it would proceed from a better illuminated portion of the sky.

The only additional arrangement I employ consists of a light framework about six feet square, formed by nailing together four strips of deal. Over this, when placed in position, I throw a sheet to act as a reflector for lighting up the shaded side of the figure—a purpose which it answers admirably. I obtain a variety of effects in lighting by merely altering the position of the sitter with regard to the window and arranging the reflector accordingly. When the relative positions of the sitter and the window are such that the camera cannot be conveniently got into position I frequently, with advantage, interpose a mirror between the lens and subject, and thus secure a result equivalent to placing the camera outside the window.

I never attempt anything beyond a bust or vignette portrait, as my light is insufficient to properly illuminate a larger area; indeed, confining myself within those limits, I find it necessary to place the sitter as close as possibly can be to the window and to bring up the reflector in close proximity to the shadow side. It is surprising how small a space between window and screen suffices to leave a clear background space round a bust or half-length figure. I have sometimes worked within the limits of barely three feet, securing ample room for vignetting.

For general purposes I place the screen parallel with the window at a distance of about four feet, and the sitter and the camera at the opposite ends of a line drawn midway between them. A full face taken in this position (direct front light being totally absent) would have a peculiarly harsh effect from the strongly-marked contrast between the two sides of the face; the shadows are, of course, much stronger with this style of illumination than if a direct front light, or a side light extending to a greater distance from the sitter, were used, and hence the object is to avoid presenting too much of the shaded side to the lens. If we cause the sitter to turn slightly towards the window, so as to present a three-quarter face, we find that, though the eyebrow and the curve of the cheek are lighted up, the rest of the "off" side of the face remains in deep shadow, and the result, unless a very long exposure be given, is harsh and patchy in the extreme. If the inclination be in the opposite direction, however, we have three quarters of the face lighted, while the heavily-shadowed quarter face is in better position to catch the light reflected from the screen, which is then arranged to produce the best effect.

If a more evenly-lighted picture be required—that is to say, one presenting less of the "Rembrandt" effect—the sitter must be placed directly facing the light and the mirror brought into play. The reflector is then scarcely required, the shadow being produced by moving the sitter more or less away from the centre of the window, the mirror being placed so as to catch the desired "view" of the face. Half-an-hour spent in studying practically the various effects obtainable will teach more than columns of written instructions, so I will now pass on to another subject—development.

For landscape purposes I am not greatly in favour of carrying the use of alkaline pyro. too far—certainly not to the complete intensification of the negative; but when a portrait negative is in question I think it is decidedly better than silver. Its progressive developing action even during intensification tends to soften the harsh shadows which silver intensification gives, especially on a slightly under-exposed plate or when a slow emulsion is used. Ferrous oxalate answers admirably for the development; but density must be obtained by means of *alkaline pyro.* and not with silver, or the result will prove to be much inferior—such, at least, is my experience. Two plates similarly exposed and developed respectively with alkali throughout and with ferrous oxalate followed by pyro. and silver showed so strong a difference in favour of the former as to suggest a difference of nearly two to one in the exposures.

In conclusion: I think the character of negative obtained with bromide plates developed entirely with alkali is eminently adapted to portraiture, and, if properly exposed, the image is soft and round. A very little under-exposure, however, produces an opposite result; but I think I may fairly say that my failures in this direction arise from working a slow emulsion under decidedly trying and disadvantageous conditions. In a properly-constructed studio and with a sensitive emulsion I have not the slightest doubt that much quicker exposures may be given than with wet plates, and that the results obtained will be in no way inferior. In fact, I am sanguine enough to join Dr. Nicol in believing that the general adoption of emulsions in the studio is but a "matter of time." W. B. Bolton.

THE APPLICATION OF PHOTOGRAPHY TO THE PRODUCTION OF PRINTING SURFACES AND PICTURES IN PIGMENT.

IN SIX LECTURES.

I.—PHOTOLITHOGRAPHY AND PHOTOZINCOGRAPHY.

[A communication to the Society of Arts.]

When a photographer wishes to take a picture he, as a rule, begins by making what is technically known as a negative, this being a transparent picture having the lights and shades reversed. Now, here is a negative. As I hold it before the lime light you see that the parts corresponding to the dark portions of the original are transparent, and those parts which correspond to the lights of the original are opaque. Here, on the other hand, is a positive or transparency, of the same subject as the negative which you have just seen, the lights and shades of this being as those of the object represented. A negative taken from nature should show the reverse of all those gradations of light and shade which characterise natural objects, while a negative taken from a line engraving or a page of letterpress should show only two gradations—complete opacity and clear transparentness. Here is such a negative; and, notwithstanding the fact that the opaque parts are not quite opaque to the sight, they are chemically opaque—that is to say, they will not allow the photographic rays to pass through. I have nothing to say to you regarding the making of negatives, as this matter belongs to photography proper and not to our present subject.

Here is a sheet of paper which has been so prepared as to become darkened on exposure to light. Let us place this behind our negative, and allow the light of burning magnesium to shine on the face of the negative. You see the result: those parts of the paper which were covered by the transparent parts of the negative have become dark, while those parts which were protected from the light by the opaque parts of the negative retain their original white colour. Thus a positive print is obtained on paper; but if the paper print be now exposed to daylight the whole will become dark, the picture, consequently, disappearing.

This operation illustrates the first phase in the process of photographic printing as usually practised, the next step being that of unsensitising the paper, so as to prevent the complete darkening which would otherwise ensue on the further exposure of the print to light. Our object now is to study the means of producing printing surfaces (plates or blocks) from which copies can be printed without the direct action of light being concerned in the production of each print.

The piece of paper which I now hold in my hand is sensitive to light, and I will place it under this negative of a line drawing, and expose to the action of an intense light. You observe that a very faint brown image is now produced on the sensitive paper by the action of the light shining through the transparent parts of the negative; and I now hide this from your view by covering the face of the paper with a thin and uniform layer of printers' ink. For this purpose the ink is diluted with a little oil of turpentine, and applied by means of a dabber made of the glue and treacle composition which typographic printers use for making ink-rollers. The oil of turpentine soon evaporates, and leaves a compact and thin film of printers' ink on the paper. I next put the inked print into water, and leave it there while I tell you how the sensitive paper was prepared. A sheet of plain paper is first floated on this warm solution of gelatine (containing six per cent. of gelatine), and it is then hung up to dry (as I do now). When dry it is insensitive to light, and it may be kept any length of time without injury. To make it sensitive to light it is soaked for a few minutes in this solution of potassium bichromate, which contains about three and a-half per cent. of the salt, and it is once more hung up to dry, but this time in a dark room, or in a room illuminated by yellow light. When dry it is ready for exposure under the negative.

Let us now return to the inked print which we left soaking in water, and try the effect of gently brushing the inked surface with a wet camel's-hair brush. You see that the ink is gradually coming off; but in order to save time let us employ a little warm water, and, at the same time, continue to use the brush. Now, the end of the matter is that the printers' ink becomes removed from all those parts of the paper which were not exposed to the action of light, and an image in fatty ink is thus obtained on the gelatinised paper. From this I now remove the excess of water by means of blotting-paper, and lay the print, inked face downwards, on a clean and slightly-warm lithographic stone. The stone and paper being now passed through the press, you see that the paper adheres firmly to it, but on moistening the paper with a sponge it becomes easily removable. Now I strip it off, and you see that the fatty ink is fixed on the surface of the stone, leaving a perfect but reversed image thereon. Remember that this image consists of fatty printers' ink, and that it penetrates a short distance into the porous stone. Next, I put some thick gum water on the stone, and this also penetrates a short distance into those parts of the stone not already covered with printers' ink. I now rinse off the excess of gum and apply the inking roller. You see that the ink only adheres to those parts already inked; the gummed parts resist the ink, and consequently remain white. A sheet of paper being now laid on the stone, I now pass the stone and paper through the press, and you see that I get an exact counterpart of the original fatty image (technically called a "transfer") which was put down on the stone. Numerous copies may be printed from the stone by repeating the damping and inking.

You will recollect that when the light-brown image was inked with printers' ink the ink covered the whole face of the paper; but when this inked image was put into water the ink became easily removable from the unexposed parts. Now, gelatine which contains potassium bichromate undergoes a remarkable change when exposed to the action of light. It not only becomes brown in colour but it loses its property of swelling in water, and, at the same time, it refuses to be moistened; in fact, water rolls off it just as from a duck's back. Now, when the inked print (transfer) is put into water the unexposed parts of the bichromated gelatine swell and loosen their hold on the fatty ink, while the exposed parts neither swell nor absorb water but hold the ink firmly. In this dish are some uninked transfers, which have been soaked in water, and, if you examine them closely, you will be able to trace those parts of the gelatine which have swelled, leaving in each case a delicate *intaglio* image or representation of the negative employed.

Instead of putting the photolithographic transfer down on a lithographic stone, it may be put down on a zinc plate, and the plate can be printed from, if treated exactly as the stone was treated. There are on the table some zinc plates and stones, with images transferred thereon, together with proofs from them; and there are also specimens illustrating the various phases of photolithography and zincography. Messrs. Whiteman and Bass, who have been most successful in the commercial practice of photolithography, have kindly lent me some very fine specimens of their work, which I am sure you will examine with much interest. There are also on the table some admirable specimens of work by Mr. Maurice Adams.

You understand that, in its usual form, photolithography is only adapted for the reproduction of line subjects, or subjects in extreme black and white, and various attempts have been made to render it available for the reproduction of the gradations of a negative taken from nature. By a modification of Asser's starch process I have been enabled to get results which are at least encouraging. Here is a sheet of blotting-paper, which I now cover with ordinary flour paste containing eight per cent. of flour. The paper having been coated it is next smoothed with a soft badger brush, just as I am doing now, and when dry the paper is soaked in a three and a-half per cent. solution of potassium bichromate, in order to make it sensitive to light. This piece of the sensitive paper, being placed under a negative, and exposed to the light of burning magnesium for a few minutes, soon becomes tinted with a brown colour where acted on by light, as you see. The light-brown print is next soaked in cold water in order to remove the unaltered portion of the potassium bichromate, after which it is dried and ironed with a warm flat-iron, just as I am ironing this one. This last operation is to harden the coating. I now put the ironed print into water, take it out, lay it on blotting-paper, and dab on printers' ink with a stiff brush. You see that the ink adheres to those parts where the bichromated paste has been made insoluble by the action of light, and it refuses to adhere to those parts where the paste remained unaltered. In this way a fatty transfer is obtained which, as you see by these examples, shows all gradations of a negative taken from nature—not, however, as a true half-tone, but as a grain or stipple well adapted for transferring to stone or zinc. As a fine image of this kind is liable to get clogged up when printed from stone it is better to transfer it to a plate of zinc, and to make a typographic block from this by the method which I shall describe in a subsequent lecture. In the interval I will convert this zinc plate into a typographic block, and you will be able to compare these proofs, printed by the lithographic method, with others which I will take from the typographic block.

I hope some of you will experiment on Asser's process with the view of improving it, as this method affords a promising field for work, it being specially adapted for large pictures.

THOMAS BOLAS, F.C.S.

EDINBURGH PHOTOGRAPHERS' HOLIDAY.

THE annual holiday under the auspices of the Edinburgh Photographic Society came off on Thursday, the 18th inst., the locality chosen on this occasion being the beautiful grounds surrounding Winton Castle—the quaint, picturesque residence of Lady Ruthven. As year by year the advantages of such holidays become more significantly recognised, the exertions of the acting committee in bringing about something like a general closing of the establishments in the city is found each year more easily accomplished, and on this occasion a very close approximation to a universal suspension of business was attained. The original object of the institution of the holiday was to afford an opportunity for employer and employed to meet together on equal terms in the enjoyment of social intercourse at least one day in the year, and with the view of inducing as many as possible to join the excursion it has always been the aim of the committee to afford the best possible entertainment at the smallest possible cost. How well they succeeded in the present instance may be gathered from the fact that, for a payment of seven shillings and sixpence and five shillings for gentlemen and ladies respectively, the party was conveyed to and from Winton, and luncheon, dinner, and tea were provided, including an unstinted supply of beverages, ranging from soda water to champagne—so unstinted, in fact, that even some of the latter was brought back to town. Food for the mind and ear and a stimulus to "twinkling feet" was also provided by a string band, which at intervals was wont to "discourse most excellent music," while prizes to the value of over ten pounds were given to successful competitors in athletic and other games.

Of course on all such occasions there are many who, when such opportunities occur, prefer to visit friends or relatives, or plan individual trips on their own account; but notwithstanding such defections from the general excursion the party numbered one hundred and five when assembled at the Waverley station. At 9 30 a.m. the special train started, and had a pleasant run to Winton station.

Winton Castle is a picturesque building of the time of Charles II., with some modern additions not by any means so picturesque. It contains some exceedingly fine carvings and mouldings, and a series of perfectly unique chimney-pieces of exquisite workmanship. The Castle is surrounded by many fine, old, and large trees and extensive shrubberies, affording most grateful shade from the intense heat that prevailed.

The party having assembled in front of the Castle, the President, through whose influence permission to visit the grounds had been obtained, briefly intimated the orders of the day, and in the name of Lady Ruthven gave them a hearty welcome. Her ladyship, he (the President) said, regretted very much her inability to be present, and had even wished the meeting postponed for one day to enable her to meet the members; but, as that had been found impossible, her ladyship had requested him to give the assemblage the welcome he then did.

A substantial luncheon commenced the business of the day, and then the party broke up into groups, all betaking themselves to the kind of amusement best suited to their individual tastes. The younger members joined heartily in various games under the direction of Messrs. Pringle, Bashford, Mathison, and Wishart, or were tempted to "chase the glowing hours with flying feet." The more elderly preferred to recline in the shade, listening to the music and watching the ever-changing gaiety of the scene—a "sight the careful brow might smooth."

At 1 30 p.m. two photographic groups were successfully taken by Mr. John Annan, after which all sat down to dinner, the President occupying the chair. Mr. Pillans was, as on several previous occasions, purveyor, and discharged the duties to the satisfaction of all present, the viands being of the best quality, in ample abundance, and well and promptly served. After dinner,

The PRESIDENT said that it was neither the time nor place for many toasts or lengthy speeches, but as patriotic Scotchmen, who thoroughly appreciated the liberty which they enjoyed, and who loved the Queen with all the heartiness of a loyal people, they could not rise from the table without the time-honoured toast. He then proposed the health of the Queen and all the members of the royal family.

The toast was, as usual, enthusiastically responded to, followed by the singing of two verses of the national anthem.

Mr. J. G. TUNNY said the only other toast was that which he had been asked to propose, namely, "Prosperity to the Edinburgh Photographic Society." He thought it unnecessary to say a word on behalf of the toast, as the Society and its work were as well known to most of those present as to himself. It was a satisfaction to all connected with the Society to know that although advancing in years there were no visible signs of decay, and that it was one of the most useful and hard-working societies in existence. Not the least important of the many good works it had accomplished in its time was the inaugurating, and year by year carrying out, the annual holiday; and for this, if for nothing else, it deserved the warmest thanks of all present. With the toast he begged to couple the name of Mr. Lessels, the President, to whom the Society was deeply indebted for many favours, and who had been one of the best presidents they ever had.

The toast was received with acclamation, and, in reply,

The PRESIDENT said he undertook the duties of the office with much uncertainty as to his ability to discharge them properly; but in consequence of the courtesy of the members generally, and the ever-ready help of those more intimately acquainted with the working of the Society, he had found less difficulty and more pleasure than he had anticipated.

After dinner the games were resumed, the amusement generally being carried on with unflagging energy. The whistle gave the signal for tea at five o'clock, but "the cups that cheer but not inebriate," did not seem so much in favour as the previous repast, as it was with difficulty the party was gathered together for the presentation of the prizes at half-past five o'clock. This was, however, at last accomplished, and the prizes were presented by Mrs. Lessels as follows:—

Games.	Prize.	Winners.
Bowls.	1.—Gentleman's silk umbrella	Mr. W. D. Young.
	2.—Gentleman's sporting knife	Mr. G. N. Campbell.
Skipping Rope.	1.—Ladies' companion	Miss Davies.
	2.—Silver pebble cross	Miss Johnston.
Battledore.	1.—Handsome lady's parasol	Miss McGregor.
	2.—Album	Miss Finlayson.
Spelling Bee.	1.—Stereoscope and dozen slides	Mr. Hannah.
	2.—Book	Miss Finlayson.
Ladies' Race.	1.—Ladies' companion	Miss Ann Calder.
	2.—Silver pebble cross	Miss Calder.
Gentlemen's Race.	1.—Album	Mr. Calder.
	2.—Large photograph	Mr. W. Mathison.
Hop, Step, and Leap.	Concertina	Mr. Maclean.
Sack Race.	1.—Water-colour drawing	Mr. W. Mathison.
	2.—Framed picture	Mr. W. D. Young.

Probably the most interesting feature of the day was the "Spelling Bee," which was admirably managed and well contested, the excitement towards the close being very intense. Miss Finlayson and Mr. Hannah were well matched, and went through a rather severe ordeal with many words not in frequent use, the lady ultimately making a slip by doubling the "l" in "stalactite."

At 5.30 the order of march was given, and at six o'clock the train left Winton station and rapidly conveyed the party back to Edinburgh —all highly delighted with the proceedings of the day, and feeling that another success was scored in favour of the Photographers' Annual Holiday.

PHOTOGRAPHY IN COURT.

LOMBARDI *VERSUS* VANDERWEYDE.

This case was heard in the Queen's Bench Division of the High Court of Justice before Mr. Justice Field and a special jury, in the Guildhall, on Wednesday and Thursday, the 17th and 18th inst. It was an action instituted by Mr. Lombardi, the well-known photographer, of Pall Mall, London, and Brighton, to recover from Mr. Vanderweyde, Regent-street, the sum of £72 10s. upon an "I.O.U.," and a further sum of four guineas the cost of a picture frame. The case arose out of certain transactions in connection with a patent studio window which, as every reader of The British Journal of Photography is aware, was patented by Mr. Vanderweyde a few years ago, and which was the subject of much comment in this Journal. Mr. Murphy, Q.C., and Mr. Findlay, instructed by Mr. Percy Burt, appeared for the plaintiff, the defendant being represented by Mr. M'Intyre, Q.C., and Mr. Kingsford.

From the opening remarks of Mr. Murphy it appeared that soon after Mr. Vanderweyde introduced his patent studio window an arrangement was made in accordance with which the defendant was to erect a window of this kind in the Pall Mall premises of the plaintiff, and which was to cost a certain sum. When the accounts were handed in by the builder it was found that the amount claimed was £72 10s. in excess of that agreed upon. Mr. Lombardi, however, paid all the claims and took Mr. Vanderweyde's "I.O.U." for the sum in excess, that gentleman representing that he had no money at all at that time. Upon being afterwards applied to Mr. Vanderweyde refused to honour his "I.O.U.," alleging that he had given it as a guarantee that he would erect a similar window in the plaintiff's studio in Brighton—an order which, although agreed upon, was afterwards countermanded. From what was further said it appeared that the case had been previously heard by the Judge in chambers, who granted permission for its being tried only on condition that Mr. Vanderweyde should first deposit the amount craved for in court, to recover which the present action was brought.

Mr. Lombardi said that in September, 1875, he first saw the defendant at the studio of Messrs. Fradelle and Marshall, Regent-street, where several gentlemen interested in photography were present to witness the trial of a new studio window erected under the supervision and in accordance with the patented method of the defendant. That studio was erected by way of experiment. He (the plaintiff) was subsequently informed by defendant that he had quarrelled with Fradelle and Marshall, and being at loggerheads with that firm he could not use their studio for show purposes, as originally intended, more especially as it had not been constructed entirely in accordance with his plans, and that the district surveyor had found fault with it on the ground that it had been erected contrary to the regulations of the Board of Works. He further stated that the position of the witness's studio in Pall Mall East would be a most desirable position, and that if the glass-house were erected it would be to the mutual advantage of both of them. The witness explained that, as the lease had only six years to run ere it expired, he would only consent to it in the event of the cost being moderate. The matter, however, ended in his being persuaded to have one of the defendant's windows erected. Mr. Thomas Over, a builder, having been sent for, the defendant explained to him the nature of the alterations he wished to be made. Mr. Over gave an estimate for £49 10s., which sum the plaintiff agreed to pay. The work was then proceeded with under the direction of Mr. Vanderweyde, the plaintiff not interfering with the work. Without the knowledge or consent of witness the defendant caused considerable alterations to be made which had not been included in the builder's estimate, thus increasing the amount of the bills, which, instead of amounting in all to about £50 as had been anticipated, amounted to £149 10s. It was not until several months afterwards that witness discovered that so much additional work had been done, and on the 17th March, 1876—at which time he had become aware of the additional expenses incurred—he had an interview with the defendant and severely remonstrated with him for having incurred so much additional expense, when the defendant admitted he was entirely to blame, and that as the bills were so much heavier than at first proposed he was willing to pay one half the expenses, amounting to £72 10s.; that he would leave witness to settle with the builder upon the best terms he could, at the same time stating that he was quite penniless, but would give witness his "I.O.U." for £72 10s. This offer was accepted the same day, and witness paid all the bills upon receiving the "I.O.U." in question. Having frequently made application for payment of this amount without avail, the witness placed the matter in the hands of a trade protection society. The witness then discovered that defendant had no means of paying the amount, and that he had a bill of sale on his furniture. The matter was then abandoned for a time until he was known to be in a position to pay, when the present suit was instituted. On the 14th March, 1876, or three days before the "I.O.U." was given to him, the defendant asked him for a testimonial for his window, at the same time stating that he (witness) had a very commanding position to show off his patent at his Brighton establishment, and that if he (witness) would give him a testimonial he (the defendant) would erect one of his windows there free of charge. Witness thereupon, at defendant's dictation, wrote a letter ordering the erection of a window at his West-street studio in Brighton. As that letter did not state anything as to who was to bear the expense of the window in question, witness called defendant's attention to this fact, who promised to speak to his partner upon the subject and then to write a letter to witness indemnifying him from any responsibility or liability in connection with the expense to be incurred. Witness waited two or three days for the promised letter, but not receiving it, and fearing that he might be involved in expenses as he had been in connection with the Pall Mall studio, he wrote on the 16th March countermanding the order.

Cross-examined by Mr. M'Intyre. In reply to the question why, if the Pall Mall studio had proved such a failure as he had reported it to be, did he give such a powerful testimonial in favour of it as he had done in the form of an order to erect a second window in Brighton, witness said that the failure of the Pall Mall studio window did not arise from any defect in the principle of the method of lighting, but in the special manner in which that principle had been carried into effect in the Pall Mall studio.

Mr. Over, builder, was examined and gave evidence in detail in regard to the nature of the alterations made upon the studio. He had received all his orders from Mr. Vanderweyde, and not from Mr. Lombardi.

Mr. Vanderweyde said that he was the inventor of the patent window in question, which was a great success. He was an artist and not a photographer, never having taken a photograph in his life. He superintended the erection of the new window in Mr. Lombardi's studio, which was to be for show purposes as an advertisement for both of them, and which photographers were to be invited to see; but, while doing so, he never authorised the builder to make any departure from the terms of his contract or to incur additional expense. When the plaintiff afterwards complained to him about the increased cost he replied to him that it was not his fault; he had used his best exertions to have the work done properly. The plaintiff then suggested that as the testimonial which he might give defendant would be from such a well-known man in the profession it would be worth his (witness's) interest to pay half the bills. He was disgusted with the plaintiff for having so offered to sell him a testimonial, but as the plaintiff had hinted that he might do his invention a great deal of harm, he considered in what manner he would be able to protect himself; so, abandoning the idea of using the Pall Mall studio as an advertisement, he offered to build another studio at Brighton instead of paying any part of the bills. He urged this proposal upon the plaintiff, and asked for a letter to the effect that owing to his (plaintiff's) being so much satisfied with the studio in London he wished him (defendant) to build another one at Brighton. The plaintiff said he must give him some security that he would pay the workmen, because if he (defendant) did not meet the claims, the workmen being on his property, he (plaintiff) would have to pay them. Thinking that the cost of building the new studio would be about half that of the London one he gave plaintiff the "I.O.U." for the £72 10s. He said, however, that he must consult his partner before he proceeded with the new studio. He had at that time made up his mind not to build the new studio, but only to use the letter as a means of defence. As plaintiff had remarked that it would not do for his letter and the "I.O.U." to be of the same date, he dated it the 17th instead of the 14th October. He soon afterwards received a claim from the plaintiff for £76 odd, and then he wrote a letter asking particulars of the claim, which were furnished by the trade protection society as consisting of the "I.O.U." and the frame.

The Judge: What did you do after this?—Witness: Nothing. I never heard from them again.

The Judge: Were you not applied to by the solicitor of the society? The defendant denied that this had been the case; he had never heard from them.

The Judge then requested the production of a letter which had been written by the defendant in reply to the solicitor of the society.

The counsel for the defendant had never seen such a letter.

The Judge, however, asserted that he had seen it on the previous day in their possession.

Mr. M'Intyre: Then your lordship must have got it, for it is not here.

Mr. Lombardi (starting up) said that if the original could not be found he had an authenticated copy which he would be happy to submit to his lordship. The letter was read by his lordship, who inquired of the defendant's counsel what he could possibly have to say in the face of such a document.

Mr. M'Intyre said that whatever the defendant might think as to the rights of the case nobody else could now possibly have any doubts on the subject. The letter in question came upon him like a thunderbolt.

Defendant: But the "I.O.U." is worthless!

Mr. M'Intyre (addressing defendant): That may be your opinion, Mr. Vanderweyde, but it is not the opinion of any honest man in this court; and, throwing down his brief, Mr. M'Intyre sat down.

The Judge said that Mr. M'Intyre had done his duty bravely on behalf of his client, and no blame was attributable to him. One of the stories told was consistent with the documents in the case, and the other story was not consistent. The jury must therefore give a verdict for the plaintiff for the full amount, with interest and costs.

A verdict and judgment were then entered in accordance with his lordship's instruction.

CLUB PORTRAITS.—WADE *VERSUS* EVANS.

At the Clerkenwell County Court, on Monday last, the 22nd inst., the case of Wade *versus* Evans was heard before Mr. Besley, the deputy-judge.—The plaintiff said he was induced to become a subscriber to the defendant's photographic portrait club by seeing some specimens exhibited in the Hope public-house, Calverton-street, Islington, in consequence of which he, from time to time, had paid in small sums the sum of twenty-one shillings; but as the defendant had not executed the portrait nor returned the money he had brought the present action, which he would have done earlier but the defendant had left his old place of business, and he had great difficulty in finding his address.—Henry Hare, the landlord of the public house in question, proved receiving the plaintiff's subscriptions and handing them over to the defendant from time to time. This evidence completed the plaintiff's case. The defendant said the plaintiff having also changed his address he had difficulty in getting him to sit, or he should have been glad to have finished a portrait for him, and he told the plaintiff this when he called; but the plaintiff became so very abusive he had ordered him out of the shop, as he created quite a disturbancce at the time. He (the defendant) said he had offered that morning to pay the costs of the summons and take the plaintiff's portrait, but he refused. The plaintiff (recalled) said he refused because the defendant's portraits were not equal to the specimen, and because he had got one elsewhere much better at less cost.—The Judge ruled in favour of the plaintiff for the full amount claimed with costs, remarking in doing so that from the recurrence of these cases before him he was of opinion that people were very foolish in parting with their money to these so-called clubs, when they could go to well-known photographers who would at once submit their negatives to the public without prepayment.

ON THINGS IN GENERAL.

One of the latest absurdities is the pre-exposure of sensitised albumenised paper to obtain extra rapidity in printing. Can there possibly exist a photographer who would risk the spoiling of his pictures by the degradation of the whites through letting light upon them after printing? The effect would be precisely the same if he allowed excess of light before printing. And this promised gain—what is it? The diminution of the time occupied in printing by a few seconds. The thing carries its contradiction on the face of it. Most of us have had our printers use paper that had accidentally got a slight tint from the light getting to it, but I am sure no one ever heard of such paper printing any quicker than usual.

This suggestion will help Mr. Foxlee's experiments in carbon and silver. Here is silver printing twenty or thirty years' old, and yet this wonderful improvement was never before discovered! What may we not expect carbon to do twenty years hence at the same rate? I am inclined to think that Mr. Foxlee has hit the nail on the head, and it is the apparent simplicity that fascinates the learner in carbon printing, and leads to all the more disappointment when it is found that the process is not such child's play after all.

When M. Lambert was exploiting his process through this country all who saw the methods of working, which were simplicity itself, were so charmed with their ease and beauty that the purchase of a licence followed as a matter of course. And yet I fancy at the present day there are many more licensees than workers, and this not through any fault whatever in chromotype, for it is unquestionable that this gentleman's tour was the means of popularising carbon printing to a vast extent. It is only as yesterday that the beautiful prints in pigments done by his process were exhibited to the wonder of the profession, and the improvement that has taken place since then is most marked, and now for every single carbon printer before this event there must be dozens now in actual practice. I should think that not the least of the disappointment in the details of the process would be found when, a good sheet of carbon prints having been obtained, an attempt was made to mount them upon the cards. To this day this is by no means a light trouble.

I am rather amused to see gravely put forward as a reason for selecting carbon before silver that it will not distort a picture as printing in silver does. Truly I have now and then seen a silver print that seemed a little "out of square," but out of a thousand *cartes* done in silver I will undertake to say that not more than one prominently distorted case could be found. How would this distortion act in the case of the typical photographs which we are asked to aid in collecting out of our own districts? The "anthropologicals" should see to it.

Pre-exposure and fogging, wet collodion negatives, pre-exposure and spoiling of albumenised paper, having been duly suggested, I found myself trying to imagine what next could be invented in opposition to accepted canons of photographic practice. Strongly-acid bath, alkaline bath, alkaline collodion, iron developer without acid, all had been recommended—what else could be thought of? Happy thought! Throw something in the negative bath and spoil it, and get poor, washy negatives, and then patent the process. And here is the very thing in print:—Put a quantity of sugar of lead in the silver bath and then a good dose of nitric acid, and proceed. It gives thin, grey negatives and seldom fogs, and it would just be the thing for Rembrandts. During winter it gives "well-harmonised light and shade." So says the *Archiv*. Who will try this and report? I do not think I shall be able to find time, much though it may be desirable, to obtain weak, grey negatives.

It will be strange if we do not hear of some case of sunstroke among photographers from the effects of the tropical heat we have experienced of late. Let me advise one and all not to touch alcoholic liquors as a drink quencher. I am not at all a teetotaller, but I can recommend a drink of aerated water as being better than anything for the purpose, and a good-sized gazogene would be a most desirable addition to every photographic studio in the kingdom at this period. I saw a communication from Mr. E. Dunmore in these pages describing the erratic behaviour of some carbonate of soda, and it occurred to my mind that either he or the chemist who supplied him must, in these days of effervescing drinks, have made a substitution of tartaric acid for the soda, the two substances, in due proportion with a little sugar, forming a decidedly pleasant and often-vended mixture in hot weather. Any way, to see carbonate of soda of the most inferior description turn litmus paper pink is a most marvellous phenomenon! Free Lance.

THE BIG SHOW.

The Smoking-Room.—The Tharsis Photographer.—The French Pictures.

Going into the smoking-room after the day's pleasures are over we drop upon another field of research. Everybody wants to know what everybody else has seen, and all seem to be at sixes and sevens, each taking an interest in some department quite different from that which engages his neighbour's sympathies.

"Show of fine arts magnificent, sir," said one gentleman to another who was seated at the other side of the table, and who replied—"Haven't been to see the pictures yet; I've been here for three days, and have been amongst the machinery all the time. The Americans are making great headway in that department"—

"I don't take an interest in machinery," the fine-art gentleman replied, turning to find a kindred soul elsewhere.

"Talking of machinery, sir," said an old man from the corner of the room, "Did you see that new reaping machine, by————?"

"No!" the other broke in, "I don't go in for agricultural implements; they possess no interest for me." The old man said no more.

A gentleman who sat next to me quietly smoking his cigar remarked, with a smile, "Whenever he gets the chance that old man has been doing nothing but talk of the cattle show and agricultural implements for the last six or eight nights."

"Every man will have his speciality," I replied, "and that being the subject that is uppermost in his mind he will naturally like to talk of it." "Yes, that must be it," he said, taking the cigar from his mouth and sending the smoke whiffing up into the air. "Personally," he continued, "I'm not great in any particular branch of manufacture or production save what we produce from our own mines, and that holds no interest at the exhibition."

"Your own mines?" I remarked inquisitively, seeing he was so communicative.

"Yes; I hold the position of chemist at Tharsis, and have been taking a tour to improve my health. I've been in Paris for about two months, and I can tell you that sitting here of an evening listening to the various ideas propounded I gain more information and enjoy more fun than you would ever dream of."

"I do not doubt it," I said, as the hum of many voices came upon our ears as we conversed.

"And it is strange to sit and see the faces changing day after day—new men ever coming, and the faces that were beginning to grow familiar melting out of sight for ever."

"You will get up many of the subjects without going to the exhibition at all" I observed, with a smile.

"Oh! yes; and the eagerness with which they tackle the subjects is marvellous," my friend replied in an easy manner. "I just sit in amazement." "Have you seen the Japanese court?" one friend will say to another, evidently quite full of it; and without preliminary he starts at once to unload his treasures in glowing description, when the other would break in with—"I don't care for Japanese stuff! I hate *papier machie* and bronze; and their goods always smell of snuff, which makes me sneeze." And thus Japan is sneezed out.

Another will say, "The French pictures are very fine—magnificent conception and careful execution." But his companion, with a curl of the lip, would reply—"Yes; you've hit it when you say 'careful execution,' for it seems to me that the artists use their lives to paint the horrors of death. Why it's all blood and murder and dead men's bones! Drinking wine out of skulls, and that sort of thing, is'nt in my way."

"Why, sir," continued my friend, "I have seen twenty men sit down here during the evening, each possessed of a subject of his own, and differing from all the others, as if each had started a liking on his own account, and so in conversation he failed to get that sympathy from his neighbours that he could have wished. Now *you* will have some special liking," he said, looking at me and smiling.—"Yes, I replied; photography is what I take most interest in."

"Oh! indeed!" he said; "that puts me in mind that there is a man in that art did the art-ful by us in our town. Why he owes a dozen of *cartes* to every inhabitant in the place, save and except those that were born since he visited us!"

"How could that be?" I asked; "was it a bet?" "Oh! no, a regular business transaction. He came amongst us as a photographic artist, and not having one resident amongst us we engaged him; old and young, rich and poor rushed to his tent to have their likenesses taken, and which had to be paid for at the time of sitting. After performing with his camera and lens on every soul in the place, he told us that he would have to print them at home and send them on to us, carefully noting down our addresses, and blessing us ere he departed. 'Only that and nothing more,' for never a picture reached us from that day to this, and it is a year ago now! For a few weeks after the artist had left the ladies especially were all impatience, waiting and wishing for a sight of these pictures; but mail after mail brought disappointment after disappointment, and hope died out. Some folks thought that the artist must have been a thief, and others that he might have fallen amongst thieves, but in either case we were *taken* in."

"Not a pleasant recollection of our profession," I said. "Oh! it would never do to judge of the firmament by a falling star," he replied, smiling.

It was evident that his remarks had drawn two or three together that took some interest in the art-science, for a gentleman who had sat himself down at our table remarked—"Photography is well represented in the French department of the Exhibition. I spent the best part of the day there, and, although it is only from an amateur's point of view that I take an interest in it, I felt well repaid for the time spent."

"I was also in the French department today," I replied. "Liebert's work was what first attracted my attention, and it is really well worth a careful inspection."

"Yes; carbon work seems to be his special feature, and his specimens show that he is a thorough master of that branch of the art."

"M. Alophe shows two cabinet pictures fitted into one frame—back and front—which moves round on a clockwork stand. Did you see them?" "No."

"Both pictures are of the same lady and gentleman. As the frame comes round, moved by the clockwork, the picture shows the gentleman's back to you and the lady facing you, with a balustrade dividing them; then, this moving round, the other picture comes into view, the lady's back being shown and the gentleman's front view. The idea is novel and the effect pleasing."

"I did'nt notice that; I must look out for it when I go again. But I saw some instantaneous work, by Sauvager, of Fontainbleau, as good in that way as anything I have ever seen."

"Yes, it was very good indeed. Thiers' dry-plate work was also excellent."

"The way they have the lantern transparencies fixed up is very effective—running them up in a framework against the window; with that black box, about a foot deep, fitted round them, it produces an effect which can never be obtained by leaving them open to the daylight all round."

"Yes; and I'll tell you another thing I saw there, which, if introduced, would extend the sale of transparencies for window decorations. That was the edged framing of different-coloured glasses—ruby, and blue, and green, and yellow—leaving the centre square for the transparency. Many beautiful things could be got in that way."

"You would see Walery's enamels;" "my friend said they were exquisite."

"Ioliot's pictures attracted a great many of the visitors. The backgrounds were printed in quite black, so that the figure had the effect of standing out, producing a statuesque effect."

"Oh! yes; I saw them."

One thing I observed in connection with the French department in which my newly-found friend agreed with me; it was this—that the richness of the frames and fittings in almost every case took away from the beauty of the picture, and the tendency was to forget the jewel in admiration of the setting.

MARK OUTE.

Meetings of Societies.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

A MEETING of this Society was held on Friday, the 17th May last,—Dr. Vogel, the President, in the chair.

Two new members having been admitted, a number of cabinet pictures by Dr. Richard, of Männedorf, were laid upon the table. These were portraits of living persons, having for backgrounds different Alpine views.

Herr Hartmann thought that scenes of dramatic interest, such as those shown in Dr. Richard's pictures, lay beyond the proper limits of backgrounds for pictures.

Herr QUIDDE asked what were the gold contents of the different gold salts used in photography.

The PRESIDENT replied, giving the following particulars:—Anhydrous chloride of gold ($Au\ Cl_3$) contains 64·9 per cent. of gold; chloride of gold and sodium ($Au\ Cl_3\ Na\ Cl + 4\ H_2\ O$) contains 45·4 per cent. of gold; chloride of gold and calcium ($Au\ Cl_3\ K\ Cl + 5\ H_2\ O$) contains 42·08 per cent. of gold. He also expressed his preference for chloride of gold and calcium, as it crystallises well and is not acted upon by the atmosphere, while the other gold salts (such as chloride of gold), are deliquescent, and thus undergo a change in their combination. The formation of beautiful crystals is a sufficient guarantee of the purity of the preparation. If it contain an excess of the alkaline chloride the preparation will be powdery, as in the mixture of chloride of gold and sodium and common salt, well known under the name of "gold salt," in which one cannot tell the proportion of gold contained without analysing it chemically.

Herr MAROWSKY remarked that it was principally for the last reason that he preferred to prepare his gold salt himself; but the details of his process would be rather long to give here.

Herr QUIDDE asked whether the present gold money of the German empire could be used for that purpose.

Herr WENSKE said it contained too much copper.

The PRESIDENT remarked that he considered pure chloride of gold ($Au\ Cl_3$) too deliquescent for photographic purposes as usually sold, but that it could be obtained in hermetically-sealed glass tubes from Herr Schering.

Herr JOOP did not permit his chloride of gold time to absorb moisture from the air, as he dissolved it as soon as he got it.

Herren WENSKE and SCHAARWÄCHTER, who both use chloride of gold, said they kept it in a dry place, and had not been troubled by its melting.

The PRESIDENT showed a very successful daguerreotype from an oil painting taken in the year 1839, by the late Herr Sachse. The picture was in very good preservation, though most of the others of the same date had faded. He (the President) further said that the most even of M. Daguerre's own pictures of that period had fallen victims to the action of time, but in the King of Bavaria's private collection he had seen some that were in good preservation.

Samples of Berthold's plate-cleaning paper were then laid on the table.

The PRESIDENT introduced the subject of Mr. J. W. Swan's dry plates, remarking that they required a strong alkaline developer, and that with its assistance it might be possible to work as rapidly as with wet plates, but that the strong developer was more likely to produce stained plates than a weak developer.

Herr SCHAARWÄCHTER remembered that the rapid action upon Mr. Warnerke's plates was most evident when the light was good, but that when the light was poor these plates were far behind wet ones.

The PRESIDENT said that phenomenon generally accompanied all bromide dry plates, as they were most sensitive to the light blue rays, the intensity of which was much less in poor light, while ordinary wet plates were more sensitive to the violet and dark blue rays, which were proportionately less weakened in bad light than the light blue rays.

Herr HENSCHEL showed a number of prints the lights of which were covered with yellow spots. The spots generally made their appearance about a day after the prints were mounted, and with greater frequency when glazed with gelatine. The speaker had tried English paper, which remained free from spots; but as, on the whole, he preferred the German paper, he was anxious to discover the cause of the spotting.

Herr SCHAARWÄCHTER said he had found these spots make their appearance when blotting-paper was used for drying and rubbing them down, and when the blotting-paper was too often used.

Herr HENSCHEL admitted that the pictures had been dried with blotting-paper.

Herr SCHAARWÄCHTER observed that he had once had some paper covered with black spots when printed (iron stains he thought they were). He gave some to Herr Fechner, whose prints were likewise spotted, and some to Herr Marowsky, whose prints were quite free from specks, but neither had been able to find out why.

Herr SCHAARWÄCHTER then asked whether any one had tried the muriatic acid cure for blisters in albumenised paper.

Several members present said they had tried it, but not always with good results.

Herr RICHTER remarked that it could only take effect when the directions for its use were followed out exactly. The process was as follows:—When the pictures have been taken out of the toning bath wash them once or twice with clean water, and then place them one by one, if possible, in a bath to which three or four grammes of muriatic acid is added for every litre of water. In this bath move them about two or three minutes, and then float them for the same time, but no longer, in pure water, so that the muriatic acid may be rinsed off, but not be altogether removed from the interior of the paper. Then place them in the fixing bath. According to his (Herr Richter's) view of the matter, the muriatic acid remaining in the paper decomposed some of the hyposulphite of soda, and threw off some sticky sulphur, which made the albumen adhere better. He thought most of those who had tried this plan had washed too long before fixing, and thus completely washed out the muriatic acid.

The PRESIDENT had great doubts as to the correctness of Herr Richter's theory, and saw no advantage in precipitating sulphur, but feared rather that it would have a bad effect upon the permanency of the picture.

The discussion then wandered to other methods which had been formerly recommended as cures for blistering; after which

Herr WENSKE said he had found his plan a radical cure, even in the most obstinate cases. When he found his albumenised paper beginning to blister he floated it, with the albumen side up, upon a water bath containing four per cent. of a mixture of chloride of sodium and chloride of ammonium. Upon that bath the sheet was allowed to float until the albumenised side felt sticky. It was then dried and silvered as required for use. The addition of the salt to the water was necessary, as otherwise the water would soak out all the salt from the paper. Care must be taken not to let the water rise over any part of the albumenised side, or else the skin of the paper would be injured. He (Herr Wenske) wished the albumenisers would undertake the operation, and save photographers the trouble.

Herr HARTMANN stated that his printing-room, being in a cellar, was cool, even during the hottest summer, and he was never troubled with blisters.

Herr VAN RONZELN asked—(1) Whether paper-makers were able to produce paper which could be warranted absolutely blister free, he having seen a statement to that effect in a photographic journal. (2) Whether paper made at once from one lot of pulp could partly blister and partly be quite free from blisters.

The PRESIDENT said he must answer "no" to the first question—that, to his knowledge, a paper which would under all circumstances remain free from blisters did not exist; and, as even the best paper would blister if kept long in a very hot, dry place, he must answer "yes" to the second question.

At the conclusion of the meeting the President showed a very interesting experiment. It is known that most collodion cotton gives an opalescent collodion. This appearance is caused partly by fibres of the cotton wool having remained undissolved, and partly by the calcium contained in the cotton, where its presence can easily be demonstrated by spectrum analysis. He (the President) then burnt a small particle of collodion cotton before a spectroscope, when two very characteristic lines—one green and the other red—appeared, though, owing to the rapidity with which the cotton exploded, a good look-out had to be kept in order to distinguish them. To show that these were really calcium lines he then put some calcic chloride in the flame, when precisely the same lines showed themselves in the spectroscope as with the collodion cotton. At the request of Herr Quidde the President also showed the spectra of the absorption of fuchsine and naphthaline red. First the light of a gas flame was thrown by means of a mirror upon the spectroscope, upon which a continuous spectrum was shown. Then a test tube filled with fuchsine was placed in front of the slit in the spectroscope, whereupon the green of the spectrum was extinguished and a black line of absorption took its place. The colour of naphthaline red can scarcely be distinguished by the eye from fuchsine, yet its absorption in the spectrum is quite different; it shows two lines, while fuchsine only shows one.

ANOTHER meeting of this Society was held on Friday, the 7th ult.,—Dr. Vogel in the chair.

Herr Schaarwächter showed a camera, after which,

Herr Herrmann (of Siemens', of Dresden, glass manufacturers) read a paper upon toughened glass, in which he remarked that they had not yet been able to cut it with a diamond. The speaker then exhibited a variety of articles made of Siemens' pressure-hardened glass:—

1. Some thick pieces of glass which had crystallised during the eight days it had taken to cool them. This glass had no resemblance in appearance to what we understand by glass, it being much more like stone or slag.

2. A sheet of glass which had taken eight days to cool, and which looked like opal glass.

3. Plates of matt glass. These are produced by coating a sheet of glass with a mass of glass and burning it in. The grain is so fine that there would be no difficulty in using it as a foundation for carbon pictures. It has the advantage, also, over a grain produced either by etching or by grinding of not being injured by the touch of greasy or dirty fingers. Amongst the sheets of ground glass were some having a pattern produced in the same way.

[On being asked whether Siemens' factory could produce ornamented sheets of glass for carbon window transparencies like the French ones which were in the market, Herr Herrmann replied that he had no doubt it could.]

4. Some bent sheets of glass for windows, roofs, &c.

5. Photographic glass plates which were perfectly clear and smooth.

[Herr Herrmann thought that the use of this glass would in a great measure prevent cracks in varnish caused by the expansion of the glass, as the pressure-hardened glass did not expand nearly so much as ordinary glass. Several of the members present took plates with them for experimental purposes.]

6. Transparencies and negatives upon hardened glass. Pieces of the glass were thrown about, and one piece broke, showing a crack like ordinary glass, and not crumbling to atoms like *verre trempé*.

Herr HERRMANN showed the peculiar polarisation of the hardened glass, and said he believed it could be sold at about thirty per cent. over the price of common glass. The hardened glass was stated to be perfectly clear and not dim, like *verre trempé;* it would also stand changes of temperature better, and could be bored or ground, though not cut with a diamond.

A letter from Herr Wilde was then read, and a negative which accompanied it was laid upon the table. It was a reproduction of a linear drawing taken by Wilde's process, and very powerful though not intensified.

The subject of the transmission of collodion cotton was again brought up and discussed at some length, but nothing new transpired.

Herr MARTINI mentioned Schering's non-inflammable collodion gelatine, which furnishes collodion on simply being dissolved, but said that the collodion was turbid.

Herr HERRMANN gave an account of photography by electric light in England, which was supplemented by Dr. VOGEL giving an account of Mr. Vanderweyde's studio.

The meeting was shortly afterwards adjourned.

Correspondence.

BANQUET IN PARIS IN HONOUR OF PHOTOGRAPHY.

A BANQUET to the foreign members of the Jury for Class XII. (photography), at the International Exhibition, Paris—namely, M. Luckhardt (Austria), Mr. William England (Great Britain), M. J. J. von Kerkwyk (Holland), M. Louis Lechner (Hungary), M. Lewitzky, Vice-president (Russia), and Mr. Henry C. White (Connecticut, United States)—was given by the Photographic Society of France, the Syndical Chamber of Photography, and others, and was honoured by the presence of numerous distinguished guests, among whom I recognised Mr. A. L. Henderson and Professor Stebbing.

Before each chair at the substantial and elegantly-furnished table in the banqueting room was a prettily-decorated *menu* of the dinner, bearing the printed name of each guest and thus marking his place, and which was provided by the photographer's friend, the well-known M. Hutinet.

During the dessert,

M. PELIGOT, member of the Institute of France, and President of the Photographic Society of France, rose and made a speech, in which he said, in effect, that it was his pleasing duty to welcome and honour the photographic community of all countries. Photography was everywhere progressive, and still produced new results and created new wants little dreamed of at the time when the three illustrious inventors—Niepce, Talbot, and Daguerre—first heralded their discoveries. He well recollected when, in 1839, Arago, with all his powerful and soul-stirring eloquence, proposed that France should present to all peoples the great discovery of photography. Daguerre was pensioned by the French nation with six thousand francs a-year, which was then thought a large and adequate remuneration; but, judged by the sum of thirty millions of francs—the amount realised by the affairs to which the art-science gives yearly life and movement—it seemed a small gift. Since that epoch what changes have been wrought! Pictures and portraits had ceased to be produced on silver plates; and paper, albumen, collodion, and the carbon process have, in succession, usurped its place. It was at first considered wonderful, and was patronised by the wealthy and well to do; but now photography had penetrated everywhere, receiving hearty welcome in a million homes, and providing daily bread for thousands, while it is now, when greatly perfected, aiding us to study the scenery of every clime and enabling men of science and astronomers to show us details of other worlds before unknown. An old proverb said that it was beautiful to see oneself in a mirror; but now they had reason to be content, for they could hold the mirror up to Nature herself. The utility of the science and art of photography could not any longer be contested, and the world acknowledged the aid it received. Let them fancy for one moment what would be their position were they suddenly deprived of its help and solace. Instead of their standing still their daily appliances aided the progress of photography, and France in her noble and honourable *rôle* offered to their international colleagues her hearty welcome and generous hospitality. He proposed this toast:—"Let us honour our guests, the foreign jurors of Class XII., who have responded to our invitation and graced this grand assembly with their presence."

The toast was enthusiastically received.

Dr. Hornig, President of the Photographic Society of Vienna, in responding, said that he could never forget that he then stood in the birthplace of photography, and remembered the memorable occasion when that great orator, Arago, aroused the world with his eloquence upon the then recent great event and discovery which resulted in his noble idea. And what an idea it was! That the conquest of mind over matter should, by the generosity of the great French nation, become the property and inheritance of all, thus enabled to reap what was so generously sown. Arago, no doubt, in the poetic visions of his eloquence, had seen the future birth of the Photographic Society of France, who cherished his great idea, and who would continue to do as it had already done, by its powerful assistance, propagate to the further ends of the world the art and science of photography—that great and ever-memorable work of distinguished and noble Frenchmen, from whom it had derived thought and being in the birthplace and cradle of the arts—in noble Paris!

M. Lewitsky proposed the health of M. Davanne, to whose integrity, impartiality, and scientific abilities they were so greatly indebted.

M. Davanne, in acknowledging the toast, said that he could accept only a share of the praise thus bestowed, for much honestly belonged to his colleagues. Photography might justly raise its head; for, commercially, it produced yearly thirty millions of francs. It was all-popular for the good it did. In the cottage, by its images, it replaced the absent ones, however far distant they might be; and in the council of the state, as well as in the study of the *savant*, it was equally welcome, for its works were truth itself.

Thanks were also accorded to M. Peligot, M. Berger, M. Dietz-Monin, and to M. Jules Simon.

M. Jules Simon, Senator, then made an eloquent speech, which was listened to with profound interest. At the close of his remarks he (M. Simon) said:—"Much has been said about the transformations of our time, of the telegraphs, of our increased means of communication. The world will be the gainer. You, who compel the sun to do your bidding and transfix the human lineaments imperishably upon your tablets, regardless of the class they represent, have reason to be glad; for science has progressed for the advantage of all, irrespective of class, as may be seen in the repetition of universal exhibitions—even in congresses, united as now, let us hope, for the mutual benefit of humanity, and to promote the interests of peace and labour and concord. Multiply international exhibitions, which lead to know—and to know is to open the hearts and arms of the people one towards the other—and thus make hatred to sleep for ever. May our foreign visitors return to their cherished homes bearing good seed! And may they plant in their turn what they have seen and heard, so that swords and guns shall be turned into ploughshares and spears into pruning hooks!"

Thus ended this notable instance of "the feast of reason and the flow of soul." W. Harrison.

Asnières, Paris.

INTENSIFYING GELATINE NEGATIVES.

To the Editors.

Gentlemen,—Having been troubled for some time by the thinness of the image obtained upon gelatine plates, I read the letter of Mr. A. J. Reily in last week's number with a sympathising interest.

It is a long time since I ceased to be thus troubled, and for the benefit of this gentleman, and perhaps of other readers who experience the same annoyance, I will describe my method of working.

First of all, I may state that I *now* obtain all the intensity required in my negatives by the expedient of dissolving my gelatine in water to which has been added a tolerably large proportion of beer; the particular kind which I make use of is an old Burton sample, for which I pay at the rate of five and sixpence per dozen imperial pint bottles. Other ales would doubtless answer quite as well; I only mention this kind as that which is used by me. Two or three years ago I saw this beer-y suggestion made in this Journal, and I immediately adopted it with much success, and several times since then I have mentally recorded a vote of thanks to him who made the suggestion, but whose name is to me at present unknown.

In the second place, even although the image upon the gelatine film be very feeble, it may be intensified with greater ease than if it were a collodion picture. The method I adopted, and which I still adopt when I decide upon further intensification, is to fix the image in hyposulphite of soda, wash it very thoroughly, and allow it to become dry. I then immerse the plate in a very weak solution of pyrogallic and citric acids, to which about two or three drops of a ten-grain solution of nitrate of silver have been added. Under this treatment the image acquires the requisite degree of intensity, and the only care that is needed to be exercised is to prevent the image from being over-intensified, for the peculiar colour of the deposit in a gelatine negative, although it may appear thin, is so non-actinic as often to lead to the over-intensification of the image by the photographer who does not sufficiently realise this fact.

If these hints prove useful to any reader I shall be pleased.—I am, yours, &c., T. J.

July 23, 1878.

To the Editors.

Gentlemen,—In reply to your correspondent who cannot succeed in obtaining density with gelatine plates made in accordance with Mr. Bennett's formula, my own experience is just the opposite. I get too much density, some negatives taking a day to print. I find the cause generally of non success with Mr. Bennett's formula is that photographers do not adhere closely in all the minutest particulars which he has laid down as essential.

I never use distilled water for developer, nor do I ever intensify with silver. If a negative is properly exposed, rather over than under, any amount of density I find obtainable from this process, and this, I think, is the peculiar charm, as with other gelatine plates I have never been able to get sufficient density in the sky.

To show how difficult it is to make people understand: in answer the other day to a gentleman's inquiry as to how he was to develope gelatine plates I sent him minutely-detailed instructions. By the next post I received a letter asking the following questions:—Did I really mean strong ammonia? Should he not add half of water, and could he not use a little bromide?—I am, yours, &c., Wm. Wainwright, Jun.

Hoe Place, Woking, July 23, 1878.

MR. C. BENNETT'S RAPID GELATINE PLATES.

To the Editors.

Gentlemen,—I was very much interested in reading Mr. A. J. Reily's experience with these plates, for I, too, have experienced precisely the same results; in fact, it seemed like reading my own experience to the very letter.

I know that thin negatives by this process are attributed to over-exposure; but in my case I am sure the plates have not been so treated, for I have exposed with a drop shutter and an exceedingly small stop—in fact, tried every conceivable means to obtain a good printing negative, but all to no purpose. I may say I have used up eighty-five ounces in experimenting and cannot succeed, although the emulsion is all that could be wished for as regards rapidity. I am fully aware that I must be wrong somehow, but where I cannot possibly tell.

I think I shall express the wishes of numerous other readers by asking Mr. Bennett if he will kindly give us a helping hand out of the dilemma.—I am, yours, &c., J. M. J. Danks.

5, *Jesson-street, Coventry, July* 20, 1878.

Ways and Means.—Quick processes appear to abound, and photographers will no doubt ultimately realise their obligations to the lightning man for kindling the fire that has smoked them out. Various are the ways and means by which compensation is sought. One man sells "permits." Another sells the "secret." A third sells the collodion and developer at an enormous price, so as eventually to get as much as the secret man and the permit put together. You pay your money and you take your choice, and *vice versâ*. *Vive la rapidité!* This is the sum total up to date. We are equally ready to get up the chemicals for anybody else's process, or to publish any good process anybody may send us. If anybody has any lightning in him with which he wishes to electrify the profession gratuitously, now is the time for him to strike.—*Anthony's Photographic Bulletin.*

EXCHANGE COLUMN.

No charge is made for inserting these announcements; but in no case do we insert any article merely *offered for sale*, that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a *nom de plume* be thought desirable), otherwise the notice will not appear.

I will exchange a No. 5 wide-angle landscape lens, by Dallmeyer (never been used), for a half-plate, quick-acting portrait lens by the same maker.—Address, "Photographer," 45, Claypath, Durham.

ANSWERS TO CORRESPONDENTS.

Photographs Registered—

A. G. Massey, Armagh.—*Three Portraits of W. G. Lyttle.*

Edmund Eccles, Bury.—*Photograph of Bury Parish Church.*

Charles F. Perry, Birmingham.—*Two Portraits of the Rev. C. Leach.*

Charles Cook, Scarborough.—*Four Photographs from "Colleen Bawn."*

Adam Gosney, Sherborne.—*Two Photographs of G. D. W. Digby, Esq.*

Edwin Debenham, Weymouth.—*Photograph of the Rev. T. A. Greaves.*

John White, Salford.—*Two Portraits of Francis Harrison Walmsley, Esq., Mayor of Salford.*

James Cooper, Darlington.—*Group of Wesleyan Ministers.—View of Darlington Grammar School.*

☞ *Correspondents should never write on both sides of the paper.*

Notice.—Each correspondent is required to enclose his name and address, although not necessarily for publication. Communications may, when thought desirable, appear under a *nom de plume* as hitherto, or, by preference, under three letters of the alphabet. Such signatures as "Constant Reader," "Subscriber," &c., should be avoided. Correspondents not conforming to this rule will therefore understand the reason for the omission of their communications.

B. F. Villers.—Your theory is defective; the thing has been done.

Charles F. Richardson (Wakefield, Mass.)—Remittance to hand. Thanks.

W.—The old and much-overlooked glycerine process will answer your purpose quite well.

Charles Waldack (Cincinnatti, U.S.A.)—Remittance to hand, and placed to your credit. Thanks.

C. D. B.—Let the portrait partake more of the profile nature, and, of course, do not let the defective eye be seen.

J. D. M.—By making use of a dish the same solution of pyrogallic acid may be utilised in the development of several negatives.

G. W. Brown.—Old lacquer may be removed from brasswork by immersing it in a boiling solution of washing soda. The solution should be a somewhat strong one.

John Simpson.—We are familiar with the process indicated; it is that of Whipple, of Boston. It certainly was patented, but the patent expired several years since.

Electro.—We are using your cardboard dark slide as a guide, and are trying to construct one of a similar kind for ourselves. We shall report upon it after a trial. Thanks.

J. M.—It is probable that there is a chloride mixed with the carbonate, and that, in consequence, chloride of silver is formed, which lies at the bottom of the bath after the carbonate has been used up.

Tyro.—When in a formula the proportions are given in "parts," it may be held as indicating either grains, ounces, or any other kind of measurement, which, however, must be adhered to throughout.

J. T. Robinson (Sunderland) encloses a few samples of portraits taken in a private room several years ago when he was acquiring a knowledge of photography. They are certainly excellent specimens of our art.

J. K.—It does not seem probable that the acetic acid can be at fault; we, at anyrate, are not aware of any instance in which the contact of a cork with the acid has caused fogging when such acid was used in the developer.

W. W.—Most of the iodides will impart a slightly yellow colour to the alcohol. If a deep colour be wanted, which, with some samples of pyroxyline is desirable, the addition of a few drops of an alcoholic solution of iodine will secure this end.

X. Y. Z.—1. Change the sample of collodion for one rather more porous, and see that the plate be well drained after removing it from the bath.—2. If thoroughly drained and kept in a damp atmosphere the plate will remain quite good for three hours. See also answer to "W. D. H." in our issue of July 12.

One in a Fix.—To remove the scum from the top of the solution in the sensitising bath, lay upon it a slip of blotting-paper, to which, when raised up again, the scum will be found to adhere. It would, however, be much better if the chemicals were kept in such perfect order as to prevent any scum from forming upon the surface.

S. S. S. (Dalston).—Now that the weather is so hot, it might prove interesting if you were to try the effect of placing in the bottom of the camera an india-rubber tray containing ice. This would soon enable you to determine the influence of a high temperature upon the formation of "oyster-shell" or other surface markings on the plate.

A Merchant.—When sending collodion abroad it is not sufficient that you intimate to the shippors that the case contains collodion; this must also be marked upon the case itself. This question has, possibly more than once, been tried at law, and fines have been imposed for neglecting to mark the case in the manner we have indicated.

Geo. Ewing, Jun.—No better plan for a studio could be devised than that which has been sketched by your friend. With regard to the point upon which you differ, we, too, disagree with you and hold with your friend. He appears to have a very accurate knowledge of the requirements of photographic portraitists, and we should feel indebted if he could be prevailed upon to extend his observations in the form of an article upon lighting the sitter.

A South London Reader.—A very rapid way of washing prints consists in pinning them upon a board and forcibly projecting over them a spray of water by means of one of the ordinary syringes now in common use. The construction of the nozzle ought to be such as to cause the water to be projected as a fine spray but with great force. This will effect the removal of the hyposulphite of soda in the course of a few minutes, and the print will not sustain any damage.

F. R. S.—We have some recollection of a method having been described at the Exeter meeting of the British Association, by means of which all the oblique rays not required in spectroscopy could be got rid of. It consisted of three prisms of such a form, and placed together in such a manner, as to allow the direct rays to be transmitted, the oblique rays being so reflected that it was impossible they could be transmitted. These conditions are fulfilled by placing two rectangular prisms in such a manner that one of the surfaces of each shall be at a right angle to the direct ray, the space between the prisms being occupied by a third prism, the surfaces of which are cemented to the others.

Midland.—You never, on any account, ought to allow the sitter to handle the negative after it has been taken and while it is still wet. This practice has led to numerous fine negatives having been destroyed. If, however, you have any customers who, as reported of the King of Greece, *will* insist upon being shown the negative and handling it in a careless manner, take the precaution of placing it in a light frame, by which the collodionised side of the plate will be protected by means of a plate of glass. With regard to the other query the posing is good, but the print is too full of strong contrasts. This is especially the case with the face, which presents a hard and patchy appearance. This indicates one or other of the following faults:—Defective arrangement of the lighting of the studio; too brief an exposure followed by over development; or chemicals which are of too intense a nature. It will remain with yourself to discover which of these causes is the true one.

W. M.—If the lens be genuine the chemical and visual foci will be sure to coincide, as its reputed maker is very particular upon this point. The want of sharpness will, therefore, have to be attributed either to the dark slide or the ground-glass frame, one of which must be misfitted. To ascertain whether the lens or the camera be at fault, insert a plate of ground glass in the *dark slide*, and, having focussed carefully upon that, remove this slide and insert that containing the usual ground-glass focussing screen. If the image is not quite as sharp on the latter as it was on the former then the camera will require adjustment; but if both are equally sharp the lens must be subjected to a confirmatory test for non-coincidence of focus. To do this, let the image be very sharply focussed upon the plate of ground glass that is inserted temporarily in the dark slide as in the previous experiment, and then let its place be supplied by a sensitive plate of the same dimensions. If after exposure and development the image obtained upon it be found not as sharp as that seen upon the ground surface, then the lens is imperfectly corrected for colour; the chemical and visual foci do not coincide.

Received.—Geo. Cecil Hance; George Young; Colonel Mason; Silvester Parry; and B. Wood.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician.

For the two Weeks ending July 24, 1878.

These Observations are Taken at 8.30 a.m.

JOURNAL OF PHOTOGRAPHY.

No. 952. Vol. XXV.—AUGUST 2, 1878.

AN UNSUSPECTED CAUSE OF FADING OF CARBON PRINTS.

With as much grief as surprise we have received from Mr. J. G. Tunny, of Edinburgh, the details of a discovery made by him in connection with the recently well-worn subject of the "fading of carbon prints."

It appears that Mr. Tunny had received specimens of the "chromotype" method of printing and finishing pictures which had been sent to him with a view of enlisting his sympathies in this class of photograph. These examples possessed a rich bloom, but for some reason which he does not give Mr. Tunny conceived the idea that they were not entirely above suspicion; hence he exposed one half of them to light with the unpleasant result that he found a sensible deterioration caused in the portion exposed to light.

Here is the important point in this discovery: it was found that the alizarine or other pigment by which the tone of the carbon was modified had in this case nothing to do with the fading in question, for the deterioration was most marked in the whites. Of one of the prints, which had been exposed to light for several days, Mr. Tunny says:—"At this moment it presents the appearance of a silver print on albumenised paper when it gets into the yellow or 'old cheese' condition." As we have in our possession the specimen thus alluded to we are in a position to confirm Mr. Tunny's estimate. "After many experiments," he continues, "in the hope of discovering the cause of the dreadful deterioration that had taken place, but without having been successful, the idea struck me that possibly the evil might reside in the first preparation of the transfer-paper."

Acting upon the impulse of this happy inspiration Mr. Tunny immediately exposed to light slips cut from sheets of transfer-paper. These slips he has sent to us, and they unmistakably reveal the fact of Mr. Tunny's having made the important discovery that in the transfer-paper is found the origin of a large amount of the fading which has hitherto been attributed to the pigments mixed with the carbon. In the specimen picture received the yellowing of the print has so reduced the lights that the original brilliancy has been completely lost. The fine bloom and richness imparted by the alizarine has been quite overpowered by the discolouration of the paper support under the action of light. Mr. Tunny remarks:—"At this moment carbon printing is at a standstill; I have not a roll of double transfer-paper that I would risk sending out a picture upon. The commercial loss will be nothing to the heartburnings expressed by dissatisfied customers that we shall have to endure."

This, truly, is one of the most important discoveries in connection with carbon printing that has been made for a long time past. We wish very much that there had been no foundation for the alarm expressed, but of the facts we cannot entertain a single doubt; for we have now before us three slips of transfer-paper which have been partially exposed to light, with the result that the protected portions of each slip retain their pristine purity, while the exposed parts are of a nondescript-yellow colour. These slips are respectively "special double transfer," "single transfer," and "opal transfer." They each bear date of having been exposed to light (part of them being protected) from June 15, 1878, to the 28th of the same month. The kind of paper last named has sustained the least degree of discolouration.

Let us now look this matter squarely in the face. The complaint respecting the fading of carbon prints is very far from being new to us; but on theoretical grounds we have all along insisted upon the impossibility of the whites becoming deteriorated, and on the assumption of the purity of the paper upon which the print is transferred our theory is absolutely unassailable. In the employment, however, of paper so impregnated with any kind of material as to be amenable to the action of light the conditions become altogether changed. That the whites, under proper conditions, *do* remain pure we know both on theoretical grounds and on those based on experience. Even in the letter we received from Mr. Tunny there was enclosed a carbon portrait of his deceased son taken previous to the meeting of the Photographic Society of Scotland held in May, 1864; for, as we very well remember, the picture in question, together with several others in carbon, was exhibited at the meeting of that Society in the month mentioned. This portrait, although over fourteen years' old, possesses whites of absolute purity. It was printed by a modification of Fargier's process, and was transferred from the glass plate upon which it was exposed to a sheet of albumenised paper on which it was developed.

It has always been imagined that a film of gelatine rendered insoluble with chrome alum, and which is popularly believed to represent all the material on transfer-paper, was unacted upon by light, however protracted might be the exposure; but in subjecting this matter to investigation we are met at the outset by this difficulty—that we are not by any means certain in what manner or with what preparations the transfer-paper in question was manufactured. On referring to Liesegang's *Carbon Manual*, recently published, we find that the method of preparing double transfer-paper there described consists in coating paper with a forty-eight grain solution of gelatine containing five to ten grains of glycerine and forty-eight minims of a saturated aqueous solution of chrome alum. It is also stated that, in order to impart a finer surface to this paper, twenty grains of sulphate of baryta, together with small quantities of indigo, ultra-marine, carmine lake, or other colours, may be mixed with the gelatine. If such mixtures as these are to be applied to the paper it is not difficult to discover the point at which fading is induced.

Be the precise cause what it may, we are very certain it is only sufficient that the existence of the evil be pointed out to ensure the speedy application of an effectual remedy; and it is not saying too much that, after having attention thus publicly directed towards a serious shortcoming in transfer-paper, no manufacturer of this article will do his duty properly to the public unless the issue of such paper be henceforth restricted to that which has either been tested or prepared in such a way as to render its stability under exposure to light a matter above suspicion. That such will be the case we are quite confident. Meanwhile, the thanks of photographers are due to Mr. Tunny for having made the discovery of a hitherto "unsuspected cause of fading of carbon prints."

THE FUTURE OF WET-PLATE PHOTOGRAPHY.

If we search through the whole range of photography we shall probably not find one of its adjuncts which through a long course of years has been more consistently abused than the nitrate of silver bath. We need not stay to particularise its numerous faults. Each reader will be ready with a list of real or fancied ones which have been discovered in his own practice; but it is noteworthy that, despite this wholesale condemnation, the bath still retains, in certain quarters at least, its "proud pre-eminence," and forms the basis of all professional work.

Judging by results it can scarcely, then, be said that the bath has proved otherwise than a faithful servant. It has its vagaries, no doubt; but the majority of professional photographers are content perforce to put up with these occasional eccentricities for want of an equally competent but more reliable agent. It is now many years since the bath was doomed *in prospectu* to the limbo of the past; but, though in dry-plate work it has almost disappeared, there are very few professional studios in which it has been altogether relinquished. Many wet-plate workers have long since recognised the advantages to be derived from the occasional use of dry plates; others, again, have been successful in utilising emulsions for certain branches of their work; but, as we have said, very, very few have altogether adopted the latter mode of working.

We can, however, point to a few professional photographers in different departments of the art who have altogether banished the bath from their laboratories, and who, after a careful trial of the new method, declare themselves unlikely to return to the old *régime*. These men we look upon as the leaders of a new movement in photography—a movement which, having already succeeded in landscape work, is now turning to portraiture and other branches of the art, and its final success is, we think, not far distant.

It is so long since the first cry was raised that emulsions would drive the bath out of the field that we have almost come to regard the hopes and expectations in that direction as utopian, and our reiteration of the well-worn opinion will possibly do no more than raise a smile of incredulity on the countenances of our professional readers, who have become so accustomed to the cry of "wolf" as to pass it by unheeded now. But it must be borne in mind by that class that they have listened to the too sanguine views of enthusiastic workers of emulsion processes at a time when emulsion photography was in its probationary stage, and when it had not yet the high degree of excellence which is necessary to their particular requirements.

Now, however, this is changed; for the general principles of the process having been established, progress has settled down into a fixed channel, and the results of recent improvements may be said to lie entirely in the direction of those special qualities which have been hitherto wanting to fit emulsion photography to take its place in the studio as it has already done in the field. The qualities to which we allude are, of course, chiefly rapidity and uniformity, in which respects the best emulsions of the present day are in no way inferior to wet plates under the most favourable conditions. The introduction of improved methods of development, too, will go far to remove the prejudice which exists in some quarters against the adoption of the new mode of working.

We have frequently expressed an opinion that it is the development which forms the chief obstacle in retarding the progress of emulsion work amongst professional photographers. Alkaline pyro. is so entirely different in every respect from any of the methods in use in connection with wet plates that it requires a certain amount of careful study in order to master its action. Professional photographers either cannot or will not afford the time necessary to acquire this mastery, and, if they try at all, give up the attempt in disgust after a few failures. Such, at least, is the only explanation we can give of the apparent apathy in this matter; for in no other manner can we account for the strongly-worded opinions we have heard expressed by some who have tried the alkaline development of bromide plates.

Prejudice, also, we are inclined to think, has a good deal to do with the apparent dislike of emulsions in any form—a prejudice which is by no means confined to wet-plate men. An amusing instance of this came to our knowledge some time ago. A dry-plate worker of many years' practice, and who had in his time worked and succeeded with most descriptions of bath processes, was being inducted into the mysteries of emulsion work by a friend who had become *au fait* in the new style of working. But it was no use, for success refused to attend his efforts. Even when under the direct supervision of his mentor a result *was* scored, it was only acknowledged to be "passable;" some fault was to be found with it. It was too thin, or too dense, or wanting in harmony—in fact, altogether very inferior to a bath plate; and, finally, the experiments were entirely relinquished.

Time passed on and our friend took with him upon a brief tour a packet of plates prepared for him by his quondam instructor by "a new process." Approximate directions as to exposure were given, and the development was to be conducted, according to his usual method, with alkaline pyro. The new process was declared to be excellent, some of the best negatives secured during the trip having been produced by its means. Our friend was all anxiety to learn the details of a process which had succeeded so perfectly at the first trial, and which would in all probability be capable of even better things upon a closer acquaintance. His surprise and, we may add, disgust may be imagined when he was informed that he had unwittingly succeeded in working *the same* emulsion process he had previously rejected as worthless.

But *revenons à nos moutons*. It will be evident from the purport of our remarks that we are in favour of the substitution of an emulsion for the ordinary wet process. Before we can hope to convert the sceptical to our way of thinking the task remains to us of showing that some probable advantage is to accrue from such a change. Let us then endeavour to do so. There are three important points to be kept in view—sensitiveness, reliability, and quality of result; and if without deteriorating any of these properties we can bring about a saving in time, labour, or expense, the subject is one worthy of serious consideration. Let us see what the chances are in this direction.

First, as regards sensitiveness, which is all important in portraiture. It is beyond all doubt, at the present day, that an emulsion may be prepared fully equal in sensitiveness, when used dry, to the ordinary wet plate; but if the same emulsion be employed in the wet state an astonishing increase of sensitiveness is attained, and according to the circumstances attending the preparation of the plate the gain has been variously estimated at from two to four times the rapidity of the bath plate. We need only point to the recent statement of Mr. H. J. Newton, of New York, who declares that with his emulsion he can do anything that can be done by a wet plate and in *one-third of the time*. As to the quality of the results shown in support of this statement we have the authority of Mr. Bierstadt that he had "never seen them excelled, if equalled, by any photographic process."

We come next to the question of reliability. We must admit that one of the charges made against emulsions—especially the more rapid ones—is *want* of reliability or, at least, uniformity. This may be true in one sense, but is not, we think, altogether so. It may arise in two ways: first, from a defect inherent in the emulsion itself; and, secondly, from circumstances altogether outside the emulsion. We can, of course, urge nothing in favour of a defective or unreliable emulsion; but, as it was truly remarked during the recent discussion of Mr. Newton's results, "there is no *chemical* reason why a quick process should not work with the same certainty as a slow one." This brings us to the second consideration; for it is evident that, given a perfect emulsion, elements of uncertainty may (and do) creep in from the difficulty of accurately timing the exposure under varying conditions of light and subject. But in studio work, or even out of doors, when the development follows immediately upon the exposure, this difficulty is removed, or, at anyrate, reduced to a minimum, and the emulsion is placed upon equal terms with a bath plate. From a purely chemical point of view a good emulsion (and no difficulty attends the preparation of such) presents far greater probabilities of uniformity than plates prepared in a bath which is constantly changing in character, and which is, besides, liable to innumerable vicissitudes and accidents.

In the matter of quality of results at least as much will be dependent on the operator as upon the emulsion. We have Mr. Bierstadt's testimony as to the character of Mr. Newton's work, and our own experience leads us to express the opinion that, in regard to quality, the capabilities of emulsions are in no way inferior to the best bath plates when worked with equal intelligence and care. We may, indeed, venture further to predicate that the adoption of the new mode of working will lead to the production of portraits requiring less aid from the retoucher, and presenting in themselves finer modelling than is obtained, except under extraordinary circumstances, in the present mode of working.

Amongst the minor but by no means unimportant advantages is the expulsion of the bath and its concomitant troubles from the studio and the tent; matt stains, "oyster-shell" markings, "dipper marks," and even dust, will cease to trouble. Dust, it must be remembered, forms a very different sort of enemy to wet and dry films respectively. It is no doubt the bane of dry emulsion, but when the film is simply immersed in water immediately after coating the plate it has little power for evil; and even should any become attached to the wet surface it may be rinsed off under the tap, which is not possible under ordinary circumstances with a bath plate.

The saving of time—which, according to proverb, is "money"—forms an important item in favour of the new *régime*. Instead of coating and sensitising each plate separately while the sitter is kept waiting, a number of plates may be coated first thing in the morning before the sitters commence to arrive and immersed in a trough of plain water until required for use. The plate is thus always ready, the sitters are not kept waiting, and no matter how rapidly they come the operator is always prepared. On a busy day the gain from this cause alone would, we opine, be found very considerable in a pecuniary point of view.

Looking at the change from a purely economical point, we may mention the actual experience of a professional photographer who has discarded the bath entirely in favour of emulsion which he prepares himself. Whereas, under his old system of working, his expenditure in silver averaged about forty ounces per week, much of which was wasted, he now turns out the same amount of work with from *six to eight ounces*.

It rests now with the manufacturers of commercial emulsions to push their preparations in the direction we have indicated, and to place before professional photographers an emulsion of good quality—sensitive and, above all, uniform in character. Finally: it might be worth the while of some enterprising manufacturer to institute a series of practical demonstrations, with a view of persuading the profession to give the new system a trial.

PHOTOGRAPHING ANIMALS.

There are few persons known to be possessed of a camera—whether the tyro of a few weeks old or the professional photographer—who have not received an appeal to take a picture of a pet dog, large or small, or a favourite horse, not to speak of cats, which, however, it is but fair to their owners to say are not so often brought forward for the purpose, though they really give less trouble than other animals. The very remarkable Brighton cats that figure so much in the windows of the print shops are not much to the point, as it is evident that to some extent they must be trained; yet, allowing that, we must say that we do not know of any pictures of dogs, trained or untrained, showing such successful effects.

To secure success in this department of photography the operator should possess some little knowledge of the ways of dogs and horses, and some fondness for them; for it is a well-known saying that dogs and babies can tell whether a person cares for them or not, and we believe there is some truth in the idea. In the case of a dog, the first thing he wishes to do when he appears on the scene is to make himself acquainted with the appearance of everything about him, and for a few minutes he should be allowed to investigate matters closely without interruption; he will then be more easily brought into the sitter's portion of the premises, and the difficulty will begin. At the outset the owner, or the man in charge of the dog, should be cautioned not to rate it or speak loudly to it; for if once the animal gets cowed by its master in such an exceptionally strange place as a photographic studio it takes a considerable time to regain its natural bearing, and nothing looks worse than a photograph of a cowering animal, looking as though it were dreading the whip every moment. This caution is all the more necessary seeing that very few dogs are really well trained or obedient, and when the owner wishes one to lie down or stand up, or to assume a particular position, in a particular spot in a strange place in a manner to which it is entirely unaccustomed, it happens more frequently than not that it tries to get behind the nearest chair or table. Then at once its owner will shout at it, angry that his dog refuses to obey; for most dog proprietors are especially touchy about their pet's obedience—just as every Englishman thinks himself competent to drive a gig every dog owner believes he can make his canine companion do whatever he wishes. This bargain being made, the operator will have half his labour saved. The animal must then be walked gently about till he is somewhere near a suitable place, and then either taken standing or persuaded to lie down. A properly-trained sporting dog will do this at once, while some domestic pets are quite beyond control in this respect. It is much easier to take them lying or sitting than standing, as they are less likely to move after focussing, which in any case must be got through very expeditiously. Here much patience will be required. The dog may have to be walked about a dozen times or more before his position is approved of, and when that is found he will, perhaps, move at the moment of uncapping; but with time and patience, combined with *quiet* and *gentle* treatment, he will soon be got into position again and focussed. We may here state that an inside shutter will be found most useful for making the exposure.

The chief point now is to arrest for a moment or two his ever-wandering attention. A *variety* of noise-making toys will be found invaluable, for it is often noticed that a sound that will arrest attention and cause complete immobility for a second or two will utterly fail to cause any impression when repeated a second time. A whistle, a musical box, squeaking dolls, and toys of all sorts will now be found very valuable; and if the operator can mimic barking and growling or imitate a cat-call he need not have much fear of failure. A shuffling of feet or a voice in the dark room will also attract when everything else has failed, and this may act also as a caution that no sound whatever must be made in the dark room while the photographing is going on or the dog will inevitably turn his head or perhaps leap up. A toy carried behind one's back and thrown across the field of view into a corner will often arrest attention sufficiently long to enable a picture to be obtained.

We spoke of the desirability of the photographer possessing some knowledge of the animal he was to photograph, and if a prize dog be brought he will soon find out the wisdom of our recommendation; for its owner will not look at a picture unless its "points" are properly displayed. Thus, if a Skye terrier be brought and so excited that he has curled his tail high in the air in a very pretty fashion—so the operator thinks—and secures him all animation, the latter will be wofully disappointed at being told that his client could not think of sending out "a squirrel-tailed thing like that," and all would have to be gone through again; or the client may become vexed and lost—a consummation most desirable, perhaps, in the case of a tyro, but not to be anticipated by the professional photographer.

When horses have to be taken the same walking backwards and forwards has to be gone through, as a horse with one leg a little awkward looks very bad in a picture; and it is surprising how frequently they stand unsymmetrically, one common mode of posing themselves being to place the hind legs sprawling considerably behind their due position. It generally looks prettier to take a horse with its mane in view, and it is very desirable that, unless a small picture with a long-focus lens is being taken, the animal be exactly square to the camera, as the foreshortening caused by a perspective view of the body causes the hind- or fore-quarters to appear malformed, and is really ugly, though in a sense correct, a horse being such a beautifully-symmetrical animal that the mind cannot make sufficient allowance for the eye when a perspective representation is presented to it.

To attract the attention of a horse is more easy than that of a dog—the waving of a coloured shawl, a whistle, or if these fail the firing of a pistol out of sight, will generally be found to answer all requirements.

If our remarks will aid any one in being successful in this interesting branch of photography we shall be much pleased, for a collection of portraits of "dumb animals" forms an interesting and most attractive sight.

Of the many methods of transferring negative films from the glass, in order to lessen the weight and bulk of the photographer's *materiel* when travelling, perhaps the easiest and most convenient consists in the use of paper coated with insoluble gelatine. But though the removal of the collodion film from the glass is perfectly easy and certain, a difficulty, or at least some trouble, arises if it be desired to re-transfer the negative to glass for printing purposes, from which cause many photographers have been deterred from utilising the system worked with such success by Mr. Woodbury in the production of his series of Italian pictures. If the negative be allowed to remain upon its paper support its printing qualities are seriously interfered with—it may be only as regards rapidity, or it may be by the reproduction of the "grain" of the paper. To obviate this many plans (chief of which is waxing the paper) are in vogue; but none of them are perfect in their action, and all have a tendency to gradually deteriorate the value of the negative by discolouring the paper support. In working the carbon process with such transferred negatives it is only necessary to moisten the paper support with benzole immediately before placing it in the printing-frame—a course of treatment which renders the negative temporarily transparent and free from "grain" so long as it is kept closed in the frame. This plan is not, however, under ordinary circumstances available when silver printing is used; but by a very simple contrivance we have recently been able to apply it with perfect success. The method consists in interposing between the negative and the silvered paper a sheet of transparent gelatine of the thickness of a sheet of note-paper. This does not in any way interfere with the definition of the print, while it is quite sufficient to prevent the benzole contained in the pores of the negative reaching the silvered paper.

ON THE USE OF ALBUMEN IN THE ALKALINE DEVELOPER.

For the past two years I have been experimenting with albumen in various ways in conjunction with the alkaline developer, and have found it to give very admirable results, both as regards being able to give a shorter exposure and extreme delicacy of the image. I also find it very useful in cases (out of doors) when the light is weak and overcast, and when in the ordinary way it would be almost impossible to get a decent result. With its aid I have been able to obtain the most brilliant negatives—equal to anything I have seen. It is my opinion that albumen is almost indispensable where first-class results are to be obtained in collodion dry-plate work, as well as in collodion emulsion used in the so-called moist state. I find, in the last issue of The British Journal Photographic Almanac, an article by Captain Abney, F.R.S., in which he advocates the use of albumen in the preparation of dry plates. In this case he uses it in the preservative; but whether used under certain conditions in the preservative as he describes, or in my way in conjunction with the developer, the results are almost identical. It has always been said by many writers that albumen is a restrainer or retarder—that is, when it is used pure and simple; but when used in an alkaline condition I find its effect is entirely altered. I believe that of late this is getting to be fully recognised.

I think that many are deterred from using albumen for various purposes in connection with photography, as they imagine that it requires to be worked up to a froth and allowed to subside, and necessitates other elaborate preparations. It does nothing of the kind; the preparation is a very simple affair, and can be prepared one or two years in advance. In my hands a sample that has been prepared six months answers better than one that has been prepared and used at once. It can, therefore, be prepared in quantities when eggs are cheap, and be stored away for future use, having it always ready at hand.

I prepare it by the formula originally given, I believe, by Mr. W. Ackland many years ago. After it has been prepared I find that it is best not to put it up in bottles too large. I should advise amateurs to put it up in half-ounce bottles with good corks, as when opened and a portion is used it soon spoils; for professional photographers larger bottles can be used to suit their requirements.

To prepare the stock albumen I break each egg separately in a cup and separate the yolk carefully, taking care to see that each egg is perfectly fresh and free from smell before adding to the whites of the other eggs already broken, as one bad one will spoil the whole. New-laid eggs are best, but shop eggs answer very well. After the requisite quantity of albumen is obtained, according to the quantity that one requires to make, to every eight fluid ounces of albumen mix together one ounce of water and twenty-four drops of glacial acetic acid, and add, pouring it into the albumen in a fine stream, and stirring with a glass rod constantly for one minute. On no account is it to be beaten or whisked up, or the resulting preparation will have a milky appearance. It is allowed to rest for one hour or more, and then strained through a piece of course muslin. To this strained albumen is to be added one drachm of the *strongest* liquid ammonia, after which it is put up in bottles and tightly corked. It is the most elegant preparation of albumen that I know of, and involves very little trouble in its preparation.

Now for its use. Presuming we have to develope a collodion emulsion dry plate: first flow over the plate some dilute alcohol—alcohol four parts, water one part. Allow this to soak well in, pour off, and then place in a dish of clean water to soak, well wash under a tap, and then flow over it of prepared albumen one part, water four parts, sufficient to cover the plate, well rocking the plate all the time. Not less than one minute must be allowed for this operation, or the desired effect will not be obtained. Pour off, and *without washing* the plate pour on the ordinary strong alkaline developer, and if the plate has been properly exposed the image will almost instantly appear and gradually gain in intensity, giving the most beautiful gradations that can be desired, while any amount of intensity can be obtained. If the plate has been under-exposed, after washing the plate it can again be treated with the same solution of albumen, of a similar strength as before, and on the second application of the alkaline developer the image will rush out suddenly. I thought at one time that perhaps it was due to the ammonia contained in the albumen solution, and I found that if four times the amount of ammonia were added without the albumen it would not bring out the image as it would when used in conjunction with the albumen. I believe its action is due to the ammonia dissolving a portion of the bromide of silver, and the albumen then instantly takes it up, forming the organic salt, albumenate of silver, which is very rapidly reduced on the application of the pyrogallic acid. If the albumen were not present, and only the ammonia used on addition of the pyro., the result would be a badly-fogged image. Again: if we omit the application of the alkaline albumen and supply the alkaline developer in the ordinary way the image will come up tardily and sluggishly. If the developer be now washed off and the albumen solution applied, and then once more without washing the alkaline developer is again applied the image will come out with a rush. This system can be repeated provided too much density is not obtained. The most remarkable part about it is that although there is so much energy there is an entire absence of fogging.

In regard to a plate that has been exposed in an even, weak light out of doors it is very common to hear the remark made—"Well, how can you expect intensity if exposed in a bad light? All you can expect is a thin image, and if you push the development all you get is fog." Now by this system of mine in using the albumen, providing sufficient exposure has been given, any amount of density can be obtained with entire absence from fog. At times I have been obliged to expose plates in the worst of light, not expecting to get a decent or passable result, but have obtained a good image—better than could be obtained by ordinary alkaline developer alone. In using it on moist collodion emulsion films I find it of very great service if the plate has been under-exposed, taking care not to use too much pyro. (to give too dense an image). If the image do not appear to come up the plate is well washed and the alkaline albumen solution is applied for a minute, when, on the second application of the alkaline pyro., the state of things will be found to be materially altered, and a good negative obtained.

I also find that if there be a tendency of the film to lift during development it is not found to do so if albumen be used; it is also an aid in developing the plates rapidly. Under good conditions a plate need not take more than two, or at the outside three, minutes to develope, which is a great saving of time; and the resulting image is not to be compared with a negative developed without it, the colour of the image being a rich, creamy colour, with very fine detail.

In conclusion: I would suggest the use of albumen in the development of gelatine plates. I am of opinion that it would give good results, and by its means, I should think, any amount of intensity could be obtained, of the lack of which so many seem to complain. I have not as yet tried it myself on gelatine films, but will do so and report the result. WILLIAM BROOKS.

DENSITY IN GELATINE PLATES.

I WOULD recommend those correspondents who are not obtaining density in gelatine plates to test again for actinic light in the operating-room. The only other causes I know of that might account for the fault are over-exposure, incorrectly weighing the ingredients, and imperfect emulsification.

Faulty scales, which do not, perhaps, weigh to a nicety, might cause thinness, as *less* bromide or *more* nitrate would cause the emulsion to be less dense. With collodion emulsion the action is so tardy that a considerable excess of the nitrate may be present for hours, or perhaps days, and is even necessary. Not so, however, with gelatine, as the latter emulsion immediately loses density, and otherwise becomes uncontrollable. I should recommend great care in not having a larger proportion of *nitrate* than that already proposed.

If the temperature of the bromised gelatine is not so high as 90° Fahr. when the silver solution is poured into it perfect emulsification sometimes does not take place, and the result will not be a creamy film. It also ought to have a very energetic shaking after the silver is added, which helps the emulsion forward into that state; and unless the films, when dry, are creamy it is useless to expose them. Imperfect emulsification is not easily discovered till the films are dry, in which state they are too transparent, and are most frequently granular and slow, being wanting in density—in short, they are useless; but when the right heat is observed and the other points already named are correct perfect emulsification is certain.

If, now, the exposure in the camera be reduced till the plate is decidedly not over-exposed, taking for granted that the light has been thoroughly tested, the result with this exposure must be sufficiently dense; and if reduced till it is *under*-exposed, it will be so dense as to be quite unprintable. I have not yet tried any sample of gelatine that was deficient in respect of density.

I think more mistakes are made in respect of the light than any other part of the process. If the light be not almost perfectly non-actinic the operator cannot employ the strong developer to bring up any density, because he simply developes his fog instead of his picture. CHARLES BENNETT.

A CONTRIBUTION TO THE "FADING CONTROVERSY" IN CONNECTION WITH CARBON PRINTS.

IN April, 1864, when Mr. J. W. Swan communicated to the London Photographic Society his modification of Fargier's process, and for a considerable time afterwards, he would have been a bold man who ventured to express a doubt as to the stability of carbon prints, and probably had photographers been content with the process as then promulgated, or as rendered more practical and easily managed by Mr. J. G. Tunny during the following month, no suspicion of fading would ever have arisen.

That a print in carbon which will not fade can be produced I had ample evidence during a visit paid to Mr. Tunny a few days ago, when he showed me one of the prints exhibited by him at a meeting of the Photographic Society of Scotland, in May, 1864. It was then declared to be superior to a silver print from the same negative, and although no pains had been taken for its preservation—it having recently been unearthed from a collection of rubbish—it is as pure in the high lights and brilliant in the middle tints and shadows as when first exhibited. The method of production, as explained by Mr. Tunny, was as follows:—The glass plate was prepared as usual by a rub with ox-gall, and coated with the bichromatised solution of gelatine, to which had been added a quantity of "gas black obtained by holding a plate of iron over a gas flame. This, when quite dry, was coated with collodion, and then printed under a negative. A piece of albumenised paper, adhesively moist, was now pressed into contact with the collodionised film, sponged over with strong alcohol, allowed to dry, and a knife passed round under the edges, rendering the removal of the tissue so formed an easy matter. The picture was developed with warm water in the way recommended by Mr. Swan.

A print so produced consists simply of unalterable carbon, gelatine, and paper, and, theoretically as well as practically, is what Cæsar's wife ought to have been. Photographers, however—no doubt, in the first place at least, from the difficulty of toning to the pure black of an engraving—had long been sending out their prints in warm shades of purple brown; and, instead of trying to lead public taste back to permanent carbon, Mr. Swan and his followers aimed rather at meeting it by the introduction of questionable pigments. They, of course, had their reward in the almost universal expression of delight which their productions elicited, and consequently when the day of reckoning began to come, and the "thing of beauty" gave indications of a tendency to pass into "the sear and yellow leaf," they tried, and are trying still, to find a purple-brown which *may* not fade, rather than be content with a pure black that they know *will* not.

The controversy regarding this fading is now pretty old, and, like almost everything else, it has its ebbs and flows. At present the tide is somewhat high—mainly, perhaps, because of the importing of a new factor into the question in the shape of an assertion that carbon prints cannot be fixed by the simple action of hot water, and that the fading is caused by a chromium salt left in the paper. Whether this be so or not is a question I shall leave to more experienced carbon printers than myself, as I wish to direct attention to yet another possible cause, and one not, so far as I know, hitherto suspected.

During the already-mentioned visit to Mr. Tunny that gentleman showed me a series of specimens, the result of a number of experiments he had for some time been making, which established beyond a doubt the fact that prints as made at the present time, even with absolutely-permanent pigments, and in which no trace of the exciting chromium salt has been left, are affected by light to such an extent that the whites become brown, and the purity and brilliance are destroyed. The specimens included prints on tissue made by himself as well as on that supplied by the Autotype Company, and also prints the Company had sent him. The half of each print had been exposed to light for about fifteen days, and while the protected half retained its purity and whiteness, the exposed portion had lost much of its beauty and become a dirty brown, easily noticed in the whites by reflected light, and very distinct all over when examined as a transparency. After much trouble and many experiments the fault was traced to the transfer-paper, and Mr. Tunny exhibited several pieces of it, both for single and double transfer, that had been exposed in a similar way, and on every one of which the same degradation of tone was painfully visible.

I am aware that connoisseurs of engravings profess to value the mellow yellowish tint which paper is apt to assume in course of time, and believe that the fashion of printing on "India paper" had its origin in a desire to imitate that tint. But the colour produced on transfer-paper by the action of light is not at all like that acquired by print paper through age, and, if it were, it would still be objectionable, as we have no reason to suppose the maximum effect would be produced in ten or fifteen days, and it is more likely to continue until the beauty of the print is altogether gone.

Assuming, then, that the transfer-paper at present in use is liable to darken by exposure to light, and that it consists of paper, gelatine, and chrome alum, the question as to which of the three substances is to blame is not difficult to settle, although it may not be quite so easy to find a substitute for the offender. There can be no reasonable doubt that pigment printing will by-and-by supersede all other methods, and therefore it is the duty of everyone, as opportunity occurs, to do all he can to eliminate from it every cause of weakness. With this object in view I hasten to direct attention to this objectionable quality of the present transfer paper, in the hope that some of those best qualified to grapple with this matter will turn their attention to it, and I shall return to the subject as soon as a series of experiments now going on are completed. JOHN NICOL, Ph.D.

THE APPLICATION OF PHOTOGRAPHY TO THE PRODUCTION OF PRINTING SURFACES AND PICTURES IN PIGMENT.

IN SIX LECTURES.

II.—PHOTOTYPIC OR RAISED PRINTING BLOCKS, BY SWELLED GELATINE PROCESS, ZINC ETCHING, AND OTHER METHODS.

[A communication to the Society of Arts.]

HERE is a fatty-ink transfer, similar to that which I put down on a lithographic stone during the first lecture. I now lay it on a smooth and clean zinc plate, and pass through the press. On removing the paper, by soaking, we find that the ink firmly adheres to the zinc, just as it previously did to the stone. A treatment with gum now protects the clear parts of the zinc plate against the adhesion of printing ink, and the application of the ink roller adds more ink to the fatty image already on the surface of the zinc plate. So far our present process resembles the photolithographic process described last week; but, instead of printing from the zinc plate, I dust powdered resin over it in order to give firmness to the fatty image, very slightly warm the plate, making the resin and ink partially blend, and then put it into dilute nitric acid, containing one part of acid to about forty parts of water; here it remains for about three minutes, during which time the acid dissolves away those parts of the metal which are not covered by the waterproof coating. Now, let us take the plate out and examine it. We find that the covered parts stand slightly in relief, but only very little, and if we were to continue the etching without further preparation the acid would gradually undermine the lines, and the image would be lost. Now the undermining action of the acid can easily be prevented by washing the plate, drying it, and then heating it sufficiently to just melt the resin. Under these circumstances the melted resin blends with the printer's ink, runs down over the sides of the little ridges left by the etching, and protects these sides from the further action of the acid. Having done this it is well to gum the plate once more, ink again, dry, and dust with resin before proceeding to another etching. This second etching may be done with stronger acid than the first (say one of nitric acid to thirty of water), and it may be continued longer—say for six or seven minutes—and when this second etching is finished the whole series of operations must be repeated until sufficient depth is obtained, care being taken that the melting of the resin is only carried far enough to allow it to flow just over the sides of the relief left by the previous etching. In ordinary cases ten etchings are enough to give the necessary depth; but in the case of important work it may be necessary to give twenty or thirty very slight etchings in order to obtain the same depth, without endangering very fine lines or details.

On the table are some zinc plates illustrating the various stages of the process, and there are also some admirable specimens of finished work by Messrs. Leitch and Co., and by Messrs. Dellagana and Co.

The process of zinc etching has been largely employed for the production of typographic blocks from fatty transfers, either drawn by hand or printed; and this phase of the process bids fair to compete successfully with the art of wood engraving.

There are other methods of producing phototypic blocks, among which may be specially mentioned the method which is founded on the swelling of gelatine. These admirable phototypic blocks, which Mr. Dallas has lent me, are done by a method that he has perfected, but the nature of it has not been made public. Mr. Dallas was the first to introduce phototypic blocks into the English market, and if you carefully examine some of his specimens you cannot fail to be struck by the fineness and perfection of the details.

By the following modification of the swelled gelatine process I have succeeded in overcoming many of the difficulties of the methods already published.

We start with some clear sheet gelatine about one-thirtieth of an inch in thickness. This can be prepared by drying a layer of gelatine solution on a sheet of waxed glass, or it can be purchased from Mr. Cornelissen, of Great Queen-street. To make this gelatine sensitive to light it is soaked in three and a-half per cent. solution of potassium bichromate until it becomes flaccid; it is then laid on a piece of clean glass, and the excess of solution is removed by an application of the squeegee. The plate bearing the wet gelatine is then placed in a warm and photographically-dark place to dry, and when dry it can be easily separated from the glass by raising one corner with a penknife. We obtain in this way a flat sheet of sensitive gelatine having a smooth surface and all ready for exposure under the negative, and this exposure may last from ten to twenty minutes in sunshine, or a corresponding longer time in the shade.

I now take the exposed film and put it into water to soak, and you will perceive that those parts which were protected from the light begin to swell immediately, while the exposed parts refuse to swell in the water. The soaking should last several hours, but as we cannot spare that time I will take a gelatine which has already soaked the necessary time, and make a cast from that. For this purpose I lay the wet gelatine film on a piece of glass, exposed side upwards, and squeegee it down as before; you see that it adheres to the glass quite easily, and, after having made it surface-dry by dabbing with a soft cloth, a little oil is applied and distributed over the surface. Now that the excess of oil has been removed by a soft cloth I pour on plaster of Paris to a thickness of about an inch, taking care to remove any air-bubbles by the application of a camel's-hair brush through the liquid plaster.

Now, this plaster will take about ten minutes to become solid, so let us take another one which was cast just before the lecture, and which is now set. If we violently tear the plaster and the gelatine apart the fine details of the cast are almost sure to be damaged. But, instead of doing this, let us hold the glass plate in one hand and gently push the plaster cast with the other. Now you see that the gelatine is slowly sliding over the glass, and finally it will slide quite off, the plaster still being adherent to the gelatine. It is now merely necessary to turn up one corner of the gelatine film and slowly fold it back so as to draw it off the plaster gently and without fear of damage, either to the gelatine relief or the plaster, just as a lithographer draws a thin paper proof from the stone. The next step is to make a cast in stearine from the plaster, and for this purpose the plaster should be soaked in rather warm water about 50° Centigrade, and on this soaked and warm plaster, just as I have it here, a layer of stearine about an inch thick should be cast. Such a cast takes a long time to cool, so I have provided myself with one previously done. There it is; see how easily the stearine separates from the plaster. I now dust the stearine cast over with bronze powder, the best being a kind specially manufactured by Mr. Allen, of Mansfield-place, Kentish Town; and, this done, I put the cast into the electrotyping bath, and when a sufficient quantity of copper has been deposited it is merely necessary to back up with type metal and mount on a wood block, as in the case of this example, our work being then ready for the typographic press. If the process I have described is gone through with an ordinary half-tone negative an exceedingly beautiful electrotype is obtained, in which the gradations of light and shade are represented by varying degrees of relief. These, or even plaster casts, ought, I think, to have a very good sale if photographers would only take the matter up. The ease with which they can be made is surprising.

I may mention that, instead of taking a cast from the plaster in stearine, gutta-percha may be used, a press being employed to force the plaster cast—which should be in an iron chase—into the soft gutta-percha. Here is a cast, and here a piece of soft gutta-percha. I now put them into the press and apply pressure, and in a minute you will see what a good impression it is possible to get by this means. Of course electrotyping on the gutta-percha is very easy, but the examples on the table will illustrate the matter sufficiently.

The depth of the relief obtainable by the swelled gelatine process is about equal to that of an ordinary visiting card, and, where large surfaces of white occur, it is necessary to deepen the plate in these parts. This may be done either by cutting out the metal from the finished plate, or, in most cases, more conveniently by raising the surface of the mould, whether it be wax, stearine, or gutta-percha, on which the electrotypic copper is to be deposited. This is best done by holding a stick of stearine or wax in the left hand, and a warm pencil of metal in the other hand, and so holding the wax or stearine as to let a thin melted stream flow down the warm pencil. This stream is allowed to flow on those parts of the mould which require raising.

Most commercial phototypers content themselves with producing a very slight relief by photography proper, and they then deepen by hand-work. THOMAS BOLAS, F.C.S.

NOTES ON PASSING EVENTS.

BY A PERIPATETIC PHOTOGRAPHER.

I WAS once shown a photograph representing a piece of artillery while being fired, and in it the projectile was plainly visible while it was in the act of passing out of the mouth of the cannon. How was it done? will be asked. The *modus operandi* was simple, and it is brought to my recollection by reading in a recent number an article on *The True Action of a Horse in Trotting Determined by Electricity*. The camera in the case of the cannon was capped by a rotating disc, the rotation of which could be induced by the release of a catch by the operation of an electro-magnet. The moment this release was effected the disc was set in rapid rotation by the action of a powerful spring, the result being that the camera lens was uncapped for an infinitesimal portion of time. The release of the catch was effected by means of a wire stretched across the muzzle of the gun, which wire was in circuit with the battery, but, being cut by the emerging projectile when the gun was fired, it caused the electro-magnet to be so acted upon as to give the exposure at the instant when the ball or projectile was emerging from the muzzle of the gun. By adopting the same method the projectile might be photographed at any stage of its onward progress. The application of the electric principle to obtain accurate knowledge of the action of a horse's feet during trotting is useful and easily understood.

We all know, or should know, the influence of a supplementary exposure or pre-exposure to very weak light of a plate intended for negative purposes. It appears that the analogue of the advantages of thus treating negative films has been found to apply to sensitive printing paper. The conclusion arrived at by a writer in *Anthony's Photographic Bulletin* is that silvered paper, which has received a preliminary exposure to light, is very much more sensitive to feeble actinic rays than if it had not been so exposed. While such a discovery is of far less value than the analogous discovery of auxiliary exposures to negative plates, it cannot fail to interest greatly the student who inquires into the philosophy of photographic action. It may be, also, that the discovery will possess some practical value; but on this subject I shall defer all remark until I have had an opportunity of trying a few experiments in this direction.

The photographic dinner at Paris must have been a grand affair. Somehow or other they really *do* manage these things better in France. I often wonder, when reading of the social feeling that prevails in such cities as Paris and Edinburgh, why London is conspicuous by the absence of any such feeling. Is it because of its almost monstrous size that the photographic inhabitants of the great metropolis cannot, like their neighbours, devote a day or an evening to the cultivation of sociality? This can scarcely be the cause, nor, I imagine, will it be looked for in the great number of the members of the chief society, for in numerical strength Edinburgh is ahead of it. To what cause, then, is due the fact that the chief London photographic society can never manage to have either a day out or an evening out? Let us hope that London, which is always a little behind the times, will yet profit by the examples so well set by the Liverpool, Edinburgh, and other societies, and at no distant period proclaim to the world that social feeling is not quite dead.

Observing that in the case of Lombardi *v.* Vanderweyde, which was recently heard before Mr. Justice Field and a jury, the defendant said in the course of his evidence that the patent studio window out of which arose the dispute was a "great success," I am induced to ask can anyone inform me where such a window is to be seen? Having made inquiry among several friends I have not been so fortunate as to find one who can vouchsafe the information as to where I can see a studio fitted with the patent window. Had it been so successful as was hinted, is it not a little surprising that in London and its vicinity I have been unable to hear of one in active operation? I imagine this must arise from the fact that, while the window answers quite well for a single sitter, its action is only sound *in principle* when that sitter is placed at a definite point of the studio, while in the event of more than one sitter being taken it is quite unsuitable. If one were to concentrate a beam of solar light upon a definite spot by means of a burning glass, while the spot itself would be well illuminated by the converging solar rays the parts adjacent to that spot would be in comparative darkness, and this is, *in principle*, something similar to what happens when a sitter is posed in the focus of a number of rays transmitted at right angles to a number of panes of glass. I should like to see this subject discussed quite irrespective of its forming part of a patent, if the patent still exist.

(To be continued.)

PHOTOGRAPHY, PHILOSOPHY, AND CIVILISATION.

"In the calm summer gloaming" thoughts wander from beauteous scenes around to their causes; man's fancy is poetic, and the poet becomes a philosopher. Myriads of the human race have inquired—Can these scenes and glories ever be depicted? Will the Great Creator ever give the means of copying in some way the ever-changing scenes of forms, lights, and colours? With these objects before man, and his power of recollection to call up memories of bygone dates, it appeared that some chain existed between aspects of nature observed and the mechanism connected with our senses and reasonings. The poet revelled in recollections of scenic images; perhaps genius had its full triumph when, by its own creations and will, it could call up those pictures described by language and gesture with "fine frenzy" to impress others, as if all were true, until some of the world exercised their right to question as to the locality of the views, and received the never-to-be-forgotten reply—"in the mind's eye, my lord!"

So the world hoped on, until at last the announcement was made that it was believed light could and did take pictures of all around; that all substances through all time, with every ray of light, are affected; film after film of surface matter yields to the forces called into play when the rays of light are stopped. Then a modest philosopher prepared thin films of matter in the dark, hoping to secure one of the many pictures light is always making. The *camera obscura*—the dark box with a hole, or the tiny crack letting light into a dark room—showed the objects in the neighbourhood even with colours and motions. If he could get only one of these scenes drawn by Nature herself—a rock, a flower, or a landscape—he would have exalted hopes; and he succeeded! Niepce, in France, and Talbot, in England, by different means, showed pictures taken with pencils of light, and so photography arose, and was received by mankind with joy. Landscapes and portraits were produced—men felt their hopes had not been in vain—and they said then, and they say now—"Will Nature ever give transcripts of herself?" "Will she ever copy her own scenes with her own colours?" Photography soon enlisted the men of genius. The formal science of optics was then questioned as to light itself—whether it did travel through all space, particle after particle travelling with untold velocity to unknown distances in the universe. Were the colours red, blue, and yellow—all that could be said of the breaking up of white light? Some few keen observers had, however, perceived fine hairlike lines, and these were always to be seen, and with increasing numbers and grouping into dark bands, as better glass and more precise instruments were employed. So philosophical observers recognised these dark spaces in the light of the sun and the fixed stars, and in minerals and salts raised into vapours, and so spectroscopy has become a study, yielding to science and the arts great assistance and rewards. Mathematics has been called in to verify the past and to predict the future of experiments.

To the literary world the power of light has become so obedient that the very choicest stores of learning can be copied with a marvellous service—the choicest, priceless manuscripts and books copied with such exactness that the stains and ravages of time become matters of pictorial interest and truth; they can be copied, condensed, or enlarged, and transferred from one material to another. In the current literature of the day especially devoted to arts and manufactures, authors, artists, engravers, and publishers have a rare aid to pictorial illustrations. Take the book illustrations by wood engraving. The wood engraver, in a sort of Chinese fashion, would and could only follow the lines traced for him by a special artist on the wood block (who rarely cared about engraving his own work). This artist was hampered by having, perhaps, a crude sketch on the one hand, to be followed out by such lines as the engraver could cut. Now the block of wood may receive a photographic picture; and thus, having truth before them of faithful outlines, due proportions, and correct light and shade, both artists and engravers can shape their lines to suit the texture and their own art sympathies of expression.

Chemistry has been called in, and metal after metal has been employed until a solid block or sheet of metal enables the picture of a once delicate film of matter acted upon by light to be multiplied and worked with all the appliances of mechanical power. Thus far the publishers have this aid. In the fine arts its place has yet to be assigned, but photography as an aid to education will soon secure recognition wherever the English-speaking race prevails. It will aid teachers and learners by supplying grace, novelties, and pleasures. To those who cry out upon the housetops, "Of what good is it?"—"What will it do?"—the answer is that men of the very class of the inquirers, in every civilised clime, are found to make it a pursuit whereby they may live.

Politicians and students of history will ever have to recollect that in these days, when a city was beleaguered so that access to it was rendered impossible by a serried military host, science made messages of greatest importance upon minute films of collodion, and sent them in balloons, asking the newspaper press to publish them. Then messages—equal to a printed sheet of *The Times*—when so printed of microscopic dimensions, sealed in quills and attached to pigeons, were sent on their way to the outer world. Now, by captive balloons, by films on rollers that may be set in motion or stopped by electricity, a country with armies may be surveyed, or sandy, trackless deserts or icy regions may be depicted where man had never been able to explore. Thus much of this globe may be made out, and the valued lives of brave men may be spared. Probably no pursuit ever had such an army of amateurs, who, at vast pains and expense, repeat processes, and give their hints to the world.

The medical profession earnestly desire to know the physiological actions of light. They ask why do mankind "bask in the glare, or shun the noontide rays?" What are the wonderful powers of the retina? What is the structure to be impressed by light? Yet the mind and memory can recal some vivid scenes, and these can be reproduced at will. Some observers have noticed very peculiar fluids in the retina, which retire soon after death, and suggest that chemical pictures are formed. Some experimentalists suppose they have been able to catch and bottle up some of these wonderful picture-making fluids. Every thinking man will hail the hope that blindness, or imperfect vision or confusion of colour distinctions, may be treated with scientific skill.

The amateurs are advanced teachers of the public, and photographers may do well to consider how far the public has advanced in matters of taste. If the professional will fix the head as he pleases, take the portraits of such tints and such sizes as he dictates, mounts them in books, or displays them in sizes which the public feel as dictated forms, he must not be surprised if the public go forward to "fresh fields or fashions new." But the amateurs look up to select men who, by birth, education, wealth, and learning, command respect, and give more precision and confidence to science and arts to benefit the world. Lord Ross gave time, money, and rare mechanical skill to perfect instruments for astronomical purposes. Dr. De la Rue assisted the "eclipse expedition" by instruments and photographic aid at great expense. Lord Lindsay may be quoted as a quiet enthusiast in a distant part of the world selected for its fitness for a station to observe an eclipse—a cold, muddy, and uninhabited place. He found that the instrument for Professor Parry had met with accidents, and he endeavoured to apply some remedy, taking different pieces of apparatus to make a new instrument. One portion was to be a plain mirror. Lord Lindsay described the fear he had lest it was not a truly flat surface, and he found it was really curved—a curve with a radius of eight miles! Such are the men who volunteer their aid. Lord Rayleigh, too, with mathematics and experiments, has worked upon colours and spectra distinctions for years. The late Professor John Phillips sought to find enthusiastic young men, of the excelsior class, to scale mountains and fix their heights by readings of the barometer; but he very frankly confessed that the weight of every pound told upon the explorers. Since then the alpine clubs and ice-hammer-men, the canoeists and bicyclists, and many in other forms of exercise show skill and training; but we have work done by many hands in many climes, also, to show the union of physical endurance and chemical skill in obtaining photographic pictures.

Indeed, on the exactly opposite spot of the globe to us—in New Zealand—the "box" camera and glass have been dragged to the top of the burning mountains, deemed sacred by the natives, who have been awed by the powers of the box; and those who saw the portraits of Hottentots taken with Kennett's dry plates would think that the savage could recognise the fidelity of every hair and foldings of the skin. But there are others besides the savage to be taught. In the travels of Anacharchus we are told of a Turk who would be too meddlesome, and was asked to state what he could see in the camera. He saw there the figure of an obnoxious person walking about. The Turk was then confidentially informed that people could be put into the box, and be kept there, but if he would take himself off the instrument should be pointed in another direction. He took the hint. Such impressive exhibitions must greatly affect the minds of those who usually follow the dictates of mercenary forces.

That the wealthy and refined classes quietly aid photography occasionally is shown by Mr. Crawshay, by medals, money, and examples to get large pictures. Piazzi Smyth, on the contrary, advocates gem-like small pictures, to be afterwards enlarged. The camera, too, besides a motive for travelling, affords the opportunity of companionship—in some pictures in far distant lands the lone figure may be "the dearer self, the partner for life," who has done the share of skilful packing, so that, whether by land or sea, or by mule or vicious dromedary, not a single glass was broken from England to Jericho and return in an eight months' journey! Mrs. Brassey, in her narrative of a voyage round the world in the yacht *The Sunbeam*, says that the party ascended the famed mountain for the Peak of Teneriffe and at about 8,000 feet above the sea she saw an overhanging ledge of rock which would offer rest and shelter from the sun, and, while the bulk of the party went on, she put her camera into use, taking memorable pictures of the visit; so there can be no doubt that photography will be welcomed by many wealthy tourists as being a true companion.

The caverns of the deep will soon be explored, and light will shine in the valleys of deep waters; will point to the dangerous rocks to shun; or how to follow a safe track if mists, darkness, and fog obscure the mariner's sky. The magnesium light and the electric light will blaze out if the sun at Stratford-le-Bow does not shine through fog and murky air; and as in the evening sky we seem to find islands in a golden sea of light, so our thoughts have a grateful feeling for the obvious union of photography, philosophy, and civilisation, and we rejoice in such reveries in "gloaming time." THOMAS J. PEARSALL, F.C.S.

THE BIG SHOW.

THE LAST DAY.—SIGHTS OF PARIS.—HOME.

FROM a photographic point of view most of our time was taken up with the French, English, and American departments, so that we had to hurry through the Italian, Russian, Austrian, and other classes of photographs shown, all of which indicated fair advancement in the various branches of the art-science. But as has been mentioned before, for comfort, convenience, and pleasure, recommend me to an exhibition of photographs where the pictures from the various countries adjoin each other, instead of being, as they are here, scattered all over the place; for as much time is lost in seeking for and finding them as could be well employed looking over the pictures three or four times.

A visit to Paris being to us a marked day in our lives, we bid farewell to the Exhibition with all its charms, and came away into the city to see the heaped-up wonders of the French capital, where all is show—show—an everlasting show.

In our sight-seeing tour we choose the churches first, and as most prominent amongst these we go to the Cathedral Church of Notre Dame, at the doors of which are sold photographs, lithographs, and charms. Like any other show we pay our money, get tickets, and enter. As you enter an old man presents a brush—the latter looking as old and worn out as himself—for those to touch whose faith it is. We walk down the aisles, where the coloured light from the stained-glass windows falls soft and subdued, seeming to bring a silence with it, for not a sound is heard save the muffled footsteps of the visitors. Here and there, in the centre of the church, are bending worshippers, still and motionless. Passing these we are ushered into a series of rooms on the right, where in a voluble manner our guide describes to us the ups and downs to be found even in the lives of monarchs, and the ebb and flow of a country's tide, illustrated by *souvenirs* of the past gathered and safely stored within these walls. Brilliants and other precious stones, robes and vestments of every varied kind, and each with a story of its own—from the emperor's jewelled cloak to the bespattered garb of the murdered priest.

Then away up into the towers we go; and as we gaze upon that massive bell, in fancy we can see it go swinging through the air—in fancy we can hear its mighty tones—and, as it quickly moves, behold upon its side clings Victor Hugo's dwarf, chuckling and yelling in fiendish enjoyment as backward and forward he floats on through the midnight air; and so, as here we stand, in our fancies Esmeralda lives with us again. We visited many churches, and all of them possessed great treasures in the form of artistic windows, masterpieces of statuary, and beautiful paintings on the roofs and walls, the inspection of which will well repay the visit of the stranger.

Our next visit was to the Louvre, where are to be seen the works of Rubens and Vandyck, Veronese and Murillo, and hundreds of other pictures by men whose names are synonymous with all that is grand in the fields of artistic conception. The museums of the Louvre (free from the picture galleries) are of such dimensions and contain such a collection of subjects of interest that it would take weeks to do them anything like justice, so that the visitor who is limited for time can but walk through. But Paris is great in museums besides this one, and of the many we visited the Hotel de Cluny and the Palace of the Luxembourg.

We next went to see the manufactory of Gobelius tapestry, situated in the Faubourg St. Marcel, on the Bièvre. It is stated that the water of this stream is as favourable to the process of dyeing as Burton water is for the making of beer. Gobelins originally were but wool dyers, the manufacture of the world-renowned tapestry being taken up by Canayes, their successors. To see this tapestry being made is one of the sights of Paris that should not be missed. We saw the tomb of Napoleon, the Invalides, the Pantheon, and the Palace of Justice.

Next we visit the Bourse, and are conducted to the gallery where we can look down upon the collected producers of those sounds which make us think that we must have got into a pandemonium. Oh! if it were possible to photograph sound what a marvellous picture this wild and ceaseless din would make! The objects below that produce it seem to run up and down, shrug their shoulders, wring their hands, and tear their hair. Surely it is the rehearsal of a burlesque! Oh, no! it is all sobriety and earnestness. This is the Exchange, and the performers are quietly doing their daily work.

In the Boulevard Capucines there is a hall in which phonographic *séances* are given five or six times a day. To visit this phonographic exhibition is time well spent; for, although it does not come up to the descriptions of it given in the daily press, where they state that speech is preserved in all its original purity and fulness, still speech and song are preserved, and can be reproduced quite plain enough to be understood by any one in the hall. As a scientific instrument it is a marvel. We heard a solo on the cornet, and one on the French horn. Speeches and songs it spoke and sang again, but it lacks the full tone. It has more the sound, in reproducing, of a ventriloquist, when speaking from a distance, than the full tones sent into the speaking tube. This, they say, will shortly be improved; but, even in its imperfect state, go and see it.

Having run over a few of the most prominent features of the great show that attracted my attention when visiting it, I have done so more especially for the benefit of those who, like myself, hail from the country, and are apt to be angular in steering their course amongst the busy crowd.

And now, as I gather my luggage together on the railway platform of our little town, I must bid you "Good bye." MARK OUTE.

FOREIGN NOTES AND NEWS.

DR. RICHARD ON POTASSIC SULPHIDE AS AN INTENSIFIER.—DEATH OF DR. WEISSENBORN.—A METHOD OF FREEZING OR COOLING MIXTURES.—UTILISING OLD AND UNUSABLE COLLODION.

IN the *Archiv* Dr. Richard, of Mänendorf, speaks of potassic sulphide as an intensifier. When used freshly-prepared with negatives not likely to require to be long kept (as in such a case the silver sulphide would become decomposed) he maintains it to shine as a quick and reliable intensifier, and that if the laboratory or dark room be lofty enough and sufficiently well ventilated, and if proper provision be made for its escape, the gaseous hydric sulphate thrown off need not be so hurtful to the operator as most people would reasonably expect.

The potassic sulphide intensifier should be used rather weak at first for fear of causing spottiness in the action, and the following is the solution recommended by Dr. Richard:—"Place a piece of potassic sulphide not larger than a hazel nut in a developing glass, and fill the glass with water. Commence at once to intensify by pouring some of the contents of the glass over the plate and then back into the glass. As the lump of potassic sulphide dissolves the intensifier will gradually become stronger and the intensification will proceed with a correspondingly increased rapidity. It is indispensable that the negative be intensified with pyrogallic acid before being fixed, and that it be well washed after fixing. Thus the intensification with potassic sulphide takes place in the usual order in the picture-producing process. The negative acquires, in the course of its second intensification with potassic sulphide, a purplish-brown colour, which may be increased at will to any density." Dr. Richard concludes by saying he thinks this method preferable to the mercuric chloride and ammonia intensifier, to Dr. Eder's lead intensifier, and to the mercuric iodide intensifier.

The *Photographisches Wochenblatt* gives the following formulæ for cold mixtures, consisting either of snow or ice and chemicals, or of chemicals alone, which may be of use this exceptionally warm summer:—

I.—*Mixtures of ice and chemicals.*

		Temperature.
1.		
Snow or ice broken in pieces	1 part.	15° C.
Chloride of sodium (common salt)	1 ,,	
2.		
Snow or ice	1 part.	11 to 12°.
Chloride of sodium (common salt)	2 parts.	
Sal ammonia	1 part.	
3.		
Snow or ice	24 parts.	6·66°.
Chloride of sodium	10 ,,	
,, ammonium	5 ,,	
Potassic nitrate	5 ,,	
4		
Snow or ice	10 parts.	4°.
Chloride of ammonium	5 ,,	
Nitrate ,,	5 ,,	

II.—*Chemicals only.*

1.		
Water	16 parts.	12°.
Chloride of ammonium	5 ,,	
Nitrate of potassium	5 ,,	
2.		
Water	1 part.	14°.
Nitrate of ammonium	1 ,,	
Carbonate of sodium	1 ,,	
3.		
Water	1 part.	15·5°.
Nitrate of ammonium	1 ,,	
4.		
Sulphate of sodium	3 parts.	16°.
Nitrous acid	2 ,,	

In the *Mittheilungen* the death of Dr. Weissenborn, at the age of 42, is mentioned. The deceased gentleman took a lively interest in photo-chemical matters—in connection with which his name may be familiar to some of our readers.

In the same journal Dr. Vogel says:—"Many photographers have a habit of adding fresh collodion to an old collodion that has become red, and then using the mixture to the deterioration of their silver bath and the decrease of the sensitiveness of the plates. Others use their old collodions for clearing, a purpose for which it is far inferior to ammonia. It does not pay to use the ether and alcohol distilled off as a burning material, as it always contains acetic acid, and fills up the wick of the lamp. The method now recommended for employing old collodion should therefore be very welcome. I use it up instead of alcohol in the *developer*. When the ferrous sulphate is dissolved in water with a little acid I add, instead of alcohol, the same quantity of old collodion. The cotton is then thrown off and filtered off. The small quantity of iodising salt which is thus added to the developer does not do the least harm."

THE ECLIPSE OF THE SUN.

In connection with the eclipse of the sun, which took place on Monday last, the 29th ult., the services of photography, as usual on such occasions, were largely utilised. The special correspondent of the *Daily News*, writing from Rawlings, Wyoming, says:—

The eclipse has been most satisfactorily observed at all the northern stations, and at all the southern ones, from which news has been received up to the present time.

The corona was markedly different from those observed in 1869, 1870, and 1871, and this year the observations have demonstrated the great variation in the structure and condition of the sun's outer atmosphere when there are most and fewest spots on his disc. The corona was small, of a pearly lustre, and the indications of definite structure were limited to two portions. Several long rays were seen, and Professor Newcomb, who had created a screen on a high pole, thinks he detected the zodiacal light extending six degrees from the sun. Professor Draper, who used a Rutherfurd grating two inches square and a camera of large aperture, and Mr. Lockyer, who placed a small grating in front of an ordinary portrait camera, both obtained photographs of the spectrum of the corona. A continuous spectrum only was recorded, and in ordinary spectroscopes the bright lines usually seen were altogether absent. Mr. Lockyer, who observed with a simple grating, saw no rings.

All these are so many indications of a wonderful change since 1871, and there is great probability that the substance which gives rise to the continuous spectrum is not that which produces any of the lines.

Professor Newcomb's party and Professor Barker made a careful search for the dark lines in the corona, but none were observed. Professor Young has telegraphed that there were no lines observed in the ultra violet at Denver. It would appear, therefore, that he also has obtained photographic evidence of a continuous spectrum. The radial polarisation observed in 1871 has been confirmed by Professor Holden.

A new use of the eclipse has been introduced on this occasion. Professors Newcomb, Watson, Holden, and others have included a search for intramercurial planets in their programme, and Professor Watson has been fortunate enough to detect a body of four and a-half magnitude near the sun, which certainly is neither a known star nor a planet.

Every facility has been afforded to the astronomers, and a fourth station along the northern line crossing the belt of totality was at the last moment organised by the Union Pacific travelling photographic car being run to a point between the eclipse camps at Separation and Preston.

The tasimeter, the new instrument on which Professor Edison has been working unceasingly here, has proved its delicacy. During the eclipse he attached Thomson's galvanometer, the index being set to zero, when the telescope carrying the tasimeter was pointed several degress from the sun. The point of light rapidly left the scale, when the corona was brought upon the fine slit by which the tasimeter itself was protected. There was no chromosphere to speak of, and only one prominence, like the horn observed in 1868, but very dim.

Through Reuter's Agency we have the following from Denver, Colorado:—

The astronomers assembled to watch the total eclipse of the sun visible today succeeded in taking most satisfactory observations, drawings, and photographs along the line of totality. The corona was unusually bright, extending 70,000 miles from the sun in all directions. The chromosphere appeared to be about 2,000 (?) miles in depth. Two protuberances only were seen, very faintly visible on the western side of the moon. There was an entire absence of the pinkish red flames observed on some previous occasions, and the spectroscope revealed no extra red or violet lines. At the moment of totality the Fraunhofer lines and both the H lines were reversed.

Very bright lines near large B, and also bright lines F and 1474 Kirchoff, were observed. The temperature fell from 18 to 33 degrees in different localities during the eclipse. No intermercurial planet was observed. The weather was perfect.

Professor Norman Lockyer reports that the solar protuberances were fainter and fewer, but that the corona was ten times brighter than in the eclipse of 1871, thus indicating a variation with the maximum and minimum sun-spot periods.

The New York correspondent of the *Daily News*, writing under date July 20, gives the following interesting description of former eclipses of the sun:—

Captain Parsell brought among his passengers in the good ship Baltic, which arrived at New York yesterday, the last of the contingent of European observers of the approaching eclipse, and as the arrangements of the peaceful campaign are now nearly completed, your readers, or, at all events, some of them, may be glad to know something of the work to be done, and how and where it is proposed to do it. It must be borne in mind, however, that the Atlantic is not yet so perfectly bridged as to avoid all danger of the results secured by the astronomers reaching you by telegram before you get this letter.

We have first to consider the various problems which the astronomers have to solve, and the methods they propose to bring to bear—methods which, although they have cost months to prepare, can only be utilised for the short space of 183 seconds at the outside till another eclipse darkens the land. Although work connected with the physics of the sun forms part of the daily routine of observatories in all civilised countries, it is very convenient to consider the advances which have been lately made and the points which await solution in connection with the eclipses which have happened since 1860. It was in that year that the first results achieved by the spectroscope dealing with the constitution of the sun became generally known. The idea that the sun was a cool, habitable globe received its deathblow; it was made certain that it was a globe so hot that the vapour of iron and other metals played exactly the same part in its atmosphere as the vapour of water does in our own. The photographs of this eclipse put beyond all doubt that many of the coloured appearances observed in solar eclipses round the dark body of the moon were really at the sun, not round the moon, as had been previously suggested. Whether this region, then, represented the true atmosphere of the sun was a point of extreme interest, and the determination of its chemical nature became a matter of the first order of importance. Nothing, perhaps, can show the want of receptivity on the part of men of science more than the fact that there was no spectroscope employed by any of the observers of the eclipse of 1860—a neglect which retarded the solution of one of the principal problems nearly for a decade.

It will be well to enter a very little into detail before we refer to the next eclipse on the register—that of 1868. The objects round the dark moon, which had been proved in 1860 to be partly at the sun, are first an irregular ring of exquisite pearly lustre, crossed by radiating lines, which give it the appearance of a decoration or stars; this is the glory or corona. Next here and there close to the moon coloured and much brighter objects called flames or prominences. These are generally, but not always, red; they may be yellow or violet. Now, the brilliant achievement of the eclipse of 1868 was the determination that these prominences were masses of incandescent—*i.e.*, glowing gas; and it was not very long before it was conclusively demonstrated that the gas was hydrogen. The eclipse of 1868 was observed in India. It was next the turn, as it is now, of America. During the eclipse of 1869 which swept over the United States, not only was the base of the corona photographed as the prominences had been in 1860, but its spectrum was observed with the greatest care, and it also was determined to be gaseous like the prominences, the gas, however, not being the same. So much for the base of the corona. The exterior portions, including rays a degree or so long sometimes seen, were still left *sub judice*.

The next eclipse happened next year, that is in 1870, and English expeditions were sent to Sicily, Spain, and Africa to observe it. The weather was bad at many of the stations, and the work was considerably interrupted; some of the American observations of 1869 were, however, carried further, and the existence of hydrogen above the prominences was demonstrated. The same differences between the "photolytic" and the visible corona were recorded as in the American eclipse of the previous year. In addition to much knowledge gained by the spectroscope and polariscope, the general result of this eclipse was to endorse the opinions expressed by the Astronomer Royal and Professor Mädler after the eclipse of 1860, namely, that the appearance called the corona was due to a complex cause. Part of it was certainly solar, as it was seen both before and after totality, as well as during the eclipse itself; part of it was as certainly due to some cause at work, not at the sun, but rather partly in our eyes and partly in the regions of space between us and the moon. It may be here remarked, *en passant*, that the appearance of the rays seen (not photographed, and this is an important distinction) in the corona are exactly similar to those which may be seen by anyone who will watch from one end of the platform of the Metropolitan Railway Station at Baker-street the solar rays piercing the smoke.

Here we are dealing with a period rich in eclipses, for again the next eclipse happened next year and in India. The British Association, the French Academy, and the Indian Government had observing parties out there, and records were secured of extreme value, because the eclipse happened at a period of maximum sun spots—that is, at a period when there are most spots on the sun, and other evidences of the maximum of activity, the ebb and flow of this activity spreading over a period of eleven years, so that the next similar occasion will occur in 1882. Owing partly perhaps to this increased activity, the hydrogen was discovered to extend beyond the photosphere of the sun to a height about equal to one-third of the sun's diameter—that is, to a height of 250,000 miles, or thereabouts. The corona was photographed better and to a greater height than it had ever been before with certainty; the difference between the photographic and the visible corona came out as strongly as ever, and the structure of the corona was minutely examined with a powerful telescope. It was found to be identical with that of the prominences, and the non-solar origin of the radial structure was conclusively established. At the same time, the brightest lines in the spectrum of the corona and prominences were carefully recorded by a novel method, the corona itself being made to replace the slit of an ordinary spectroscope. Not till 1875 were photographs of the spectrum of the corona and protuberances secured. This eclipse, the last utilised, was observed in Siam by an English government expedition, and by Dr. Janssen, on behalf of the French Academy of Sciences. A new field of inquiry was opened up by these photographs, for it was found that the actinic region of the spectrum contained marked lines, the exact position of which, however, could not be ascertained. Some photographs of the corona were also secured with various lengths of exposure, and the solar portion was found, as it had already been—especially in 1871—to be symmetrically situated with reference to the sun's axis of rotation.

So stands the problem now, then. All the points referred to are so many stepping-stones to a knowledge of the changing energies of the sun, and of the manner in which they manifest themselves in the atmosphere of our central luminary. It will be clear that there is here a rich crop of pure knowledge to be gained; but there is something more. The more the energies of our own atmosphere are studied the more closely are they found to correspond with solar changes, and our solar astronomers, whether they know it or not, are really recording meteorological facts, which, in the coming time, will bear rich practical fruit. There is little doubt that attempts will be made to render our information more complete along all the lines already indicated. One of the most interesting among the methods to be employed will be the application of diffraction gratings to this kind of work. There is only space here to say that in this case we have a spectrum produced by the light falling upon a finely-ruled surface—17,300 lines to the inch—instead of by its passage through a prism—the mode ordinarily employed. Several new instruments have been constructed in which the attempt to photograph the spectrum thus obtained will be varied. If anyone succeed, the question raised by the Siam eclipse will be settled.

We next come to the region from which the eclipse will be observed. The eclipse of the present year may be regarded as the return of that of 1860, which was made memorable by the expedition which left England for Spain under the guidance of the Astronomer Royal in the *Himalaya*. In 1860 the eclipse swept over the Hudson Bay Territory, the North Atlantic, and then struck Spain and Africa. This year the shadow path first strikes Siberia, goes north-east, then east, tends south-easterly as it leaves Asia, and falls on British America. In the United States, where the stations are more accessible than in the regions we have named, it first follows the western slopes of the Rocky Mountains, then passes over Texas on its way to the Gulf of Mexico and Cuba. The wonderful Yellowstone National Park is in all probability the most northerly station that will be occupied. The advantage of the northerly stations being that the sun is higher and the totality longer; in the Park, for instance, the sun will be 49 deg. high, and the totality will last three minutes and a few seconds. The next most convenient station, so far as railways are concerned, is near Sherman, on the Union Pacific line, and the highest point on it (over 8,000 feet) a little to the west of the Laramie plains. To the south, the line which runs from Cheyenne, on the Union Pacific, through Denver and Colorado Springs to Pueblo, cuts the eclipse track to the north of Denver; and there is little doubt that taking all in all, we have here the most convenient observing ground, choice of almost any altitude, from Pike's Peak (14,147 feet) and Long's Peak (14,271 feet), which is almost exactly on the central line to Denver (5,197 feet) on the junction line, where the ocean-like prairie beats on the bases of the outliers of the mountain range. At Pueblo, the most southerly station we have named, the locality is reduced to two minutes forty-seven seconds—167 seconds in eclipse language. There are few things connected with the recent progress of the United States more remarkable than the ease with which these regions can be reached. Four days' and nights' travel in a Pulman car is all that is required nowadays to make the railway journey from New York, or any port on the Eastern seaboard, to any of the places on the north and south line joining Cheyenne and Pueblo, to which reference has already been made; and indeed no better instance of the perfection to which travel has been brought need be quoted than the fact that London is now only fourteen days from the Rocky Mountains, and that the journey can be made with next to no fatigue, and next to no risk. To such an extent does modern civilisation profit by ten thousand peaceful victories of science. Risk and emotion, however, are not the same thing, and the words must not be confounded. There is emotion connected with a summer voyage to America. The fog that will not lift; the sun and stars that will not be observed; the complicated throbbing of the iron heart; the ice which will not be content to anchor itself in the polar regions, but floats across the well-beaten ocean track to be dissipated by the breezes of the sunny south. All these strain man's powers to the uttermost to abolish risk, but he does it—at least some men do, and all may.

We come finally to the actual distribution and *personnel* of the various parties, so far as these are known. Most of them are already at the front, and are to be congratulated upon having missed the present torrid temperature of the central plain and eastern seaboard—St. Louis with its forty cases of sunstroke in a single day, and New York with a climate like Calcutta, and next to none of the Calcutta precautions against over-exposure. There are going to Rawlings, a station on the Union Pacific Railway, in Wyoming Territory, two regular parties from the Naval Observatory—one under Professor Newcomb, which Mr. Lockyer will probably join, and one under Professor Harkness. Professor Newcomb will make enlarged photographs of the corona, by means of one of the photo-heliographs used in photographing the transit of Venus in December, 1874. Professor Harkness will use a direct image photographic instrument with the same intention; he will also make spectroscopic observations, and, perhaps, observations for determining the heat of the corona. There are about four or five observers in each of these parties. Both will be near Rawlings. Mr. Trouvelot and his son will also go to some place near Rawlings for the purpose of making a drawing of the corona during the total eclipse. Professor Langley, of Pittsburg, will go to Pike's Peak for the purpose of studying the structure of the corona during the totality. There will also be at Pike's Peak General Myer, the director of the Signal Office, and Professor Abbe. Professor Holden, of the Naval Observatory, will go to Central City, near Denver, to observe contacts and make polariscopic observations. There will also be three of the Fathers Sestini (of Georgetown, D.C.), near Central City, and Mr. George W. Hill, of the *Nautical Almanac* office, will observe the corona from one of the high peaks near Central City. Professor Hall (Naval Observatory) will go to Las Animas, in South Eastern Colorado, and will make photographs of the corona, with a direct photographic objective; there will also be polariscopic observations made there of the light of the corona. The contacts will be observed, and it is intended also to make a drawing of the corona. Professor Eastman will go to the same vicinity, and he will make polariscopic observations and also drawings of the corona. Professor Hall's and Professor's Eastman's parties each contain four or five observers. Mr. D. B. Todd has been sent to Texas, and will make arrangements there with observers who may live near the limits of total eclipse for the purpose of observing the duration of totality in order to fix the position of total eclipse. These are all the Government parties that are sent out, unless, perhaps, Professor Watson, of Ann Arbor, may go. Some observers in nearly all the Government parties will make a careful search for intra-mercurial planets during the time of totality, which is about three minutes. Professor Young, of Princeton College, has a large party also among the mountains to the west of Denver. Mr. Ranyard accompanies him. Professors Eastman and Holden, with their parties, left some little time ago. The other parties from the Observatory, Professors Newcomb, Hall, and Harkness, left on Tuesday. The route to Rawlings is through Chicago, Omaha, and Cheyenne. To Colorado is generally by the way of Pittsburg, St. Louis, and over the Kansas roads to Denver. Professor Wright, who goes to Las Animas with Professor Hall, will leave Newhaven about the 20th of July. Professor Thorpe and Dr. Schuster have joined his party.

From the statistics at the Signal Office the chances for good weather on the day of the eclipse are about eighty per cent. in Wyoming and in South-Eastern Colorada, near Las Animas. Nearer the mountains in Colorada, as at Denver and Colorada Springs, the chances are only about fifty per cent. The railroad car containing all the instruments of the Government parties left Washington on July 2, and reached Omaha July 8. After the eclipse all the parties will meet at Denver.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
August 5	West Riding of Yorkshire	Oddfellows' Hall, Bradford.
„ 7	Edinburgh	Hall, 5, St. Andrew-square.
„ 7	Bristol and W. of Eng. Amateur	Museum, Queen's-road.
„ 7	Photographers' Benevolent	160a, Aldersgate-street.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

The July outdoor meeting of this Association took place on the afternoon of the 25th ult. Permission had been kindly granted by Miss Watt to the members to photograph in her grounds at Speke Hall. Had it not been for the unavoidable short notice of the meeting no doubt a larger number of members would have attended. As it was about sixteen met at the rendezvous; but a downpour of rain and a leaden sky, which gave but little promise of breaking up, so disheartened one or two that they declined going. Mr. Councillor Forrest, who was unable to go, observing the disappointed looks, generously offered a prize for the best negative taken that day.

The party started at 1.30 p.m., in a waggonette, and had gone but a short distance when the rain came down so heavily that one or two more desertions took place as a passing omnibus or friendly shelter offered. A consultation was held as to whether the excursion should be abandoned, as, from the appearance of the sky, no signs of the rain ceasing could be observed. One of the members would not hear of turning back, expressing his wish to proceed if only to have the pleasure of competing for Mr. Forrest's prize. Owing to his enthusiasm the others rallied round his *banner*, and the waggonette proceeded onwards. Jokes were passed freely in order to revive their drooping spirits, which the Secretary did his best to depress by stating that he was afraid they would not be allowed to photograph, as he had only asked permission to go to the Hall on "a suitable day," and it was announced that though all had intended to use *dry* plates every one would be obliged to work *wet*, and that india-rubber coatings were only allowed on the *h*edges. The proverb "None but the brave deserve the fair" was verified, as before the cameras could be unpacked it became fair; and, although there was no sun, the light was such that several views were taken where in sunshine the exposure would have been difficult. Speke Hall is a very fine specimen of the black-and-white timbered Lancashire manor house of the time of Elizabeth, bearing over the porch the date 1598. The light was not strong enough to take any views of the interior courtyard, in which are two flourishing yew trees, but about thirty-two plates were exposed on the exterior.

The party afterwards drove to the Old Hut, another specimen of the timbered black-and-white—now a farm house, but formerly the gatehouse of the ancestors of the Ireland family of Hale. Here a few plates were exposed, and the members then went on to the residence of Mr. E. Twigge, of Halewood, who had kindly invited them to join him in what proved to be a most enjoyable and substantial tea, which, no doubt, counteracted any ill effects of the previous wetting.

No formal business was transacted afterwards beyond reading the minutes of the last meeting, which were confirmed, and, after spending some time in the garden, and viewing some of Mr. Twigge's photographic treasures, the members started homewards, having, notwithstanding the miserable weather at the outset, heartily enjoyed a very pleasant afternoon.

The resulting negatives are understood to have been very successful.

It is expected that arrangements will be made for another outdoor meeting about the end of August.

Correspondence.

AMATEUR PORTRAITURE BY THE LIGHT THROUGH A PARLOUR WINDOW.

To the Editors.

Gentlemen,—In reference to this subject, treated so ably last week by yourselves, and this week by your very able contributor, Mr. W. B. Bolton, I will mention just one point, having experimented a little in this direction, both with wet and dry plates.

My last experiment was made nearly two years ago with a gelatine plate, under these conditions:—In my apartment in London, the landlady being the sitter, the sun shining directly through the window, I placed the sitter near the window, just so far back that the direct rays could not fall to dazzle her; but passing her they were received by my screen, a white sheet, and reflected on to her. I believed I could get sufficient light by this arrangement, when without the sun I could not do so. The result appeared to me quite satisfactory; but I left the negative with the landlady, and have never seen a print from it.

Over Mr. Bolton's light wooden frame I think I should paste some paper, of such a kind as would reflect more light than a sheet can do. A screen on a clothes horse answers well for throwing a sheet over.—I am, yours, &c., Wm. Washam.

Eastbourne, July 29, 1878.

LOMBARDI *VERSUS* VANDERWEYDE.

To the Editors.

Gentlemen,—To your report of this very complicated inquiry I would only venture to add the following:—It should be understood that the case had been already adversely criticised by the judge in chambers. I was resolved, however, to have an investigation into all the particulars at issue between the complainant and myself through the only course open to me—a searching cross-examination of us both before a jury. Unfortunately for my case I had no opportunity or sufficient time allowed me to communicate with the counsel engaged for me.

Now, having all along held that my two letters in reply to the same letter addressed to me by the two parties engaged by my opponent, at short intervals, were one and the same, my holding to this opinion in court led to the extraordinary misconception on the part of my advocate which brought the investigation to so unsatisfactory a termination.—I am, yours, &c., Henry Vanderweyde.

182, *Regent-street, July* 30, 1878.

INTENSITY IN GELATINE PLATES.

To the Editors.

Gentlemen,—I notice there are again several questions respecting the thinness of the negative image obtained from gelatine plates, and the means of obtaining more intense negatives.

I scrupled very much, at first, to begin working with gelatine, because I felt the images were much thinner than I should like them to be in order to obtain the results I desire in printing. At the same time, the superior sensitiveness seemed to me very desirable for certain purposes, such as photographing interiors. It was at this stage that I thought of the advantages which a second film—one of collodion—superimposed might confer. Later on, the results obtained by the use of a certain proportion of beer in the solution of the sensitised pellicle were made known by Mr. R. Kennett and the Rev. H. J. Palmer. This I looked upon as the salvation of the gelatine process. Under the ægis of the former gentleman it had indeed already been fighting a good fight; but I felt then that it was about to become a great commercial reality. The great convenience of the dried pellicle, and the readiness of Mr. Kennett at all times kindly to demonstrate and explain to those who were in difficulty, I think must have been the means of setting many to work with gelatine.

Before beginning, myself, I had seen Mr. Kennett develope a plate. One thing struck me as a cardinal point, and I have since found that whenever I have taken the precaution to use a certain proportion of beer in emulsifying the pellicle and have rightly exposed—not too short a time—my obtaining an image too thin or not depends mainly on my attention to that point. I saw a right idea of the progress of development could not be obtained by examining by transmitted light, as with ordinary emulsion plates, but only by reflected light. When the developer was on portions of the film began presently to darken, as in any other development. When this darkening had spread so far that I thought the plate must now be fixed—nearly the whole plate being darkened—the developer was perseveringly kept on the plate, and finally one drop more of the ammonia added. As the last traces of the lighter portions had disappeared—if my impression be right—or were just about to disappear, the developer was washed off and the negative fixed. That, I say, is the impression which has remained with me, and I have found that just that last operation makes the difference between a thin negative and one of printing, or nearly printing, intensity. My patience is sometimes, if the negative have been a little under-exposed, nearly exhausted, and am tempted to omit it. This was the case in the last gelatine plate which I had exposed as a trial plate in Gibraltar. The consequence was a thin negative. Foliage in foreground, buildings, the sea beyond, the hills, and floating clouds in the sky (I always use a backing)—all are there in proper gradation. My negatives have since been packed away; but I think that when I can work at them again I shall find this, which is from one of Kennett's plates, will intensify to printing density.

I rarely find a difficulty in this respect, whether working with plates prepared from the pellicle sent to me by Mr. Kennett or with plates prepared by himself. I believe that, in most cases, with the formula sent out with the plates and the pellicle I would intensify to opacity. In my first trials, having obtained negatives that most photographers would consider sufficiently intense, I experimented further, and the result has been that the first negative I can only print through in direct sunlight, and the second I cannot print through at all.

I have not yet experimented with any of the gelatine plates which have since appeared in the market, so that I cannot, of course, say how far the same principles apply to them. I shall hope to experiment with others as opportunities arise, having a packet by me with that object at the present time.—I am, yours, &c., WM. WASHAM.

Eastbourne, July 29, 1878.

P.S.—The intensification ought by no means to take place immediately after the development and fixing. By the time the last stage of the development has been completed the film must have been softened almost, or quite, through; and if the plate be kept longer wet I should fear reticulation of the film would commence. One is also better able afterwards to judge of the amount of intensification required.—W. W.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

*** We are compelled to leave over several reviews, critical notices, exchanges, and photographs registered till next week.

E. P.—"Exchange" notices are not repeated unless paid for as advertisements.

NUMBER TEN.—Yes; for printing upon opal glass it is good. This is all that we are enabled to say from our own experience.

"LUMINOUS" (Edinburgh).—The windows must be extended. The lighting of the studio, as shown on the plan, will not be good.

AQUILA.—The *carte* is of a high class, and if this be an average sample of your work you will be quite qualified for the situation.

"TONALD."—We have never recommended an acid toning bath for albumenised paper prints; on the contrary, we have always enjoined the use of the alkaline bath.

"ANXIOUS."—Place gelatine in water until swollen, pour off the water, and add methylated alcohol, applying a degree of heat sufficient to melt the gelatine.

V. A. V.—Fogging may arise from several conditions, to none of which have you given any clue. Unless you send us more particulars we cannot impart the desired information.

G. B. DOUGLAS.—Get the names engraved on the sides of the bottles by the recently-introduced sand-blast process. This will not cost a tenth of the price of hydrofluoric acid.

R. D. B.—You are in error; the raising of your glass house is not a subject of interest to our readers. If you wish for advice on the subject send a plan, showing full details, to the Editors.

W. L. R.—Let us know the method which you tried without success, and before our next issue we will have found a formula which was published eight or ten years ago, and by which good results were obtained.

E. K.—Make a strong solution of cyanide of potassium of good quality, and dissolve in it a small quantity of iodine, the proportions not being of any consequence. Apply this to the silver stains on the linen, and they will disappear.

B. P. P. R.—Do not allow the strength of the hyposulphite of soda bath to be less than six ounces to the pint. Under some circumstances it may exceed this strength; for example, when the paper is a thick or strongly-albumenised sample.

SPES.—From the symptoms indicated we should have thought the silver bath was less than half the strength you imagine it to be. Do not forget that the hydrometer is not an accurate test for the strength of a silver bath after it has been in use for some time. The volumetric test is the only one upon which implicit reliance can be placed. But we do not think the precise degree of strength is of any consequence in this case; of far more importance appears to be the condition of the bath with respect to alkalinity or acidity.

J. FAVERHAM.—A vignetting glass may be made by pasting a black patch of the form of the aperture desired upon a white sheet of paper, and then taking a negative of it by means of the camera. The focus must be adjusted so as to cause the edge of the patch to be soft and hazy.

PHOTO. ASSISTANT.—Previous to making an endeavour to "improve" the process it would be well for you to acquire a more intimate practical acquaintance with it. The objections which you urge against emulsions are only fanciful, and do not exist in fact. Had you made only a single experiment you would have found that the film given by the use of an emulsion is very far indeed from being "necessarily coarse and granular."

MARY AND SUSAN B.—The following is said to form one of the very best mixtures for mounting photographs:—Take three teaspoonsful of starch mixed to a paste with cold water, and an ounce of good glue dissolved in hot water. Boil the two together till quite thick, and pour into a pot for use. A piece can be melted with a little warm water to the proper consistency. By the addition of an antiseptic this mountant will remain good for several months.

COLONEL BRYCE.—1. The coffee process may be practised either with or without sugar.—2. A teaspoonful of coffee to half a breakfast cup of boiling water. Stir up well and allow to stand for at least a quarter of an hour, after which decant and filter.—3. The only distinction we can suggest between *eau bouillante* and *eau distilée* in the formulæ alluded to is that in the former case ordinary rain water may be used if it be "brought to the boil;" while in the latter cold distilled water must be used.—4. When very freely translated *café moka en poudre* means merely a good sample of ground coffee.

AN OLD PROFESSIONAL.—It would afford us great pleasure to give you all the details of the processes respecting which you inquire but for one consideration—we never devote the column of "Answers to Correspondents" to the mere teaching of a trade, which would most assuredly be the case in the present instance. If you can make the large sums you mention by adding to your present business that of a photolithographer you must do one of two things—first, either educate yourself in the technical details of the business by reading the various articles which have appeared in previous volumes of this Journal, and conducting experiments based upon such reading; or, secondly, apply to a qualified instructor in the art, and by payment of a suitable fee—which we understand varies from twenty to fifty guineas—obtain in this manner such an amount of knowledge as your instructor is able to impart or you to receive. In reply to the question in the postcript of your letter, we are quite conversant with the Gillot process of producing surface blocks.

GEORGE SCOTT.—The defect described is one for the remedy for which you must apply to the camera-maker. Your description has been so clearly written that we are enabled without any doubt to indicate the cause of the fogging of the plates. There is a leakage of light—or, more correctly, an admission of light—between the shutter of the dark slide of the camera and the face of the portion against which it slides. Pull the shutter half way out and examine, from behind—by opening the door of the slide—whether a small portion of light is not admitted owing to the imperfect fitting of the shutter. We have more than once found it necessary to insert a slip of velvet ribbon in the slide, in order to thoroughly prevent the admission of light. It is due to our leading camera-makers to say that *they* invariably take steps to provide against the admission of light in the manner indicated, and hence we infer that your slides have been constructed by a maker who has not had great experience, or, at any rate, an adequate knowledge of the requirements of photographers.

THE PHOTOGRAPHIC EXHIBITION.—We have received the following announcement made in connection with the forthcoming exhibition of the Photographic Society of Great Britain. The exhibition will be opened to the public on Wednesday, the 9th October, and close on Tuesday, the 12th November. Pictures must be sent in not later than the 28th September. Each frame shall have the exhibitor's name and subject, written on a *label*, fastened on the left-hand lower corner of the picture; but no address, or anything in the character of an advertisement, will be permitted.—Bronze medals will be awarded as follows:—Two medals for the pictures, or series of pictures, which, in the opinion of the judges, shall display the greatest amount of excellence. One medal for the best landscape, or series of landscapes. One medal for the best portrait, or series of portraits. One medal for the best single figure study. One medal for the best *genre* picture, or series of pictures. Two medals for the best photo-mechanical prints. One medal for the best transparencies. One medal for the best microphotograph, or series of microphotographs. One medal for apparatus.—Medals will be placed at the disposal of the judges for any novelty, or other form of excellence, in process or result.—The medals will be awarded by a jury of seven gentlemen, as follows:—Two artists (painters): E. J. Poynter, R.A., J. Brett. The President of the Society: James Glaisher, F.R.S., &c. Two members of the Council: Francis Bedford, H. P. Robinson. Two members of the Society: F. Piercy, H. White.—The exhibition will be open to all photographers; but to non-members a charge of one shilling per square foot will be made for wall space, the minimum charge being five shillings.—L. DARWIN, Lieut. R.E., Hon. Sec.

PHOTOGRAPHIC ENGRAVING IN HALF-TONES.

Our attention has been directed by Captain J. Waterhouse, B S.C., Assistant Surveyor-General of India, who is at present on a visit to this country, to a method he has adopted of obtaining a grain in plates prepared for photographic engraving. We may premise that numerous methods for securing this end have been suggested and published, some of them, including the processes of Talbot, Placet, and Woodbury, being highly successful. In most of the methods which have been published the grain has been obtained by mechanical means.

When trying some experiments with a process invented by M. Audra, a French amateur, in which the grain upon the plate is secured by the interposition of a collodion film upon which the required grain has been impressed, Captain Waterhouse was led to try if this mechanical proceeding could not be superseded by chemical means. The result of several experiments was the discovery of a method by which a grain possessing great fineness and excellent effect was obtained.

Ordinary autotype carbon tissue having been sensitised in a five-per-cent. solution of bichromate of potash is dried and exposed to light under a reversed negative. A well-polished copper plate having been provided, its surface is silvered by being rubbed with a mixture of tripoli and the following solution:—

Nitrate of silver	1 part.
Cyanide of potassium	10 parts.
Water	100 ,,

To a plate prepared in this manner the exposed carbon tissue is transferred in cold water, and by means of the squeegee is pressed in intimate contact with it. The object of the silvering is to prevent subsequent adherence to the newly-deposited copper in the electrotyping bath in a succeeding operation.

The gelatine tissue attached to the copper plate is allowed to dry, and is then developed in warm water in the usual manner, great care being taken not to allow any of the lines to become loosened—an accident which is very liable to happen, though the preliminary drying of the tissue before development tends to prevent it.

After all the soluble gelatine has been removed from the surface of the plate, it is immersed (after being drained) in a bath composed of—

Tannin	5 parts.
Alcohol	100 ,,

This at once removes all moisture from the gelatine relief, hardens it, and gives it a fine grain, coarser in the shadows than in the lights. The plate remains a few minutes in this bath till the action is complete in the deepest shadows; the tannin is then washed off with a little spirits of wine, and the plate is allowed to dry.

It will thus be seen that, so far, we have obtained the most perfect conditions under which granularity can exist, namely, a fine grain in the high lights, a coarser degree of granularity in the middle tints, and the shadows possessing the greatest coarseness of grain.

The next step consists in obtaining from the gelatine picture a metallic cast which will faithfully reproduce its various phases of granularity. Captain Waterhouse adopts the following method:—A band of copper having been soldered to the copper plate, its back is coated with Brunswick black, to prevent deposition of the copper upon it. When the backing is dry the margins of the picture are cleaned with a little of the silvering solution. The gelatine surface then receives a very slight coating of wax dissolved in turpentine, which is well polished off, and is then rubbed over with fine plumbago or bronze powder, to render the surface conducting. The plate is then ready to be placed in the depositing trough.

Although any good electrotyping arrangement may be used, Captain Waterhouse prefers a Smee's battery, with a separate depositing trough, containing a solution of ten parts each of sulphate of copper and sulphuric acid in a hundred parts of water. A plate of copper—to serve as an anode, and connected with the silver plate of the battery—is laid horizontally about an inch above the bottom of the depositing trough, which should be large enough to allow the plate bearing the gelatine relief to be slipped under the anode. The relief plate is connected with the zinc plates of the battery, and when everything else is ready the circuit is completed by slipping it into the depositing trough under the anode. By laying the plates horizontally the deposit is more even, and the gelatine film seems to be more readily covered with copper. When the deposit of copper is of sufficient thickness it is separated from the matrix, and after a gentle rubbing with an oiled cloth is fit for printing.

DISCOLOURATION OF TRANSFER PAPER.

When we wrote our article, in last week's number, on *An Unsuspected Cause of Fading in Carbon Prints*, we were not sufficiently sanguine to expect that out of that publication would so very soon have arisen the exceedingly important discovery to which it is now our privilege to direct attention. Prompt to enter with avidity into all that concerns the progress of carbon printing, the Autotype Company have, it appears, been of late intensely alive to the subject of the discolouration of the whites of carbon prints, by which is really meant the permanence of the paper upon which these prints are presented to the public. Of course we knew that the Autotype Company, having access to the best chemical skill available in this country, were exceedingly likely to have this matter brought under their most careful consideration; for, in their recognised position as occupants of the chief place in the carbon world, it was most unlikely that they would allow anything affecting the character of carbon printing to escape their notice.

The discovery of Mr. J. G. Tunny, that transfer paper was affected by light, has been followed by the still more imposing and, we might almost add, appalling discovery by the Autotype Company that it is not the transfer paper, *as such*, that fades, but the plain paper as supplied by the paper manufacturer which is liable to such a disagreeable change. The evil has at length been "run to earth;" and notwithstanding the small individual losses that may have accrued pending this great discovery, these sink into insignificance in the presence of the immense gain secured by the discovery. We earnestly direct attention to the article by the Autotype Company in the present number; and we believe that they have, by their experiments on the discolouration of plain paper by light, also imparted most important information upon certainly obscure, if not altogether unknown, causes of the fading of silver prints upon albumenised paper. Several specimens of the fading of plain paper upon exposure to light under suitable masks disclose the fact—interesting to all, but doubly so to photographers—that numerous samples of exceedingly fine paper, as supplied from the mill in rolls, are liable to become rapidly discoloured when exposed to light.

We hail this discovery with great pleasure, because we shall now have a fair guarantee that in future no samples of paper will be imported into carbon printing that are liable to discolouration; and we call upon albumenisers to exercise a similar amount of watchful care over the paper made use of by them. They, as well as others, are much indebted to the researches of the Autotype Company recorded in another page—researches which, it appears, have been conducted for some months past.

Upon a careful examination of a large number of specimens of paper—prepared and unprepared—we have received from Mr. J. R. Sawyer, the director of the Autotype Works at Ealing Dene, we are compelled to admit that the preparations to which they are subjected, and in virtue of which they are converted into "transfer" papers, not only do not conduce to their becoming coloured under the prolonged action of light, but actually retards such discolouration.

ON DIFFERENT MODES OF DEVELOPMENT.

In the course of our recent experiments in connection with indoor portraiture we have availed ourselves of numerous opportunities of testing the respective merits of the various methods of development applicable to the particular description of plates we have employed, and the experience gained may probably be of use to some of our readers who may take up the same line of practice.

Wet emulsion plates, which we have principally employed in our experiments, offer a pretty wide choice in the matter of development; for with very slight variations in the treatment of the plate previous to exposure any of the modes of development in ordinary use may be applied. It will be our aim to describe the peculiar features of each combination of circumstances in order to assist beginners in this branch of photography in selecting the particular system which may seem the most suitable. We may premise that the action of the different developers when applied to portraiture differs in some instances very materially from the result obtained under similar conditions when a landscape is in question; but the apparent difference, when it exists, is clearly explainable when we consider the altered requirements in the two cases.

It is scarcely needful to refer to the different circumstances of light which prevail in either case, though this to a certain extent exercises an important effect upon the result. The real or principal cause of difference consists in the character of the picture required. A landscape may be photographed under almost any conditions of light without any incongruous result, but in portraiture this is not so. If from defects in the system of lighting, or from any other cause, the shadows are brought into a little greater prominence than ought to be the case from a pictorial point of view the result is neither a picture nor a portrait. The so-called "Rembrandt" pictures, which revel in contrasts of light and shade, are not unfrequently, in the hands of a clever manipulator, made to combine a likeness with picturesque effect; but the ordinary operator will find it better and more to his interest to abstain from any attempt to introduce strong contrasts into his pictures—at least until he is thoroughly master of his light—and then to bear in mind that what may seem to him a "picture" is not necessarily a "portrait" when viewed by the critical eyes of intimate friends of the sitter.

We have said that defective lighting is the cause of this inharmonious result; but defective or improper development combined or not with errors in exposure is quite as fruitful a cause of failure. With the most perfect system of illumination emulsion plates frequently fail in giving an equal result to a wet plate, simply from want of proper development. Our first experiments in portraiture upon this class of plates were made in the studio of a professional photographer, and side by side with wet plates for comparison. The conclusion arrived at was that, though the emulsion plates were quite equal to the others in rapidity, the quality of the picture was inferior, being "patchy" and wanting in harmony. A very considerable prolongation of the exposure failed to improve matters, and we have now reason to believe that the inferior result was entirely due to the employment of the same mode of development adopted for landscape work.

To illustrate the different effects obtained we may commence with the most generally employed—alkaline development. This term covers a very wide range of modifications; but, for practical purposes, we may divide it into "weak" and "strong." Now, in landscape work a developer strong in alkali is known to give with a short exposure an image vigorous and full of detail, and requiring very little after-intensification. With weaker alkali we obtain a less vigorous image at the outset—a prolonged application is necessary for the production of the same amount of detail, and greater trouble is required to produce printing density; but the picture when completed presents a softer, perhaps "flatter," appearance. The difference amounts merely to this—that the subject is rendered in each case in a slightly different style, each in its way excellent and presenting no defect either manipulatory or pictorial.

We have before us as we write two portraits taken in a bi-lens camera with simultaneous exposure. After exposure the plate was cut and each half developed separately—the one with strong, and the other with weak, alkali—and the best result in either case obtained. With the strong ammonia we have a picture with powerful contrasts, the line of the cheek and the shadows under the eyebrows being strongly marked and forming a somewhat patched appearance. The other half, which took a much longer time to develope, presents a more even, almost "flat," picture, the most prominent markings of the face consisting of but faint suggestions of shadow. Though neither of them perfect, the last named forms by far the most pleasing picture *as a portrait.* Had the subject been a landscape the choice, if any, would probably have fallen the other way.

After varying the experiment in a number of ways we have arrived at the conclusion that the best result is to be obtained with weak alkali. Let the development be commenced with pyro. and the smallest quantity of ammonia, without bromide, and bring the detail well out before attempting to intensify. If strong alkali be used at the outset the contrast produced by its first application cannot afterwards be subdued. We have used Mr. H. J. Newton's sal soda developer, and though it works well and rapidly on an evenly-lighted picture it makes a complete "muddle" of anything in the shape of a "Rembrandt." One recommendation in its favour is the rapidity with which the development is completed; but unless this can be combined with quality of result we fear that for portraiture it will not find favour.

Ferrous oxalate works in a directly opposite manner—the stronger solution giving a harmonious, the weaker a vigorous, result. The intensification, however, must be performed with alkaline pyro., as silver, even after a concentrated ferrous oxalate solution, runs very much in the direction of "hardness." Unlike landscape work, portraiture seems to be better adapted to intensification with ammonia than to silver reinforcement; and we therefore prefer the former mode, no matter whether the first development be performed with alkali or ferrous oxalate.

The preceding remarks apply to plates used dry, simply washed, or treated with an alkaline organifier. Silver development under the same circumstances not only requires a longer exposure but produces an inferior result. There are many who still prefer silver development, though ferrous oxalate leaves little to be desired in the way of simpltcity; and to such we recommend the following modification in the preparation of the plates. The same emulsion is used, but, after coating and rinsing in a dish or under the tap until the greasy lines disappear, it is flooded with a thirty-grain (or stronger) solution of silver and transferred to the slide. In this state and with ordinary iron development it requires little, if any, longer exposure than if developed with ammonia, and behaves much in the same manner as an ordinary wet plate.

With a plain bromide emulsion and silver development a difficulty may sometimes be experienced in acquiring density; but this is entirely obviated by the introduction of a small proportion of iodide. Bromide *per se* appears to be almost as ill adapted to silver development as iodide is to alkaline; but a very slight trace of the latter makes all the difference without in the slightest degree deteriorating the sensitiveness. The best form of iron developer we are unable to indicate, having used several without discovering any marked difference; perhaps *the* best will be found in individual cases to be the one most generally employed.

We desire to impress upon all intending experimentalists in portraiture with wet emulsion the importance of noticing the difference between the requirements of that branch and landscape work, as by commencing with the eyes thus opened they may be saved a considerable amount of trouble and failure.

A NEW HEAD-REST.

It is a remarkable fact that, from the sitter's point of view, head-rests are an unmitigated nuisance. The charge against them is that they make one feel cramped and uncomfortable. It is even insinuated that a sitter's back hair will sometimes become uncomfortably "annexed" by the instrument, and it has been known to even snatch "borrowed" locks from off the head of a fair sitter—a state of matters that must be felt to amply justify the indulgence of splenetic observations on the part of the victim. "I am sure," said a lady who was forcibly expressing her opinions on head-rests, "that I can sit a thousand times steadier without the aid of one of these rests than when its horrid prongs are clamping me round the back of the head;" and, to prove the accuracy of her statement, she sat still and allowed her head to perform a series of oscillatory movements with every inhalation of her breath. The truth is that, mince the matter as we may, not more than one sitter in fifty can sit motionless without the aid of a head-rest; and, this being the case, it is absolutely indispensable to the success of the photographic artist that he make use of this instrument.

There is, however, some foundation for the well-worn assertion respecting the discomfort attending the use of the head-rest. To possess firmness a head-rest must be heavy and repose solidly upon the floor; but this quality, so conducive to its excellence, militates against its being adjusted readily and with facility. It was, we presume, when searching for some means to combine the somewhat opposite qualities of solidity and portability that Mr. Emmerson, of Leeds, who is a practical engineer conversant with the requirements of photographers, devised a method for which he has obtained a patent, and by means of which he has been enabled to combine in his head-rest several important mechanical powers, all tending to render it more efficient than hitherto.

We have been especially struck with the ingenuity by which the rest—which is both body- and head-rest—is allowed to run lightly over the floor by means of castors. Suppose the rest to be standing solidly upon the floor of the studio, and it is thought desirable to remove it a short distance, backwards or forwards, or from one side to another: we all know that with an ordinary rest this becomes a somewhat serious matter, involving, at the least, a heavy lift. But in the "standard carriage rest" of Mr. Emmerson all that is necessary to ensure its freedom of motion is that the photographer should press his foot firmly upon a small iron treadle which projects behind and is connected with a lever, when immediately three small castors, concealed in the base of the stand, are brought into play and sustain the whole weight of the rest, which can now be moved with the greatest facility. When it is required to restore the rest to its state of immobility a handle, or trigger, projecting behind forms the means of doing so; for no sooner is this pulled in an upward direction than a powerful spiral spring is brought into play, by which the castors are all withdrawn from action and the stand made to repose upon its own base. Further mechanical details will be given in a subsequent article when the specification of the patent has been published.

In addition to the feature we have described, the vertical rod upon which the rests proper are supported is affixed to the stand by means of a ball-and-socket system of peculiar construction, by which it receives a great universality of motion in every direction. A pleasing novelty has been introduced with respect to the use of horn, both as tips to the head-fork and as the material of which the large screw-handles are made. These, with the other points described, will indicate Mr. Emmerson's new head-rest to be an instrument possessing a good claim upon the attention of photographers.

WATER-HEATING APPARATUS.

We believe there is one particular cause that frequently operates in deterring photographers from taking up carbon printing, but which need by no means be looked upon as the bugbear it appears to be. We allude to the necessity for a plentiful supply of hot water. Where only an occasional "kettleful" is required the photographer who works at his art in connection with his private residence may not experience much difficulty, beyond an occasional anathema from the domestic powers that rule in the quarters he would needs have to apply to for his supply. But the photographer who can only rely upon his own professional premises, and who, as a rule, makes use of every available corner in the place, what can he do, or where, if he start enlarging, chromotype, or, in fact, autotype work generally on a large scale? The fire in his printing or varnishing room is allowed to die down as soon as possible in summer time, and in winter, though it may possibly be kept at a good heat all day, he would require to have kettles going all day long to supply anything like the demand for a reasonable amount of business. Hence he puts it off, and "will think about it," or perhaps he applies to a builder and gets an estimate for fitting up a hot-water boiler, with cistern, &c., which is likely enough to startle him by its amount into giving up the idea till that indefinite future occasion "some other time."

We would, however, at the outset remind him that there is not that need for the immense supply of water so often assumed. For such delicate work as carbon printing for *cartes*, cabinets, and such small work, generally, it is desirable to have a continuous supply—but not necessarily a large one—of clean, filtered hot water; but for an occasional enlargement, including the making of transparencies, a good-sized vessel—one holding (say) a gallon of boiling water, such as could stand by any ordinary fireplace—will be quite as much as is necessary. The very ingenious gas arrangement, for giving a continuous supply of water at any heat, which we described a year or two ago in these columns is, we believe, made use of by many, who are entirely satisfied with it, and it is quite sufficient to produce water enough for a good-sized batch of prints. Its drawback is necessarily the fact that, though a continuous supply may be obtained, it comes slowly, and if a large quantity be wanted at once for any purpose it can only be had by waiting till the required amount has dribbled out. It is not difficult to imagine cases when this would be an intolerable nuisance.

We therefore, today, will describe an apparatus in use at Mr. G. Watmough Webster's studio, which is perhaps the most economical hot-water boiler reservoir ever produced, and as efficient as economical, we believe. The hot- and cold-water reservoirs are formed by two second-hand casks holding about twenty gallons, each of which is placed on a strong wood support in a room contiguous to that containing the fireplace. The boiler, in place of the bulky constructions usually employed for such purposes, is simply a half cylinder of copper that had been used for some other purpose and discarded. Its dimensions are only ten inches long by five inches wide, and about the same height. It is not built into the wall, but merely rests on a couple of iron bars placed across the fireplace, and is kept rigid by the lead egress and ingress pipes. Naturally it blocks up a considerable portion of the fireplace, but still leaves room for an occasional vessel that may be required for any other purpose. The pipe is taken from the cold-water cask or reservoir, and leads to the bottom of the copper boiler, and from the top of the latter a pipe communicates with the hot-water cistern. Then, again, a lead pipe connects the two casks through the bottom, to prevent the water all being run off, and so leaving the boiler dry. Connected with these pipes are sundry taps, hot and cold, which need not be detailed, any plumber being able to fit and lead them in any required direction. It is hardly necessary to say that the supply finds its way through a ball cock into the cold-water cistern, and if our description be apprehended it will be seen that, when the fire is lighted under the copper the hot-water cistern is heated from it direct without circulating at all through the cold reservoir, any water drawn off being made up by fresh cold water passing through the boiler till the level of the two is alike. We believe that in the course of an hour or an hour and a-half after lighting the fire there is, as long as it is kept alight, a plentiful supply of hot water all the day through.

It is by no means an infrequent occurrence that after fixing, drying, and perhaps varnishing, a negative it is found to be too dense, and in order to obtain a satisfactory print it is desirable to reduce it. Such a case arose in our own practice a short time back, the negative being one which for various reasons we did not wish to spoil, though in its then condition it gave anything but a satisfactory print. We had the option of several published plans, all of which are more or less incorrect in principle, though they may answer moderately well in some cases, as, for instance, with a negative which is uniformly too dense in every part. For our purpose they seemed entirely unsuited, the negative being slightly under-exposed and over-intensified, presenting very dense lights with soft, delicate half-tones, and shadows verging on transparent glass. Now, with the ordinary modes of procedure, whatever action occurs takes place uniformly over the whole surface, and therefore the half-tones suffer more in comparison to the high lights. Moreover, if any of the methods based upon the partial iodising or chlorising of the image and subsequent treatment with hypo. or cyanide be used, the delicate shadows are the first to suffer reduction, and this was exactly what we wished to avoid. We put the question in this light: the image as it exists in the film commences at the surface and extends downwards to the glass (we are speaking of an alkali-developed image), the most delicate details being almost *on* the surface, the highest lights perhaps extending right through the film. By attacking the surface we remove the finer details before the denser parts are materially affected; *ergo*, to produce an opposite result we must commence on the under-side of the collodion. At first sight we could find no practical solution of the problem thus set; but after a little thought we hit upon a plan which was immediately put into practice (upon a worthless negative), and after a few experimental trials we ventured to operate upon *the* negative, the result being in every way satisfactory, though fear of spoiling the picture prevented us getting the best possible result. The method adopted was as follows:—The image was first "bleached" *throughout its whole thickness* with chloride of copper, and after well washing it was treated with an extremely weak alkaline developer in order to again reduce it. This reduction is not development proper; it is merely a chemical reaction which goes on without the aid of light, commencing at the surface and proceeding gradually downwards. If, then, we allow it to penetrate *nearly* through the film, we have a certain portion of the chloride forming the denser parts of the image still unreduced, and by removing this with hypo. we arrive at the desired object, for we, in fact, attack the under-side of the film. The chief element necessary to ensure success is to use the reducing solution sufficiently weak to enable the operation to be watched carefully. Guided by the colour of the image by transmitted light, and its appearance when viewed from the reverse side, it is easy after a little experience to judge when to stop it. It is better to over- than under-do the reduction with alkali, as the whole operation may be repeated if the first effect be not sufficient; if the hypo. be applied too soon the injury is irreparable.

INCREASING THE SENSITIVENESS OF DRY PLATES.

I believe that the following experience has not been published before in your columns, and may, therefore, be of interest to your readers.

I have an emulsion which is rather contractile, and given to splitting during drying if the film should have become loose during development and washing. This emulsion gives plates of much greater sensitiveness if, instead of allowing the latter to dry in the usual way, they be placed in distilled water till "greasiness" has disappeared, and then dried.

Still greater sensitiveness and density is obtained by coating the washed and dried film with a one-grain solution of pyrogallic acid, and again drying. This latter is an idea obtained from Mr. England's late communication to the Photographic Society. The effect of the coating of pyrogallol solution is also most marked when it is flowed over a dried but unwashed plate, greater density resulting than with washing alone.

A soaking in pyrogallol solution immediately after washing does not seem to be so beneficial as the coating when dry.

These results are, in my hands, easily observed with the ferrous oxalate developer; and sometimes I have found what would make all the difference between complete failure and success by merely coating the dried and unwashed plate with the pyrogallol solution. With the hydrosulphite of soda developer these results appear, perhaps, less marked, though I cannot say with certainty.

Perhaps some reader may attempt to repeat these experiments. It should, however, be borne in mind that a more perfect emulsion than the one experimented on may not be affected in the same manner. A probable explanation of the action of a short soaking in water is that the pores of the collodion are thereby left open to the developer. Then we must seek some other reason for the increase of sensitiveness caused by the application of the pyro. to the dried and unwashed film. But it is found that when a film is both washed, dried, and coated with pyro., the sum total of its sensitiveness is not double, or, indeed, much more than when either of the two operations are conducted singly. It appears reasonable to expect a large accession of sensitiveness from both of the modifications—one of which might be looked upon as mechanical in its operation and the other as chemical. I do not, however, find such to be the case. For the above emulsion I find French chalk very effective in keeping the film on the plate; and, even should a corner loosen during washing, a splitting does not commence at that part, as is usually the case with this particular emulsion. I find that the gelatine solution with chrome alum, unless very carefully filtered indeed, gives white, insensitive spots.

It is best to immerse the dried plate in the pyro. solution, as otherwise markings may result.

It would be interesting to know whether the pyrogallol would prevent those spots to which plates prepared from washed emulsions are so addicted after having been kept for a few weeks.

So far as I can see, the hydrosulphite of soda as a developer is preferable to ferrous oxalate, the quality of the image being superior in colour and gradation.

Perhaps a word of advice to any who may wish to try this developer will be permitted. While I do not go so far as to say that failure *must* result from the use of most samples of bisulphite of soda in the market, I may say that they are not all equally suitable. The quality I use contains water of crystallisation, whereas that generally sold does not, and, as far as I can ascertain, is sold in London only by Morson and Son, Southampton-row. The bisulphite should be obtained, as far as possible, in shining crystals, which state, in the case of the hydrated salt, ensures the absence of sodic sulphate, to which it is oxidised by the air—at least it is very unlikely to be then present in large quantity. In the case of the anhydrous salt the test of appearance is not admissible, as this is opaque and powdery. The solution must contain no free sulphurous acid; if it do it should be neutralised with sodic carbonate. The salt should be kept in closely-stoppered bottles. I give these details as I do not think this developer has received the share of attention which it deserves.

Since writing the above I have continued similar experiments with a new emulsion, and I find the same result. It is more marked than I had thought with the hydrosulphite developer. One thing I notice is curious: if a coated plate be only half moistened with water, and then dried, exposed, and developed, it will be seen that the bromide at the line of junction of the two portions is more transparent than the rest, and is also less sensitive. The transparency is also seen before development. Perhaps some organic matter collects at this point.

We hear of some difference of opinion as to the advantages of exposing emulsion plates in the moist condition. This is probably due to the different kinds of pyroxyline. If this be powdery there will be no advantage in exposing the plates in the moist condition.

It seems to me very probable that, wetting a washed emulsion film made with a tough pyroxyline with distilled water previously to drying would, at least to a very considerable extent, approach in effect to the exposing of the plate in the moist state. I shall make a trial in this direction. Herbert B. Berkeley.

"AN UNSUSPECTED CAUSE OF FADING OF CARBON PRINTS."

A leading article in your last week's Journal calls attention, under the above heading, to a new and until lately unsuspected cause of deterioration in carbon prints; and the specimens brought to our notice by Mr. J. G. Tunny place the matter in such a positive and unmistakable form as to admit of no doubt whatever, and rendered it absolutely necessary for us to probe the matter to the bottom.

The new cause of evil shows itself in the discolouration of the transfer-paper under the influence and prolonged action of sunlight. It has lately been our opinion that what has been termed "fading in carbon prints" is not a fading at all, but a discolouration, and the cause not any instability of the colour employed in the tissue or the preparation used for the transfer-paper, but the actual discolouration of the paper itself.

Some time ago Mr. Tunny sent us some prints which he said had faded. These were prints made in autotype tissue, the colouring matter being alizarine in combination with blue and black, both of known permanency. The prints were evidently discoloured in the portions to which the light had had access; those portions which had been covered by the mask retained their pristine brilliancy. We expressed our opinion to Mr. Tunny that no change had taken place in the colour employed, but that, somehow or other, the transfer paper had become discoloured, and this matter we immediately proceeded to test.

On the 13th of June we exposed in a south window in the tower of our works strips of plain paper, and also strips of the transfer-papers made upon the paper corresponding to the strips of plain paper. These were allowed to remain untouched till the 28th of July, when they were taken down and examined.

On that day we received a letter from Mr. Tunny, stating that he also had exposed pieces of transfer-paper, had found them discoloured by the action of light, and expressed his opinion that the chrome alum employed was not to be depended upon, and that it underwent a change by being exposed to light. The specimens that he enclosed showed that a change had taken place, and there appeared an *a priori* reason for supposing that the change was due to something in the preparation of the transfer-paper. Fortunately we had taken the precaution to expose at the same time as the transfer-paper strips of the paper *before* any preparation had been placed upon it, and we now lay before your readers the exact state of the case.

For transfer-paper we use two kinds of paper—one a fine Scotch paper, the other obtained from Germany of a very fine kind made expressly for us, and costing us 50 per cent. more than the best home-made paper in roll. These we marked A B C as being papers made at different dates. We found that the one marked A so slightly changed as to be almost imperceptible, that marked C had slightly discoloured, whilst that marked B had gone from a brilliant white to a cheesy colour. Now these samples of papers were exactly as they came from the rolls, without any preparation, chrome alum, or manipulation of any sort by ourselves.

The corresponding transfer-papers had also changed their colour, but not to so great an extent as the plain papers, clearly proving that, whatever may be the cause of the deterioration, nothing in the preparation of the transfer-papers has anything to do with it.

The Scotch paper bore the test a great deal better, the discolouration being extremely slight, and the transfer-paper made from it as nearly as possible unchanged.

On inquiry amongst our paper-makers, we find that it is a well-known fact that certain papers do change with the action of light, more especially that in which Esparto grass is employed in any quantity. In order to get this up to a saleable colour it has to be bleached chemically to a very great degree, and is probably tinted with aniline colour, which is of a known fugitive nature, the result being that the aniline colour flies, the bleach disappears, and the paper returns to its original hue.

Our own carefully-conducted experiments prove that the chrome alum is practically inert, and may be used with perfect safety; but it is necessary to guard against the proceedings of the paper-makers themselves. No doubt, in a variety of circumstances, the discolouration does not signify. Everybody knows how old books, old engravings, framed diplomas, and show-cards in shop windows are constantly seen in a discoloured state. We have before us a lithograph of the city of Paris the centre of which has become discoloured, leaving about three inches all round, where the stretcher covers the original tint.

But all this does not touch pigment printing, excepting that it shows the absolute necessity for testing the paper before it is used. A six weeks' exposure to a summer sky, in a south window, is a sufficient trial for any paper; if it remain practically unchanged after passing that ordeal no fear need be entertained of the permanency of the carbon print placed upon it.

It would be interesting to know how much of the discolouration—the abnormal discolouration—of silver prints of late years is due to the paper. Does not this go some way to account for the extraordinary discrepancies in the behaviour of silver prints? The most careful treatment, perfect washing, the best manipulation in every stage, may be completely neutralised by some treatment the paper may have received before it ever comes into the hands of the persons who prepare it for photographic purposes.

Amongst all our own papers we find only one batch really bad, and another is slightly imperfect; but it was scarcely possible to foresee the weak point in this matter. The imperfect papers were bought as papers of the best quality from a maker of reputation. Economy has always been out of the question with respect to the Autotype Company; they have always bought to the best of their judgment the highest class of material that money could command. It is unfortunate that the weak point was not discovered before, but now that it is found it is easy to guard against it. It must also be remembered that the paper, even at its very worst, though it may discolour under a six weeks' exposure to a summer sun, changes but little exposed in a room or under ordinary circumstances; but it is of the greatest importance to insist that our paper-makers shall supply, for all photographic purposes, absolutely pure and unadulterated material. We beg to enclose the samples referred to.

The Autotype Company.

ON THE ACCELERATION OF OXIDATION BY THE LEAST REFRANGIBLE END OF THE SPECTRUM.

[A communication to the Royal Society.]

In my first note on this subject it was stated that further experiments would be undertaken, in which sensitive films would be exposed to the action of the spectrum in atmospheres free from oxygen. These have been carried out by means of apparatus specially designed for the purpose, hydrogen and nitrogen being the atmospheres employed, and in some cases hydrogen vacua. In every case the experiments were confirmatory of what was previously surmised, the image showing no signs of oxidation; and there is evidence to show that the limit of sensibility of the compounds used is lowered towards the least refrangible end of the spectrum.

Exposure of films in solutions which readily combine with oxygen, and at the same time with the halogens, have given most remarkable results. For instance: silver bromide, which by its colour should have proved sensitive to the red end, yet when exposed in the usual manner was insensitive below B in the spectrum, proved sensitive when exposed in sodium sulphite (Na_2SO_3), and arrived at the lowest limit (about W.L. 12,000) which I have as yet photographed. In the same solution, to quote another experiment, silver iodide proved sensitive to a point between a and A. The experiments were carried out in duplicate. In one the plate was immersed in the solution, and in another the salt was dissolved when possible in glycerine and applied to the film. Both methods answered equally well, but for some purposes the latter is more convenient.

My experiments also prove that what is technically known as solarisation is due to the oxidation of the image, accelerated by light generally, be it the more or less refrangible end of the spectrum. This oxidation causes the formation of a compound which is undevelopable, as has already been pointed out. It has thus been found impossible to produce solarisation in solutions which have oxygen absorbents. We may therefore conclude that the whole spectrum exercises a reducing action on the sensitive salt, and that this reduced compound is again capable of being oxidised by it.

The relative power of the two actions seems to vary according to the part of the spectrum. This subject is still under consideration.

In my first note I also mentioned that photography in natural colours probably depended on the same action. My surmise is confirmed to a great extent. If silver sub-chloride or silver sub-bromide be produced chemically we have a dark compound formed which, if exposed to the action of the spectrum whilst in an oxidising solution (such as hydrogen peroxide), rapidly takes the colour of the rays acting upon it, the yellow being the least marked. The red, green, and blue are, however, particularly well rendered by reflected light, and the plate shows the colours as seen when a dull light is thrown on the slit of the spectroscope—a simile which was suggested to me by Mr. Norman Lockyer.

From the evidence obtained by these experiments it appears that two or three molecular groupings are sufficient to give the necessary colours—a subject which I only allude to since the more general question of molecular groupings is being considered by others.

W. de W. Abney, R.E., F.R.S.

NOTES ON PASSING EVENTS.*

By a Peripatetic Photographer.

To expose a plate in the camera by means of electricity is doubtless a very pretty idea, and also one that can very easily be carried into practical effect, especially as regards the requirements of the professional photographer who keeps his battery in a garden or cellar and "leads on" the electric current into the operating-room by means of a small wire. But what about those who have neither garden nor cellar, nor even a spare cupboard in which to place the battery so necessary to the electrically-moved lens cap? What about those peripatetic photographers, like myself, who are continually finding themselves here, there, and everywhere? The reply is—You are to conceal a tiny, yet powerful, battery inside the camera itself. True; quite possible and practicable and very easy to boot. But—is it not known that there is a liberation of ozone by the action of a galvanic battery? And has it not been shown at a recent meeting of the Photographic Society of Great Britain that ozone acts in a most deleterious manner upon an impressed photographic plate? If such be the case I think it will be found in practice to be inexpedient to place a battery, however small, inside the camera in which the plate is to be exposed. Old daguerreotypists well know the astounding and sometimes disastrous effects that were produced by allowing even the faintest trace of the vapours of iodine, chlorine, or bromine to fall upon the surface of an exposed but undeveloped daguerreotype plate. Expose as long as you like, and a clever trickster who may have had access to your camera could effectually prevent you from ever being able to develope an image upon a daguerreotype plate.

Window portraiture is a subject of attractiveness to every amateur and not a few professional photographers. When I read the article on that subject in a recent number of The British Journal of Photography I thought of a little bit of experience I recently had in that direction. My sitter is one whose name is illustrious in history. He has long been unable to leave his room in consequence of an illness which, in all probability, will eventually terminate fatally. He can be wheeled from his bedroom to a parlour, the bay window of which "looks" into a garden whose dimensions are so small that there is a distance of only twenty feet between the window and the thickset, laurel hedge which isolates it from the public gaze. The window, I may state, is open to the south. Now, to obtain a proper portrait by placing the camera *inside* the room was found to be impossible, no matter how skilfully the subject was hedged round with reflectors and screens. But, bearing in mind something that years ago I had read in one of The British Journal Photographic Almanacs, I had my sitter wheeled up close to the window, which was then thrown wide open, the camera being placed in the garden. Owing to the southern exposure I had to wait until the sun was overcast with clouds before I could take the picture; but the three negatives that I obtained as the result of this composite order—indoor and outdoor—of "window portraiture" attest the great value of this method of proceeding, when under other conditions failure would inevitably be the result. If I thought that I should not incur the charge of occupying too much valuable space I could easily and willingly have devoted a whole article to this subject.†

Bravo! A duel! By all means let us have it! Comparisons may be "odorous," as the elegant Mrs. Malaprop hath it; but if one man in Paris and another man in London possess processes which "lick creation" as respects rapidity, the only way to have the question of individual superiority determined is to have them to meet together on neutral ground, and in the presence of a jury to fight it out in the only way in which such a matter can be determined, namely, by practical demonstration. This is *apropos* of a recent brief article by Mr. A. L. Henderson, in which he gives a hint respecting a practical trial, on Paris ground, of his method of working compared with that of M. Boissonnas, whose charming pictures when exhibited here last year elicited unqualified expressions of approval. Now, if M. Klary, who is about to visit this country, can be prevailed upon to meet Mr. Henderson in a friendly tournament it would be exceedingly interesting; and to place it on a very low ground it would pay well, for numerous professional photographers would most willingly pay a liberal fee to be present during the trial of skill. Rapidity in the wet collodion process is a point of vital importance to a portrait photographer. In the meantime I, and many others, look forward with impatience to the time when Mr. Henderson is to redeem his promise of supplying particulars of the method he employed when he competed successfully with M. Klary in Paris.

Those photographers who are intending to contribute to the next exhibition of the Photographic Society of Great Britain must "look alive." August is one of the finest months in the year for obtaining landscapes replete with beauty.

The members of the South London Photographic Society met a few days ago at the house of their highly-popular and much-respected President to enjoy his annually-proffered hospitality. Is this fair? and should not meetings of this kind be "stamped out?" I know several who are presidents of societies, but who are not perhaps so fortunately situated as respects worldly surroundings as Mr. Statham. Moreover, what is a mere "flea-bite" when a society numbers a dozen members becomes a serious tax when it expands as the South London Photographic Society has done. It is my opinion that private hospitality under such circumstances is an entire mistake, and that "the saddle ought to be put upon the right horse." If a gentleman—and I don't now refer to any society in particular—is good-natured enough to take the often onerous office of president, the members of that society should, as a *quid pro quo*, enact the *rôle* of host to such president or other officers to whom they stand indebted. I feel this is a delicate matter, but it is one that must be referred to sooner or later. You must know that I myself have some intention of becoming a member of the South London Photographic Society, but am deterred by the thought that I may be elected president (you see that I am modest), and, if so, that I may not be able to follow suit in the sumptuous entertainments so liberally and generously provided in past years. *Verb sap.*

* Concluded from page 365.

† Our peripatetic correspondent is irritating. He knows, or ought to know, that the treatment of this subject in even the *fullest* detail would be most welcome to ourselves and readers.—Eds.

THE APPLICATION OF PHOTOGRAPHY TO THE PRODUCTION OF PRINTING SURFACES AND PICTURES IN PIGMENT.

IN SIX LECTURES.

III.—LINE ENGRAVING ON METAL PLATES.

[A communication to the Society of Arts.]

We now go back to the first photographic process discovered—that is to say, the first process which gave photographic representations which could be exposed to light without destruction—the bitumen process of the hard-working and patient Niépce. This investigator noticed that the residue left on the drying of certain varnishes became insoluble by exposure to light. About the year 1814 he covered metal plates with a bituminous varnish, exposed them in the *camera obscura*, and after exposure he subjected them to the action of similar solvents to those originally employed in making the varnish. Under these circumstance those parts of the film which had been exposed to strong light refused to dissolve, while the unexposed parts dissolved, a negative image being thus formed on the metal plate. To convert this negative image into a positive those parts of the metal which were uncovered by bituminous matter were darkened by the vapour of iodine, and the bitumen was then removed by the use of a more powerful solvent. By the application of a suitable acid to the bitumen pictures on metal the bare parts were dissolved away and engraved plates were obtained. Here is a specimen of bitumen or mineral pitch—a substance which is found in most quarters of the world. Let us powder a little and pour benzole on it. You see that it dissolves quite easily, and the solution runs freely through this paper filter. You see that the solution is about as thick as collodion, or, perhaps, rather thinner. Now, here is a carefully-cleaned copper plate, such as the engravers use, and you see that I am going to clamp it down on to this turn-table. The next step is to flood the plate with bitumen solution, and then to make the table revolve quickly. Now it has revolved a few seconds, and I think the film will be dry. Here it is. I hand it round, so that you can judge for yourselves as to the advantages of this method of coating the plate. I know of no other method by which such an uniform and compact film of bitumen can be obtained. After coating it is well to put the plate aside for twelve hours, in order that the film may become harder. It is then necessary to dust it over with French chalk, to remove stickiness; and, after this, it is placed behind a transparency and exposed to light. The time of this exposure may vary from twenty minutes to two days.

Here is a plate which has had the requisite exposure, and the next matter is to dissolve away that portion of the bitumen which has not been made insoluble by the action of light. Now, benzole is too energetic a solvent for my purpose, and oil of turpentine is not sufficiently active; but, by mixing these together, you can get any degree of solvent power which you may require. I will get Mr. Barker to treat this plate with the solvents. You see that he commences by flooding the plate with oil of turpentine, and, as this has not sufficient action, he pours it off and adds a little benzole. This begins to produce an effect, and enables him to judge as to the amount of benzole which he may safely add to the oil of turpentine. He has added this quantity, and has now washed away all the soluble bitumen from the plate, which is next thoroughly rinsed with water to remove the oil of turpentine. You see how extremely sharp and well-defined the lines are. I next place the plate in nitric acid, so as to etch the lines where the metal is bare; and, while the etching is in progress, I will get Mr. Barker to dissolve away the soluble bitumen from this glass plate, when we shall find remaining the bituminous reproduction of a page of letterpress, which I can show you by means of the lantern. Our first plate is now sufficiently etched, and when I have cleared off all the bitumen, by rubbing with a rag and benzole, the plate will be ready for the printer. It is now clean, and I will hand it round for you to examine.

Mr. Barker has now the bitumen image on the glass plate, ready for the lantern. The image is now on the screen, and you see how sharp and well-defined the lines are. I take the plate out, and if you examine it you will notice that the letters are raised on the glass, they being, as you know, formed of insoluble bitumen. If we wish to etch the glass it is merely necessary to expose it to the action of hydrofluoric acid, as I do now.

So much for the line-engraving process of Niépce; but before you go I want to show you that very perfect half-tone transparency pictures may be produced by means of bitumen. Here are some pieces of sheet gelatine and some pieces of talc which have been varnished on one side with bituminous varnish. I hold two of these—one being on talc and the other on gelatine—over against the lime-light, and you merely see even films of bitumen, but no image. There is, however, in each case a picture of insoluble bitumen imbedded in the films, and I will get Mr. Barker to dissolve away the soluble portions, so as to lay bare this hidden image. He will use a mixture of oil of turpentine and benzole as a solvent.

Supposing that the varnished side of the talc or gelatine is placed in contact with the negative, and the light is allowed to shine through it: those parts of the bitumen film which are under the perfectly transparent parts of the negative become insoluble, let us say, all through. Now, those parts of the film which are under less transparent parts of the negative do not become insoluble all through, but a skin of insoluble bitumen is formed on the surface of the bitumen film, this skin varying in thickness according to the amount of light which has given rise to it. Put a varnished and exposed gelatine sheet of this kind into the solvents, and note the effect. When the film is made insoluble all through it resists the action and remains on the talc; but where only a skin of insoluble bitumen exists on the surface of the film the solvents loosen and dissolve the bitumen from underneath this skin, and away it floats. Now you can understand why the bitumen process, in its ordinary form, is only adapted for the reproduction of subjects in extreme black and white, such as line engravings or letterpress. Now, if we wish to preserve the half-tone picture intact we must expose through the transparent medium (talc or gelatine) so as to ensure every part of the insoluble image, whatever its thickness, being in contact with the transparent support. Those prints which Mr. Barker is developing were done in this way, the talc or gelatine being placed in contact with the negative. The small thickness of talc or gelatine does not render the image notably unsharp. It was only during the last week that I thought of making bitumen transparencies by this method of printing against the back of the film, so I have not had time to make many examples. Mr. Barker has now finished the washing away of the soluble bitumen from those which he took in hand some minutes ago, and as I exhibit them on the screen you will see how perfectly all the gradations of half-tone are represented. You quite understand that a picture of this kind is solid, the gradations of light and shade being due to a greater or less thickness of bitumen, and that the essential points in producing them are to varnish a thin, transparent medium with bitumen, to expose to light through this medium, and then to dissolve away that portion of the bitumen which has not been acted on by light. The ordinary black varnish sold for backing glass positives will answer very well, and so will some samples of Brunswick black. Here is a transparency which was made with ordinary Brunswick black; remember, however, that some samples of Brunswick black are not sensitive to light, these being probably made with coal pitch.

I think that by the method which I have just indicated very fine lantern slides may be produced, as there is an entire absence of texture or granularity, and it is possible that the bitumen pictures may be stained or toned without difficulty. As I told you before, I only recently thought of this method, and perhaps some of you will experiment with it.

On the table are some plates and specimens illustrating the process of engraving on bitumenised plates, and you will specially notice the great clearness and sharpness of the lines produced by this method. Messrs. Leitch and Co. have kindly lent me some of their photo.-engraved plates, which you will examine with much interest. These copperplates have been covered with a thin film of iron, by the electrolytic method; and as the film of iron is extremely thin it does not in any way interfere with the printing qualities of the plates. When the surface of a plate begins to wear a little, and the impressions show signs of deterioration, the plate is sent back to Messrs. Leitch and Co.'s factory, where the film of iron is dissolved off by means of dilute sulphuric acid, leaving the copperplate as good as ever. The film of iron, although so thin as not to injure the printing qualities of the plate, is nevertheless sufficiently thick to protect the copper from injury in printing. The plate having been freed from the first worn-out film of iron, is once more coated with a layer of iron, and is again ready for use. When the second film of iron is nearly worn away, and the printer approaches near to the true surface of the copper plate, the iron is again dissolved away, and a new coating of iron is put on. According to this system one really prints rather from a cast of the plate than from the original plate, and new casts are made as required.

Here are some admirable specimens of photographic engraving by Mr. Dallas—a gentleman who is always to the fore in matters connected with photo-mechanical printing.*

Before you go I wish to call your attention to a very simple and expeditious way of making engraved plates from line subjects. Here is a photolithographic transfer made from a positive instead of from a negative, as is usually the case. You see that the ground is black and the lines are white; in fact, by far the greater part of its surface is black. I now lay it on a zinc plate and pass it through the press. Now, what will be the result? I will tell you beforehand. So much of the paper being covered with printing ink, and so little being white, moist, and gelatinous, the transfer will slide over the zinc plate and we merely get a smear. Here it is. I have here another transfer similar to the last, excepting that white patches are introduced on it wherever they can be introduced without falling foul of the picture. This is done by painting on the transparency with Brunswick black. On putting this transfer down on a zinc plate you see that it adheres properly, and we have a perfect image on the metal. As the white patches are now done with I varnish them over, and you see that the zinc is covered everywhere except where the lines of the engraving are bare. The covering on the zinc is now made denser by inking and dusting with resin, as I explained in the last lecture, and the plate is then etched by dilute nitric acid. Here is a plate already inked and dusted; I place it in this dish of nitric acid and allow it to remain a few minutes. I now clean off the ink, and you see the lines are engraved on the zinc plate. The plate may now be printed from in the copperplate press, or, as zinc is not a convenient metal for deep plate-printing, it may be reproduced by the electrotype process. THOMAS BOLAS, F.C.S.

* After the lecture Mr. Dallas informed me that he has been in the habit of coating the surface of his plates with iron, as described above.—T. B.

NOTES FROM AMERICA.

THE MAGIC LANTERN IN JAPAN.—THE STEREOPTICON.—RAMBLING HINTS.—REVERSED NEGATIVES.

FROM the *Exhibitor*, a new quarterly serial devoted to the subject of the magic lantern, issued by C. T. Milligan, Philadelphia, we get a peep into the palace of the Mikado of Japan, through the descriptive powers of Professor E. W. Clark, late of the Imperial University, Tokio, Japan. This gentleman had the privilege of giving a stereopticon exhibition in the presence of the Mikado and all his household and a few of the officers of state, at his Majesty's palace at Akasaka, in Tokio. Arrangements had been made for the exhibition some time beforehand, but owing to the sickness of the Tokudaiji, or Lord Chamberlain, it was somewhat delayed; besides, no such thing as a foreigner obtaining access to the imperial household for such a purpose as this had ever been heard of before, and of course the numerous officials connected with the Kunaisho, or Emperor's household department, felt in the beginning not a little shy about it. However, it was finally decided that the Mikado, the Empress, and her ladies should have a fine series of views of foreign lands:—

On July 3rd, therefore, says Professor Clark, I proceeded to the palace, in company with Hatakeyama, to select the rooms best adapted to my purpose. Crossing over the narrow embankment of the moat at Akasaka, where Iwakura was cut down some months ago, we passed through the outer gate and by the line of guards, and then through a second guarded gate, showing our wooden passports to the sentries as we entered; and walking up a broad stone path, we were received by the Kunaisho officers, and led in through an endless labyrinth of rooms to the inner reception parlours of the Emperor. These parlours are large and elegantly carpeted, and though the ceilings were not so high as I wished, yet I selected the best apartment as the place suited for the exhibition. On Tuesday evening I had my instruments all set up in the palace in readiness, and the large curtain was suspended from the top of one of the partitions of the apartment. I had two large screens arranged around the instruments, which the officers had first fixed so as to shut off the seats intended for the Emperor and his household from all the rest of us in the room. But, as soon as they had retired to give notice that all was ready, I made a slight but quick change, and pulled the screens backward, so as to make the way clear for a clearer and larger picture on the curtain, and I caused the Mikado's elegant chair to be placed in the little alcove, formed at the end of the zig-zag screen, and just to the left of my stereopticon, where he would have the finest possible view in the room. In front of his chair was a small table, covered with a rich gold-embroidered silk cloth; on his left was another little table, and a seat for the Empress, while in the rear were several lines of upholstered chairs, of very handsome style, for the maids of honour and other members of the household. A few days previous to the exhibition I had requested Mr. Katz and other officers of the Naval Department to lend us one of the marine bands to give music to the occasion. Consequently, on riding up to the gate of the palace in the evening, I met two bands instead of one, just marching up the hill; they formed in line in two companies, inside the gate, numbering sixty men in all, and began tuning their trumpets for the "show." After waiting for some time for the foreign leader of the band to make his appearance I got the musicians all together in a side room near the large parlours, and, giving them directions to play the hymns appropriate to the foreign countries, which would be shown in regular order, I left them to do the best they could, even though their proper band-master was not with them. At first they did splendidly, though the volume of sound of so many instruments was considerable; but later in the evening they lost discipline a little, and numbers of them came up slightly behind the stereopticon to see the pictures, though they made believe they had come merely to hear what particular piece they should play next! However, it was only a little amusing on the whole. As soon as everything was ready for the exhibition, notice was sent to the Mikado's apartments that all things were awaiting His Majesty's pleasure. The Emperor and Empress were ushered into the room, followed by quite an impressive retinue, consisting chiefly of young ladies dressed in white, with their long dark hair streaming behind, and broad red sashes encircling their waists; the effect was really very pretty, and quite unique, as this charming procession of fair ones entered, and quietly seated themselves behind His Majesty, while the band struck up the "Mikado's Hymn," and the word "Welcome," with the wreath of flowers, was thrown by the brilliant light upon the curtain. The chief officers of the Kunaisho, or the Household Department, sat on the opposite side of the room from His Majesty, and a little to the right a few attendants were also placed. Arisegawa, Fushinomiga, and Tokudaigi, the Lord Chamberlain, and several other high officers were in attendance on His Majesty; and everything passed off in a very pleasant and social manner, there being nothing stiff or formal, and yet there was a subdued stillness and becoming dignity about it. At the outset dissolving views were exhibited, showing Windsor Castle, Sandringham Hall, the Parliament Houses, and other English and Scottish places of interest, during which the band played "God Save the Queen." Then followed many American views of interest, such as Niagara, the Yosemite, and the principal scenes in Washington, New York, Boston, &c. After these, magnificent views of Paris, Berlin, Switzerland, and Northern Italy were presented in brilliant succession. Mr. Hatakeyama (who accompanied the Embassy in all their European experiences, and at their various court receptions, &c., abroad), sat near His Majesty, and explained all the views as they were announced, designating, at the same time, the particular places visited by the Embassy, and enlivening the occasion by little incidents of their experience. At Hatakeyama's request I announced briefly the names of all the places as they appeared, and he immediately translated it to the Emperor, adding such remarks as he wished. The Mikado seemed exceedingly interested, and although nearly everybody else was quiet in his presence, yet he conversed freely and naturally, asking many questions upon places of particular noteworthiness. After nearly a hundred of the various well-known scenes in Europe and America had been shown, interspersed with some very curious revolving chromatropes, and an ocean scene which was particularly impressive, a few very comic movable figures were introduced, which created considerable merriment among the fair ones of the white-robed retinue sitting to the left, though they were very subdued and dignified in their expression of it. But I did not consider it in good taste to show too many ludicrous views, for it would hardly be compatible with the dignity of the occasion, so thirty or forty slides were omitted. As it was, however, the exhibition lasted one hour and twenty minutes, and though they seemed a little disappointed that it ended so soon, I thought better to make it too short than too long. It was on the whole quite successful, and seemed to give pleasure to all concerned. At the conclusion I raised the lamp out of the instrument, and turned the full blaze of light down the corridor, while the procession of fair ones and officials passed quietly out, two by two; and it was really a very pretty sight, and one rarely seen by an outside individual, much less a foreigner. The Mikado and Empress, of course, passed out first. The officers of the Kunaisho expressed much pleasure and gave many thanks for the pleasant evening all had passed; and then I was led, with Hatakeyama and my two Japanese assistants, into the little room where the Mikado's ministers are usually received personally. Here refreshments were awaiting us, and after a little talk and congratulations for our success we rose to leave. The Mikado, and especially the *ladies* of his household, have since expressed great pleasure in all the sights they saw; and I'm sure it was a great pleasure to me, personally, to have the privilege of affording them enjoyment.

From the same "quarterly" we extract a brief article on the stereopticon, which, it will be seen, is merely another name for a magic lantern of the better class—a name, however, which is quite inaccurate in a scientific sense:—

The word "stereopticon" is derived from the Greek *stereos*, firm, and *optikos*, having reference to sight; and is believed to have been first applied to magic lanterns by Dr. R. Shelton Mackenzie, the distinguished author and literary critic of the *Philadelphia Press*. It means *to see solid*, and from its resemblance to the stereoscope has been sometimes tortured into that ungraceful word "stereoscopticon." It should never be applied to lanterns using other than the oxyhydrogen light, because the most intense illumination is required to produce this appearance of solidity, which is most remarkable in statuary where the background has been blacked and the figure appears to stand out in relief, and in public buildings, streets, &c. The principle on which the stereoscope depends is not of modern invention; it was known by Euclid, B.C. 300, and was described by Galen in 174. The first stereoscope, however, was not made until 1851, when Duboscq, of Paris, delighted the world with this wonderful optical instrument, which Professor Wheatstone, of London, was the first to explain. He showed that every *solid object*—such as a tree or building—is different with every changed position of the eye. Thus, two slightly-different pictures of any solid object will be simultaneously impressed on both eyes. The combination of these two dissimilar visual images thus depicted on the two retinæ convey to the mind the idea of relief or solidity. In accordance with this law stereoscopic views are made by taking two pictures of the same object by lenses placed somewhat apart. The two scenes thus obtained are united into one by viewing them through two semi-lenses, whose centres are usually two and a-half inches apart. The result is, of course, an optical illusion, for we do not see a solid object; we only think we do. The paper is perfectly plane. And the same law applies to the projection of a *single* picture by the stereopticon. Dazzled by its light, lines, and shadows we seem to see solid objects in relief. Certain purists have objected to the use of the word "stereopticon," because, *theoretically*, a stereoscopic effect cannot be obtained from one picture. But what are these theories worth when practice demonstrates that one picture, thoroughly illuminated, is sufficient? The looker-on who has gazed wistfully up a Parisian boulevard, or with curiosity beheld a street in Pompeii, or with admiration peered through the richly-sculptured corridor of a castle in France or a convent in Spain, can with difficulty convince himself that these are but semblances of things far away, so real do they appear; and he will unhesitatingly admit the force and propriety of calling the magical instrument a "stereopticon."

Our intelligent friend, Mr. J. A. Todd, of Sacramento, whose acquaintance we made three years ago, and whose pictures were so well received at the London Photographic Society's Exhibition of that period, contributes to the *Philadelphia Photographer* a few remarks suggested by the editor's offer of a prize for the six best negatives of a certain kind. From these we make an extract:—

You have (Mr. Todd says) often impressed upon the minds of your numerous readers the importance of more studious attention to art principles in the practice of general photography, and more varied attention to posing, lighting, and accessory effects. In many other branches of art this is nearly always possible, but in photography it is only practical in very exceptional cases. Undoubtedly the most tutored of our patrons are apt to admire a nicely-posed head, a graceful display of pretty hands and arms, even down to upholstered chairs, backgrounds with windows in the corners, vases, pillars, curtains, &c.; but my experience has been so far that in nine cases out of ten the photographic subject objects to what he terms "make-ups" (call it what you will), to obtain an effect that is foreign to the idea and condition of the person that is expected to pay you for your labour. Remember, I am speaking from a country town. I often wish that all this was different—different in many ways; different all through; different in regard to price for faithful services rendered; different, so that a more respectful consideration might be paid to the suggestions we make; different, so that more credit should be given us for using our best endeavours to make the most of the subject in hand; different, so that we could build up or scratch out after the subject had vanished; different, so that the good public would have more faith in our experience and common sense. The sculptor takes license with his patrons' ideas in a manner that would bankrupt any photographer. Even though justified by what is often termed high art principles, and other higher sounding phrases regarding light and shade, &c., only just think for a moment of the effect of art or art rules applied in this kind of tableaux:—Customer, "I want my 'dogtype' tuk. How is your charges? Well, that suits; fire away." "Certainly, sir; please take a seat," or a stand, as the case may require; that is, pose him. Turn him this way and that way, so as to make the best of my common, not unusual, customer. He has very likely just come from the barber's shop, so be careful about touching his wet, greasy, shining hair. His standing white collar makes it almost impossible to turn his head without injury to his throat. Finally, hang a cloak around him (example: Lincoln's statue in Union-street, New York); do you think he would like it? He has his notion about a "pictur," and he has to be suited if possible; that is, if you expect to live from the process of picture-making by the photographic process, and yet the above class of customer is the very life-blood of our business. I mean, from such like we get the most profit—money. They seldom require a sample print, nor do they ever wish to take counsel of a friend before they themselves are satisfied.

Writing in the *Philadelphia Photographer* on the subject of "Reversed Negatives," and *apropos* of an article in the *Mosaics* bearing this title, but about which, not having seen it, we are unable to speak, Mr. I. B. Webster says:—

It is now many years since I was first called upon to photograph a daguerreotype view which showed all the signs with letters reversed, as all opaque plates do when taken direct in the camera. Of course, we picture men all understand this without my explaining it. In the photograph the negative steps in between the original and the print, and turns everything back to the first position. This being true, how will we turn back on paper the reversed letters on the daguerreotype? If we proceed in the usual way, the negative will impress upon the paper the reversed letters again. The virtue of the *Mosaics* process referred to consists of its thinness, rendering it easy to print from either side of the negative. It, however, is too complicated for the limited demand of reversed negatives, and we propose to resort to a more simple way. It can be done by placing the original in front of a mirror, so placed as to allow the camera to bear upon the reflection in that mirror, which position is not always attainable. My brother invented an attachment, to be placed upon the hood of the tube, containing a reflector, which was a perfect success in making signs read right (and cipher) upon the opaque plate. This was in 1852. We always used one of these in taking views until the photograph was introduced. The principle that produced that effect is identical with that of the reversed negative. The most simple way to produce a reversed negative is to place the prepared plate in the shield with the coated side towards the back of the camera, thus allowing the light passing through the tube to carry the image through the prepared plate, and impress it upon the prepared surface of the said plate, then the farthest from the tube. I am prepared to hear several objections raised by some about not being able to get a good focus, or a failure to see how it is possible to hold the plate in the shield, on account of the springs upon the shutter of the shield, &c. I will meet you upon these points right at the threshold by telling you how to do it. First, how to focus:—Try and select a plate about the thickness of your focussing glass (you need not be particular to a hair's breadth). Proceed to arrange for your copy just as you would for any other copy. When you come to focus, turn your ground glass over by taking it out of its frame and putting it back, so as to have the ground surface towards the back of the camera; then replace the frame in the camera, and proceed to draw the focus. Second, to safely carry the prepared plate in the shield:—After carefully placing it in the shield (face up), put a very small piece of blotting-paper right on the prepared surface at each corner, after which lay another glass the same size as the prepared one on to it. The pieces of blotting-paper at the corners will keep these two glass plates from coming in contact, and the back plate will prevent the spring on the door injuring the prepared surface. Now shut up your shield, go on and make your exposure, and when you return to the dark room to develope do not forget that the plate is in the shield wrong side up. I have made many a reversed negative this way, and saw no difference in the result, other than that it was reversed—just what I wanted.

CHEMICAL MANIPULATION.

In your *(Practical Photographer)* bureau of information is a German formula in which the toning bath contains half-a-grain of chloride of gold to each fluid ounce. I would characterise this as a horrible bath. If the German artists use such a toning bath as this it is no wonder they asked H. Rocher, of Chicago, for his formulæ. According to my experience it would tone so fast that it would take half a day to tone a fair day's printing, and it would be impossible to produce a batch of prints any way near an even or uniform tone. Why? Simply because it is about eight times as strong as it ought to be, and about twenty times as strong as some of our best printers use. I formerly used one grain of gold to sixteen fluid ounces of bath, and my prints toned so fast that I could not manage more than six or eight at a time. When I visited Chicago, in 1874, I was surprised and delighted with their brilliant tones; being known as one of the old fogies from the daguerreotype times, I was at once admitted behind the scenes, and to my intense surprise I found men toning with from fifty to one hundred prints in the bath at once. I looked on in amazement, expecting to see some prints reach the old blue-black tone before they could be got out of such a mass, but no such thing occurred. The reason was the prints required from fifteen to twenty-five or thirty minutes to tone, and the tones were beautifully uniform. I remember when I published the albumen process in 1861 to have stated that one grain of gold was sufficient for a sheet of paper. When the journal was received in Rochester, N.Y., where I then was, the leading operator called on me and swore roundly I was a fool or a liar, he did not know which, because his experience taught him that a sheet of albumen paper required three grains of gold. In 1874 I called on the same artist, now doing a splendid business in Detroit, Mich. I asked how much gold he now used. He replied that his toner calculated one grain of gold for one hundred card prints, or about one grain to three sheets, as it is usually cut. Try to precipitate nitrate of silver with a strong solution of chloride of sodium, and notice the grossness of the precipitate. Next take some of the same silver solution and add a weak solution of chloride, and notice the result; the precipitate will be fine. Or try to do silver plating with a strong cyanide solution; the result will be rapid coating, but it will flake off, whereas if the coating be done in a weak bath it will work slow but sure, and will be as firm as if it were not plated but solid metal.

As I do not believe in denouncing any formula without offering what I conceive to be a better, I will here give one that has stood the test of ten years' everyday practice:—

Silvering Solution.—Soft water one ounce, nitrate of silver forty grains; float from thirty seconds to two minutes, according to temperature and the requirements of the particular sample of paper in use. When dry fume until it prints a rich purple black, slightly bronzing in the deep shadows—say fifteen minutes as an average; wash in four changes of water, *no acid*, but to the fourth water add sufficient salt to make the prints decidedly red. This salt has a double effect—first, the red colour it gives to the print enables the toner to decide at once when the colour he wants is reached; second, and most important, it changes any free nitrate which the washing has left in the prints into chloride—a very important item, because a very little free nitrate will precipitate the gold from the toning bath. Soft water for the first washing is also important; if water containing lime, commonly known as "hard water," be used a scum of chloride of silver is apt to form on the surface, which colours with great rapidity in the toning bath, often leading the novice to suppose his print over-toned, while really scarcely begun. In consequence, when immersed in the soda it is instantly dissolved, leaving the blue-black print brick-red.

I make my own chloride of gold by dissolving twenty-five grains of dentist's waste gold in acid nitric C. P. sixty minims, acid muriatic C. P. 120 minims. This will give a solution of which you know the exact value. Dilute to twelve and a-half ounces with soft water. If the acid does not dissolve all the gold add more until the gold is entirely taken up, but in diluting keep it to twelve and a-half fluid ounces. This gives a solution containing two grains of gold per ounce. Take of this solution one-quarter fluid ounce, equal to one-half grain of gold; soft water sixteen ounces; neutralise with a saturated solution of bicarbonate of soda, and use at once. Washing soda will do, but I prefer the bicarbonate. Any required tone can be obtained with this bath, from blue-black to chocolate brown, which is at present a very popular tint. Do not throw away the bath when used, but when next wanted decant the clear liquid, leaving the precipitate in the bottle. Add gold from the stock solution, and neutralise. Some other time I will tell how to utilise the precipitate. Fix in hypo. one part, water six to eight parts; keep moving for fifteen to twenty minutes, and then wash.

I will also give a developer, not because it is so much better than any other, but because I make it "different from white folks." Take a wide-mouthed quart bottle (a fruit jar answers well), make a bag of very coarse muslin (Swiss double is first-rate) large enough to hold eight ounces of protosulphate of iron, *weigh* your iron and put it in the bag; now let the bag into the mouth of the bottle, and with a rubber band fasten it so that the iron will remain just even with the top of the bottle. Fill up with *soft water*, and set it aside while you go on with other business; by-and-by you will find the bag empty and the iron all gone to the bottom. Stir it up and spread the bag over the mouth of the bottle to keep out dust. This is the stock solution, and contains a quarter of an ounce of iron to each fluid ounce. For ordinary use take four ounces of stock solution, twelve ounces of soft water, one ounce and a-half of acetic acid No. 8, and half-an-ounce of alcohol. This gives a developer of twenty-four grains per ounce. For redeveloper take of stock solution one ounce, citric acid half-an-ounce, water fifteen ounces; grind the citric acid in a mortar with a little water and add to the iron, then fill up with the rest of the water. (Of course every photographer knows that a little silver must be added to the redeveloper before using.) *Soft water must be used.* If hard water be used the silver on the plate is instantly changed to chloride, and development ceases, giving thin, worthless negatives where first-class negatives might as easily be obtained.

With this stock solution I can mix a pint or quart of developer in two minutes—strong or weak as circumstances require. I take a bottle that will hold twenty ounces fluid measure, cut a strip of white paper half-an-inch wide and long enough to reach the top, paste this on the side of the bottle, and when dry measure four ounces of water into the bottle, and on the paper mark its surface; repeat and mark at 8, 12, 16, 17, 18, 19 and 20 ounces. Varnish this paper with negative or positive varnish and it will last until the bottle breaks. I never put iron solution into a graduated bottle if I can avoid it, and by this plan I never have occasion to do it.

In regard to collodion: where only a small business is done I have a plan not new but good, which I have practised almost constantly since 1865; it only needs to be tried to be adopted in every small gallery:—

Ether, sulph. con., twenty ounces; alcohol 95, ten ounces; cotton, 200 grains; put the cotton in the bottle and add the alcohol, shake well, so as to thoroughly wet the cotton, then add the ether. If the cotton be good it will leave no precipitate, and will settle perfectly clear. It will keep indefinitely. This I call plain collodion.

Sensitising Solution.—Alcohol, ten ounces; iodide of ammonium, 200 grains; bromide of cadmium, eighty grains, or, alcohol, ten ounces; iodide of ammonium, 150 grains; iodide of cadmium, sixty grains; bromide of cadmium, eighty grains. Dissolve the iodide and bromide in the alcohol by grinding in a glass mortar, and filter into a tall narrow bottle. This will keep indefinitely. When collodion is wanted, decant three ounces of plain collodion and add one ounce of the sensitising solution. It will be fit for use immediately, but will be at its best in twenty-four hours. By this plan there is no old collodion standing by. Old red collodion may be renewed by setting a strip of clean, scoured zinc into it; in a day or two a precipitate will be formed on the zinc, and the colour will be nearly or quite gone. This makes good ferrotype collodion, but is not so sensitive as new. LITTLE CARBON.

Meetings of Societies.

THE PHOTOGRAPHIC SECTION OF THE AMERICAN INSTITUTE.

AT the June meeting of this Society Mr. H. J. Newton, the President, occupied the chair. The minutes of the previous meeting having been read and confirmed, some formal business was transacted.

The SECRETARY: I received some time since a communication from Mr. J. Solomon, of Red Lion-square, London, as follows:—"I beg you will try the enclosed non-actinic cloth as a substitute for non-actinic glass for chemical rooms. If you require a few samples for distribution I shall be happy to forward them," &c. Here are the samples. I had them some time before I could test them. I prepared very sensitive paper and exposed pieces to bright sunlight under the non-actinic cloth, and I exhibit the pieces so exposed here. I may say that I selected the time of exposure in the afternoon between three and half-past three o'clock, as I find that in New York City the light is strongest in actinic force at that time.

Mr. CHAPMAN: In what position and under what light were those experiments tried?

The SECRETARY: In a south window, the bright direct sunlight not passing through glass. This piece, No. 1, was exposed three-quarters of an hour. You will see no effect of light through the cloth. This other piece of paper, No. 2, was exposed fifteen minutes.

Mr. CHAPMAN: The thick cloth is too red. Light passing through it would, I should judge, be very trying to the eyes.

Mr. BROWN: You will find canary-coloured tissue-paper is the best for ordinary light; it may be used in more than one thickness if necessary.

Mr. MASON: Mr. Bierstadt used yellow paper known as "post wrapper." I hardly think the red would be so pleasant to work by, though it is effectual in stopping all, or nearly all, the actinic rays of light.

The PRESIDENT: I have of late talked of emulsion so much at these meetings that I feel a little reluctant about saying anything more in relation to it. I feel as if it would be better for some one else to say what is to be said. In order to enable Mr. Mason to corroborate my statements in regard to emulsion, and to dispel the idea to a certain degree prevalent that it is a fiction of mine in some way unaccountable, I took a bottle of emulsion over to Mr. Mason's studio at Bellevue Hospital yesterday morning between nine and ten o'clock, and asked him to sit me for a picture and use his bath. He did so, and sat me fifteen seconds and produced this negative (exhibiting). I then prepared an emulsion plate and asked him to give me a sitting with an exposure of two seconds, which he did, and the result was this negative (exhibiting). Then he tried his bath again, giving four seconds' exposure, and produced this negative (exhibiting). You will notice there is very little image seen on the last plate, except in a few parts of the high lights.

Mr. MASON: I can fully corroborate these statements. Mr. Newton came to my studio yesterday morning at half-past nine and asked me to make a negative with a bath plate by my ordinary working process. He told me he wished to try comparisons with his emulsion, which he had with him. I made negatives exactly as he has stated here—one in fifteen seconds, as you see here. Then he prepared a plate, the preparation being very simple, and requested me to give an exposure of two seconds. We used the same instrument and the pictures were made one immediately after the other—the same position and conditions. The emulsion picture, as you will see, shows the greatest amount of exposure. The difference seems to be very great, and if the emulsion can be made successful—and I have no reason to suppose the contrary—I shall certainly adopt it, as a great deal of my work, being upon people who are in pain, necessitates short exposures; and if I can get a picture in two seconds which now requires fifteen seconds it will be a great improvement. Is is certainly as simple, and in many respects for my work it will be more simple, from the fact that I can keep the emulsion plate ready prepared, which is also an important point. I must say that this demonstration, coupled with others which I have made myself and which I have seen Mr. Newton make, has convinced me that emulsion really is a vast step in advance of anything we have ever before had. The only question which arose in my mind was in regard to the stability of emulsion, from the fact of its being a compound made out of the usual order of our work and requiring careful manipulation in its production. I see no reason why, under Mr. Newton's method, the wide-awake photographer should not be able to compound an emulsion with as great certainty of its working as he would find in the manufacture of collodion. Of course there are some compounds used in the making of emulsions which are simple, but not well known to the majority of photographers.

Mr. CHAPMAN: There is no question in my mind about the emulsion; I have had experience enough in that matter to assure me of its great value. But I have never used it in my special work, because it is of such a character that you cannot see the image when you are developing. In my case there is nothing to be seen by the unaided eye.

Mr. NEWTON: With the emulsion as I now make and develope it the image is as distinct by reflected light while developing as the image on a bath plate. It is, in fact, more brilliant and distinct as a positive than by any other process with which I am acquainted.

Mr. CHAPMAN: That is exactly what is wanted; previously there were no means of determining when to stop the development, from the fact that by the processes which I have worked the image was nearly visible, except by transmitted light. As to solar work, there was plenty of light. I did not require a quick process, because we had light enough; but with lunar and stellar work it is different, there being times when it is of the greatest importance to have rapidity. The only trouble I have had with emulsion has been in the preservatives. Emulsion dry plates, when developed within a few days after exposure, in my case have been exceedingly fine and good, and as quick—not as quick as desirable; but then it was within a reasonable time of exposure—twenty, thirty, or forty seconds' time. This was out-door work. But after the plates remained from four to eight weeks after exposure, in every case it was almost impossible to bring out a vigorous picture with the alkaline developer. I could save the plates, however, by simply bringing out a very light outline of the image with the alkaline developer, and then complete the process by the use of acid pyro. and silver. Since then I have learned that by adding gallic acid to the preservative these plates will keep after exposure. I think I may go out on the Eclipse expedition, and in that class of work we are going to attempt a new order of things. The attempt is to be made to photograph the spectrum of the corona of the sun while in a total eclipse. We were once very well satisfied to get the picture of the corona; but now they are going to stretch that out and separate it into its different wave lengths and photograph the different portions of it, and for this reason it is a matter of the greatest importance to have the utmost sensitiveness. Some experiments have been tried on photographing the spectrum from the moon, to see how weak a light may be photographed. If this bath of Mr. Mason's was as good as the ordinary baths that photographers use, and I have no doubt it was—his experience in this matter, of course, none of us doubt—here are two negatives, one made in fifteen seconds, the other in two seconds, one-seventh of the time, and showing at least double the exposure, or effect of light, as nearly as I can estimate, which amounts to a sensitiveness equivalent to about fifteen times greater. It seems that one second with the emulsion would give as much detail as the fifteen did on the bath picture; and this emulsion of Mr. Newton's, I understand, is of a permanent sensitiveness, which will continue as long as the material lasts.

Mr. NEWTON: Perhaps I have one hundred different samples, all labelled and dated. I recently found a sample of April 6, 1876 (two years old last April), and tried it; it worked as fine as any emulsion you ever saw, though it was not so sensitive as some made by my recent formula.

Mr. MASON: In regard to any special manipulation about this emulsion work, I have seen nothing difficult. Of course Mr. Newton developed the emulsion plate here shown; but he was not very particular with the material, using that which was in my place without any special proportion. There was nothing further in the manipulation than what he has told you, except that he brought with him what he calls his accelerator; that he will probably give you to-night.

Mr. Newton: I spoke of the way in which this extreme sensitiveness is produced at one of our meetings in the winter—in February or March. The plates are flowed before exposure with a modified alkaline developer. I experimented to get the minimum amount of bromide in this modified accelerating solution. The compound I now use for this purpose is as follows:—Water, twelve ounces; carbonate of soda, 180 grains—that is, fifteen grains to the ounce; and two grains of bromide of ammonia to the twelve ounces. That is a homœopathic dose, but it is effectual. If you use the soda solution without that small quantity of bromide your plate will be fogged after exposure—that is, it will fog all over during exposure; but two grains of bromide are sufficient to restrain all tendency to fog, and you get all the advantage of the alkaline condition without any unnecessary restraining action. This accelerator increases the sensitiveness of any wet emulsion plate from four to six fold.

Mr. Chapman: You mix your developer for each plate?

Mr. Newton: No; I take six ounces of carbonate of soda and dissolve it in a quart of warm water. That is a stock solution. Now take an ounce of this and add ten or twelve grains of bromide of ammonium and four ounces of water. When the bromide of ammonium is added to the soda solution there will be a strong smell of ammonia, by the liberation of ammonia when the carbonate of ammonia is formed. When I develope a plate I take enough of this solution to flow it and no more. Perhaps I ought to say something in reference to the ferrous oxalate developer. It is not quite clear in the minutes. The ordinary way of making the ferrous neutral oxalate of potash had been by making two separate solutions of the potash and the oxalic acid and putting them together; but in simplifying it I merely made a solution of the potash and added the oxalic acid in crystals, to save one operation. I think I stated that I used all the way from five to thirty-five grains of the protosulphate of iron to determine about the best quantity, and found fifteen to twenty grains to the ounce of oxalate of potash solution was sufficient. It dissolves very quickly and forms a ferrous oxalate, which turns the solution a deep orange colour. I have further simplified the manufacture of the oxalate developer by making it acid at the time of compounding. This obviates the necessity of any further manipulation for acidifying. When the solution is so prepared it is only necessary to add the iron as before stated and the developer is ready for use. Prepared in this way I obtain all the intensity desired.

Mr. Chapman: Would you recommend the use of this ferrous oxalate developer instead of the alkaline developer?

Mr. Newton: My experience with the developer has been so limited that I cannot well give a decisive answer to the question. It produces no fog and you can use it repeatedly; that is a great advantage. It gives very fine detail in all the weaker lights; that is very difficult to get by any photographic process, and not have the high lights overdone before you get the shadows done enough. From my experience up to this time I feel justified in saying that it promises to be the developer of the future for emulsion plates.

Mr. Chapman: I am much encouraged now by seeing these negatives; I think this is going to be the direction to work in.

A motion was put and carried that the President and Secretary be authorised to prepare the minutes at this meeting for publication.

The Section was then adjourned until the first Tuesday in September.

Correspondence.

TRANSPARENT POSITIVES BY THE NITRIC ACID PROCESS.

To the Editors.

Gentlemen,—I was very glad to read your article the week before last on the above process, and shall hope to find it useful to me whenever I can experiment in this direction again. Meanwhile, I will endeavour to add my mite of experience to the general fund.

I may premise that I am not fond of operations in which nitric acid is concerned. I do not like the fumes of nitric oxide which arise. I took my precautions, however, to reduce the unpleasant effects of these to a minimum.

In my first trial with one or two plates, a considerable time back, I used those which had been prepared with the Liverpool emulsion. Notwithstanding the precaution which I always take of edging with india-rubber solution, I found the film became very tender and liable to slip after treatment with nitric acid. I resolved, therefore, in any further experiments, to apply some kind of substratum which would not be injured by the nitric acid. It seemed to me that albumen might be best adapted for the purpose. Accordingly, in my more recent experiments with dry plates, a certain number were prepared with this substratum and the Canon Beechy emulsion, which I was using at the time. Two plates were always exposed on the same subject. Of these one was developed into an ordinary negative, and the other made, by the nitric acid process, into a positive, to be kept for enlargement at a future time. The strong nitric acid was diluted with about an equal bulk of water. Many of my negatives after a full exposure had been developed rather far, with the object of printing from them without further intensification. Those intended for positives I developed rather farther still; either because I had read that the development ought to be very complete, or because I thought that unless in the high lights the development were carried right through the film the whole of the silver bromide in those parts would not be reduced and removed by the nitric acid, and the portions which remained would be reduced in the second development, destroying the transparency of those portions. I soon found, however, that this precaution had been carried to an extreme, and that such large portions of the silver bromide had been reduced and dissolved out that on redevelopment considerable portions of the plate were left bare, with a deficiency of detail in the remaining portions.

In the next trial I was careful not to push the development nearly so far, and then I found, what I had endeavoured to avoid in the first instance, that in no part of the film was the whole of the silver bromide reduced and dissolved away; but, besides what was required to form the positive image, there remained, as it were, a veil of bromide through the whole film. In developing again, however, I took care not to push the operation too far. Then I used the fixing solution, as with ordinary negatives, and had the pleasure of seeing that this veil was almost completely dissolved away by the hyposulphite; any slight portions that remained on one or two spots arose, it seemed to me, from an undue thickening of the film in those parts, owing to imperfect preparation of the plates from want of convenience. Except for this the best results were just what I was wishing them to be. I think, perhaps, that next time I may be able to secure this with more mechanical certainty by adopting your precautions of a developer of measured strength, and a limited exposure adapted to that developer.

So far as I can judge the Beechy emulsion appears to lend itself admirably to the process. With the full exposures which I give I use in the developer a smaller quantity of the carbonate of ammonia than that prescribed. After treatment with nitric acid I gave the plate a thorough washing, and then flooded it with water to which a few drops of the solution of carbonate of ammonia had been added, in order completely to neutralise any remains of nitric acid in the film. The plate, after standing to dry, was put away in the plate-box, that the remaining operation might be afterwards more conveniently performed by daylight.

The re-exposure took place from my bedroom window, and I found that by shielding one part of the plate behind the window-frame while the other part projected into the light, enabling me to give one part a fuller exposure than another—and also by keeping the developer more in one portion than another—I could modify the result which would otherwise be obtained.

I give these particulars thinking they may, perhaps, be found useful by others serving their apprenticeship like myself, and glad, as I am, of any hints that may be thrown out.

I will now only trespass a moment longer to mention a typographical error in what I wrote last week. In page 370, first column, line 29 from top, for "I would intensify to opacity" *read* "I *could* intensify to opacity."—I am, yours, &c., Wm. Washam.

Eastbourne, August 6, 1878.

LOMBARDI *VERSUS* VANDERWEYDE.

To the Editors.

Gentlemen,—I had intended to let Mr. Vanderweyde "cook his own broth." He, however, regardless of accuracy, the respectability of the parties concerned, and of his own documentary evedence, has rushed into print and endeavours to mystify facts.

Allow me, therefore, in reply to his communication in your last issue, to say that I was present at the hearing of my cause before the judge in chambers, who, on reading Mr. Vanderweyde's affidavits, said at once that they were contradictory on his own showing, and that there was no defence to the action. Mr. Justice Field thereupon ordered the full amount claimed to be paid into court within ten days. The defendant appealed, and your readers know with what success.

Mr. Vanderweyde says that he had no time to speak to his counsel. Considering that three months elapsed between the application in chambers and the hearing of the appeal, I leave it to your readers to draw their own conclusion respecting his assertion.

Now about his letters. The defendant, being without funds, gave me an I.O.U. on the 17th March, 1876. I applied several times for a settlement, but ineffectually. Three weeks afterwards I placed the matter in the hands of the Trade Protection Society. The defendant asked for particulars of the claim for £76 14s. At the end of April he got them, but took no notice. On May 10th, 1876, the solicitor of the above society applied for the amount. The defendant wrote admitting the debt, but asking for further particulars, which were supplied, and he took no further notice of the matter.

From inquiries instituted two years ago I found that the defendant was unable to pay the amount of the I O U. At the beginning of this year, however, I was informed that he had formed a partnership with Mr. Willing, and had succeeded in establishing a first-rate business in Regent-street. I called at once on the defendant, who informed me that he was in a very good position, that he had no partner, that he had just escaped from the danger of Mr. Willing becoming his partner, and that he had secured furniture and lease for twenty-one years.

I offered him my hearty congratulations, and joyfully presented to him his I O U, fully hoping in the success of my application. I was disappointed, however. The man of genius, the inventor of the electric light, the major of the American army of secession refused to honour his I O U. I felt then that as long as he was poor and could not pay he had admitted the debt but pleaded poverty; now, however, that he was successful, rich, and powerful he was willing to dishonour his I O U, and frightened me with an expensive lawsuit. I was not afraid to face a searching cross-examination before a jury; for, although at a very great expense and personal discomfort, I felt I had a duty to discharge towards myself, my family, and my photographic brethren.

The fact of the defendant's case breaking down so abruptly without my counsel even saying a single word; the fact of the defendant's counsel throwing up his brief, and apologising for himself and the gentleman who had instructed him for having undertaken such a defence; the fact of the judge turning round to, and directing, the jury to return a verdict for me for the full amount claimed with interest—I hope such facts will serve as a good lesson to all concerned that "honesty is the best policy."—I am, yours, &c., A. LOMBARDI.

Brighton, August 6, 1878.

[On the principle of giving fair play to all parties in a dispute, we have admitted the explanatory letters of both defendant and plaintiff in this case. Here it must now rest.—EDS.]

EXCHANGE COLUMN.

No charge is made for inserting these announcements; but in no case do we insert any article merely *offered for sale*, that being done at a small cost in our advertising pages. This portion of our columns is devoted to exchanges only. It is imperative that the name of the person proposing the exchange be given (although not necessarily for publication, if a *nom de plume* be thought desirable), otherwise the notice will not appear.

Wanted to exchange, *Blackie's Encyclopedia*, quite new (£7 14s.), for good portrait lens, &c.—Address, MASTER, National School, Blyth.

Wanted, a whole-plate or 10 × 8 bellows camera, in exchange for a well-made, large box tent.—Address, G. PRATT, 32, Kennett-road, Harrow-road, W.

A dark box on wheels, size 25 × 18 × 13, weight 42 lbs., value £2, will be exchanged for a whole-plate view lens, or anything useful in photography. Photo. three stamps.—Address, W. PHELPS, photographer, Dartmouth.

A telescope, by West, London, 3 feet 6 inches long, 2¼ inches object-glass, rack adjustment, with pillar and claw stand, all brass, with Spanish mahogany stand, cost £10, is offered for a modern Ross or Dallmeyer portrait or rectilinear lens.—Address, F. MASON, 45, Treverton-street, N. Kensington.

ANSWERS TO CORRESPONDENTS.

PHOTOGRAPHS REGISTERED—

John Beringer, Helston.—*A Photograph of the "Nautilus."*

John Owen, Newtown, North Wales.—*Two Interior Views of Montgomery Church.*

☞ *Correspondents should never write on both sides of the paper.*

W. SUTCLIFFE.—Send an addressed envelope for private reply. The list you enclose is not sufficiently comprehensive.

F. R. M. S.—It is probable that Mr. Jabez Hughes's *Manual* will answer your purpose quite as well as any other. It is published by Mr. J. Werge.

W. W.—After removing the free sulphur you need not entertain the slightest fear that the use of the glove will cause fading. It is returned as requested.

JAMES BURNSIDE.—There is no doubt that the principle of the safety lamp could be applied to the electric light. We are not, however, conversant with the details of the subject.

M. R. O.—To use the front lens of the combination alone it must be reversed, the flat side being placed towards the landscape. It is also imperative that a diaphragm be employed, which must be placed outside the lens.

L. M. CLARK.—The yellow incrustation is persulphate of iron, caused by exposing the protosulphate to the air. To avoid the formation of this salt care must be taken to keep the bottle containing the protosulphate well stoppered.

BENJAMIN HOTSON.—The values of the two diaphragms are respectively $\frac{f}{12}$ and $\frac{f}{21}$. Neither is sufficiently small for copying engravings of the dimensions proposed. It will be advantageous to reduce the aperture to the fortieth part of the focus of the lens.

A. W. W. B.—Having tested the mount we find that it contains a large proportion of hyposulphite of soda, which has, doubtless, been used by the paper-makers as an antichlor. You must immediately discontinue making use of that sample and obtain another, otherwise your reputation will be seriously jeopardised.

A. M.—We regret our inability to give such a lesson as you require. What is worse, we are not aware of anyone in this country to whom we can recommend you to apply. Those who are competent to teach such a process entertain a decided objection to imparting any information concerning it. We shall make inquiries, however.

A PROVINCIAL.—There certainly was a patent granted for enamelling paper photographs, but this was fourteen or fifteen years ago, and if we recollect rightly it expired at least twelve years since. Hence you have been partially misinformed; at any rate, you have nothing to fear from indulging in this department of photography, either as a trade or a pastime.

W. L. R.—To the glycerine and nitrate of silver solution at present made use of by you add a considerable proportion of kaolin; shake well together and expose the mixture to strong sunlight. It will rapidly become dark, but will soon begin to clear again, commencing at the top. When the whole of the discoloured kaolin has subsided decant the clear portion for use. This is applied to the plate after its removal from the nitrate bath; allow to flow well over every portion of the surface, drain, and place the plate in the dark slide. The plate will remain good for several hours.

CAUTION TO PHOTOGRAPHERS.—The profession and dealers are cautioned with regard to a thief who is going round purloining anything photographic he can lay his hands upon after being admitted on any premises on a plea of charity or starvation. He is a photographic printer, an American by birth, about 5 feet 9 inches high, about 24 years of age, dark complexion, black hair and eyes, thick eyebrows, slight black moustache, wears light tweed suit and a black hat. There is a warrant awaiting him at Bristol for stealing about £120 worth of lenses from Mr. Protheroe, photographer.

"ONE IN A FIX" writes:—"Can any of your numerous readers tell me what ink to use for collotype plates—the name it is called by the trade or its composition? Also, what condition should the plate be in just previous to inking? and should the ink be dabbed on or rolled on? Should the ink be applied all over the plate previous to developing in water, or is the bichromate to be washed out and the plate dried, and then slightly damped and inked? I refer to gelatine surfaces with the natural half-tones of nature. Will simple gelatine and bichromate be sufficient, or does it require other ingredients? Any light thrown on these queries will much oblige."

WEST RIDING OF YORKSHIRE PHOTOGRAPHIC SOCIETY.—The committee of this Society have arranged to hold the summer outdoor meeting at Bolton Abbey, on Wednesday next, the 14th inst., to be a full-day excursion, to meet the Sheffield Photographic Society. Members are desired to make their own arrangement for arriving at Ilkley in the morning, where conveyances are always in waiting for Bolton Abbey. A knife-and-fork tea is to be provided at Ilkley, about six p.m., of which due notice will be given to those intending to join the party.

THE BRITISH ASSOCIATION.—From all quarters we learn that the forthcoming meeting of the British Association, which commences, at Dublin, on Wednesday next, is expected to be one possessing an unusual degree of interest. We have received the following circular, which we cordially commend to the notice of our readers:—"I am directed to inform you that a *conversazione*, to which the members and associates of the British Association have been invited, will be given by the Royal Dublin Society on the evening of August 15th, and that on this occasion every facility will be given for the exhibition of objects of interest in science and art. The committee will take great care of all objects entrusted to them, and the cost of carriage to and from Dublin will be paid.—Richard J. Moss, Registrar." Photographs and objects of interest intended for exhibition should be addressed—"The *Conversazione* Committee, Royal Dublin Society, Kildare-street, Dublin."

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. STEWARD, Optician.

For the two Weeks ending August 7, 1878.

"INCREASING THE SENSITIVENESS OF DRY PLATES."

Mr. Herbert B. Berkeley's article in our last number, on *Increasing the Sensitiveness of Dry Plates,* brings to our recollection certain peculiarities of a similar nature which we have from time to time noticed in the behaviour of various emulsions. The phenomena we have to describe have been witnessed—many of them—at wide intervals, and in the almost entire absence of any means of comparing notes; hence we have not been able to trace them to any common cause, nor, indeed, do we imagine that they arise, strictly speaking, from the same or even similar causes in different instances. The cases we shall mention, however, possess one noticeable feature in common, namely, a defective emulsion which is capable of giving an improved result under treatment which, with an originally good emulsion, produced no apparent alteration.

There are numerous ways in which an imperfectly-prepared emulsion (we speak of washed emulsions) has shown this tendency to improvement, amongst which we may mention the washing of the film before drying, the application of an organifier as in Mr. Berkeley's case, and also the addition of various substances to the emulsion itself. The substitution of a smaller quantity of plain collodion for an equal bulk of the plain solvents we have found, in many cases of defective "pellicle," to work a great change for the better in the quality of the emulsion; while in at least as many instances, both with good and bad pellicle, it has proved entirely without effect. What may be the true explanation of this partial behaviour we do not offer to explain; but it would certainly seem to point to the supposition that the purely physical character of the film of collodion has a great deal more to do with the photographic result than is imagined by many.

A curious part of the business is that rarely (we have noticed but one instance where such is the case) does the same emulsion prove susceptible to improvement by more than one of the various modes of treatment, from which we draw the deduction that the changes brought about in the nature of the pyroxyline, either in its preparation or during the washing of the emulsion, are widely different in character. Thus, we can speak of a sample of washed bromide emulsion which, though to all appearances perfect, it was quite impossible to intensify by any ordinary means. This, when organified by means of various substances applied to the film in the state of solution, produced no variation in the result; but, when allowed to stand for a few days after the addition of a grain or two per ounce of pyro., tannin, or quinine to the emulsion itself, the films gradually acquired the power of taking density, though not to the fullest extent. Gallic acid produced no effect whatever. In other cases almost the reverse has occurred, as by treating the washed film with a suitable organifier the intensification has proceeded without any hitch, while the addition of the same substance to the emulsion has proved ineffective.

Then, again, the employment of a small quantity of collodion in redissolving the pellicle will sometimes give a richly-coloured and finely-divided emulsion, when plain ether and alcohol would merely produce a poor, granular result; but such is not invariably the case, as with some samples of cotton, or when the emulsion has been precipitated, nothing will restore the colour, which appears to have been wholly lost in washing.

One particularly anomalous instance may be mentioned as illustrating the possibility of the formation of some compound only slowly soluble in water, and which, if not thoroughly removed, exercises an injurious effect upon the resulting emulsion. The emulsion was one we had prepared for a friend, employing his own collodion—a sample which had been bromised for two or three years, if we remember rightly. From an error in his estimate of the quantity of silver required to sensitise it, it was poured out to set while still containing a much larger excess of silver than we intended, and with a very small proportion of restraining acid. The result, as we anticipated, proved a complete failure, general fog without a trace of an image following upon development. But we discovered accidentally that by merely rinsing the plate, after coating, until the greasy lines were removed the film developed perfectly clean and with moderate density; the emulsion was washed a second time, but, perhaps, too thoroughly, for it afterwards worked perfectly free from fog, and gave a miserably-thin picture. It may be stated that we made no departure from our ordinary method of working; the same water, the same utensils were employed, and the operation of washing conducted exactly in our accustomed manner. The only feasible view we can, therefore, take of the case is that a silver compound of low solubility was formed *in* the pellicle, which the first washing was incapable of removing. The loss of density after the second washing may, no doubt, be attributed to the inability of the cotton to withstand the double operation.

Another instance may be noticed as bearing upon the peculiar action of certain organifiers when allowed to remain long in contact with the emulsion itself. An emulsion prepared by a modification of the Chardon method, and containing a full dose of quinine, was found after several weeks to have completely lost its sensitiveness. We do not mean that it had become absolutely insensitive, but it required at least ten times the original exposure to produce an impression. Washing the film in plain water produced little or no effect, but by using water slightly acidulated, or by three or four alternate washings with methylated spirit and water, something like its pristine rapidity was restored. In this case we imagine the quinine to have entered into some sort of combination with the emulsion, its injurious action being removed by the washings described.

With regard to the treatment of the plates with an organifier, we have shown that a different effect is obtained accordingly as the organifier is added to the emulsion or applied to the film, and a still wider difference is noticed when the conditions attending the application of the organifying solution are varied. But, after all, the principal cause of this difference of behaviour rests in the emulsion itself, and it is possible, with separate samples of emulsion, prepared by the same formula but with collodion of different character, to secure the most opposite results under the same kind of treatment; and hence it is only fair to suppose that the physical state of the collodion film, rather than the bromide it contains, is chiefly responsible for the altered effects produced under the action of various organifiers.

Mr. Berkeley, indeed, appears to hit the point when he states that a powdery pyroxyline shows no advantage in sensitiveness if exposed moist, though in the case of a "horny" sample such a gain does accrue. We do not assert this to be invariably the case, but we have frequently noticed that certain emulsions show a much higher degree of sensitiveness in the moist or washed state, as compared with the same films when dried, than others which apparently exhibit no difference whatever. Since reading Mr. Berkeley's remarks we have made the experiment, with several emulsions, with this result—that the greater the normal sensitiveness of the emulsion the less difference is there between its rapidity, wet and dry respectively; and that, though a comparatively slow or a defective emulsion may be greatly improved in this respect by treatment with an organifier or accelerator, or even by mere exposure in the moist state, the most highly sensitive and perfect ones show little, if any, gain under similar treatment.

This, no doubt, supplies an explanation of the great discrepancies in the published opinions as to the degree in which a wet emulsion plate exceeds a dry one in rapidity. Mr. Newton states the gain to be from four to six fold when an accelerator is employed, while we have heard one of the greatest emulsion authorities in this country state there is no difference at all except in rapidity of development and density. Possibly each may be correct so far as his own emulsion is concerned.

OBLITERATING OPAQUE DEFECTS IN NEGATIVES.

Under circumstances which need not here be detailed we acceded to a request that we should, on the occasion of a visit recently made to the country, take with us a sample of dry plates of a certain manufacture. In due course these plates were exposed and developed. Subject to one defect, they were quite as sensitive as we were informed they would be found to be. The quality of the negative, also, was excellent; but in the majority of instances the negatives were rendered apparently worthless by the presence of numerous opaque spots with which the surface was plentifully studded. Regarding the cause of these spots we have nothing at present to say; the preparer of the plates has a theory on the subject which, when tested by practice, will eventually be submitted to our readers. It is with these spots in themselves, and as they exist upon the negatives, we concern ourselves at present.

Prints of interesting subjects and scenery besprinkled with white spots, varying in dimensions from mere specks up to those of the heads of large pins, form a sight not calculated to engender pleasant feelings on the part of the photographer conscious that the blame rests not with himself. Several proof prints, mal-adorned in this manner, were eventually made presentable by being carefully worked upon by the pigments of the skilled "spotter." This process was both expensive and unsatisfactory; for the pigment applied to hide such defects is itself a defect from the fatal facility with which the eye rests upon it, and the still greater facility with which it is removed, thus leaving the spot revealed in all its naked deformity.

After various suggestions respecting the reproduction of the negatives through the instrumentality of transparencies, upon which the offending spots would be touched out previous to making use of them for forming printing negatives, the idea occurred to us to dissolve the spots themselves out of the negative, and then to have the transparent holes thus made properly filled by pigment of the same density and colour as the portions immediately surrounding. The great success we achieved in carrying this idea into effect induces the belief that the details of the method employed in doing so will prove useful to many who may be placed in a similar situation.

The first difficulty we had to encounter in the endeavour to bring a solvent to bear upon the spots was found in the fact of the negative having been protected with a coating of strong lac varnish, which it was obvious would have to be removed before the abnormal reduction of silver forming the spot could be operated upon. The removal of a coating of varnish is generally presumed to be a very simple matter. It is only necessary—so runs the popular belief—to immerse the negative in a vessel of alcohol for a short time, when the lac will be found to have been dissolved away. Now, inasmuch as lac which has been previously dissolved, dried, and exposed to light and atmosphere, in the manner of a negative-protecting film, becomes by such treatment more insoluble than it was previously, this necessitates the prolonged employment of very strong alcohol, to which we have known the negative film itself to succumb. It is a process both slow and attended with some danger.

The following is the method we adopted on the occasion to which we refer, and we very strongly recommend it as being at once simple, expeditious, and certain:—Take a bit of caustic potash—there is no necessity whatever for weighing it—a piece the size of a bean, greater or less, answering quite well. To this add about an ounce of water, and when it has dissolved, which will be the case in a couple of minutes, add a quantity of methylated alcohol equal to the water present. Now, holding the negative either by one corner, or, as we prefer, upon a pneumatic holder, pour this solution upon the surface, taking care that every portion is covered. Allow it to remain on for about half a minute, pour off into a porcelain or glass measure, and again apply it to the surface as if it were a developing solution. Pouring off once more, apply to the surface a little plain water with alcohol, and follow this by copious washing with water. When the plate is dried there will not be a vestige of the varnish found on its surface.

We here pause to observe that, if by accident, bad varnish, or inadequate temperature, a negative has been damaged in varnishing, the method just described will prove a most effectual means of denuding the collodion film of its resinous, pellicular coating.

By means of the treatment described the opaque spots upon the plate were rendered in a proper condition for being operated upon by a solvent. Naturally, recourse was had to a solution of cyanide of potassium, and a strong solution was carefully applied by means of a camel's-hair brush. It was of no use whatever; the spots could not thus be induced to disappear. The power of the solvent had to be increased, and some quality had also to be imparted to it by which its action should be confined to the spot upon which it was to be applied. The chemical conditions were amply fulfilled by making use of a somewhat strong solution of iodine in cyanide of potassium, the relative proportions being such as to leave the solvent salt in excess. This is easily effected by adding iodine until the cyanide solution is incapable of dissolving more, and then making a further addition of cyanide. The mechanical conditions are secured by the addition of a few drops of mucilage of gum arabic.

The negative having been placed upon the retouching desk, and a tolerably strong magnifier utilised, a camel's-hair brush, charged with the solution described, is deftly applied to each opaque spot, which, after a few seconds, is seen to become quite transparent. When the whole of the spots have been touched in this manner a gentle stream of water is applied to the film, so as to clear away all the solution of iodine. The spots, previously opaque but now transparent, are next touched in by means of an appropriate pigment to be selected from the colour-box—a mixture of burnt sienna, Prussian blue, and China ink forming a pigment which answers every purpose.

The negatives treated in this manner yield prints which do not demand any artistic operation, and in which it is almost impossible to discover any fault indicating there having been at one time something seriously amiss with the negative.

PAINTED CARBON PICTURES.

The widespread interest with which Mr. J. G. Tunny's communication on the fading of carbon pictures has been received shows the great hold the process has already obtained; and the desire to commence carbon printing will, after the convincing and satisfactory nature of the explanations from the Autotype Company, still increase, we are assured.

There is, however, grave probability of future complications with those who have in their possession valuable paintings with the carbon basis; but it must be remembered that the action that takes place when a silver print which has been worked up in water colours begins to show signs of fading is entirely different from any that might occur in the case of carbon. In the former case there is a continuous and, we may say, strong action occurring between the silver of the image and the pigments that are laid upon it, and beyond this there is also the natural tendency of most silver prints to fade. But in the latter, though there is the faintest possible chance that an action might take place between the slight amount of chromium compounds present and the artist's colours, we think such a possibility may practically be dismissed from our minds; and hence the only danger to be apprehended is that from the cause so recently pointed out. But when we consider that, in most cases, there is an actual stratum of colour—thin it may be, and no doubt is, in the majority of instances—covering the whole image, the comparatively slight alteration of tone may fairly be expected to be free from any evil effect upon the delicacy of the picture, even granting that paper of the now condemned kind had been employed.

Before entering upon the second phase of our observations we would wish here to call attention to the fact that there is a charge to be brought against the painting itself. It is well known that the majority of artists who undertake this class of painting—one of daily increasing importance—are fond of using body colour, with the purpose not only of obtaining their effects but also covering the often too heavy shadows and patches of black in which photographs prepared for the artist too often abound. Now we do not here wish to raise a discussion as to the legitimacy of opaque colour, high authority as there is for its practice apart from photography; what we desire to draw attention to is the fact that there is such a fatal facility about the employment of some of them—effects to be obtained with ease which with other colours require much more time and labour to produce—that sufficient discrimination is not employed in their selection, and, in consequence, those pigments which in themselves are fugitive or discoloured by the action of the air are largely employed.

We give a single instance, and in a future article may return to the consideration of the chemical constitution of some of the more popular pigments of the artist's palette. Naples yellow is of most common employment. Mixed with a little madder it forms, especially for slight and simple (so-called) "tinting," the chief groundwork of the colour of many thousands—we might say tens of thousands—coloured *cartes* annually spread broadcast over the land. We do not hesitate to condemn in the strongest manner the use of this colour in any way for flesh tints. The pictures upon which it is employed are sure to fade, and thus innocent photography will again have to suffer in reputation from the sins of another.

We know that in some establishments coloured pictures—even to five and ten thousand pounds' worth or more in a year—are produced; and to those conscientious principals who have employed a carbon basis as a sure safeguard against fading much consternation may have been lately caused. There is, however, a most excellent method in high-class work of obtaining the highest excellence in painting, while retaining the verisimilitude of photography; and we shall now give details of the method employed in practising it as communicated to us by a professional photographer who has employed it for some time.

When the subject or negative is determined upon, and the style—say, for instance, a half-length vignette—chosen, the first step after the enlargement is obtained is to get a carbon print, as a guide, from the negative, and then to stop out the whole of the negative but the face and neck down (say) to the collar. The negative should be reversed, of course. The guide print will enable the necessary size of paper to be chosen, and also the relative position on the figure upon it. There is then marked in pencil a square which will contain (and leave a little room to spare) that part of the negative which is left to print from; and in this space the paper must be covered with the usual chrome alum and gelatine preparation and allowed to dry, when it is ready to receive the picture. A carbon print on a small piece of tissue is then obtained of the head, &c., and squeegeed on to the marked-out spot, and in due course developed. If everything has been successfully performed there will be a head photographed on to the middle of a blank piece of paper, leaving pure unprepared paper for the artist to trace from his guide, the body and limbs, &c., and to give him that freedom of handling which can only be obtained with such an accustomed surface as ordinary drawing-paper. The picture, when finished, is practically a water-colour drawing, with the aid of photography to preserve the likeness of the features.

We advise those of our readers who supply their clients with the most expensive class of work to give this method a fair trial; they cannot but like it and its accompanying freedom from doubt of any kind. If even to avoid the dreadful expedient of cutting out a photographic head and, after paring it down, mounting it on a plain paper, the process is to be praised and recommended.

We frequently have occasion to find fault with our American friends for the extremely loose manner in which they sometimes state their chemical formulæ or describe various chemical manipulations. We have now to complain of the verbal instructions in manufacture of the ferrous oxalate developer, given by Mr. H. J. Newton at the last meeting of the Photographic Section of the American Institute, and reported at page 381 of our last number. It is due to Mr. Newton to remark that his directions were given in a familiar and conversational way, under which circumstances there is a strong tendency at all times to depart from the strict accuracy of chemical phraseology; but, on the other hand, it is the duty of every speaker at a *public* meeting to make himself as clear and explicit as possible, and not to inflict upon his hearers or his *readers* a series of disjointed statements which savour considerably of the cross-examination of a witness in a law court. Mr. Newton, too, should be specially particular, as from the great things he promises for his emulsion he is likely to have a numerous following; but if he gives his information in the careless, offhand way we speak of, though it may be sufficiently plain to those who happen to be well up in the subject we fear that there is a large class who will be only misled thereby. We must ourselves confess to a considerable amount of uncertainty as to Mr. Newton's meaning in the paragraph to which we refer. "Ferrous neutral oxalate of potash" is a rather peculiar term, but one which we fancied we understood until we found it was made by mixing two solutions of potash and oxalic acid, or by placing crystals of oxalic acid in a solution of potash. But, perhaps, to use Mr. Newton's own words, "it is not quite clear in the minutes." The more serious point we wish to come to, however, is the method which Mr. Newton recommends of simply adding solution of ferrous sulphate to the mixed solutions of potash oxalate. The result may be, no doubt, a workable developer; for, as Mr. M. Carey Lea has shown, the developing action is easily set up, the mere addition of oxalic acid to the ordinary iron developer being sufficient. But we strongly question the advisability of this mode of preparation. Nothing can be clearer or more explicit than Mr. Willis's directions—a saturated solution of neutral oxalate of potash; even if it be not employed of that strength it forms a trustworthy starting-point. But the plan proposed by Mr. Newton not only gives rise to some uncertainty with regard to the strength of the solution, but gives a product which, even when newly prepared, contains foreign matter. Our own experience of this and similar modes of preparing ferrous oxalate is that, setting entirely on one side the question of efficiency, the keeping qualities of the solution are much impaired by the presence of any traces of decomposition products, such as are likely to be formed in the course of treatment proposed by Mr. Newton. We cannot, therefore, see the advisability of departing from the older and likewise *simpler* plan.

A NEW METHOD OF MAKING GLASS STEREOSCOPIC TRANSPARENCIES.

I have heard many express regret that the stereoscope is almost a thing of the past. Booksellers and dealers in photographs say at the present day that stereoscopic pictures are very seldom asked for by their customers; now and then, occasionally, they may have an inquiry for some. I attribute this to the market being overstocked with such miserable, wretched trash as we have seen exposed in the shop windows for sale, and I think the paper print in the stereo.

form will never have the sale that it has had. By all true lovers of the picturesque I am sure the glass stereoscopic transparency is always admired. As for myself, I am never tired of looking at them when they are properly made.

Hitherto the trade has been in the hands of a few, among whom I may mention the names of Soulier and Co., of Paris, and Breese, of England. I have seen many of their subjects that I have considered perfection itself; but there has been one great drawback, and a very serious one, and that is the high price charged for them. I know that some of the processes adopted by those gentlemen were very elaborate, requiring very skilled operators, and hence the expense; but now that photographic processes of the present day are very different from those of days gone by, I am perfectly sure that, if a few were to take to preparing and issuing at a moderate price good stereoscopic transparent slides by the process now to be detailed, it would add considerably to the income of the producer, for many thousands of stereoscopic negatives are at the present day idle and buried in the plate-boxes of both amateur and professional photographers.

There is another obstacle which has hitherto been in the way of the photographer in producing them, and that is that when the negative has been taken with a binocular camera, the two separate halves having to be transposed, the best way has been to cut the negative in half in the first instance; and I have scarcely ever found a photographer who did not object to such a system. Then, again: to make two exposures on the two different halves of the plate was attended by a great loss of time in making the proper arrangements, which added greatly to the cost of production; so a high retail price having to be charged on the one hand, and the cost of production by the photographer on the other, have prevented more being made than have been. I am sure that something in the way of business may be done in this direction if only pushed.

Of late several photographers have been writing and asking me if I could propose a system whereby transparencies might be produced easily and at not too great a cost; so for some time past I have been at work making experiments in that direction, which have been very successful, and I now offer the details of the results obtained for the careful consideration of those who may be interested in the matter.

First, as respects the negative: almost any class of negative will do, but, generally, those which are considered to give good paper prints I find secure the best results. Negatives which are somewhat too intense can be used, and yield, with care in developing, first-class results, while the defect of hardness is modified. On the other hand, a negative that is fogged and gives a flat result on paper can also with care be made to yield excellent results. So it will be readily seen that almost any class of negative can be used, and many, perhaps, which are useless for ordinary work.

I must not forget to mention that the negative must be well varnished with a tough varnish, especially if the system of printing by contact is adopted. Any slight defects must be very carefully spotted out in the negative, and not, as I have seen some photographers stop out a negative, as they call it, with a great blotch of black; for every print on paper printed from such a negative has to be spotted out, which entails endless work if large numbers are required. In transparencies, for whatever purpose they may be required, any defects or spots look very bad on glass and are difficult to touch out; so it is always better to spend a little time over the original negative in order to gain the best results.

Preparation of the Glass Plate.—The glass plate must be perfectly clean and free from scratches; bubbles in the glass on which the transparency is made is not of the slightest importance, as they will not show in the finished production. No substratum of any kind whatever must be used. The method I adopt in cleaning all my glass plates used in photography is very simple, and I never have a dirty plate. If the glass be new I place the plates in a gutta-percha dish or tray of—

Sulphuric acid	1 ounce (fluid).
Water	1 pint.

I allow them to soak for about an hour or more (this acidulated solution can be used over and over again). Any other acid can be used, such as nitric or hydrochloric—whichever is readiest at hand. I then take them out one by one and wash them under the tap, rubbing them with a bit of common hard sponge and using plenty of water. I then set them to drain and afterwards polish them with a leather, using methylated spirit. If old glass be used I remove the films in boiling soda and water previous to applying the acid solution; dry and polish as before, using methylated spirit. In all photographic processes too much care cannot be taken to ensure a chemically-clean plate.

To get the best results, both as regards tone and quality of the picture, I always use the collodion emulsion process; at the same time, however, those who prefer it can use wet collodion with the nitrate of silver bath, but it gives very inferior results when compared with collodio-emulsion. After the plate is clean a slight edging of india-rubber dissolved in benzole is run round the edge of the plate to about one-eighth of an inch. I use a stumpy, common camel's-hair pencil tied on to a narrow strip of glass, the glass projecting about a quarter of an inch below the pencil. The solution I use consists of—

India-rubber	3 to 6 grains,
Benzole	1 ounce.

When dry (which will only take about one minute) the plate is placed on a pneumatic holder, and any dust which may be on the surface removed by passing over it a broad, stiff, hog's-hair brush; it is then carefully coated with emulsion, and set to dry in a cupboard free from dust.

The Exposure.—This can be accomplished in two ways: either by contact in a printing-frame or in the copying camera; but I prefer the former system, as giving better results than the latter. I must not omit to mention that all my stereo. negatives are taken on $7\frac{1}{2} \times 4\frac{1}{2}$ plates, and from negatives of that size I use plates $7\frac{1}{2} \times 3\frac{1}{2}$ on which to make the transparency, thus allowing plenty of room for working. But, whatever be the size in length of the original plate, the plate for a transparency must be the same, and the $3\frac{1}{2}$ in. depth of the plate must always be adhered to. I always use a printing-frame with a thick plate-glass bed-plate somewhat larger than the size of the negative used, and into that I cut a piece of six-sheet cardboard, which fits well the full opening of the frame. I then lay the negative on the middle of the cardboard and mark round it, cutting the centre out with a mount-cutting knife, so that the negative will fit tightly into it. This both prevents blurring at the edges of the plate and keeps the negative from shifting and getting damaged. When the negative is in position it is carefully dusted, and the prepared plate placed in contact with it. In putting in the backboard of the frame always be careful to keep the side where the hinges of the bars are kept close up (pressed tight); for by such means, when the bars are brought over into position, there will be no dragging motion in that direction to injure either of the films. It is the sliding or grating movement that is liable to injure the film. It is then exposed to the light in the usual way. Avoid sunlight. If the exposure be made at a window facing the north the light is, as a rule, very regular all day. The length of the exposure, of course, depends upon the rapidity of the emulsion used; also on the density of the negative and the brightness, or, I should say, the intensity, of the light, the time of year, and method of development employed. Taking all the foregoing conditions into consideration, the time will vary from about one second to half-a-minute or more. After the exposure has been made the same precaution must be taken in removing the backboard. The fingers of the left hand must be pressed tightly on the backboard with a downward pressure, the bars unfastened, the backboard removed without any sliding movement, and the exposed plate carefully removed. All this can be accomplished with very little practice.

With respect to making the exposure in the camera: it has one great advantage in its favour in some instances, which is this—if the image on the original negative be too large it can be reduced by the camera, which is of great importance. The original negative is placed in the frame of the camera to receive it, film side of the negative to the lens, focussed, and exposed in the ordinary way.

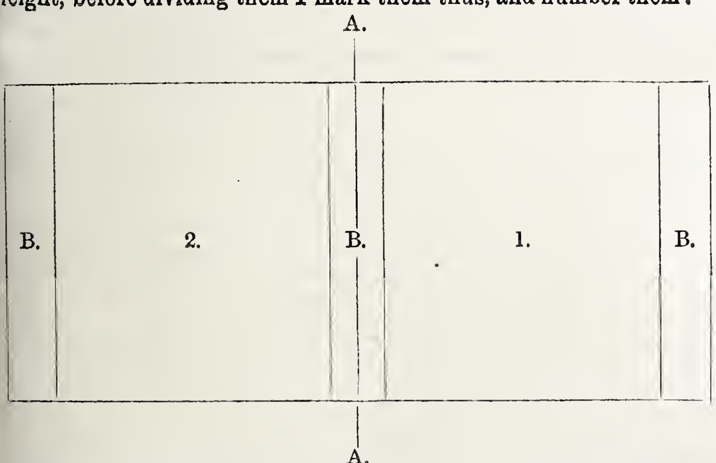
The next point is the development of the transparency. After it has been exposed by either method, the system of developing is conducted in the ordinary way or to the fancy of the operator, according to the process with which he is working. A few words will not be out of place respecting the class of image required. The parts representing the high lights of the picture must be bare glass. The fine lines of the deepest shades *only* must be intense, and all the true gradations in the negative must be preserved, and not buried, which is very often the case, and by which the whole effect is marred; for in a good transparency, properly developed, there is a greater amount of detail visible than in a paper print, and that is why a print on albumenised paper is at times so unsatisfactory. A transparency well made is the most perfect transcript of nature that photography is capable of rendering. After the plate is sufficiently developed it is fixed (or cleared) in the usual way, with either hyposulphite of soda or cyanide of potassium, according to circumstances, and great care must be taken to well wash the film free from all the soluble salt of the fixing agent used. I prefer to soak plates by leaving them in a tray of clean water for half-an-hour or an hour and then well wash, because if any trace of the fixing agent be left in the film it is liable to eat away part of the fine detail and spoil its beauty.

The next operation is to prepare for transferring the film. Take a sheet of fine grained paper, either Saxe or Rives, and float for about one minute, or until it lies flat, on a solution of—

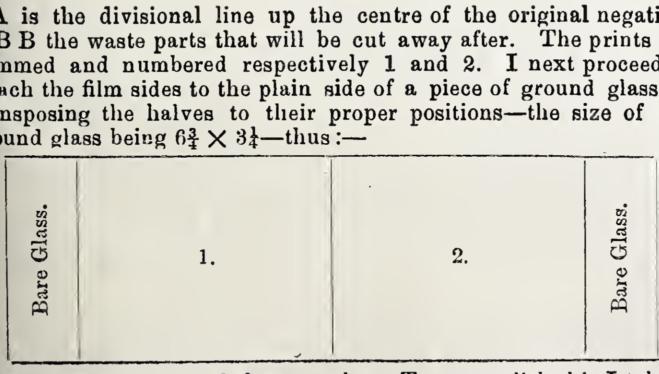
Gelatine	60 to 80 grains.
Glycerine	2 or 3 drops.
Water	1 ounce.

It is then hung up to dry. I have prepared this paper myself, but am very thankful to say that I have got rid of this part of the manipulation, as I find that I can purchase it ready prepared in the market, which I consider a great boon. I do not think that I shall, in this instance, be overstepping proper bounds by stating that Mr. J. Solomon, of Red Lion-square, London, keeps it in stock. I have not heard that anyone else prepares it, as at present it is very little used. If I have committed myself I claim the indulgence of the Editors.

The transparency must be allowed to dry *spontaneously*. A piece of the gelatine paper is cut just the size of the glass carrying the transparency and immersed in a dish or tray of clean water for about one minute; the transparency is then well wetted under a tap and laid on a flat board (film side up, of course). The gelatine paper is then lifted out of the water, being allowed to "bag" in the middle, and is brought in contact with the wet film of the transparency, the two ends being gently lowered; a very soft squeegee is then passed over it, lightly at first, in all directions, increasing the pressure as the water is pressed out, taking care to remove all overlapping paper at the edges, or it will curl up in drying. The plate is now set up to dry spontaneously; on no account must the drying be hastened by heat. When perfectly dry cut with a sharp knife just within the india-rubber edging, and lift one corner, when generally it will be found to leave the glass without any trouble; but should there be any tendency to stick place it in a dish of *cold* water for a few minutes, and it will then readily strip off. It is now allowed to dry gradually. When perfectly dry lay the film side down upon a glass plate to trim, and take a piece of glass three and one-eighth inches wide and about eight inches long. The three and one-eighth will be the height of the picture, which must be trimmed to this size. Now take another piece of glass two and seven-eighth inches wide; this will be the width of each half. After I have cut the prints to the height, before dividing them I mark them thus, and number them:—



A A is the divisional line up the centre of the original negative, B B B the waste parts that will be cut away after. The prints are trimmed and numbered respectively 1 and 2. I next proceed to attach the film sides to the plain side of a piece of ground glass by transposing the halves to their proper positions—the size of the ground glass being $6\frac{3}{4} \times 3\frac{1}{4}$—thus:—



The halves are mounted close together. To accomplish this I take—

Gelatine	45 to 50 grains.
Water	1 ounce.

I allow the gelatine to soak in the water for about half-an-hour, and then dissolve by heat and strain through a piece of muslin. To each ounce of this solution I add about four to six drops of a saturated solution of chrome alum. It must be kept hot by the vessel containing the gelatine being placed in an outer vessel containing hot water; for if once this sets no amount of heat will effect its solution again. But care must be taken not to add too much chrome alum, or it will set at once. The cleaned plain side of the plate is now coated with this, being guided over with a glass rod, and the surplus returned as in the case of collodion. Allow it to chill a little, but not get cold. To this point special attention must be paid, or failure will be the result. Each half is now put down in its proper place, as shown above; a sheet of clean blotting-paper is laid over each and gently rubbed down with the fingers, working from the centres of each half and pressing out all air-bells, if any, which can be readily seen through the ground side. The plate is then laid aside to dry, or it can be reared up on end in a rack. The drying will take about one hour at this time of the year, but longer in winter. No heat must be used on any account. When dry the plate is put into *hot* water, which soaks through the paper in about one minute and dissolves the gelatine with which the paper was coated, and which can now be easily stripped off. By virtue of the chrome alum added to the gelatine that layer or coating becomes insoluble and holds the collodion film fast to the plate. Gently wash the plate with the hot water, and rear it up on end to dry; by this means we shall obtain the stereoscopic transparency without cutting the original negative, and in its most perfect condition.

Before I conclude I must give a caution. In case a difficulty arise in removing the paper from the film, it is generally caused by bringing the film of the collodion into contact with chromatised gelatine while it is in a too liquid state, causing the fluid to find its way through the collodion film, and rendering the gelatine with which the paper was coated insoluble. If this occur it is impossible to remove the paper, as the whole of it is made fast. To guard against any difficulty that may be thus experienced proceed as follows:—Before the paper is attached to the collodion film the latter may be coated with india-rubber dissolved in benzole and allowed to dry, and then coated with Mawson's enamel collodion, and, when dry, the gelatined paper attached as before described. This stops the soaking through of the gelatine and chrome alum, and prevents the mischief; but with ordinary care this can be dispensed with.

I have now entered into this matter with the necessary detail, but should I not have made myself quite understood I shall be most happy to answer any queries through the medium of these columns. I do not in any way claim any originality as respects the use of the gelatine in this way. I am aware that it has been used for several purposes, and I have here pressed it into service in order to accomplish the end I had in view. Wm. Brooks.

THE APPLICATION OF PHOTOGRAPHY TO THE PRODUCTION OF PRINTING SURFACES AND PICTURES IN PIGMENT.

IN SIX LECTURES.

IV.—PRINTING OF HALF-TONE SUBJECTS FROM METAL.—APPLICATION OF ASSER'S PROCESS.—TALBOT'S PHOTO-ENGRAVING.—WOODBURY'S METHODS OF ENGRAVING AND PRINTING.

[A communication to the Society of Arts.]

When treating of photozincography I gave details of Asser's process, and I showed you a zinc plate bearing the fatty image. Since then I have etched that zinc plate, so as to convert it into a high printing block suitable for the typographic press. Here it is. Here is an electrotype cast of it; and yonder is a proof from it, hanging side by side with a proof from the unetched plate. In comparing these proofs you will see that a little of the detail has been lost during the etching; but this is not due to any defect in the process, but to the fact that I etched the plate too rapidly. In etching a plate of this kind the re-inkings must be done with great caution, and the acid used for the earlier etchings must be very dilute—say one part of acid to one hundred of water.

I hope to see Asser's process come into use for large and comparatively rough work, it being well adapted for this. Mr. Dallas has brought the manufacture of typographic blocks, for the representation of half-tone, to great perfection, and he has kindly lent me some of these, and also prints from them. Although we do not know what method Mr. Dallas employs in making his "tint" blocks, we can all appreciate the excellence of the results.

The illustrious Talbot discovered a method of printing in half-tone by means of etched copper or steel plates, and very beautiful results have been obtained by his method, which I now intend to illustrate to you.

Here is a copper plate which has been carefully cleaned and charcoaled. I slightly warm this and fix it on the turn-table. I next pour on it a warm solution containing six parts of gelatine, one hundred parts of water, and one part of ammonium bichromate. The table being now rotated all excess of the gelatine solution is thrown off, and a thin, even film is left on the copper plate. The plate must next be dried at a gentle heat, after which it is ready for exposure to light under a transparency. Here is a plate which has been so exposed, and you will notice that, where the light has acted, the coating has become brown, and at the same time it has become insoluble in aqueous liquids, the degree of insolubility depending on the extent to which the light has acted. The next problem is to etch through the soluble parts of this film without destroying its continuity. This cannot be done by nitric acid, as the acid destroys the gelatine film at once; but a strong solution of iron perchloride will answer the purpose. The plate being now put into this solution of perchloride of iron the etching has commenced. Those parts of the gelatine film which have not been acted on at all by the light remain very soluble and allow the etching to take place rapidly, while those parts where much light has acted resist the solution altogether, and those parts which have been acted on by a small proportion of light allow a proportionate amount of the iron perchloride to penetrate. Thus all degrees of light and shade are represented by corresponding amounts of etching. The plate is now sufficiently etched. I take it out, clean off the gelatine, and now it is ready for the press. Here is a proof from a similar plate.

The next process to which I direct your attention is one discovered, perfected, and carried out on a large scale by Mr. Woodbury. The Woodburytype process consists in casting coloured gelatine pictures in a metal mould. Here is a metal mould—the method of making it I will describe directly—in which the image is hollowed out, the depth of the hollow being greatest in those parts corresponding with the dark parts of the picture, and everywhere deep in proportion to the intensity of the shade. I place this mould in a dish containing blackened water, so that the water just runs over its face. You now see no picture or anything approaching to a picture. Now notice the effect of pressing a piece of plate glass down on the surface of the mould. The excess of blackened water is forced out, and the hollows of the mould alone are filled up with the blackened water. Now, as these hollows vary in depth, varying degrees of shade are produced, and a perfect picture is produced. I take the glass off, and the picture disappears; put it on once more, and it re-appears. Instead of coloured water I pour on this mould a little coloured gelatine, and press a piece of plate glass down on the surface. The excess is forced out, and the mould filled with coloured gelatine. In a few seconds the gelatine will have set, and I shall be able to lift off the glass, which will carry with it the gelatine image. Here it is; it forms a transparency suitable for the magic lantern. If, after having flooded the mould with coloured gelatine, a piece of paper is laid on and the excess of gelatine is forced out with a plate of glass, a picture composed of coloured gelatine is moulded on the paper, and can be removed as soon as the mould is set. When removed it is dipped into a solution of alum, in order to render the gelatine image insoluble in water.

So much for the general principles of Woodburytype; and now let me show you how you can work this process yourselves.

The first thing is to dissolve about six parts of easily-soluble gelatine and two parts of lump sugar in fifteen parts of warm water. Here is the warm mixture already strained through muslin, and here is a waxed glass plate, set level and bordered with a little ledge of wood. The warm gelatine solution being poured on spreads itself over the plate, forming an even layer, which, in the course of some hours, will dry, forming a uniform sheet. Well, here is a dry sheet of the gelatine on another piece of glass, and you see that the introduction of a penknife under one corner of the gelatinous sheet brings it off the glass at once. The next thing is to make this gelatine sensitive to light, and for this purpose it is soaked in a solution of potassium bichromate containing three and a-half per cent. of the salt. You see that it has now become quite flaccid by absorbing the solution, and I now lay it on a sheet of glass and remove the excess of solution by means of the squeegee. The bichromated gelatine adheres to the glass, but when dry it will be easily removable.

Here is a glass plate with a dry sensitive film on it. I take the film off and place it under a negative. It is now ready for exposure to light, and would require about two hours of such light as we had today at noon. Here is a printing-frame containing three such films, which have had the necessary exposure under their negatives. I put these films in water and let them get moderately soft, but not so soft as the film became during the sensitising. One of these I take out and lay face downwards on a piece of finely-ground glass; another is similarly placed on a piece of glass covered with gold-beaters' skin, and the remaining one is put down on a sheet of collodionised glass. The squeegee is now applied to each, and adhesion takes place. In order to enable the gelatine films to firmly fix themselves to the supports they should remain at rest during a period of about half an hour; but, as we cannot wait that time, I have provided a duplicate set previously prepared. Mr. Barker will now put these into warm water, and the gelatine soon begins to dissolve. Now, remember that certain parts of the bichromated gelatine have been made insoluble by the action of light shining through the negative, and these insoluble parts will remain undissolved on the supports (ground glass, gold-beaters' skin, and collodionised glass). It will take some little time for Mr. Barker to wash away all the soluble gelatine; but towards the end of the lecture you will see his results in the shape of gelatinous reliefs—thick where corresponding to the blacks of the picture, very thin in those parts representing the whites, and finely graduating between these extremes. When the reliefs have been sufficiently developed they must be dried; and here is a finished and dry set. You see that, having only one hour, it is necessary to get continually in advance of the work, and to take fresh materials which have been previously worked up to a certain stage. Let me begin with the relief on finely-ground glass. This, being gently warmed, I put a border of wood round it and pour on some fusible metal, made by melting together one part of cadmium, two parts of tin, four parts of lead, and seven parts of bismuth. Well, now, if I left this to cool in the ordinary way the top would solidify first, and the lower layers of metal in contracting would leave small vacant spaces next to the surface of the gelatine, thus rendering the cast imperfect. To obviate this I place the glass on this cold block of metal, and cover the top of the fluid fusible alloy with warm sand. The rest explains itself; the portion of fusible alloy next the face of the mould becomes solid first. Here is a fusible metal mould made in the way I have just illustrated to you; I oil it slightly, pour some coloured gelatine solution on it, and force away the excess by means of flat glass, and when the gelatine has set the glass can be removed, carrying with it the moulded transparency.

Here is the relief on gold-beaters' skin, and here is the one which was developed on collodion. These can easily be stripped from their glass supports, as I now show you. One corner being liberated, off they come; I will pass them round for you to look at. Now, in the actual commercial practice of Woodburytype printing, a film relief, such as you are now passing round, is forced into a plate of lead by means of the hydraulic press, and the leaden mould thus obtained is used for printing. I now lay a film relief on the smooth steel base of this screw press, place a piece of lead on the top, and apply pressure. You see the result—the lead has become an exact counterpart of the gelatine relief, which you will notice is in no way damaged.

Here is a leaden mould, together with the corresponding relief, kindly supplied by MM. Braun and Co., of Dornach, and here is a very fine mould made by Mr. Woodbury himself. I will make a cast in this, and you see that the result is one of Mr. Woodbury's magnificent lantern slides which are now so popular. It is now projected on the screen, and you can all see it. I take it out, or the heat would melt the wet gelatine, and I pass it round for you to examine; but remember that it is not yet dry, so do not touch the face of it.

I think I explained to you that, in order to get a Woodburytype picture on paper, it is merely necessary to interpose paper between the gelatine, as poured on the mould, and the plate-glass cover, which forces out the excess. To illustrate the matter, I will print one from this mould. Now, notice the paper I use. It is thin, hard paper, surfaced with shellac, to prevent the gelatine from penetrating it, and heavily rolled, to make it even in thickness. There is much more which I would like to tell you about the Woodburytype process, but I have not time. You will not fail to notice the admirable collection of prints and illustrative specimens kindly lent me by the Woodburytype Company, MM. Goupil and Co., Braun and Co., Bruckmann, and others, who are working the process on a large scale, not forgetting these very fine specimens lent by Mr. Woodbury himself.

I may mention that, in actual practice, one Woodburytype printer can attend to several moulds, and by the time he has filled the last of the series the first is ready to give up its picture. The moulds are arranged on a circular table, which revolves in front of the operator.

Mr. Woodbury has modified his process so as to obtain copper plates suitable for deep printing in the ordinary copperplate press, and this modification has been worked with the greatest success by MM. Goupil and Co., of Paris, who have kindly lent me these magnificent specimens of their work.

A gritty powder is added to the gelatinous mixture employed for making the relief, and, when the relief is made, it is found to be more or less rough, from the projection of the gritty particles. The relief is then rolled against a sheet of lead so as to make a perfect reverse in this metal. As far as form is concerned this plate of lead is perfectly adapted for printing in the copperplate press, the hollows left by the projecting particles of grit holding the ink to perfection. But as lead is much too soft to be used as a deep-printing plate, the leaden plate is reproduced in copper by the electrotype process, two electrotypings being, of course, necessary—one to make a reverse mould, and a second to make a cast of this mould, or a duplicate of the original leaden plate. THOMAS BOLAS, F.C.S.

NOTES FROM AMERICA.

THE PREPARATION OF SENSITIVE PLATES IN DAYLIGHT.—KLARY'S WET COLLODION FORMULÆ.—HINTS ON PHOTOGRAPHING CHILDREN.—LAMBERT'S LIGHTNING PROCESS.

Our energetic friend, the editor of the *St. Louis Practical Photographer*, expresses something akin to ecstatic delight at the bare idea of the preparation of a sensitive plate in daylight. After alluding with pardonable pride to the achievements in practical science by Americans, and especially in photography, he says:—

While thus glorying in what we have done we must admit that our friends in Europe are doing something also. While we are puzzling our brains over lighting and carbon processes—both very good, of course, and well worthy of our closest study—our friend, Herr Obernetter, of Munich, has turned his study in another channel, and succeeded in evolving a process by which plates may be prepared in open light, no dark room being necessary. This is a very important discovery. We have before us a number of specimens of carbon photography by the lichtdruck process, also invented by Herr Obernetter, in which the negatives were made in his garden without a dark room, the plate being collodionised and excited or sensitised in open daylight. They are fine specimens—clear in light and shadow and full of detail, not the most feeble indication of fogging, and the modelling perfect. Usually outdoor portraits are lacking in rotundity; the gradation from high light to deep shadow, so pleasing in portraiture, is wanting, and we have the light and shade in masses. In these specimens there is no lack of half-tone, no mass of deep, impenetrable darkness nor glaring high light, but a fine, harmonious picture, as nicely balanced as if made in a first-class studio, with all the conveniences for modifying the light to suit the whims of the sitter or the taste of the artist.

Onward and upward—higher, still higher, is the flight of our noble art. What may we not hope for now? The daguerreotype came and went, leaving as its successor the ambrotype, which, in its turn, gave way to the photograph. Slow old processes like the albumen negative process died a natural death, and now we can produce outdoor work so rapidly that the rain-drop is caught falling, the swallow poised in mid-air, the locomotive as it thunders past; yea, even the shell on its murderous way, hissing and screaming through the air, carrying confusion, or may be death, from the cannon's mouth to the ranks of the foe. Heretofore a costly or cumbrous machine, to exclude white light from the plate from the time it was collodionised until it was developed, has been a prime necessity, and scores of inventions have been introduced having this end in view. This grand forward movement of Herr Obernetter, rendering these troublesome accompaniments to a photographic tour or excursion totally unnecessary, is important beyond conception, and we can hardly contain ourselves until the details of the process are made public. We do not know if the inventor intends publishing it for the benefit of the fraternity at large—a thing we doubt very much. Our readers can rest assured we shall spare no pains on our part to lay it before them at the earliest possible moment in any shape it may be brought forward.

Apropos of this, it may not be generally known that so long ago as the spring of 1865 a gentleman and (we know that our brother of the *Practical Photographer* will appreciate this) *an American* had made the discovery that sensitive plates could be prepared in daylight. Professor Charles F. Himes, the gentleman referred to, in an article contributed to THE BRITISH JOURNAL OF PHOTOGRAPHY of April 28, 1865, explained the principles upon which he based his process. The process, which we here only give in rough outline, consists in collodionising and sensitising the plates at spare moments during the day and in *daylight*, followed by transferring them to a desensitising bath of iodide of potassium, and in the evening treating them with a solution of tannin, by which their sensitiveness is restored. We cannot resist the temptation of giving a brief extract from the article in question by Professor Himes:—"The fears sometimes expressed in regard to exposure to light during the preparation of plates which are afterwards treated with a desensitised agent seem to be entirely groundless; and plates prepared up to the point of sensitising with tannin might be found convenient in travelling, as they free photography from the drudgery of plate-cleaning, and, at the same time, leave nothing to fear from custom-house officers or accidental exposure to light." We feel assured that our reproduction of this paragraph will set some of our more recent readers "athinking."

From the same journal *(Practical Photographer)* we extract what has been designated "Klary's formulæ." Whether they are or are not the formulæ by which M. Klary is at present working in Paris we know not. We give them for what they are worth:—

COLLODION.

Ether	16½ ounces.
Alcohol	16½ ,,
Cotton	150 grains.
Cadmium iodide	80 ,,
Ammonium iodide	80 ,,
Potassium bromide	50 ,,
Cadmium bromide	50 ,,

NEGATIVE BATH.

Distilled water	3½ ounces.
Silver	123 grains.

DEVELOPER.

Water	35 ounces.
Iron	2 ,,
Acetic acid	2½ ,,

INTENSIFIER.

Water	7 ounces.
Iron	185 grains.
Citric acid	30 ,,

In use, a few drops of a three-per-cent. solution of silver is added to the usual quantity of this solution.

PRINTING BATH.

Water	3½ ounces.
Silver	185 grains.

TONING BATH.

Chloride of gold	15 grains.
Water	18 ounces.

In use, to two and a-quarter ounces of this solution are added six or eight drops of a saturated solution of sodium carbonate, twenty-six ounces of water, and 308 grains of common salt.

A little handbook published by Messrs. North and Oswald, of Toledo, Ohio, for the guidance of their clients, contains the following excellent remarks on the subject of photographing children:—

We are always glad to take a reasonable amount of pains with children; they are subjects that make lovely pictures, and every parent should see to it that they are photographed regularly once a year at least. If you could see the tears and sorrows that we do on account of the *neglect* of having this done when it is too late, and the lovely child is dead, and parents have often *nothing* in the way of a picture, or at best a poor tintype, taken by some Cheap Jack, and paid for by the servant girl, which is good for nothing to copy or to make an enlarged picture from, you would not put off nor neglect to have, at least, a good card photograph of each of the family, old and young. Let us make a negative for card photographs of your little babies and older children; we keep it here in a good state of preservation, then in case of sudden death we can give you a splendid, lifelike, desirable picture of them, which is a joy for ever. They are difficult to secure, it is true, but we always get something of them; and if it be not satisfactory the first or second time it is not apt to be so at all *that* day, and it is best to bring them again. Never threaten a child if it will not sit, and never coax it with sweatmeats; permit the operator to manage it from the beginning. Dress the little one with care and good taste; avoid startling plaids and gaudy colours, or a variety of colours. Dark dresses should not be put on them. Let the photographer choose the position. A sitting or kneeling attitude, or vignette head, is generally best; for few little ones *stand* still long enough to have a picture taken, though we make cards and cabinets, in our new styles of *rustic* or *seaside* photographs of children full length, and in groups, if not *too young*, that are pretty and natural and very much admired. Mr. North is very successful with children; he likes them, and they in turn like him—or, rather, they take to him, and he always succeeds in *taking* them well. Experience in the photographing of children, from three weeks up to three years of age, teaches us that it is better to have the child come with the *one* person the child likes best and who has the most control over it. Too many gives the child the idea that it is a terrible thing to have a picture taken, and in very young children we notice that we secure a better result with no one but the *one* person in the room besides the operator, as they do not have so many to look at, and are more apt to keep their eyes still, and make a more natural picture.

We have on more than one occasion spoken of "Lambert's lightning process," which is being industriously pushed in America. Concerning the preparation of the collodion, bath, and developer we do not possess reliable information; but the following instructions respecting the method of using the preparations—which are only sold in America ready for use—will not be without interest. We are indebted for them to the *Philadelphia Photographer*:—

Collodion.—The lightning negative collodion will keep indefinitely, and is sent ready for use. Carefully coat the albumenised plate, allowing the film to become well set before immersion in the bath. Keep the plate in motion in the bath, and remove it as soon as the greasy lines have disappeared. The dark room must be *absolutely* free from all actinic light. To have the maximum of rapidity the plate must be exposed as soon after removal from the bath as possible. Filter, and thin the collodion as usual, if necessary.

Bath.—Usually the first bath sent is of proper strength, and ready for immediate use; afterwards it will be sent in concentrated solution. Test it, and dilute it with distilled water or ice water, so as to make forty grains to the ounce, keeping a little of the concentrated solution to strengthen the bath, when necessary, to keep it at forty grains to the ounce. After the bath has been in use for some time it will naturally deteriorate, from the absorption of alcohol and ether and an excess of iodides. It should then be rendered alkaline with liquid ammonia or weak cyanide of potassium, adding distilled water equal to one-half the quantity of the solution, and evaporate in the usual way to its original quantity; then expose to the sun until all precipitation ceases, and when cold filter twice through clean filters. See that the bath is in strength forty grains to the ounce, or make it so by adding either distilled water or some of the reserved concentrated silver solution; also add sufficient C. P. nitric acid to show the slightest trace of acidity on blue litmus paper after one minute's immersion, for the bath works best when as nearly neutral as possible.

Should the plate be *fogged* try to remove it by rubbing lightly with the fingers; if it come off it is a proof that the bath is too acid, so treat it with liquid ammonia or weak cyanide of potassium. If the fog be in the body, and cannot be rubbed off, it is evident that the bath is too alkaline; then treat it with a little C. P. nitric acid.

Developer.—This developer will keep indefinitely, and must be mixed with its own bulk of distilled water before using. The development must be continued as *long as possible, being unusually slow*; it will take up again any precipitation without injury to the negative. Use just enough developer to cover your plate. Some photographers catch their developer in a tray, and after filtering it use it over again without any bad results. Should the subject have required an unusually short exposure allow the plate to remain in the holder a few minutes after exposure before development. If the picture flash out suddenly in the development throw off the excess of the developer, and rock the plate quickly until the proper density be obtained. Should the picture develope with too much hardness reduce the strength of the developer.

Fixing.—Fix in hyposulphite of soda, as usual; but if the negative look too hard a dash of cyanide of potassium will soften it, but it must be used carefully, and not too long.

Continuator.—The continuator is rarely needed, but, if so, add to it an equal quantity of water and a few drops of a ten-per-cent. nitrate of silver solution at the moment of using. It is only used after development to bring out the details of an under-exposed negative when the developer fails to do so.

Reintensifier.—Very seldom necessary, being only used to obtain greater intensity, when it takes the place of the continuator. Dilute it with five times the quantity of water, and add, at the time of using, a few drops of a weak silver solution. It should be used carefully, as it gives a very strong colour.

N.B.—Be careful to have the glass perfectly clean, as foreign organic matter causes fog and stops detail in development.

FOREIGN NOTES AND NEWS.

Herr Birfelder on Collodion.—Dr. Richard on the Gradation of Light and Shade in Portraiture.—Herr Stefanowski on Reticulation of the Carbon Film.—Professor Böttger on a Good Iron Salt for Copper Plates.

In the *Wochenblatt* Herr Birfelder discourses on collodions, but he has nothing strikingly new to tell, except his amazement at a friend of his who, in speaking of instantaneous collodion, defined an instant as five seconds. As a good collodion for landscape work, very sensitive and moderately quick acting, Herr Birfelder revives Dr. Reissig's formula, which he finds the best of the many he has tried:—Place 192 grammes of alcohol in a shallow vessel, and rub down in it, until they dissolve, two grammes of iodide of potassium, two grammes of bromide of cadmium, and four grammes of iodide of cadmium. The solution takes place with ease when all the three salts are placed in the vessel together, as otherwise iodide of potassium does not readily dissolve in strong alcohol. When all is dissolved add, first, two or three grammes of cotton and shake well; then add 200 grammes of ether, and shake again until the cotton dissolves. Let it stand for about an hour, and then pour a little on a plate and test its quality with the finger nail. The nail should cut the film readily, and no skin should form to dissolve off in pieces. If a skin form add a few drops of distilled water and let stand for a few days. If all the chemicals are pure this collodion should be colourless, but a little clear yellow colour does not do much harm. When the colour is too dark put a strip of metallic cadmium in the collodion, and the fault will soon be rectified. The collodion is strongly iodised, but if it give too weak an image add a little more pyroxyline. Herr Birfelder is further of opinion that a thick film always gives a softer picture than a thin one.

In the *Archiv* Dr. Richard gives the following directions by scale for regulating the gradation of light and shade in photographic portraiture. He would commence by constructing a scale like the accompanying, the perpendicular line of which is to be eighteen centimetres high and the transverse line fifteen centimetres long—nearly the natural size of an ordinary head as seen against a background:—

To obtain a well-lighted, full-face study from a head he would place it so that on the transverse line—

A from 1 to 6 would be in the shade,
B from 6 to 12, or even 14, would be the half-tones,
C from 14 to 15 would be the high light.

On the perpendicular line—

A¹ from 3 to 10 would be in shadow,
B¹ from 10 to 18·5 would be in the half-light,
C¹ from 18·5 to 20 would give the high light.

It must be observed that the lowest point of the perpendicular line is numbered 3, because in intensity of shadow it corresponds, not to No. 1 of the transverse line, but to No. 3; so that the intensity of shadow represented by 7 to 1 of the cross line is greater than by from 12 to 3 of the perpendicular scale. For a three-quarters the perpendicular lighting remains as before, but the cross line runs thus:—

Shadow	1 to 9·5
Half-light	9·5 to 13·5
High light	13·5 to 15

In the *Mittheilungen* Herr von Stefanowski has something to say on the reticulation of the carbon film. As the result of a prolonged series of experiments he is convinced that reticulation only shows itself on certain kinds of tissue, namely, upon tissue prepared with light and easily-dissolved gelatine, and never upon tissue prepared with strong gelatine, which is difficult to dissolve, unless the latter contains either an intentional or accidental addition of organic matter.

In the course of his remarks, which are to be continued next month, he distinguishes three different sorts of reticulation:—

1. A granulation in the form of more or less regular polygons, visible to the naked eye, and which increase in size in proportion to the thickness of the picture film.

2. A fine network of broken lines, the size of the meshes of which has also a certain proportion to the thickness of the film. This second sort of reticulation occurs oftenest on carbon pictures developed upon collodionised glass plates.

3. A course, irregular network which appears especially on the edges and shadow parts, and separates the picture from its support. This appears everywhere, but preferably where the collodion substratum, which secures adhesion, is wanting.

In the *Polytechniches Notizblatt* Professor Böttger writes—"The iron thrown off by electricity from certain iron double salts appears particularly adapted, on account of its property of extreme hardness (exceeding even that of steel) to the purpose of covering, with a polished iron surface, copper plates intended to be engraved or for artistic printing plates. In this way the necessity for the troublesome and tedious multiplication of such plates in the galvanoplastic manner is avoided, and when, after long use, the plate is at last partially deteriorated by blackening, the thin snrface coating can be entirely removed by acid and renewed again in a few minutes. For this so-called steeling of the plate one has until now used almost exclusively the ferric sulphate of ammonia, which I first discovered and warmly recommended. I have lately observed, however, that an iron solution, prepared as follows, is even better adapted for this steeling process. Dissolve in—

Distilled water	200 c. c.,
Ferrocyanide of potassium	10 grammes,
Tartarate of sodium and potassium	20 ,,

and add a solution of ferric sulphate—three grammes in fifty c. c. of water. This will cause a copious discharge of ferric-ferrocyanide (Berlin blue). Now add to the whole mixture, drop by drop, stirring all the time with a glass rod, a solution of caustic soda, continuing until the blue precipitate has disappeared again, leaving a perfectly clear, slightly-yellow fluid, which can at once be used for the steeling operation in question. This fluid may also be used for dyeing cotton yarn and webs a beautiful blue, without the usual accompaniment of a mordant. For this purpose the material to be dyed is placed in the slightly-warmed fluid until it is quite saturated. It is then dried in air, and is finally laid in dilute sulphuric acid (1·50). After being properly washed and dried it is of a beautiful blue colour.

ON THE APPLICATION OF ART TO PHOTOGRAPHY.

Nothing tries the art-skill of the photographer so much as the posing of a group. Generally the amount of unsuccess is almost proportionate to the amount of attention and skill (?) which has been brouht to bear on the task. Then is exhibited the incapacity of photographers to bring into their pictures any motive of action, any intention, any story; or, if any motive be apparent, it is only as evidence of a good intention gone very wrong.

Where the figures of a group have been stacked up against a blank, bare background, in rigid and uncompromising up-and-downness, there is an un-care apparent which deprecates criticism, because it is known full well that the author of the picture is not likely to be affected by any critical strictures on his production.

Then there is the orthodox mo le of grouping two persons—generally this kind of picture is called for by a couple tending toward matrimony—the man seated looking to the right, the lady standing bolt upright behind and looking to the left, her hand resting affectionately on the shoulder of the sitter. A load of care seems to cloud the brow of the gentleman, who looks thoroughly wretched and out of place, mean, and uncomfortable, as if he felt it was not quite the correct thing to be seated whilst the fair and beloved one has to stand. This picture is generally outrageously at variance with every rule of art composition; and, apart from its mistakes, it has the merit of being thoroughly silly. Variety reverses the order of things in giving the lady the chair and directing her eyes to the right, the gentleman with his face turned to the left, standing stiff, awkward, and more uncomfortable than before. You know the sort of "composition" I allude to. Why in the name of all that is gracious are such things made?

Then as the number of the group is increased so does the monstrousness of the exhibition. The family group, for instance, introducing the last new baby! The group of good fellows who are out on an expedition of fun! Well, these things as a joke may have their ordained place in the economy of providence, and may be smiled upon as a joke—not, perhaps, of the most refined kind, but still a joke! To art, however, it is an insult, and photography cannot but suffer in being made the vehicle of such pleasantries.

Groups are at best very difficult of artistic arrangement—primarily, from the peculiarities and shortcomings of the photographic lens and the necessity of arrangement of each individual in the group in a special manner to secure the best points of likeness. Then, again, to get equality of illumination and sharpness—points most difficult of attainment, and increasingly so as the number of the group is enlarged. But in an artistic sense all these difficulties assume such gigantic proportions as to render almost impossible any reasonable motive or intention in the posing of the group.

The great art in composing a group is in so managing the arrangement of the figures that they may have some reason for being placed together—some definite and perceptible relation to each other. It is *something* when, as in photographs of a certain stamp, a bottle and glasses placed on a table appear to supply this motive for the sitting; but then, generally speaking, everybody is looking everywhere rather than at the bottle, and even this not too-elevated *raison d'être* is lost. The group has the appearance of being disturbed at an orgie by an earthquake or explosion.

There should be some rational bond of union between the members of a group—something in which they are mutually interested. This, it need hardly be said, were, as a higher claim of art, better *suggested* rather than portrayed. The figures should not be scattered over the plane of the picture, but skilfully massed together. The consequence of too great scattering is that the eye is worried in seeking out the portraits, and thus the intention of the composition is killed.

I have dwelt somewhat on the effect of heads being turned in opposite directions, nor do I desire to suggest that all the heads should be turned to one point. It is not necessary, even where a conversation is suggested, that the pictured speaker and listener should directly face each other. In real life, and in important conversation, we often find the faces slightly averted, but still there is an attitude of attention and earnestness maintained through all.

I have seen some photographic groups that were pictures, *but not many.* Wm. Heighway.

—*Photographic Rays of Light.*

Our Editorial Table.

English Landscape Art in 1878.
By Alfred Dawson, F.R.A.S.

Mr. Dawson takes a more hopeful view of art progress than he did in his review of the position of landscape art last year. While he believes artists to be truer to nature, there appears to him to be room for complaint on that most important point—dignity of subject. The meanness of many of the landscape subjects is, indeed, something for condemnation. He passes in review the Society of British Artists, the Grosvenor Gallery, the Royal Academy, the Old Water-Colour Society, and the Institute of Painters in Water Colours. Mr. Dawson's strictures are racy, and bear evidence of thorough honesty. To the majority of his readers they will stand approved on account of their truthfulness.

Manual of Microscopic Mounting. By John H. Martin.
London: J. and A. Churchill.

This useful work has passed into a second edition, and it may very safely be affirmed of it that it has an important career before it. For ourselves, we gratefully place on record the fact that we have received much benefit from a careful perusal of Mr. Martin's practical lessons in the selection and mounting of objects for microscopic study. To photographers who pursue the fascinating occupation of reproducing on a large scale the wonders of the minute world this work is simply invaluable, for we need scarcely say how much the beauty of an object is enhanced by being properly and tastefully mounted. Mr. Martin adopts the useful *rôle* of not aiming at fine writing, but of imparting sound, practical knowledge. It was only the other day that we wished to prepare some blood corpuscles for photographing. Previous to doing so we consulted this work, in which we found the following lucid directions:—"The best method of mounting so as to show the corpuscles of blood well is to take a drop of fresh blood and spread it evenly, in as thin a layer as possible, over the centre of a glass slip, and allow it to dry; then mount in the dry, transparent method, or use the vapour of a two-per-cent. solution of osmic acid; then apply one drop of acetate of potass, and cover with thin glass as usual. * * * In spreading them evenly and thinly it will be as well to use a small piece of thin glass moved over the centre of the slip with a circular motion." There is more on this subject, but what we have quoted suffices to show the practical manner in which tuition is imparted.

One of the finest objects that can be shown by means of polarised light is a salt with which photographers are most intimately acquainted—the bromide of cadmium. We have failed in preserving the crystals, when prepared for the microscope, by means of Canada balsam; it absorbs the water of crystallisation, and by leaving the arborescent formation anhydrous destroys its beauty. From this work we learn that castor oil is the proper medium in which to preserve and mount such crystals.

All microscopists recognise the charming appearance of "crystals of silver" when mounted as an opaque object. This name, although in common use, is not quite correct. *Arborescent metallic silver* conveys a more accurate idea of its physical condition. To make this lovely object Mr. Martin recommends that a piece of copper foil be placed on a glass slip, a slight wall of wax made round it, and a little nitrate of silver poured into the cell thus formed. He follows this up by the requisite directions for washing and mounting the crystalline or arborescent deposit thus formed. While making some experiments in this direction we found that the finest crystals, both in form and colour, are obtained when a small bit of tin is placed in a solution of nitrate of silver. The reduction of the precious metal takes the form of a tree with branches of dazzling whiteness and singular beauty. This experiment should be tried by every photographer possessing a microscope, even if it be one of the most common class.

The work under notice is one of great utility to the microscopist, and, as we have said, it possesses exceptional value for the photographer who, incited by the noble examples in the last photographic exhibition, devotes his attention to this department of photographic art. It is copiously illustrated and well "got up."

Carte Portraits. By Silvester Parry.

Mr. Parry has sent us a selection of beautifully-executed *carte* portraits, showing fine modelling and softness. We should, however, have greatly preferred receiving prints from the negatives before they had been entrusted to the hands of the skilful retoucher, who has undoubtedly left his mark upon the faces of his sitters. But whether it is to science or to art these prints are mainly indebted they are certainly charming productions. Among the "subjects" is a fine dog, who has been instantaneously "caught." The expression is capital.

The University Magazine.
London: Hurst and Blackett.

The illustration in the August number of this popular monthly periodical is Mr. Charles Darwin, F.R.S. It is from a negative by his son, the recently-elected Honorary Secretary of the Photographic Society of Great Britain. The biography and photograph are alone sufficient to cause this number of the *University Magazine* to be greatly sought after.

In an article, *An Aryan Ancestor*, presumably by the accomplished editor, those who have had doubts as to difficulties in understanding the distinction between definite numbers of days as expressed by writers in the Sacred Scriptures and what our more advanced common sense tells us is proper, will here find a very satisfactory explanation of apparent discrepancies.

Meetings of Societies.

BERLIN ASSOCIATION FOR THE CULTIVATION OF PHOTOGRAPHY.

An ordinary meeting of this Society was held on the 21st June last,—Dr. Vogel in the chair.

A provincial member sent some prints which were covered with numerous small brownish-yellow spots. He had been troubled with these spots for a long time back, but could not attribute them to the paper, as he had tried various sorts without getting rid of the spots, which made their appearance in the toning bath. He had, therefore, orwarded the prints, and asked the advice of his *confrères*.

Herr Prümm thought the cause of the failure lay in the use of too strong a gold bath.

A letter from Herr Herrmann was then read, in which he gave an account of a Siemens' dynamo-electric machine which furnishes a light equal to that of 4,000 to 6,000 candles, the cylinder performing 650 revolutions per minute. This machine is used for producing electric light by which to photograph.

Herr Prümm said that, in consequence of the improvements introduced into the dynamo-electric machine by Herr Siemens, electric light would soon be much more used than one would have thought possible a short time ago. He then spoke at some length of its applicability to the lighting of streets, &c.

The President then remarked that Herr Siemens was convinced that in time electricity would be laid on in houses like gas and water, and be used for both lighting and cooking as well as for motive power for various purposes.

Herr Prümm gave an account of his visit to the photographic department of the Paris exhibition and of a visit to Herr Voigtländer's establishment in Brunswick, both of which were listened to with marked attention.

The President then read a letter from M. Boissonnas about M. Klary's rapid negative process now being exhibited at the studio of M. Franck de Villecholes, Paris, and advised any of the members of the Society who might be visiting Paris to call at 18, Rue Vivienne, and report on their return to Berlin. He (the President) himself thought that, though sensitiveness might be increased by an addition to the silver bath or collodion, it would most likely be at the expense of the permanency or some other valuable quality in the picture.

The meeting was shortly afterwards adjourned.

Correspondence.

A Visit to the Blue Mountains.

"Once in a blue moon," was an expression that I remember having heard when I was young, but I really never anticipated being in its vicinity. I am not sure, however, if I am not nearer to it now than I have ever been before. Now I fancy hearing you say to yourself, "What on earth has this to do with photography? This is a very natural question, and easily answered. I have been staying in the Blue Mountains and only returned to Sydney last night, having left behind me what I consider to be some of the most splendid scenery in the world. If you think my photographic tour interesting for your readers—*voilà mon histoire*.

The Great Western Line of N. S. W. runs through some of the most varied and interesting scenery in the country, and, passing by the mining and manufacturing districts, affords ample scope for the man with the "thing on three sticks."

The government here having decided to bring out a guide to the line, I received orders to prepare for a journey down west, and on the 11th of April, 1878, your humble servant, in company with the geological surveyor, Mr. E. Wilkinson, and his able assistant, Mr. H. Young, and party, took his seat in the 9 a.m. train for the Blue Mountains. We soon left the queen of cities behind, passed rapidly through its varied charming suburbs, stopped a minute or so at Paramatta (the land of fruit, especially oranges), and by 11 o'clock found ourselves mounting the zigzag. We had to get up to the pass on the mountains—a height of about 4,000 feet—and to do this the train has to travel up stupendous works called "zigzags," which are cut out of the side of the mountain. Nothing can possibly exceed the effect of wonder that these gigantic works produce. It seems as if the genius of man had been in a severe contest with nature, for one hardly knows which to admire most, the beautiful forest of trees all around, mountain after mountain covered with the renowned eucaliptus, or gum tree, while here and there are to be seen the malleluca, acacia, banksia, casuaina, &c., &c., broken up in a thousand places by huge masses of rocks of the most fantastic shapes and colours, with innumerable chasms or gorges making so many valleys that seem filled with a most exquisite blue atmosphere (from whence comes the name "Blue Mountains"), whilst in the now far distance we have left behind us is the lingering form of the plain, looking like a mere cloud, and one is lost in amazement at the extreme beauty of the scene, or at the masterly and superb work of man's creation that is frowning down on all around, so massive and immense that it seems to reign supreme—one of the greatest engineering triumphs of the present century

After leaving this never-to-be-forgotten wonder we pass through the lovely valley of Lithgow Bovenfels, of which you will hear later on. Suffice it here to say that this is the seat of the future Birmingham of Australia. Here are copper, coal, iron mines, iron works, smelting works, terra cotta manufactory, drainage pipe works, &c., and the Australian cloth manufactory (tweed); but our destination is the township of Tarana, so on we go for another hour, till we hear the welcome whistle of the engine, which bids us collect our coats, rugs, &c, and *nous voilà* at Tarana.

After breakfast we got the apparatus ready and started off for the Crown Rocks—a very fine ridge of rocks from where were first seen the plains of Bathurst. The story goes that in the days when the convicts were making the roads near here one of them escaped and made his way up the mountains. In the morning he climbed up the rocks and from the highest point he thought he could perceive the sea, imagining it to be the other side of the island. He at once returned to his officer, gave himself up, and told what he had seen. A party went out with him, and, being provided with glasses, found it was a most beautiful plain. He received his pardon, and the ridge of rocks was called "Evans's Crown" (after him). Since then Bathurst plains have become very valuable, Bathurst, the city of the plains, being one of the most flourishing towns in N. S. W.

We got up to the rocks, and were not long in getting a few very good negatives. I worked almost entirely by the wet process, but have taken out some of your latest coffee plates, with an alkali. In the evening we forgot all about photography, took out our guns, and by most beautiful moonlight went in search of some opossums. These pretty animals sit up in the branches of trees, and by getting them between you and the moon you get a very good shot at them. Their skins shine like silver from the reflection of the moon.

At ten a.m. the next morning we got everything packed and started off in buggies for Oberon (please not to confound this with a city of the same name in fairy land). We took our portmanteaus with us in the buggies, as also my chemical chest. The apparatus, &c., tent, and extra stock were packed in a spring cart, while the heavy materials and camping arrangements followed in a bullock team, my assistant coming on behind to see that nothing was forgotten. Oberon is a picturesque little town with two comfortable hotels, two places of worship, and several shops or stores. On Tuesday, all being reported in "ship-shape," we left for the Great Fish River caves. We got now further into the bush, and soon were going not on roads but tracks. We passed two teams—one of twelve and the other of ten bullocks—up hill and down valley—jolt, jolt, in and out the trees, full of interest to the "new chum" (all new arrivals are new chums), and at last, at five p.m., we reached the edge of the ridge from where we were to make the descent to our camping ground and the mouth of the caves.

Have you ever, Messrs. Editors, stood on the golden gallery above the dome of St. Paul's Cathedral? If so, imagine that instead of a smooth surface it was covered over with massive pieces of rock, and instead of a distance to the bottom of some 300 to 400 feet it was 1,800 feet; you will then be able to picture to yourself the task we had before us. Yet what a beautiful task! Nature seems to have here chosen one of her most lovely spots, for before you lies a vast amphitheatre, mountain after mountain covered with the everlasting gum tree, mixed up with rocks as grand as they are immense, and rising up in all directions, making huge, ugly precipices eight to ten hundred feet deep—such are the sights which greet the eye every now and again. Language indeed can scarcely describe the feelings one has on first becoming acquainted with these scenes. What immensity!

The buggies were unpacked, and the horses charged as pack horses. Each one leading a horse, we begin the descent. The way is tortuous and the incline steep, varying from 1 in $1\frac{1}{2}$ to 1 in 30. All things come to an end, so did our downward steps, for soon we saw in the hollow beneath us the camp fires of the party of surveyors from the Department of Roads and Bridges, who already had their tents pitched. Down we are. More fires are made, billies (a sort of camp kettle) are soon out, and a tent put up for the geological surveyor, his assistant, and myself.

The next day we were up by times and soon got to work. I only managed to get five negatives with hard work all day, for only those who have experienced such work can understand the extreme difficulty, being sometimes obliged to carry the plate up some 700 to 800 feet of rocky heights, it being impossible to get up a tent and chemicals. On more than one occasion the plate was three-quarters of an hour between preparing and developing. In these cases I invariably prepared my plate very rapidly, only allowing time for the formation of iodide of silver, and allowing the free silver to act on the bromide during the interim. I exposed coffee dry plates, but fear that the dampness down here will make them anything but dry.

On the morrow I made the descent into the caves with the surveyors. The entrance to the new cave is situated at about a mile from our camp, and is reached by winding along the ridge of one of the mountains, descending on the other side, when you come to an opening in the rock. This is about fifteen feet high, and in we walked to the antechamber, where we arranged our dress and lit our candles. *Apropos* of dress, any dirty old clothes will do very well, but having made the journey I should recommend a sack as being the best thing. Make a hole for the head to go through and two for the arms; when in position sew up round the legs and proceed. This matter arranged, we commence our journey along a sort of corridor, with a very rough, rocky bottom. In a minute or so the end of this passage is reached, and the first ladder has to be descended. We eventually find ourselves at the bottom, and can now look round and by the dim light of our candles enjoy the magnificent sight before us. It is an immense cave of from 150 to 200 feet; masses of rock lying pell-mell in every direction, varying in size from five to fifty feet, with shapes the most fantastic, meet the eye on all sides. Imaginary beings are called into view as you hear the cry of the bats and see them in multitudes. The hall traversed, we again find ourselves in a sort of passage very difficult of access, the rocks being slippery and steep. This ushered us into the cathedral—a beautiful hall full of fine stalactites and masses of thin rocks, resembling sheets thrown over a wall. In another part one might imagine himself in a vast theatre, the stage being formed by another and smaller cave, supported on either side by pillars of limestone and stalactites. It is from this point that one of the most difficult parts of the *trajet* is reached—the descent to the Bride's Cave. The great peculiarity of this cave consists of the singular formation of crystals, being shaped in the most fantastic manner possible; but it hardly pays for the amount of exertion (to say nothing of the fear) taken to get to it. The return from the cave was simply a tremendous bodily exertion.

Off again—climbing, squeezing, tumbling, falling, until you reach the couch. Here we lit some magnesium and saw the big cathedral, which is surpassingly grand and terrible. Looking into this darkness made light one sees, as it were, a long, thin, black-looking line reaching from almost the top of the cave to the bottom, but not in a straight line making an elbow (thus $<$). This the guide calls the "big ladder." If he had called it the "devil's ladder" it would be very appropriate, for it is fearful to see oneself standing there in mid air and right over an immense water hole. Up this we had to go to reach the Lurline Cave, and I must confess that I was not sorry to find myself safely landed on the pulpit rock, thanks to the kind help of Mr. Young and Mr. Cambridge, for there was only a thin metal wire ladder between your correspondent in possession of his body *en bon etat* and his having every bone in his body broken. More scrambling up and the beautiful Lurline Cave is reached. After examining it well to select some spots for photographing we again started off, and once more found ourselves at the mouth of the caves; but daylight had fled, for we had spent twelve or thirteen hours in these mysterious caves. Along the solitary track we wind our way, soon see our camp fires, and hungry and tired out we take a hearty meal and turn in. After two days' riding we reached the Lithgow valley—as I have already said, the future Birmingham of New South Wales.

The town has been quite recently built. Six years ago there did not exist a single house; now there are several good hotels, a bank, two churches, stores, and a goodly sprinkling of houses. The manufacturing part consists of iron works, rolling machines, terra-cotta works, brick making, copper smelting works, and several important coal mines, as also a tweed or cloth manufactory at Bowenfelt, about a mile and a-half from Lithgow. I commenced my photographic labours with the Lithgow valley colliery and terra-cotta works, and got some very nice negatives. The next day the Lithgow valley iron works became the object of my solicitude. The Hermitage, Eskbank coal mines, and copper smelting works took me another day; then came the tweed factory, and away off in a buggy for Hartley, the scene of the kerosene shale mines, from which is made the kerosene oil. I left this very interesting place two days after for the great Zigzag, where I obtained some very nice views. I now prepared my apparatus for two very important pieces of work. The first of these, called "Govett's Leap," is reached by following up a track from Blackheath through an uninteresting scrubby forest for about two miles, when you find yourself at the edge of a gorge hemmed in by perpendicular cliffs of sandstone lying in horizontal strata varying from 600 to 800 feet high. The width of the gorge is about one and a-half mile, and its length in a straight line three and a-half miles. The waterfall known as Govett's Leap is about 600 feet deep. From the nature of the place photographs give but a very poor idea of its grandeur, it being impossible to get good positions to photograph it from.

We next visited the falls of the Weatherboard. An hour's walk brought us to the edge of the cliffs, where we pitched our tent, and a descent of some 200 feet allows one a fair view of the falls. The scenery around partakes of the same character as that of Govett's Leap, but if possible more grand, the surrounding masses of rocks being more perpendicular and on a larger scale. As there was very little water the effect was not such as I had anticipated. I obtained only two negatives, taken at great disadvantage.

It would only be repetition were I to tell you more of Blue Mountain scenery. Suffice it to say—more particularly for those who know the country—that from the Penrith station to Bathurst I visited all the spots of renown on the western line, including the picturesque Weatherboard cottages of Sir Henry Parkes, K.C.M.G., Sir James Martin, Dr. Badham, and others, all of whom showed me the greatest kindness and hospitality. Picton, Goulburn, Murrum-burrah, Cootamundra, and Bethungra (all on the southern line) afforded a little work for the camera, but this part of the country is not so favoured by nature as the west. The unsettled state of the weather now compelled me to make a halt at about 270 miles south of Sydney. This halt proved to be a final one, so with wind and rain I turned again towards the Queen of the Pacific, and have arranged my negatives, from which I enclose a few unmounted prints.

I here give, for the benefit of your readers interested in the subject, the necessary formulæ for making the plates to be engraved by a needle point, and subsequently treated by photolithography or any engraving process preferred. I see by a contemporary the process is likely to be called by a new name and brought forward as new. I worked it in Belgium nine years ago. The original process was by M. Toovey. We used to call it "heliolithographic" in Belgium, and worked it with success among the artists for a time, when it declined as rapidly as it had taken root. This was in 1870-1-2. Here is the formula:—

White wax	80 grains.
Lithographic varnish	3 drachms.
Benzole	$3\frac{1}{2}$ ounces.

Dissolve the wax in the benzole and add the varnish; clean some glasses of any size, as required, and spread a very little of the solution on a stone, such as is used for rolling-up printers' ink. Now, with a lithographic roller, lay on to the glass a *very thin* coating of this varnish while still wet; shake over powdered orange chrome through a very fine sieve, and, when covered, dust it about on the plate with a dusting brush, softly and with a rotary motion; let it dry, when flow over it the following:—

Turpentine	$3\frac{1}{2}$ ounces,
Lithographic varnish	$1\frac{1}{2}$ drachm,

and let run back into a bottle, as when varnishing. When evaporated dust over, in the same manner as already given, the white colour known as "blanc d'argent;" place it aside to dry, when it is ready for the etcher or engraver. This is done by a needle point or any other instrument preferred; it is then treated by photolithography or any of the engraving processes. The photolithographic process of M. Toovey gives results equal to engraving, and, when printed on *papier de Chine*, the prints have often been taken for engraved proofs. I am now working out another mode of preparing the glass, which I will describe in my next communication.

The carbon process is decidedly making way. We have been favoured with a visit from Mr. B. J. Edwards, who has been giving lessons in enlarging and carbon printing to two or three of the leading portraitists here. He is now in Melbourne, and intends making another short visit prior to leaving for the old country again.

I think a new era is opening to us poor black paper printers. One thing is certain—that carbon printing is making good headway, and bids fair to become a general mode of printing. L. Hart.

Sydney, May 12, 1878.

FADING OF CARBON PRINTS.

To the Editors.

Gentlemen,—With reference to the very interesting and important discussion which is now going on in your pages with regard to this subject, may I be permitted to refer to some very fine carbon prints which have been in my possession for many years?

They were sent to me by Mr. J. W. Swan, in the very early days of carbon printing, before the birth of the Autotype Company. They have been hanging framed and glazed in my drawing-room exposed to the light at all times. They are wholly unaltered, and the whites are as pure and clear as the day they were executed. Very fine specimens they are of the process, and will compare with anything of later date.

I may add, too, that I have some charming specimens of the Woodburytype, also of an early date, and these, hanging under similar conditions, are as fine and brilliant as they were when first turned out—no fading or alteration in colour whatever.

I see the Autotype Company attribute the deterioration in carbon prints to the paper. Whether this be so or not I do not venture an opinion, but I simply refer to the above specimens as proof that carbon prints, whether in the form of carbon printing proper or in the form of Woodburytype, do not necessarily go to the bad.—I am, yours, &c.,

Society of Arts, John-street, Adelphi, P. Le Neve Foster.
London, W.C., August 9, 1878.

THE FORTHCOMING PHOTOGRAPHIC EXHIBITION.

To the Editors.

Gentlemen,—I do not think it possible to have passed a more suicidal resolution than that recently adopted by the Photographic Society of Great Britain, by which exhibitors not being members of the Society are to be charged for wall space. A very large proportion of exhibitors are amateurs who gain nothing by exhibiting, and they have already heavy charges for framing, printing, carriage, &c., and all for the benefit of the "Parent" Society (defend me from such a parentage!).

If the rule be permitted to stand good I think the amateur contingent will be very small. I for one shall be conspicuous by the absence of my pictures, and I know others who will follow my example.—I am, yours, &c., Baynham Jones.

Cheltenham, August 12, 1878.

EXPOSING BY ELECTRICITY.

To the Editors.

Gentlemen,—The "Peripatetic Photographer," in his notes this week, has fallen into an error which we must ask your permission to correct.

Referring to our patent electric shutter as "a very pretty idea, and one that can very easily be carried into practical effect, especially as regards the requirements of the professional photographer who keeps his battery in a garden, or cellar, and 'leads on' the electric current into the operating-room by means of a small wire," he adds the two queries—"But what about those who have neither garden nor cellar nor even a spare cupboard in which to place the battery so necessary to the electrically-moved lens cap? What about those peripatetic photographers, like myself, who are continually finding themselves here, there, and everywhere?" He then replies to these queries under the impression that it is necessary to "conceal a tiny, yet powerful, battery inside the camera itself;" and here is the error, for this would be obviously objectionable, inasmuch as the slightest fume from such a battery so placed would doubtless affect the sensitive plate.

As manufacturers of the instrument in question we have met all the requirements perfectly by adopting the use of a small constant battery, fitted into a wooden case, detached, and placed upon the camera-stand below the instrument, but connected with it by conducting wires, so that the complete apparatus is as portable as it is simple.

Any slight fumes of the life-giving principle, *ozone*, which might possibly arise from the battery would in the operating-room be rather advantageous than otherwise.

We are not aware whether our "peripatetic" friend has himself seen the working model with which we demonstrate the action of our electric shutter, but if not we shall be happy to show it to him, and to explain (as is always done by the exhibitor) that the small carbon battery which we employ in the model is only used for the sake of greater portability, and is *not* the form of battery which we supply with the instrument. When the specification of our patent is published this will be fully described.—We are, yours, &c.,

Southport, August 10, 1878. D. H. Cussons and Co.

EXCHANGE COLUMN.

I will exchange head-rests, cabinet camera, lens, &c., for posing chair or sciopticon.—Address, Fred. Daking, Bramford-road, Ipswich.

ANSWERS TO CORRESPONDENTS.

☞ *Correspondents should never write on both sides of the paper.*

Hector and Carboniensis.—Received. These, with other correspondents, in our next.

Tyro.—The firm is a genuine one. One of the members is a practical chemist of high standing.

J. R. R.—You must apply to a manufacturer of bottles such as are used by chemists and druggists.

S. E.—It is not expedient that the matter be further inquired into. We, at anyrate, decline to waste time over it.

G. M. (Ireland).—So far as we at present recollect, Mr. H. J. Newton has never exhibited any reticence in publishing freely his researches in collodion emulsions.

J. R. R. S.—The negatives are hopelessly bad; destroy them, and do not waste any more time over them. Under no circumstances will they ever produce good prints.

James Mann.—Mr. Rutherfurd was in this country very recently. We do not know his address, and we are not aware if his large photographs of the moon can be purchased.

J. P. H.—A clear, sparkling solution of gelatine can always be obtained by mixing a little albumen with such solution, and then raising the temperature until coagulation takes place.

J. E. G.—At present we are quite unable to say whether the process will be useful or not. It is probable that we may know all about it soon, after which we shall communicate with you.

Thos. Hunt.—Add zinc or silver filings to the red-coloured collodion and shake well up. This will reduce the intensity of colour, but we do not imagine that it will improve the working of the collodion.

S. Matthews.—The negative is certainly sadly deficient in sharpness, but it appears as if it were caused by imperfect focussing. You must make further trials, and, should you consider it necessary to write again, supply more detailed information than you have done.

C. M. D.—The remedy for the evil is simple enough. Now that the weather is hot remove the glass stoppers from the collodion bottles and substitute for them good, sound corks. No fear need be entertained that they will be blown out by the elastic vapour generated by the heat.

A. C. P.—Make a moderately strong solution of bicarbonate of soda, and having poured the nitrate bath solution into a clear bottle add slowly, and with intervals of shaking, enough of the soda solution to render the silver slightly opaline. Then filter and it will be in good condition.

Geographer.—We know that it was the intention of Mr. John Thomson, whose name is so well known as a traveller in China, to have proceeded on Saturday last to Cyprus, but whether he started at the time appointed or not we have not yet been informed. He was to have employed both the wet and dry processes in obtaining transcripts of scenery and life in Cyprus.

Geo. S. Stevens.—1. While the method described for ascertaining the focus of a lens is approximately accurate, it is not absolutely so. It is one of those methods that may be designated as practically, but not theoretically, correct. Had there been no refraction of the ray by the lenses it would have been quite right. If you have access to our Almanac for 1870 you will there find described a method for ascertaining the true equivalent focus of any combination.—2. The matter is under consideration.

Aliquis.—The only conditions required are—1st, the employment of a non-distorting lens; 2nd, the careful levelling of the camera; and, 3rd, the rotation of the camera upon its stand to such an extent that the subjects which are to form the line of junction between the two pictures shall in each be precisely equidistant from the centre of the ground glass. Photographs taken in panoramic perspective are much more satisfactory than those obtained in the manner you propose adopting, and in which the perspective is of a decidedly composite order, consisting, as it will do, of a mixture of plane and panoramic projection.

Received.—Robert Challenor (Liverpool). In our next.

METEOROLOGICAL REPORT.

Observations taken at 406, Strand, by J. H. Steward, Optician.
For the Week ending August 14, 1878.
These Observations are Taken at 8.30 a.m.

OPALOTYPES ON EMULSION PLATES.

Of the numerous uses to which photography is applicable there is perhaps not one to which emulsions are better adapted than to the production of the class of pictures known as opalotypes, though it may be further said that no process requires a more complete alteration of its working conditions in order to secure success in that special branch of the art. This may not be immediately plain to the great bulk of emulsion workers, who, as a rule, do not belong to the class most closely interested in opal work, and who may, therefore, be presumed to lack an intimate practical acquaintance with the particular requirements of that style of picture.

It would seem at first sight that the peculiarly-delicate image obtainable with alkaline pyro. would prove all that could be desired in the rendering of softness and delicacy in the picture, and that a judicious use of restraining bromide would readily give any desired degree of brilliancy and boldness to the result. But, alas! for the vanity of theoretical anticipations! Under ordinary conditions—that is to say, employing the ordinary description of emulsion and the method of development usually adopted in landscape work—the result is found to be the very opposite. We have the choice between a delicate, flat picture, cold and poor in tone, and one in which, though the colour may be satisfactory, the prevailing characteristic is heaviness, the shadows and half-tones being inextricably jumbled up together with but the smallest amount of contrast.

The fact is that alkaline development—at least alone—is scarcely suited to the production of the class of image required. It is certainly possible with a peculiarly-favourable description of negative to secure a passable, or even a satisfactory, result; but with the majority of negatives this is not the case. Opalotypes require an *intense* image—that is, one which, while thin and transparent by transmitted light, presents strong contrasts when viewed by reflected light. Now the image produced by means of alkali is destitute of these qualities. In its earlier stages it is thin and delicate when viewed as a transparency, but totally devoid of surface colour; and in order to obtain the necessary strength to render it available as a positive by reflection the original delicacy of the half-tones is entirely lost. The difference between the two effects may be compared to that between a print upon a weakly-salted plain paper and to a paper carbon print made with special transparency tissue; or in one case softness without vigour, in the other strength without delicacy.

If we avail ourselves of silver development, or even only intensification, the result is considerably better—indeed, with many emulsions developed with alkali and intensified (or *toned* would be a more correct expression) with silver very perfect images may be obtained if the operation be conducted in a proper manner. But here another difficulty crops up, for it is found that emulsions of pure silver bromide do not work well under acid development unless free silver be present upon the film at the time of exposure; that is to say, the emulsion must contain free silver and be employed in the moist state, or, better still, the plate must be washed and flooded with a solution of silver before exposure. If used in the dry state and the silver necessary to development added to the developing solution itself the result is invariably feeble and unsatisfactory, though in this respect a bromide plate prepared with the bath behaves in a better manner.

In order to gain the full advantage of silver development it is necessary to introduce iodide into the emulsion. It is a point upon which there are divergences of opinion as to whether for landscape work the addition of iodide is an improvement or the opposite; but for opal purposes there can be none of the usual objections to its employment, while the peculiar properties which it undoubtedly confers upon the emulsion are just those which are sought for. Thus the more ready adaptability of a bromo-iodide emulsion to silver development is one point in its favour, while the peculiarly clean and vigorous image by reflected light under alkaline development gives it another claim to the suffrages of those who prefer that method. The slightly-increased trouble in preparing such an emulsion will scarcely, we should imagine, militate against its use when its advantages are proved, as they must be, by a single trial.

The mode of printing to be followed, whether by contact or in the camera, will to some extent affect the choice of emulsion to be employed; thus those who confine themselves to the production of enlargements or other descriptions of work in which the camera is utilised have the option of employing wet plates, in which case, for the reasons we have stated, a simply bromised emulsion specially prepared will answer all purposes. Those who print by contact are confined to dry plates, and we should strongly recommend in their case the admixture of a certain proportion of iodide, which will not in the slightest degree interfere with the capabilities of the preparation when used wet.

The only special preparation necessary in the bromide emulsion is to avoid any attempt at rapidity—*i.e., extreme* rapidity. An excess of from half-a-grain to two grains of soluble bromide should exist in the emulsion; if it is to be employed wet with a wash of silver the larger quantity will be preferable, but otherwise the smaller will be found sufficient. The collodion should be allowed to "ripen" in the bromised state or the results will be cold and poor, owing to the absence of the so-called organic silver compound. Newly-made collodion works very differently in this respect with excess of silver and of bromide respectively—at least when the latter is in excess throughout. The quality of the emulsion as regards cleanness and brilliancy of image will be further improved by the following mode of sensitising. Having calculated the necessary quantity of silver necessary to leave the desired excess of bromide, add three-fourths of it in the usual manner dissolved in hot alcohol, and after thoroughly mixing allow it to stand for several days, or even weeks, to mature. In this state it will keep unchanged for months, or perhaps indefinitely, and only requires the further addition of the remaining one-fourth of silver to fit it for use in a few hours.

If the opposite course be pursued and the emulsion be permitted to rest under the action of free silver for part of the time it is sensitising, it will be necessary not only to acidify it but also to allow a considerable time to elapse after the final addition of bromide before using it. Unless this be attended to, though possibly it may not "fog" in a sense which would prove objectionable in landscape work, it will produce a sufficient "veil" to entirely destroy the purity of an opal.

Having prepared the emulsion the remainder of the work is simple enough. After coating the plate it is immersed in a dish or dipping bath of any ordinary water not badly contaminated with chlorides or carbonates. A plain thirty-grain solution of silver rendered slightly acid is then flowed over it two or three times, and it is ready for exposure, requiring the same subsequent treatment as a wet bath plate, without the corresponding liability to stains and uncertainty. As regards the development of these plates it is impossible to say much within the limits of this article, beyond reminding those who have had no experience with plain bromide plates that they differ in the style of treatment required from bromo-iodised films. Not that the results are in any way inferior when a slight experience has mastered the peculiarities; but we think it well to advise our readers not to relinquish the attempt, as many others have done, in trying bromide plates for the first time, because they do not succeed at the first trial with their ordinary developing formula. Either iron or pyro. may be used, but the latter gives the best tone.

Instead of applying the wash of silver, the plate upon coming from the water bath may be exposed at once, and developed with alkali, such an emulsion as we have described giving, with silver intensification (or toning), very pleasing results, though rather cold in colour. In the latter respect an improvement may be effected by applying an organifier to the plate either before exposure or immediately after. Tannin, coffee, tea, or a very weak solution of quinine, may be used according to the tone desired, the last giving a very pleasing purple tone, and after a little practice rendering the use of silver unnecessary.

The preparation of the bromo-iodide emulsion requires no very special comment. If for employment wet it must contain soluble haloid in excess, while the contrary is the case if dry plates are to be used. The excess of haloid renders it very insensitive unless treated with the wash of silver as we have directed, particularly so when used dry. It is remarkable that, unlike a bromide emulsion, an iodised one requires a considerable excess of either silver or haloid to keep the iodide in suspension; if the proportion be nearly balanced very great trouble will be experienced in securing proper emulsification. The proportion of iodide to bromide is, for opal purposes, immaterial, but the former may be raised considerably above the standard usually recommended in landscape emulsion.

The modes of development applicable to bromo-iodide emulsion are the same as for bromide, but the behaviour of the plates will be found to approach more closely to ordinary bath plates under silver development; indeed, where the wash of silver is given, previous to exposure, it is difficult to see in what respect the emulsion differs from the bath plate. The dry bromo-iodide films, if the proportions of iodide and bromide be about equal, or if the former be in excess, are also amenable to pyro. and silver development, which is, perhaps, *the* best mode of treating them; unless rapidity be an object, iron and silver do not answer so well. Where greater rapidity is desirable with the dry plates, either alkali or ferrous oxalate may be used; the presence of the iodide altogether changes the character of the image, and in the majority of instances renders silver toning almost, or quite, needless.

In all cases where alkali is to be followed by silver it is important not to carry its action too far. Let a full exposure be given (without overdoing it), and employ a well-restrained developer in order that the image may appear slowly. As soon as the required amount of detail is out wash off the alkali and proceed with silver for the remainder of the operation. If too much be done with the alkali, though the image may appear clear and vigorous, it is nearly certain to acquire a slight veil, or to have the shadows rendered heavy under the subsequent action of the silver.

We have seen a considerable quantity of opal work produced by means of emulsions, and can truly assert that it is in no way inferior to the best that can be produced by other means. The testimony of two professional photographers, who have entirely discarded the bath for this class of work, is to the effect that the change has brought about a saving both in time and money, and is also conducive to more uniform results.

DISCOLOURATION OF PAPER IN CARBON PRINTING.

The useful discussion upon the "fading" of carbon prints has already had its beneficial effects in causing special attention to the quality of paper employed as the final support for the picture, as a reference to our advertising columns will show. It is well that it should be so; for, at least with work not possessed of that extreme glaze so much sought after by some, the tendency of carbon prints, even when first executed, is to show a little deficiency of purity in the whites and the highest lights. This fault is one to be guarded against as much as possible, for in carbon pictures possessing a low glaze there is a general tendency to flatness, than which nothing is more likely to prejudice a photographer against taking up carbon, accustomed as he is to the beautiful richness and depth of shadow, and the absolute purity of white of silver prints of all sorts.

The Autotype Company have laid a very potent spirit of destruction in their discovery of the discolouration by light of the paper itself, to discover which is practically to find its cure. May not silver printers also look to the same cause as the origin of some of the so-called "faded silver prints?" But hitherto no one has discovered a complete remedy for that special discolouration—the staining of the single transfer-paper when once the tissue has been squeegeed upon it. This is an evil of the first magnitude, and considerably restricts the range of carbon printing as to variety of application; but beyond this it is a positive loss to the brilliancy of the image, for though India-tint engravings may be instanced to the contrary, it is not a fair parallel, and such subjects as small carbon vignettes with white grounds are virtually relegated to the region of experiment.

We are aware that the evil may be evaded by avoiding the use of such tints of tissue as experience prove to possess these evil qualities; but our range of tints would then be too restricted. The proper course is either for the makers to provide us with the due variety of tints made with non-staining pigments or to find out some method of using the tissue so as not to stain, or of discharging the colour when it has stained in the usual manner. The latter is, however, next to impossible, for the agent which is to discharge the dye—as it may be termed—from the paper would be almost certain to take it away also from the body of the tissue pigment. We have tried many papers and looked at many prints, but have almost always been able to discern in a picture of a purplish tone the faint pink stain from the washed-away tissue in the highest lights. With such tints as the black to imitate engravings, sepia, red chalk, &c., this particular stain is naturally not observed, but we would have the whole range of possible tints available to the photographer, and this, we do not doubt, will ere long be done.

We can already hear in anticipation some of our readers pointing to the now well-known carbon picture—the chromotype—and asking if they were stained, and to them we would, in anticipation, reply that our remarks merely refer, as we intimate, to single transfer. As a rule when a double transfer is made the colour forming the stain will be found in the original support, and the double transfer picture almost free from stain or discolouration. But this should not be, as we consider there ought not to arise the slightest difficulty in this direction in the use of either single or double transfer at all. We have tried a number of experiments lately, but the only method which so far has enabled us to touch the stain without injuring the colour of the picture has been to flood the sheet with ammonia. It will often take almost the whole of the stain away. This we have found very useful in printing upon opal glass. We have rarely seen a good vignette in carbon with a white ground, and as this is a style of printing much liked for *carte* and other small work we are inclined to think that so far others have also found the difficulties to be too great.

There is, of course, one other cause for the prevalence of a slight tint upon the whites of the picture, viz., that even in the highest lights there is generally a film or skin of almost infinite tenuity, as, if there were not, we are inclined to think the tissue film must wash up and spoil the picture; and, no matter how slight the film, it must contain *some* colour, as it is the whole film itself, not the colour alone, which is washed away in the developing. The older the tissue the more pronounced does the tint become from this cause; and, as we have on a previous occasion pointed out, the use of old tissue possesses several advantages in point of half-tone and softness, &c., that we cannot dispense with the use of it.

There is, however, a possibility which has often been present to our mind, and which we here make note of, trusting some of the manufacturers may be able to utilise it. Seeing that a slight film of pigment, containing insoluble gelatine, is always found in the highest lights, which are to that extent degraded, would it not be possible to prepare tissue with a very fine and slight final coat or wash of gelatine containing no pigment at all, but in other respects just the same as the usual pigmentised gelatine? We should then get enough gelatine to stand a slight exposure to light without injury, and in which the binding skin—as we might term that portion present in the high lights—would be free from all colour, and so enable us to have either vignette or ordinary prints free from any stain whatever in the lights; for it might be anticipated that that slight portion of the pigment which ordinarily penetrates the paper in staining would be withdrawn by the new suggested plan. We present the idea for what it is worth to the makers of tissue, feeling assured that it contains the germ of usefulness.

It will, no doubt, be observed by those who have followed our argument that the gelatine might be added to the sensitising bath instead; but this would entail the necessity of too frequent change, as every carbon printer knows the tissue gives up some of its colour to the bichromate bath. Then we have another advantage: with "the new tissue" the sensitising bath would be kept so much cleaner and free from colour, except that naturally produced by the reduction of the bichromate.

RECENT PATENTS.

No. XII.—THE SCOTELLARI EXPOSING CAP.

We are at length enabled to publish the specification of M. Scotellari's lens cap for giving auxiliary exposures to the sensitive plate while in the camera:—

The object of this invention is to reduce the time of sitting during photographic operations.

The apparatus made according to this invention is applicable to and placed on the rim of the objective or lens of the photographic camera, so that the light has to pass through it on its way to the lens.

The shape of the apparatus is cylindrical, like a box cover or frame. At or about the centre there is an aperture, wherein some transparent substance is placed, but rendered opaque, and coloured either violet, indigo, purple, or blue, so as to allow a certain quantity of photogenic light to pass through.

A cover is provided which may be turned or slid over the aperture so as to shut out the light, and thus prevent the action thereof when required.

Seeing that this patent—which is dated 14th September, 1877—received provisional protection only, it lapsed in March last. On the subject of auxiliary exposures in general, and of this method of effecting such exposures in particular, we do not now require to say anything, this having been almost exhaustively treated several months ago.

No. XIII.—FLUID CONDENSERS FOR PRODUCING ENLARGEMENTS.

No patent could, of course, be obtained for a mere fluid condenser lens, such a form of instrument having been described long since. But in the form now to be described an element of novelty has been imported into the construction of condensers, consisting in causing a stream of cold water to be constantly passing through them. By keeping them cool in this manner a powerful electric lamp may be used in the production of enlargements.

With these prefatory remarks we now proceed to describe in detail the invention which Messrs. Warlich and Cadett have patented:—

This invention has for its object the production of enlarged photographs direct from negative or positive pictures, whether in pigments or otherwise, by means of apparatus to be used with artificial light or sunlight.

For the above purpose, when using artificial light, the patentees prefer to enclose the light in a box or lantern to prevent any rays of light that are not used in the production of the image from impinging on the sensitive surface employed.

A condenser is placed at the proper distance from the light to condense the rays thereof, the said condenser being hollow, so as to allow of being kept filled with water or other liquid, and by means of an arrangement of pipes water or other liquid or solution of any substance that may be considered fit for the purpose is made constantly or at intervals to flow through the said condenser for the purpose of keeping it cool.

The apparatus which holds the said condenser has also a similar arrangement, by which liquid can be made to flow through it for the purpose of keeping it cool.

Glass condensers, in place of the hollow condensers just described, can be used for the purpose of this invention, but in such case it would be desirable to interpose between the light and glass condenser a glass trough or transparent receptacle for water or transparent liquid, having arrangements for changing or flowing the water or liquid through the same. Such receptacle for flowing the water or other liquid can be formed by making one face of the lens a side for such receptacle, a plate of glass forming the other side of the trough; or the space between the condensers, when two or more are used, may be used as a water or liquid compartment.

In cases where the heat would be excessive a trough or transparent receptacle might be used, in which the picture to be taken is immersed in water or other fluid, which is kept circulating through the trough or receptacle, or is changed by means such as described. On the side of the condenser, from which emanates the condensed rays of light, and at a proper distance from the said condenser, is placed the positive or negative picture to be enlarged, and at a still greater and proper distance in the same line a lens is placed parallel and concentric with the said condenser. The condensed rays of light, on leaving the said condenser, pass through the negative or positive picture to be enlarged, according to the several densities of its different parts, and are then taken up by the above lens, the result being that an image of the above positive or negative picture is projected at a proper focus, and the said image is made to project upon any suitable surface sensitive to light.

When the electric light is used an arrangement is, or may be, employed for keeping the light central with the said condenser and lens, which it does by means of clockwork or otherwise, and utilising part of the heat evolved from the light.

In using sunlight the box or lantern used with artificial light is not necessary, and the rays of light are projected into the said condenser by the usual means.

FIG. 1.

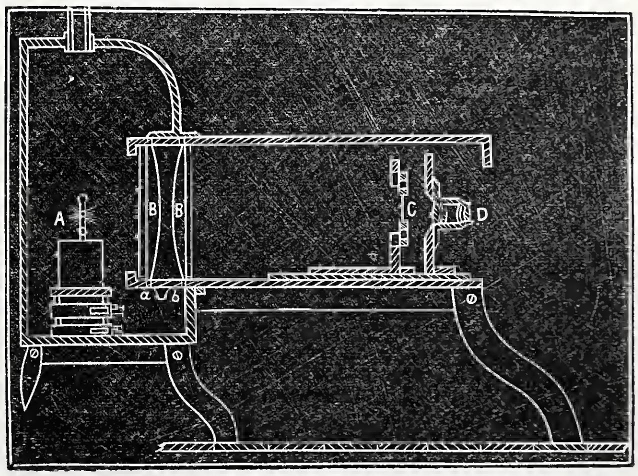

Fig. 1 shows in outline the arrangements for producing enlarged photographs.

Fig. 2 is a view in outline of arrangements for keeping the light central with the condenser or lens.

Fig. 3 shows a form of hollow lens.

Fig. 4 shows an arrangement of two lenses or condensers, with chambers at back and front.

Fig. 5 is a front view of *fig.* 4.

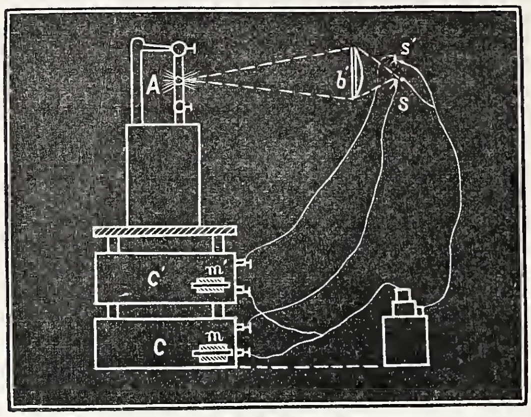
Fig. 6 is an arrangement with a separate trough or receptacle placed in front of the lenses.

A is the point where the light is placed; B, the condensers; C, position of negative or positive picture; D, lens or lenses placed parallel with the condensers B; E, position for enlarged negative.

It is to be understood that the drawing is simply for the purpose of exemplifying the method adopted, as the positions of the negative or positive picture, the lens, and the enlarged image depend entirely upon the operator and the subject to be treated.

The condenser or condensers B receive the rays of light from A, and such rays are condensed and pass through the negative or positive picture, C, to be enlarged, and are then taken up by the lens or lenses D, and projected at the proper focus to produce the enlarged image at E from the said negative or positive picture C. The condensers B are, as before described, hollow, to allow a continuous flow of water or liquid through the same, the water or liquid issuing in at *a*, passing upwards through one condenser, and thence by the pipe or other means conveyed down and into the second condenser at *b*. It thence flows upwards and out by a pipe or other means from the upper part. By this continuous flow of water or liquid through the condensers the same are kept cool and ensure the efficient working of the arrangements.

FIG. 2.

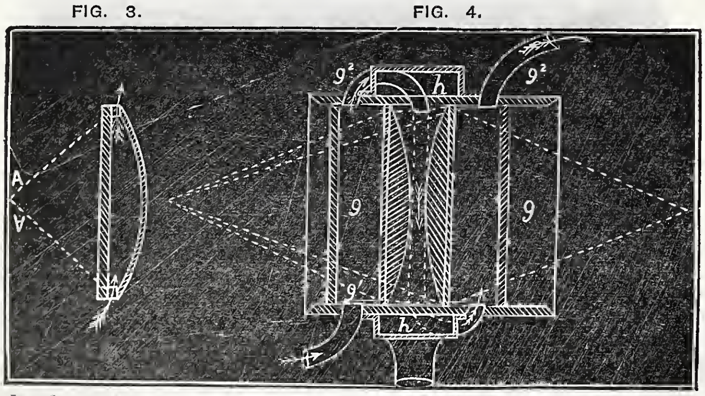


The arrangements shown in *fig.* 2 are placed so that they do not interfere with the rays from the condensers to the lenses, and such arrangements are for keeping the light central.

In any part within the path of the rays is placed a lens b^1, in front of which and at the focal point on either side thereof are springs or means, s s^1, which by the effect of the heat from the focus of the lens make contact with the electrical communication, the result being that by such contact the magnets m m^1 act upon detents which free clockwork or other means enclosed in chambers c c^1, and thus the lamp is raised or lowered to keep the light central with the condensers and lenses, as before described.

The action is as follows:—Suppose the light falls too low, the result would be that the focal point between the springs or means would rise and fall upon s^1, and contact would be made by expansion of s^1 through heat, and communication would be made by electro-magnet m^1 in chamber c^1. The detent would thus be released, and the lamp raised until the light assumed its normal position between s and s^1, as shown. If the light be too high the focal point would fall and act upon s, and, by the electrical communication, the magnet m would act upon the detent and lower the lamp.

FIG. 3. FIG. 4.



In *fig.* 3 the water or other fluid which circulates between, and in the direction of, the arrows is principally the refracting medium.

In *fig.* 4 the water or other medium flows in receptacles, of which the face of the lens forms one side, the other side being formed by glass g, which, with the condensers, is enclosed by a suitable chamber of the ordinary kind, around which is formed a hollow chamber h for the water or other liquid to flow through, so as to keep both the framework and the parts holding the lenses cool.

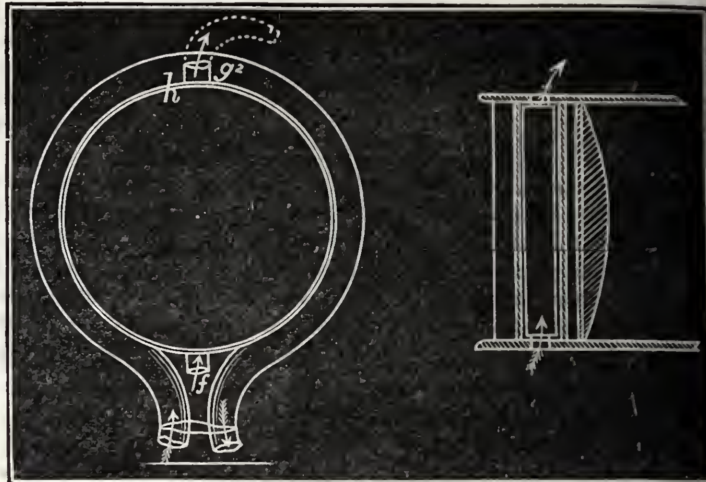
The exterior view (*fig.* 5) shows, by the arrows, the entrance and exit of the water or other liquid to the exterior of the case h. The openings, or pipes, at g^1 admit the liquid, as shown on *fig.* 4, same issuing from same at *fig.* 2.

It is to be understood that arrangements are made in each case for carrying the condensers, so as to allow of the circulatfon of cooling liquid as may be required, substantially similar to the arrangements shown in *fig.* 4.

It is also to be understood that where more than one condenser is used the water or liquid compartments thereof may be connected, as described, but be independent of each other as regards the flow.

The patentees thus conclude:—"Having now particularly described and ascertained the nature and object of the said invention, and in what manner the same is to be performed or carried out in

FIG. 5. FIG. 6



practice, we hereby declare that we claim the said invention of 'Improved arrangements or means applicable to producing enlarged pictures, and for taking pictures by the agency of light,' substantially as hereinbefore set forth and described, wherein the following are important and peculiar points or features:—

(1.) The flowing of liquid through the condenser or condensers for the purpose of keeping same cool, substantially as described.

(2.) The flowing of liquid through receptacles, troughs, or compartments, separate or in combination with the condensers, substantially as hereinbefore set forth, described, and exemplified.

(3.) The utilisation of the heat from the electric light, as a means of keeping it central with the condensers and lenses, substantially as hereinbefore described and exemplified."

We have become so accustomed to the use of "alkaline pyro." as a developer for dry plates, and it has answered all purposes so perfectly, that little if any attention has been given to the action of similar substances other than pyrogallic acid when employed in connection with alkali. The recent announcement made in our columns by Mr. M. Carey Lea, to the effect that *gallic* acid in combination with an alkali formed almost as energetic a developer as pyro. under the same conditions, caused a feeling of surprise almost amounting to incredulity. It seemed at the first blush almost impossible that gallic acid, so similar in general properties to pyrogallic, should possess qualities which have escaped detection all these years. As a developing agent in connection with silver gallic acid has, of course, been known as far back as development itself, yet we believe until Mr. Lea noticed the fact its power when mixed with an alkali was entirely unknown; certainly it had never been practically utilised. There is, however, no doubt of the truth of Mr. Lea's assertion; indeed, instead of being only "*nearly* as energetic" as pyro., we are inclined to think that in some respects it is more so. Having casually tried the experiment of substituting it for pyro. we were so struck with its behaviour that we were induced to make a series of comparative trials between the two, and though perhaps on so short an acquaintance with its action we are scarcely in a position to pronounce decidedly either for or against the new substitute, we may notice one or two points in which it differs from its older rival. Saturated solutions of gallic acid, carbonate of ammonia, and a fifteen-grain solution of bromide of potassium were used in these experiments against the usual three-grain pyro. solution. An exposed plate having been cut in two, the respective halves were treated with pyro. and gallic acid, one drop of the ammonia solution, but *no* bromide, being added to three drachms of each developer. The pyro. brought out a feeble image in a very short time, but it was not till four drops of ammonia had been added that the other produced any image at all, and then only the high lights. We then added eight more drops of ammonia, and the picture flashed out at once in all its detail and with almost printing density. After "ringing the changes" upon a number of different modes of development we arrived at the conclusion that, whereas pyro. will develope an image with the merest trace of alkali or with none at all, gallic acid requires a much larger quantity before it becomes capable of starting a satisfactory action; that as the quantity is increased so does it approach nearer to pyro. in energy, and *it will bear a very much* larger proportion than the latter. It gives great density, and the difference in its cost would render it a desirable substitute for pyro. if further experience proves it to be equally reliable.

British Association.

DUBLIN MEETING, 1878.

The forty-eighth annual meeting of the British Association for the Advancement of Science now ranks in the category of past events. In accordance with its nomadic character its meetings are held in various parts of the United Kingdom, every large city and town, with the exception of London, partaking in an occasional visit from the *savants* of whom its members and associates are composed. Last year, it will be remembered, the meeting was held in Plymouth; that which has just terminated has been held in Dublin; while next year will see the "parliament of science" assembled in Sheffield, and soforth. The meeting lasts for a week and forms a delightful *réunion* for men of science, under which designation we include the fair sex, many of whom are always present at these annual meetings.

The public proceedings began on Wednesday evening, the 14th inst., when over two thousand ladies and gentlemen assembled to listen to the President's address, delivered by Mr. William Spottiswoode, M.A., D.C.L., F.R.S., &c., who this year fills the office of President of the Association. There was nothing in the address of a character interesting to photographers as such, nor was there even an allusion to our art-science, which has too long passed the experimental stage when its marvels filled our *savants* with astonishment. From the fact that Mr. Spottiswoode has devoted so much of his time to investigations connected with the polarisation of light—upon which subject he has both written and lectured much —one would naturally have expected some special allusion to be made to that department of science. Such, however, was not the case, mathematics forming the leading theme of his discourse. Precision and exactness being taken as the characteristics which distinguish the mathematical phase of a subject, it was, he considered, natural they should be led to expect that the approach to such a phase would be indicated by the increasing application of the principle of measurement and by the importance attached to numerical results. This necessary condition for progress might, he thought, he fairly described as one of the main features of scientific advance in the present day. On this point he said:—

"If it were my purpose, by descending into the arena of special sciences, to show how the most various investigations alike tend to issue in measurement, and to that extent to assume a mathematical phase, I should be embarrassed by the abundance of instances which might be adduced. I will, therefore, confine myself to a passing notice of a very few, selecting those which exemplify not only the general tendency but also the special character of the measurements now particularly required, viz., that of minuteness, and the indirect method by which alone we can at present hope to approach them. An object having a diameter of an 80,000th of an inch is perhaps the smallest of which the microscope could give any well-defined representation; and it is improbable that one of 120,000th of an inch could be singly discerned with the highest powers at our command. But the solar beams and the electric light reveal to us the presence of bodies far smaller than these. And, in the absence of any means of observing them singly, Professor Tyndall has suggested a scale of these minute objects in terms of the lengths of luminiferous waves. To this he was led, not by any attempt at individual measurement, but by taking account of them in the aggregate, and observing the tints which they scatter laterally when clustered in the form of actinic clouds. The small bodies with which experimental science has recently come into contact are not confined to gaseous molecules, but comprise also complete organisms; and the same philosopher has made a profound study of the momentous influence exerted by these minute organisms in the economy of life. And if, in view of their specific effects, whether deleterious or other, on human life, any qualitative classification or quantitative estimate be ever possible, it seems that it must be effected by some such method as that indicated above.

"Again: to enumerate a few more instances of the measurement of minute quantities, there are the average distances of molecules from one another in various gases and at various pressures; the length of their free path, or range open for their motion without coming into collision; there are movements causing the pressures and differences of pressure under which Mr. Crookes's radiometers execute their wonderful revolutions. There are the excursions of the air while transmitting notes of high pitch, which, through the researches of Lord Rayleigh, appear to be of a diminutiveness altogether unexpected. There are the molecular actions brought into play in the remarkable experiments by Dr. Ker, who has succeeded, where even Faraday failed, in effecting a visible rotation of the plane of polarisation of light in its passage through electrified dielectrics, and on its reflexion at the surface of a magnet. To take one more instance, which must be present to the minds of us all, there are the infinitesimal ripples of the vibrating plate in Mr. Graham Bell's most marvellous invention. Of the nodes and ventral segments in the plate of the telephone, which actually converts sound into electricity and electricity into sound, we can at present form no conception. All that can now be said is that the most perfect specimens of Chladni's sand figures on a vibrating plate, or of Kundt's lycopodium heaps in a musical tube, or even Mr. Sedley Taylor's more delicate vortices in the films of the phoneidoscope, are rough and sketchy compared with these; for, notwithstanding the fact that in the movements of the telephone-plate we have actually in our hand the solution of that old world-problem, the construction of a speaking machine, yet the characters in which that solution is expressed are too small for our powers of decipherment. In movements such as these we seem to lose sight of the distinction, or perhaps we have unconsciously passed the boundary between massive and molecular motion.

"Through the phonograph we have not only a transformation but a permanent and tangible record of the mechanism of speech. But the differences upon which articulation (apart from loudness, pitch, and quality) depends appear, from the experiments of Fleeming Jenkins and others, to be of microscopic size. The microphone affords another instance of the unexpected value of minute variations—in this case of electric currents; and it is remarkable that the gist of the instrument seems to lie in obtaining and perfecting that which electricians have hitherto most scrupulously avoided, viz., loose contact."

In the Sections there were only three communications possessing photographic interest, one of these in Section A (Mathematics and Physics) being by M. Janssen, who spoke of the method by which he obtained certain solar photographs he exhibited. As at a very recent period we published an account of M. Janssen's experiments further allusion to them at present is not considered necessary. The other papers were by Captain Waterhouse, of Calcutta, and Mr. William Willis, Jun., both of which papers will be found in the present number. The former of these gentlemen contributes greatly to our knowledge of processes suitable for cartography, while the latter is to be congratulated upon having made a further improvement upon his admirable process of platinotype printing, in which the necessity, formerly experienced, for giving the paper a preliminary wash of nitrate of silver has ceased to exist.

As usual, discourses were delivered on the evenings of Friday and Monday in "Association week." That on the former evening was by Mr. G. J. Romanes, F.L.S., on *Animal Intelligence;* and on the latter evening by Professor Dewar, F.R.S., on *Dissociation, or Modern Ideas of Chemical Action.*

The following are the communications to the Sections which are likely to prove of most interest to our readers:—

Section A.—Mathematical and Physical Science.

Friday, August 16, 1878.

REPORT ON THE OSCILLATION-FREQUENCIES OF THE RAYS OF THE SOLAR SPECTRUM.

By G. J. Stoney.

The report said that so long as light was propagated through a vacuum the undulator, however complex, maintained its form unaltered at all distances from the source of light; for in vacuous spaces waves of different periods advanced at the same rate and directly forward, and therefore the simple component undulations which were represented by the several terms of a sinusoid series accurately accompanied each other throughout their whole journey. But the event was different if the light encountered an optical agent which acted differently on waves of different periods. Of this kind were the prisms and diffraction gratings of our spectroscopes. Waves of different perions were compelled to travel in different directions, and thus the several terms of the sinusoid series appeared under the form of lines in the spectrum. The wave-lengths corresponding to each position in the spectrum had been determined with great care, and these, when corrected for the dispersion of the air, were proportional to the corresponding perionic times, which thus became known. By a discussion of the observations it might be expected that much would be learned with regard to the original disturbance caused by the source of light. In the present state of science it was of importance to facilitate this inquiry as much as possible, and it was hoped that aid would be given to the student of nature by the table published in connection with the report, in which the oscillation-frequencies of the principal rays of the visible part of the solar spectrum had been computed from Angstrom's determinations of their wave-lengths in air, combined with Ketteler's observations on the dispersion of air.

A NEW PROCESS OF PHOTO-CHEMICAL PRINTING IN METALLIC PLATINUM.

By W. WILLIS, Jun.

IT is a fact well known to chemists that metallic platinum in all its states, massive and molecular, is totally unchanged or unaltered by atmospheric influences. It is also well known that platinum in a finely-divided state has an intensely black colour. Now, if a picture be produced on paper or other suitable substance, in which the dark portions and shades are formed by this black, finely-divided metal, it is evident, so far as this metallic pigment itself is concerned, that the picture is perfectly permanent and unalterable. The object of this process is to produce pictures in which this result is obtained.

The chemical reaction upon which the platinotype process is based is one discovered by the writer some years ago. He found that a hot solution of ferrous oxalate in potassic oxalate instantly reduced platinum to the metallic state from its chlorides and other salts. Now, ferrous oxalate is produced by the action of light upon ferric oxalate. If, then, paper be coated with the latter salt and exposed to light the coating will be changed by actinic action to one of ferrous oxalate. If a photographic negative be superimposed previous to this exposure to light an image of ferrous oxalate will be produced corresponding to those more transparent parts of the negative through which the light has more readily passed.

If a salt of platinum be mixed with the ferric oxalate with which the paper is coated, and the paper be then exposed to light under a negative, the image on the paper will be composed of ferrous oxalate, the particles of which lie side by side, and are intimately mixed with those of the platinum salt. This image of ferrous oxalate is soluble in potassic oxalate, but we have previously learnt that a solution of ferrous oxalate in potassic oxalate instantly reduces platinum salts. If, therefore, this image be floated on a solution of potassic oxalate, we shall expect that at the moment it is dissolved the solution thus formed will reduce the platinum salt with which it is intimately in contact. This is what in reality occurs. The ferrous oxalate is dissolved away, leaving in its place finely-divided metallic platinum. Strange to say, this reduction takes place so instantaneously that not a particle of metal is removed from its position in the picture, but is left entangled in and amongst the matted fibres of the paper.

When working this process on a large scale, the paper on which the prints were to be made received a coating of a weak solution of a silver salt previous to its treatment with the iron and platinum salts. This silver salt in some way caused the platinum, reduced by the ferrous oxalate, to be deposited in a very finely-divided state. If the paper had no preliminary coating of silver salt the platinum was always deposited in a roughly-granular form, and did not well adhere to the paper.

Recent experiments have proved that this preliminary coating of silver salt is unnecessary, and may be altogether dispensed with, if to the bath of potassic oxalate, on which the prints are floated after exposure to light, an addition of a platinum salt be made.

The remarkably simple form the process now takes may be briefly indicated as follows:—Paper is coated with a mixture of aqueous solutions of ferric oxalate and potassic chloro-platinite, then dried, and exposed to light under a negative. After it has had a sufficient exposure it is floated on a hot aqueous solution containing potassic oxalate and a salt of platinum. This solution instantly developes the picture, which is then washed in one or two solutions to remove the chemical salts adhering to the paper. When dried the print is finished.

This printing process derives considerable interest from the fact that it is the first in which platinum in the metallic state has been made use of as a pigment, and that it is the first photo-chemical process giving permanent results of any practical value, in which the particles of pigment forming the picture are embedded in and entangled amongst the fibres of the paper on which they are printed, and do not depend for their adhesion on the use of any sizing material.

The applications to be made of this process embrace all those to which photographic printing is at present adapted. The pure black colour of the images or pictures, their absolute permanence, and the important fact that the pigment forming them penetrates the paper, render the process peculiarly adapted for the permanent reproduction of important documents, archæological records, medical, geological, botanical, and other scientific phenomena; or for illustrating the results of military, naval, and engineering operations, and for the illustrations of high-class books.

SECTION E.—GEOGRAPHY.

ON PROCESSES OF MAP PRODUCTION BY PHOTOGRAPHY.

By Capt. J. WATERHOUSE, *Assistant Surveyor-General of India.*

ON leaving India little more than a month ago, on very short leave, I was quite uncertain whether I should be able to attend the meeting of this Association, and was quite unprepared for the honour of addressing the Geographical Section. The officers of the Section have, however, assured me that the subject which I have made a special study for several years past would be of interest, as inquiries were constantly being made regarding the various photographic processes by which maps are now being produced.

To explain so technical a subject properly, and make it interesting, the paper should have been illustrated by specimens showing the several processes in their various stages, and I greatly regret that I have come from India unprovided with these, and have been unable to supply the want in the short time I have been in England. Mr. Coles, map curator of the Royal Geographical Society, has, however, very kindly selected for me a few specimens from the collections of the Royal Geographical Society, and I trust that any shortcomings in this respect may, under the circumstances, be excused. I shall endeavour to make the working of the processes as clear as I possibly can without entering too much into technical details.

The ordinary processes for the production of maps are, as is well known, lithography and engraving, the latter being used in preference for maps of a permanent or standard character, in order to have the means of preserving the plates in a convenient form for subsequent correction and multiplication by electrotype or transfer to stone, and thus save the wear and tear of printing from the original plates.

Both engraving and lithography, however, require the entire copying by hand of any given subject, which in most cases demands a considerable expenditure of time and of skilled manual and artistic labour, and consequently these methods are comparatively slow and expensive.

The attention of cartographers was very soon drawn to the advantages that might be gained by the employment of photography for the reproduction of maps and plans; but for some time progress in this direction was hindered by the difficulty of obtaining accurate images, free from the distortions caused by imperfect construction of the photographic lenses and processes then employed.

Of late years, however, great improvements have been made in these respects, and photography has been largely utilised by cartographers in the production of maps by processes analogous to the ordinary processes of lithography and engraving, but vastly cheaper and quicker; and most civilised states now possess special photographic establishments for the reproduction of maps, plans, &c., for fiscal, military, and other purposes.

It is to the credit of our country that the first attempt to use photography practically in the reproduction of maps was made in 1855, by the late Colonel Sir Henry James, R.E., Director of the Ordnance Survey of Great Britain and Ireland, with the view of obtaining accurate reductions from the large scale surveys more expeditiously and with more economy than could be done with the pentagraph. These first attempts proved incontestably the great value of photography for the purpose and the enormous saving in time and money that would be effected by its use.

For some time, however, the use of photography at the Ordnance Survey Office was limited to obtaining accurate reduced prints for the engravers to trace from on to the copper plates; but in 1859-60 experiments made in the newly-invented carbon processes, with the object of finding a method of transferring the photographic image at once to the copper plate, led to the introduction of the process of photozincography, which has since been so largely and successfully utilised at Southampton in the reproduction of the *Doomsday Book* and other national records, and which, since its adoption in the three Presidencies of India, has rendered possible the early publication of vast numbers of maps that could not possibly have been dealt with by the ordinary methods of lithography and engraving.

By a curious coincidence it happened that at the very time the Southampton process was being perfected, Mr. Osborne, of Melbourne, Australia, introduced, quite independently, an almost identically similar process of photolithography, which has since been very successfully and largely used in the Australian colonies, Germany, and America. These two processes are worthy of special notice as being the first employed in a practical way for the reproduction and multiplication of maps for publication. They are still largely used, and possess advantages in some respects, especially for large work, over other processes of the same kind which give, perhaps, finer results within the limits of a single negative.

In India the ever-increasing wants in the way of communication by rail, road, or river, and the rapid extension of irrigation and other engineering projects, as well as the ordinary military administrative and fiscal requirements, make the early publication of the results of the surveys a matter of very great necessity and importance; and, as skilled lithographic draughtsmen and engravers are not to be found and have to be trained as required or brought from Europe at great risk and expense, the subject of photography as a means of quickly producing and publishing copies of the original maps of the surveys, is much more important there than it is in other countries where skilled cartographic lithographers and engravers are comparatively numerous.

The success of the introduction of photography into the Ordnance Survey Office at Southampton led to its early adoption in India; and in 1862 some sappers trained at Southampton were sent out to Calcutta, where a photographic office was established in connection with the Surveyor-General's Office for the reproduction of maps and plans of the Topographical and Revenue Surveys, as well as of miscellaneous maps and other subjects for the Survey and other Government departments, among which may be particularly mentioned the charts of the Marine Surveys, of which some specimens are on the table.

Photographic offices have also been established at Dehra Doon in connection with the Great Trigonometrical Survey, and at Madras and Bombay for the publication of maps of the Revenue and Settlement Surveys of those Presidencies, and other miscellaneous work. In all these offices the Southampton process is used, with various modifications required by the climate.

In India the principal publishing office for all general and standard maps of the country is the Surveyor-General's Office, Calcutta, and here the advantages of photography have been most marked. By its aid the publishing branches are able to keep pace with the progress of the surveys so closely that as a rule each season's mapping of the Topographical and some of the Revenue Surveys is reproduced and in the hands of the public before the drawing of the following season's maps has been taken in hand. An immense amount of work is thus done, both for the reproduction of the ordinary survey maps and of large numbers of miscellaneous maps and drawings for other departments, that it would have been impossible to cope with by lithography and engraving alone. As a rule, the photozincographic maps are somewhat coarse, but they answer well all practical requirements.

The following figures will give an idea of the large extent to which photography is now being used in India:—In the Surveyor-General's Office, Calcutta, during the year 1877, 3,038 sections or subjects were received for reproduction. From these 5,343 negatives and 5,398 photographic transfer prints were taken, representing about 21,000 square feet of glass and 22,000 square feet of paper respectively. Of these sections 2,725 were transferred to zinc, and 244,593 impressions were struck off. The greater part of this large out-turn was composed of maps of the Cadastral Surveys of the North-Western Provinces on the scale of sixteen inches equal one mile, and we are now arranging to turn out regularly between 4,000 and 5,000 of these maps yearly.

At Dehra Doon, a much smaller office, the out-turn in 1876-77 was 117 maps and 30 triangulation charts photographed, and 25,259 copies printed off, besides blue prints and silver prints for the use of the engravers.

At Poona 1,798 maps were photographed from 2,745 negatives, and the number of copies printed off (including copies of 79 lithographs) was 74,739. For Madras I have no returns.

Following the example of the English Ordnance Survey, photography has been introduced and largely used in various foreign countries for the reproduction and publication of the state maps.

Thus in Belgium a process of photolithography is used for reproducing the topographical maps on the scale of $\frac{1}{20000}$. In Austria a process of photographic engraving, called "*heliogravure*," has been introduced with very great success, and is applied to the practical production of maps and other subjects. In France, Germany, Italy, Portugal, and, I believe, other European States, various processes of photolithography and photo-engraving are in use, though not to a very large extent.

In America and Japan the same processes appear to be worked very successfully for Government purposes by a commercial company, of whose work some specimens are on the table.

The specific advantages to be gained by the use of photography for the reproduction of maps and plans are:—

1. Rapidity of production and multiplication, especially when employed for copying subjects containing close and intricate details. The gain varies according to the amount of detail and the time that would be taken by a skilled draughtsman or engraver to make the copy by hand. For instance: a highly-finished map that would take several months to lithograph or engrave may, by the aid of photography, be copied and some hundreds of copies printed off in the course of a few days. This advantage is of the greatest importance in time of war or when copies of maps are very urgently required for any specific purpose. As an instance I may mention that when the occupation of Cyprus was decided upon and maps of the island were required for the use of the Government, it was found that only one copy of a map was to be obtained in London. This copy was at once sent to the Ordnance Survey Office at Southampton to be photozincographed, and thus in the course of a few hours hundreds of copies of the map were available. In India also photozincography has served us most usefully in enabling us to reproduce maps of the theatres of war in the Franco-German and Russo-Turkish campaigns immediately on the outbreak of hostilities, and before such maps could be received from Europe.

2. The perfect fidelity with which the most delicately-minute and intricate details are copied. The most skilful and careful draughtsman is liable to make errors in copying, and never can obtain the same accuracy of delineation, especially of minute objects, as is obtained with the camera.

3. The facility with which copies may be obtained on scales larger or smaller than the original. The extent to which this may be taken advantage of depends very much upon the object in view as well as upon the style of the original, and the relative thickness and size of the lines and details composing it; but, notwithstanding certain drawbacks and inconveniences it may sometimes be attended with, this facility of enlarging or reducing the scale of an original drawing, with the most perfect accuracy and with the absence of all personal error, is one of the most important advantages of photography, and its immense superiority in this respect over the pentagraph and other methods of copying by hand has been proved to be beyond question.

4. The comparative cheapness of the photographic methods. The relative cost of hand labour and photography is affected by several considerations, *e.g.*, the nature of the subject, the process employed, the number of copies made, and the pay of the photographers as compared with that of draughtsmen. In most cases it will be found that when it is really an advantage to employ photography in reproducing maps for any particular purpose the cost will be far less than it would be by employing hand labour.

Notwithstanding these advantages, the use of photography as a means of reproducing maps and plans for publication has not extended so much as might have been expected, partly on account of defects inherent in photographic copying, and only to be overcome by great skill and long experience on the part of the photographer, and partly owing to the difficulty of making draughtsmen fully understand the requirements to be fulfilled when preparing maps to be reproduced by photography for publication in order to produce satisfactory results, and that they must strictly refrain from using colour, drawing the map neatly in black and white, so that every line may be reproduced of its proper strength, according as the map is to be copied on the same scale as the original or to be reduced.

It matters little how roughly drawn or highly coloured an original drawing or map may be if it be intended to lithograph or engrave it, because a skilled lithographer or engraver can easily put it into proper and conventional form; but when such a drawing is handed to the photographer he can only produce a *facsimile* of it with all its deficiencies—the coloured details hidden under a black mass of shade, the finer parts perhaps wanting altogether, the writing rough and broken, or so small as to be almost invisible, besides other defects caused by the unsuitableness of the drawing for reproduction by photography, and these defects are liable to be unduly attributed to the process.

The photographic processes applicable to the reproduction of maps are:—

I.—*Photographic Printing on Sensitive Papers.*—In these methods prints are obtained on a sensitive surface of paper prepared with the salts of silver, platinum, and iron, or with certain salts of chromium in conjunction with pigmented gelatine. In all of them the whole of the photographic operations connected with the printing have to be repeated for every impression.

II.—*Photolithography* or *Photozincography*, or the methods by which a photographic image in greasy ink may be produced on, or transferred to, a lithographic stone or zinc plate and printed off in the lithographic press.—The photographic operations cease with the production of the image in greasy ink, and the impressions are produced by the ordinary operations of lithographic printing. The use of these processes is, however, limited to the reproduction of subjects in line or dot, as they can only reproduce half-tones in a very imperfect manner.

III.—*Photocollotype*, or the method of producing a photographic image on a layer of gelatine applied on a suitable support, so that when the gelatine surface is moistened impressions may be obtained from it in printing ink.—By this method, also, a photographic image once produced on the printing surface of gelatine is capable of yielding some hundreds of impressions in the printing press; and, instead of the subjects for reproduction being confined to those in dot or line, as in photozincography, any subject can be copied which is capable of giving a good photograph by the ordinary process of silver printing.

IV.—*Woodburytype*, or the method whereby a photographic image is impressed into a soft metal plate, somewhat in the same manner as in the operation of nature-printing, forming a mould into which liquid coloured gelatine is poured and attached under pressure to a sheet of paper, thus yielding an image in which the lights and shades of the picture are formed by different thicknesses of coloured gelatine.

V.—*Heliography* or *Photo-engraving*, the method of obtaining on a metal plate a photographic image in intaglio capable of giving impressions in the copper-plate press.—In this method the engraved plate once obtained serves for the impression of a large number of copies, and may be indefinitely multiplied by electrotyping.

VI.—*Phototypography*, or the method of obtaining by means of photography an image in relief on a metal plate, which may be mounted on a block to be set up with type and be printed in the ordinary printing press.—These blocks may also be indefinitely multiplied by electrotyping in the same manner as ordinary woodcuts.

It will be observed that the five last-named processes all possess the great advantage that, once the photographic image has been obtained on the printing surface, the operations of printing can be accomplished by the same means and at the same rate as by the ordinary industrial methods. The printing may be performed by night or by day, quite independently of the agency of light, and requires no further chemical manipulations.

It would be beyond the scope of this paper to enter fully into the practical details of these various processes of photographic printing, as my object is merely to review those applicable to cartographic purposes, and to give a summary of the principal methods that may be usefully employed with reference to the wants of the State or of private individuals rather than those of professional cartographers and map-publishers, though the latter may, in many cases, also find photography a useful auxiliary. Photographic methods can never entirely take the place of lithography or engraving by hand, either for public or private purposes, but their use may be advantageously extended. Those who wish for fuller details may consult the text-books by Abney, M. Carey Lea, Monekhoven, Vogel, and others, and the special works referred to in this paper.

Preparation of the Original Drawing.

I have already adverted to the difficulty that has been found in this country and elsewhere in obtaining original drawings suitable for reproduction by photozincography, and to the fact that without a proper original drawing it is quite impossible to produce satisfactory results. Besides its principal use in reproducing maps of the surveys, photozincography is very largely utilised in India by engineers for the reproduction of their plans and drawings, and by other public officers for an immense variety of miscellaneous maps and plans; and, as we were constantly asked to photozincograph subjects utterly unsuitable to the process, a set of rules for the preparation of the original drawings for reproduction by photozincography was drawn up under General Thuillier's direction and published in the official gazettes all over India, and the result has been a great improvement in the execution of the drawings we receive for reproduction.

The rules are as follow:—

1. All drawings should be on white, smooth-surfaced paper, free from dirt, pencil marks, creases, and wrinkles. When possible they should remain stretched on the drawing-board.

2. The Indian ink should be freshly rubbed down and give good *black* lines, free from glaze.

3. The lines should be firm and cleanly drawn—not too fine or too close together. They must be quite *black*, and light effects must be produced by fine and open black lines, and never by the use of *pale* ink. Thick lines in the printing and borders of maps should be well filled in. Pencil marks should be carefully removed, so as not to injure the blackness and firmness of the lines.

4. All cross-hatching and shading should be as open and clear as possible, and the lines composing it firm and not too fine. Intensity of shade must be shown rather by an increase in the thickness of the lines than by placing them closer together, in order that the intermediate spaces may not become blocked up when transferred to zinc. It is better not to rule the shading of mechanical and architectural section drawings, but to show the shaded parts by a light tint of blue, violet, or *aniline* red (fuschine or roseine). These parts will reproduce white, and can have a ruled tint transferred on the stone or zinc in the usual way, which will give a much neater appearance.

5. In plans or drawings intended for photozincography *washes* of any colour, except very pale blue, violet, or aniline red, are absolutely inadmissible. Outlines may, however, be drawn, if necessary, in any strong red, brown, yellow, orange, or green pigment which will reproduce black. Any details required to be shown in the original, but not in the copy, may be drawn in pale blue, violet, or aniline red. Details that are not required to be reproduced may be painted out with Chinese white.

6. River-courses, lakes, and tanks should be left blank, and not filled in with fine lines. They may be indicated by a pale wash of *blue* without detriment to their reproduction.

7. When drawings are to be reduced care must be taken to draw the lines, lettering, and detail of sufficient thickness and size relatively to the scale of reduction, so that they may not be lost or illegible when reduced. Sufficient space must also be left between the lines to prevent subsequent blocking up.

8. When possible drawings should be made on a larger scale than they are required to be copied. Photographic reductions are always sharper and firmer than reproductions to the same scale, and defects in drawing are lessened by reduction.

9. Where plans or drawings to scale are to be reduced, the scale should be given in terms of a single unit of measurement and not as relative to any second unit. Thus, the scale on a map drawn on the scale of four miles to an inch for reduction to sixteen miles to an inch should be shown simply as a "scale of miles."

10. As photography produces a more or less perfect *facsimile* of the original drawing, it is essential that drawings intended for publication should be complete and finished in every respect before they are made over to the photographer. The drawing, printing of names, &c., should be in as neat a style as possible, and not require to be altered or touched up. The hair strokes of the printing should not be too fine.

The foregoing rules may be summed up in a few words:—*White paper, black ink,* and *firm open drawing*; and, as success in the after processes depends entirely upon the perfection of the original drawing and its capability of giving a negative on which the ground is perfectly opaque while the lines are quite clear and as transparent as the bare glass, these essentials must be most carefully observed. Their neglect will entail failure and disappointment.

For drawings intended for reproduction by the collotype methods these rules are equally applicable, especially No. 7, and there is even more necessity for perfect cleanliness of the paper and neatness and finish of the drawing, because the faintest tints will be reproduced by the gelatine printing surface, and corrections cannot be made on it, as they can on zinc, stone, or copper. For this reason, also, the greatest care must be taken to complete the drawing in every respect before it is given to be reproduced. Drawings in line may be finer and more delicate than for photolithography, but still must not be so fine as to interfere with the obtaining of a perfectly-dense and opaque negative, otherwise the ground of the print will appear dirty and stained. Pale ink may be used when necessary for effect, but not more than is really requisite. Colour may be used to any extent, having always due regard to the photographic effect when reproduced. On account of the difficulty of photographing certain colours, so as to produce the same effect as in the original picture, the best results will be produced from drawings specially prepared in monochrome, such as Indian ink or sepia.

In the case of drawings for any special purpose, or not intended for publication, the above rules may be relaxed; but the general principles laid down should be observed, as far as practicable, if the best results are desired.

When drawings are prepared specially for photographic reproduction there need be no difficulty in taking all the precautions necessary for producing good results. It often happens, however, that the photographer is called upon to reproduce drawings, lithographs, or old MSS., printed records, or engravings, which either may never have been suitable for the purpose or, if suitable when fresh, have become dirty and stained by age. Herr Scamoni, the skilful Chief of the Photographic Department of the Imperial State-Paper Office at St. Petersburg, has given some useful hints on the treatment of such subjects under these circumstances*:—

"Yellow or otherwise objectionable spots should be carefully covered over in the spaces between the lines with Chinese white, and, whenever possible, the lines should be strengthened in parts where they appear weak.

"Lithographs and engravings may be bleached by immersion in a solution of chloride of lime or *Eau de javelle* (one to ten or fifteen of water), then soaked in water for some hours, after which they are treated with a weak solution of hyposulphite of soda, and finally well rinsed in clean water.

"Fresh grease stains may be removed with chloroform, benzine, and ether, or with a weak alkaline solution of caustic potash or its carbonate.

"Old grease stains may be removed with a more or less strong solution of potash, applied at the back of the subject.

"Iron mould and ink spots may be taken out with a solution of oxalic acid or salts of sorrel."

When tracings are made on paper or vellum cloth to be reproduced without the aid of the camera special care must be taken to keep the back of the drawing clean, and to choose paper or cloth free from stains and of as even a texture as possible.

Originals drawn on rough paper may be smoothed in a copperplate press, and, if dirty, should be carefully cleaned with india-rubber or bread.

(To be continued.)

SOIREES, EXCURSIONS, &c.

In addition to the two *soirées* usually held by the British Association there were numerous excursions to scenes of interest in the neighbourhood of Dublin. Several of these parties were accompanied by local photographers, who secured groups of the members of whom they were composed. Among those photographers who were thus successful were Mr. Laurence, Mr. Lesage, Mr. Robinson, &c. Other followers of the "craft" appeared to be busily engaged during the week in obtaining single "counterfeit presentments" of the members, among whom we may mention the names of Mr. Chancellor, of Sackville-street, and Messrs. A. and G. Taylor, of Stephen's Green.

His Excellency, the Lord Lieutenant of Ireland, with her Grace the Duchess of Marlborough and suite, were indefatigable in their endeavours to do honour to the members of the Association, being present both at the meetings of the sections and at the *soirées*, On Monday afternoon his Excellency visited Mr. Howard Grubb's astronomical works. It will be remembered that at these works were constructed the great Melbourne telescope and the several great equatorials lately erected in England for the Royal Society, Lord Lindsay, Oxford, &c., and Mr. Grubb has now in construction the largest refractor ever attempted. This instrument is twenty-seven inches clear aperture, and will be erected, when complete, at the New Imperial Observatory in Vienna, which institution Mr.

* *Handbuch der Heliographie*, p. 67.

Grubb is also fitting up with all its domes and machinery. Three great domes, as large as that in the Greenwich Observatory, have already been despatched, and the great steel dome, forty-five feet in diameter, which is to cap the great equatorial room in Vienna, is now complete and ready for despatching. This is the largest observatory roof in the world, and, when we mention that it is necessary that this ponderous roof of fifteen tons' weight can be moved round and manipulated with one hand, the nature and difficulties of the work may be appreciated. A few years since almost all astronomical instruments were obtained from Germany; but the last few years have witnessed the creation of an astronomical manufactory in Dublin, employing exclusively Irish workmen, competing successfully against foreign manufacture, not only in our own country, but even in that which previously supplied all such instruments to the world. During the last few years more than £15,000 worth of astronomical instruments have been manufactured for Germany alone.

Many other members availed themselves of Mr. Grubb's kindness in throwing his extensive optical works open for their inspection.

His Excellency the Lord Lieutenant and the Duchess gave a charming garden party at the Vice-Regal Lodge, Phœnix Park, on the afternoon of Thursday, the 15th inst., which was attended by a distinguished assemblage of visitors, but the pleasure of the outdoor amusements was slightly marred by the capriciousness of the weather.

We may incidently mention that at a special meeting of the Senatus of Trinity College—in one or other of the halls or lecture rooms connected with which all the ordinary meetings of the Association were held—the degree of LL.D. was conferred upon the President and several of the more eminent members of the British Association.

At the concluding meeting, held on Wednesday last, it was decided that the next meeting of the Association should be held at Sheffield on the 6th August, 1879, under the presidency of Dr. J. Allman, F.R.S.

INDOOR PHOTOGRAPHY.

Since I wrote a few weeks ago on the subject of amateur portraiture I have discussed the subject with several amateurs who have at some time or other essayed the production of portraits in an ordinary room, but with apparently very poor success, the chief difficulties complained of being the necessity for an inordinately long exposure, or, where this was not the case, the production of too strong contrasts in the lighting. Of course, without a knowledge of the precise conditions observed in each individual case it is impossible to say what may have been the cause of these failures, but I propose to give a few further hints which my own experience leads me to believe may possibly explain the want of success.

It may seem a mere truism to suggest that the complaint of excessive exposure arises in many cases from the employment of too slow a plate, especially if it be an emulsion one. I should, perhaps, express my meaning more clearly by saying an *unsuitable* plate; for it is well known that many emulsions which, in a good light or in open landscape, work almost as quickly as an average wet plate fall far short of the latter when the quality of the light is lowered. Others, on the contrary, compare favourably with the wet plate in their power of rendering feebly-lighted subjects. It is in losing sight of this discrepancy in the sensitiveness of the plates under different conditions that I believe much of the want of success lies. I have myself, at the present time, two samples of emulsion which for outdoor work scarcely differ in rapidity, but when applied to portraiture indoors the difference is nearly three to one.

But the same complaint of lengthy exposure comes also from one who has invariably employed wet plates in his attempts at portraiture, so that the cause, evidently, in his instance amounts to one of deficiency of illumination. This may easily be the case without necessarily being the true explanation, or without proving a defect in the system of lighting that I advocate. On inquiring particulars as to the position of the sitter and distance from the light, I found that my friend had been in the habit of placing his sitters "well back—eight or nine feet from the window," under which circumstances it is scarcely surprising that a long exposure should be necessary. Even upon the ground glass the rapid falling off in the quality of the illumination, as the sitter is removed to only a slightly greater distance from the window, cannot fail to be noticed; and though at the distance named an apparently well-lighted picture is seen on the focussing-screen its actual actinic value is very small.

Speaking theoretically, the illumination diminishes in proportion to the square of the distance from the light; hence if at a distance of three feet from the window an exposure of fifteen seconds be sufficient, at nine feet two minutes and a-quarter would be necessary to produce a like result. To place the matter in terms which any photographer will understand, the difference is, in fact, the same as would occur by reducing the diameter of the stop to one-third. It cannot be too clearly borne in mind that the sitter should be placed as close to the window as circumstances permit, unless for the sake of obtaining some particular effect rapidity is sacrificed to a slight extent. In proportion as the distance from the light is increased so is the contrast between the illumined and the shadow sides of the face lessened; and thus, if we have too harsh a shadow which cannot conveniently be modified by means of the reflector, we can, by removing the sitter to a greater distance from the window and increasing the exposure proportionately, produce a more harmonious result.

The size of the window will, of course, by admitting more or less light, govern the distance to which the sitter may be moved without practical inconvenience; and the greater its height from the ground the further will the light penetrate into the room, unless cut off by local objects. An extension of the lateral dimensions admits more oblique rays, which act upon the shaded side of the figure, and soften the contrast.

Where the fault consists in the production of too heavy shadows, in nine cases out of ten the cause may be traced to under-exposure. I am assuming, of course, that proper precautions are taken in posing the sitter and in arranging the reflector. The peculiarity of bromide plates is that with a short exposure they are capable of rendering a vast amount of delicate detail, which, however, is of no practical value, as it is impossible to intensify. This is bad enough in a landscape, but when applied to the "human face divine" the result is infinitely worse. But, in addition to the under-exposure, in attempting to push density into the half-tints the well-lighted portions of the face are overdone, and the result is veritable "soot and whitewash." If a slow, or what I have termed unsuitable, emulsion be used these defects will be doubly or trebly augmented, and, indeed, unless an extremely protracted exposure be given, will be insurmountable.

The harshness may, however, arise from bad lighting, and here actual experiment is the only means of getting over the trouble. It is all very well to say, as has been said, that portraits produced in an ordinary room are more pleasing and natural than those taken in the studio because they represent our friends as we are in the habit of seeing them; but, unfortunately, in adopting this opinion, the conclusion is arrived at that nothing is wanted but "the right exposure" to produce an unmistakable *chef d'œuvre*. Nothing could be further from the truth. The simple fact is that we are attempting, under difficulties, to attain the same end which the professional photographer seeks with all the assistance that art and skill can supply, viz., to make up the deficiencies of the too matter-of-fact camera. Indoor portraiture removes many of the difficulties which are experienced in working out of doors, and many effects may be obtained which would be quite out of the question under the latter circumstances; but it is ridiculous to suppose that an ordinary room can enter into competition on level terms with a studio expensively fitted up for the special purpose.

For amateurs, however, the subject is worth studying, as it affords them the opportunity of producing very good results in a branch of photography in which hitherto, as a rule, they have not shown to advantage. But, like most other things, there is a little trouble connected with it; if it were not so, the game would scarcely be worth the candle.

W. B. Bolton.

PHOTOGRAPHY UPON CANVAS PREPARED FOR OIL PAINTING.

In producing a photographic print intended to serve as an outline for a portrait to be finished in oil colours upon ordinary prepared canvas, coatings of collodion, gelatine, albumen, &c., should be avoided, because the colours should combine directly with the grounding of the prepared canvas so that afterwards the film of colour when dry may neither spring up nor show rents.

The simplest way of reaching the desired end is to make the canvas itself the permanent support of the sensitive chemical compound; in a word, to salt and silver it as in the paper process. But as the properties of canvas cause it to require a different treatment from that adapted to paper, the following remarks, supplied by Herr Lüttgens, formerly a painter and photographer in Hamburg, may be useful:—

"The canvas should first be stretched on a frame of laths, and cleaned from all dust or dirt. This is done by pouring strong spirit upon the linen, laid horizontally, until its surface is covered, and rubbing with a clean cloth until all the spirit has evaporated. If the ground contain much oil this operation must be repeated.

"The treatment with spirit renders the canvas better suited to take on the salting solution, which consists of a filtered solution of twenty grammes of bicarbonate of soda in 300 grammes of water. The purpose of the bicarbonate of soda is to cause a slight frothing up of the oil contained in the prepared canvas, so as to make it usable with water. The above-mentioned solution must be poured quickly and equally over the surface of the canvas. The latter should then be turned round and round slowly until it appears equally damp and not streaky. The frame upon which it is stretched is then set up to dry spontaneously, but neither in the sun nor in the neighbourhood of an oven.

"As soon as the canvas is dry pour over it a solution of one gramme of common salt in 200 grammes of distilled water, or, if a bluish tone be required, use sal ammonia instead of the common salt. When this solution has remained four or five minutes on the canvas let it run off, and dry as before. The canvas is silvered in the dark room by pouring over it a solution of one gramme of nitrate of silver in thirty grammes distilled water, no larger a surface being covered than it is intended to print upon. In two minutes pour off the silver, and dry in the dark room.

"In printing one may use either a direct negative or an enlargement from a transparency. The negative may be fastened sufficiently tightly down upon the canvas by a broad band (girth bands) passing over the top and another over the bottom edge of the negative. If the edges do not project far enough they may be eked out by pasting on strips of pasteboard. As the lights must remain clear and white it is recommended to print lightly in the direct sunlight. Fix by letting a weak solution of hyposulphite of soda act on the picture from twenty to thirty seconds.

"Rinse, and then wash the pictures with water every 100 cubic centimetres of which contain two drops of sulphuric acid; then wash well with pure water. When dry the picture is ready for the painter's brush. If the picture should not appear distinctly enough coat it with oil and turpentine. Every disturbance of the prepared surface should be avoided, and from the first operation onwards care should be taken not to wet the back of the picture. Then, as there are various qualities of linen in the market, the first treatment with alcohol and bicarbonate of soda will sometimes require to be frequently repeated, as some sorts of canvas refuse to take on the watery solution, or will not take it on equally. If the picture should not be successful damp it with water, and remove it with a weak solution of cyanide of potassium in water, rubbing it on with a soft rag until every trace of the image has disappeared. Then wash well with clean water, and begin again at the beginning, the only difference being that the bicarbonate solution should not be so strong as at first.

"For direct enlargements upon prepared linen made by means of the sciopticon it is recommended that a solution of bromide of potassium be used for salting instead of the common salt. The silvering should then be done as already described, the excess of nitrate of silver washed off, and the surface coated with Wilde's preservative fluid.*

"When dry the enlargement from the negative should be projected upon the canvas by the lantern, and an alkaline developer used to develope the image. The other operations remain the same as those already described."

The editor of the *Wochenblatt* has not tested this method experimentally, but thinks it looks well on paper.

THE APPLICATION OF PHOTOGRAPHY TO THE PRODUCTION OF PRINTING SURFACES AND PICTURES IN PIGMENT.

IN SIX LECTURES.

V.—COLLOTYPIC PRINTING.

[A communication to the Society of Arts.]

You have already seen how extended is the use of bichromated gelatine in photo-mechanical printing processes, and we now have to study a method in which the gelatine itself is used as a printing surface.

The bare principles of collotypic printing are as follow:—A plate of glass or metal is coated with a uniform layer of bichromated gelatine, and this is exposed to light under a negative. Certain parts become insoluble by the action of light; others remain soluble and capable of absorbing water. The plate is damped, and a roller charged with fatty ink is passed over it. Those parts which received the water refuse the ink; and a piece of paper being laid on and pressure applied the ink sets off on the paper, forming a print. But more than this is true, as we have an infinite number of grades between the two extremes of water-taking parts and of ink-taking parts, those parts which had a slight exposure to light being capable of receiving both ink and water—the proportion in which each is received depending on the extent to which the part has been acted on by light. Here is a damp collotype plate. I hold it up to the light, and those who are near can see a very feeble image. I now pass the inking roller over it a few times, and the fatty ink adheres to those parts which have been exposed to light, the amount of ink being proportionate to the extent to which the light has acted, so that a picture is built up with all its gradations of light and shade. I hold up the inked plate before the light, and you see the image distinctly. I will now hand round the inked plate, together with a similar, but uninked, plate. Here is one more plate, which I take from this dish of water; this I will ink, and take an impression from it on paper. Here they are, you see. If you hand them round you can compare the plate with the proof printed from it.

The first step in preparing the collotypic plate is to take two pieces of plate glass, such as I have here, to put some water and flour emery on one of them, and then to grind them together until the rubbing surfaces are uniformly de-polished. It is not worth while for me to go on grinding these until they are finished, but here are some finished ones which you can examine. When the plates have been sufficiently ground they must be well rinsed and reared up against a shelf to dry. The next thing is to prepare a mixture of seven parts of albumen, three parts of commercial water-glass solution, and ten parts of water. This mixture being made, it is churned to a froth by one of these American egg-beaters. You see it only takes about two minutes to convert the whole into a froth. I now pour this froth on a paper filter, and as it breaks up it runs through. This solution is now ready to pour on the plates, and you see that it runs easily over. I now let it drain off at one corner, and allow the plate to dry in an inclined position. When dry the plate is well rinsed in water in order to remove all soluble matter, and is again reared up to dry. In this state the plate is covered with an extremely thin, whitish film, which causes adhesion between the plate and the gelatine coating which is next applied. The sensitive gelatinous mixture is prepared by dissolving six parts of gelatine in forty-eight parts of water, and adding one part of ammonium bichromate and forty-eight parts of alcohol. The mixture is then strained through fine muslin and is ready for use.

Here is a metal hot plate, made double, and in the interspace water is kept boiling. Three levelling screws support one of the prepared glass plates, about an inch from the surface of the metal hot plate. The glass plate usually reaches a temperature of about 50° C. under these circumstances, and when this is the case, and the plate is quite level, all is ready for coating it with the sensitive gelatine. I now pour on the middle of the plate as much of the sensitive mixture as it will conveniently hold, and you see that it runs well over the plate, even up to the corners. I now lift up the plate quickly, drain off the excess of gelatinous mixture, give the plate a rocking motion, and put it back on the levelling screws in its old position. In about ten minutes it will be dry and ready for exposure in the printing-frame, and this exposure is about equal to that which would be required to make a silver print from the same negative; but a plate which has been dried quickly requires a longer exposure than one which has been dried slowly.

Mr. Debus is now holding a dried plate against the lime light, and you merely see an even yellow tint, arising from the uniform film of bichromated gelatine. He will now hold up a similar plate which has been exposed under a negative, and you see a faint brownish image, showing all details and shades of the original. After having printed the plate under the negative the next step is to soak the plate in cold water in order to remove the free bichromate; and during this soaking the image becomes much fainter, as you will see when I hold this soaked plate before the lime light. During this soaking in water another change, and a remarkable one, takes place; all the exposed parts of the plate become puckered up into a multitude of little folds, which wind about in a very peculiar manner. These folds may be traced almost all over the picture, their depth being greatest on those parts which have been most exposed—at least up to a certain limit, beyond which increased exposure tends to destroy the folds. The pitch of these folds may vary from about fifty to three hundred to a linear

* 1. Dissolve in 1,000 c.c. of distilled water ten grammes of tannin and ten grammes of gelatine cut into very fine strips. After a few days, during which time it should often be shaken, filter off the tannin solution from the gelatine.—2. To 500 c.c. of absolute alcohol add five grammes of salicine; make moderately warm, and shake diligently. Into the filtrate of No. 1 filter 100 c.c. of No. 2. Then add two drops of a solution of five grammes of red coralline in forty c.c. of alcohol, or eosine one gramme, water three c.c., alcohol five c.c. This preservative solution, into which the plate may be dipped, may be used over and over again, but it should be protected from the light.

inch, and this pitch varies according to the treatment of the plate, the kind of gelatine used, the condition of the bichromate, the length of time which the sensitive mixture is kept before use, the rapidity of drying, and other circumstances. This puckering, reticulation, or grain has much to do with the printing qualities of the plate, one with a coarse grain being easier to print from than one with a fine grain, but the results are, in general, not so good. When the plate has been soaked in water sufficiently long to remove the excess of bichromate and to develope the grain it is taken out and allowed to drp spontaneously. The dry plate may then be kept without injury for several days, weeks, or even months. It should be kept in a dry, cool room, and, as a rule, ought not to be put away in a brightly-lighted place.

We now pass on to the inking of the plate and its treatment in the press. Before use the plate should be soaked in water, in order to saturate the soluble portions of the gelatine with this fluid, and generally five or ten minutes is sufficient for this purpose. It is usual to employ the ordinary lithographic roller and ordinary lithographic inks for collotypic printing, and when a lithographic roller is in really first-rate condition it answers admirably; but a new lithographic roller can only be got into a sufficiently good condition by daily exercise for about a month, and the least carelessness, the drying of ink on it, or a cessation of work for a few days, will degrade it from the state of a roller suitable for collotypic work to that of an ordinary roller suitable for lithography.

Here is a form of roller which I have devised, and have found to answer admirably, as it is always ready for use. It consists of an outer cylinder of red india-rubber, made smooth on the outside by means of fine glass paper; inside this is a thickness of about three-quarters of an inch of ordinary typographic roller composition (glue and treacle), and inside all a wooden core, provided with handles. To make this kind of roller I put the india-rubber cylinder inside this brass mould, place the core in position, and pour in a little of this glue-and-treacle composition—just enough to seal the joint at the bottom—and when this has set I will fill the space with the glue-and-treacle mixture. When a roller of this kind is done with the ink can be cleaned off by means of a rag moistened with a little oil of turpentine, care being taken not to use too much. The roller is then ready to be put away, and can be brought into use again at a moment's notice.

The labour of mixing stiff inks and colours, and of getting an even film on the inking slab, is considerable; but I have found that the following plan obviates all difficulty on this score:—The ink is mixed up with oil of turpentine to the consistency of cream, and the colour may be modified by the addition of the artists' oil colours which are sold in tubes. In this way a thorough mixing of the colours is ensured, and, when it is intended to use a portion, a piece of muslin is tied over the mouth of the bottle containing the colour; the bottle is then inverted, and the muslin-covered neck is rubbed over the inking slab. The ink thus filtered out is spread evenly by means of an ordinary typographic ink roller, and is then allowed to remain a few minutes in order that the turpentine may evaporate. Thus is obtained a layer of ink free from lumps, well mixed, and evenly spread. The collotypic plate, being now taken from the water, is laid on the bed of the press, this having been previously covered with a sheet of white paper, and is gently wiped with a soft piece of muslin. The inking roller, being charged with ink from the slab, is gently rolled backwards and forwards, as I am now rolling, it being borne in mind that a slow rolling with heavy pressure tends to put much ink on the plate, and quick rolling with light pressure tends to take off an excess of ink. It is advisable to be provided with two inks, one rather thinner than the other, as the half-tones sometimes require a thin ink to bring them fairly out. To make this thin ink a little of the very fluid lithographic varnish (known as tint varnish or S.H. varnish) is added to the mixture of turpentine and ink. The kind of press best adapted for collotypic printing is the roller lithographic press, like those commonly used in France and Italy—a Waterlow's autographic press is very well adapted for the work—but the scraper press does not answer so well. You see that the press I am using consists merely of two rollers, with the tympan and bed riding between them.

The plate having been inked, and the paper laid on, a moist sponge is passed over the back of it. I then put on a few thicknesses of blotting-paper and a sheet of india-rubber an eighth of an inch thick, shut down the tympan, and pass through the press. Here, then, is the result.

Any kind of paper may be used for collotypic printing, but if it be desired to imitate silver prints a thin and rather soft enamel paper must be used, and the prints must be varnished with a varnish prepared by dissolving two parts of white shellac and one part of mastic in a convenient quantity of methylated spirit. The strength of the solution will depend on the effect required, and it is scarcely necessary to say that the varnish must not be allowed to chill. Here is a print; I will varnish one half of it, and when dry you can compare the two sides.

The process which I have demonstrated to you is practically that of Professor Husnik, as set forth in his invaluable work on the subject,* and if I were to give you the leading features of the various collotypic processes I should occupy several hours in doing it. The characteristic feature of the Albertype process consists in covering the glass plate with a film composed of gelatine, albumen, and potassium bichromate, and exposing this to light through the plate of glass, so as to make that part in immediate contact with the glass insoluble, washing off the soluble portion in warm water, so as to leave a very thin film of insoluble gelatine, capable of serving as a bond between the glass and the actual printing film, which is now applied.

Mr. J. R. Sawyer, of the Autotype Company, has elaborated a process by which he has produced magnificent results, some of which you may see hanging up all round the room. You will see among these representatives of almost all classes of photographic work—ancient manuscripts, coins, architecture, landscapes, engineering works, and book illustrations. Directly opposite to me is an exceedingly fine collotypic print of Norwich Cathedral, and this is from one of Mr. Sawyer's own negatives. You will also notice a series of prints representing the great public engineering works of France, which are now being printed by the Autotype Company under the direction of Mr. Sawyer. The production of this series, regularly and in large numbers, proves the thorough practicability of the collotype process when in careful hands.

You see before you some admirable specimens of collotypic printing by MM. Braun, of Dornach, Herren Strumper and Co., of Hamburg, and Messrs. Wright and Co., of London.

The next great step in collotypic printing is the application of steam machinery to the process; the difficulties of wiping the plate, inking, and taking off the paper by machinery are considerable, but these difficulties are being gradually overcome.

Thomas Bolas, F.C.S.

"A NEW METHOD OF MAKING GLASS STEREOSCOPIC TRANSPARENCIES."

To the Editors.

Gentlemen,—I have read the paper on *A New Method of Making Glass Stereoscopic Transparencies* more than once with care, and, although I am ever ready to hail with delight any effort to popularise the stereoscope, I must confess I fail to see any great advantage, but, on the contrary, very many disadvantages, in the method proposed.

A more lengthy communication on the subject is quite at your service if you wish; but for the present I must content myself with this expression of feeling. At the same time I should like to add that I have every kind regard for Mr. William Brooks, and for my own part thank him for the time and trouble spent in perfecting his plan and making it public. He is unquestionably right in the main, and stereoscopic transparencies can and will in due time be produced rapidly and well at a reasonable rate—transparencies in every way equal to those by the late Mr. Breese, to whom be all honour for leading the way.

I sincerely trust, now the subject is once more *sur le tapis*, it will be thoroughly ventilated by all concerned, and especially let the manufacturers come forward with their opinions. They have had very little to say in the matter hitherto publicly, but have been content to keep up a quiet grumble to themselves ever since the first rage for stereoscopic slides died out; but let them take heart, for "there's a good time coming" for stereoscopic work yet, and I think I may venture to prophecy that a good stereoscopic transparency (not necessarily on glass) will eventually be sold to an appreciative public at a shilling, and that the manufacturers will not be able to turn them out fast enough to supply the demand.

I owe to the Manchester Photographic Society a second paper on *Combination Printing for the Stereoscope*, one word of which is not written as yet, I regret to say; but I hope, nevertheless, to have it ready during the early part of the next session.—I am, yours, &c.,

16, *Silverwell-street, Bolton*, S. H. Ashley Oakes.
August 20, 1878.

"HONOUR TO WHOM HONOUR IS DUE."

To the Editors.

Gentlemen,—Is there not a deep-seated animus between you and the editor of your contemporary? Readers of both journals well remember

* *Das Gesammtgebiet des Lichtdrucks.* J. Husnik. 3 Mark. Hartleben, Leipzig.

the manner in which you held up to ridicule the pretensions of that contemporary with regard to the collodio-chloride discovery; and I see from his issue of August 9 that you have again been attempting to deprive that gentleman of the honour of being the first discoverer of the liability of transfer-paper to turn yellow, this having, as he alleges, been done as far back as April of this year.

How come you to claim the honour for a denizen of the Scottish capital when you ought to have known that, at the best, all that can be claimed is but a re-discovery in this matter? Surely, ordinary fairness would have awarded to him who first published the important fact that photographers would require to be vigilant in submitting the permanent mediums on which their pigment pictures were to be laid down to a crucial test before doing so, as it is evident, from the facts brought out, that the papers undergo a great change when subjected to light. This, no doubt, accounts for the universal charge brought against carbon prints, namely, that they turn very yellow in the course of time. My card is enclosed.—I am, yours, &c.,

NOT ONE OF THE "BLACK CROWS."

Glenkennaquhair, August 13, 1878.

[The above was received too late to be inserted in our last number, for which it was intended.—EDS.]

MR. CHARLES BENNETT'S RAPID GELATINE EMULSION.

To the EDITORS.

GENTLEMEN,—I should like to ask Mr. Charles Bennett whether he pours the warm silver solution *bodily* into the bromised gelatine solution or whether he adds it a few drops at a time, with brisk shaking between each addition. I have again prepared five ounces of emulsion, and, indeed, it makes me smile to see the persistency of the thinness of the images, for the plates never vary, but, without exception, are all alike.

I would take it as a great favour if Mr. Bennett would expose and develope one or two of the plates for me. I certainly am unable at present to hit upon the cause of my failure. I now use three thicknesses of the darkest ruby-coloured glass and an oil lamp within a specially-constructed lantern, and feel certain no actinic light ever touches the emulsion.—I am, yours, &c., J. M. J. DANKS.

5, *Jesson-street, Coventry, August* 20, 1878.

EXCHANGE COLUMN.

ANSWERS TO CORRESPONDENTS.

PHOTOGRAPHS REGISTERED—

Alfred John Reynolds, Liverpool.—*Two Photographs of Lord Beaconsfield.*

☞ *Correspondents should never write on both sides of the paper.*

GEO. MCDOUGALL (Montreal).—P. O. O. to hand. Thanks.

TYCHO.—There is no patent now existing for making carbon tissue in the manner you describe.

GEO. SPENCE.—The top light predominates to such an extent as to render the shadows in the face unnaturally heavy.

A. F. E.—While the drab colour is not objectionable your purpose will be much better served by making choice of paper of a light green colour.

G. B.—Address a note to the Assistant-Secretary, Mr. Cocking, 57, Queen's-road, Peckham, S.E., from whom you will receive all necessary information.

C. E. ARTHUR.—1. By advertising for a van you will easily obtain one. Several have lately been offered for sale.—2. The ordinary acetate of soda bath answers very well.

GEO. THOM.—The second lens on the list will answer well for the group, but No. 5 is quite unsuitable. It is an architectural lens, and requires a stop of such small dimensions as to necessitate a long exposure.

EXCELSIOR CO.—Insufficient fixing is the cause. Increase the strength of the hyposulphite of soda solution, and allow the prints to remain longer in that solution. The washing seems to have been effected in a sufficient manner.

G. F. LITTLEJOHN.—Yes; the light from ignited magnesium will prove sufficiently powerful. Twist two or three strands of the ribbon into a taper, and keep it moving in a lateral direction during the whole time the exposure is being made.

JOSEPH W. NICKLIN.—Not being camera manufacturers we cannot give you the required estimate of cost of altering your camera, but prefer instead to refer you to any of the various makers, whose names and addresses you will find from week to week in our advertising pages.

B. B.—With one exception the composition is excellent. That exception is found in the left foreground of the picture, in which the large white boat forms too obtrusive an object; and, not only so, but it forms an angle which is a repetition of both the distant and intermediate mountains.

OLD JOE.—The registration of a photograph does not impart a property in the copyright to the individual in whose name it is entered in Stationers' Hall. You should carefully study some articles on the subject of registration and copyright which have appeared in this Journal within the past six or seven years.

"ONWARD."—This correspondent inquires—"Which are the simplest and surest dry plates in the market for an amateur in this branch?" Before this question could be answered it would be necessary for us to have tried all the plates in the market. Does "Onward" expect us to incur the trouble and expense of doing so in order to provide a reply to his query?

ROBERT CHALLENOR.—This correspondent describes his case as follows:—"I wish to ask your advice in regard to a portrait lens I have had given me. The focus when taken on the glass is all that could be desired, but after substituting the dark slide and developing the image it is quite out of focus. I have had the camera examined by a qualified maker, and he says the camera is a first-class one, and the fault must therefore be with the lens. Please tell me the cause of this, and the remedy."——The cause will be found in the lens having been either over- or under-corrected for colour—most probably the former. It is a fault peculiar to many lenses of foreign manufacture. They give an admirably sharp and clear image upon the ground glass, but as the visual and chemical foci fall at different distances from the lens they do not "work to focus." By re-grinding the front lens this defect can easily be cured.

RECEIVED.—A. E. D. In our next.

STORES FOR CYPRUS.—Stores for Cyprus have been shipped from Woolwich Arsenal, including two photographic waggons and apparatus, and large numbers of plank bedsteads. Large quantities of compressed hay have been prepared for Cyprus, and a party of men from the Ordnance Department will shortly be sent out to take charge of the stores.

PHOTOGRAPHY IN COURT.—At the last sitting of the session of the Bloomsbury County Court the case of Boyle *v.* Chaplin was heard before Mr. Judge Russell, in which the plaintiff, described as a photographic artist, of Mornington-road, sought to recover the sum of eight guineas under the following circumstances. Mr. Willis appeared as solicitor for the plaintiff, and Mr. Dunn for the defendant. The plaintiff, being called, said the defendant's wife called at his studio and ordered a full-sized portrait of herself to be taken and finished in oil. She was told at the time what the price would be and made no objection to it, but stated at the time that she wished to present it to her husband on his birthday. Upon the lady's representations he finished the picture and sent it to her address in Albert-street, with the account and instructions to wait for payment, but the defendant's wife said that as some alterations were required she would pay the amount when they were made. After several written applications had been made for payment without success the present action was commenced. This was the plaintiff's case. The defendant, being called, said that as his wife was under a deed of judicial separation, and that as he allowed her sufficient alimony, he did not consider himself in any way liable. At this stage of the case it was suggested that the name of the wife be substituted on the summons. This being done the defendant's wife stated that she never said the portrait was intended as a present to her husband. "He was not worth it," She would have paid for the picture had she considered it a good one, but it was not, and she told the plaintiff so and asked him to paint another, which he declined to do. The plaintiff, being recalled, denied this, but acknowledged the picture had been sent back after it had been three months in the lady's possession, and as it was of no value to him he had sued for payment. He had skilled witnesses in court who could prove that as a work of art the picture was complete. The picture being produced in court and pronounced by the Judge to be an excellent one, judgment was entered for the plaintiff for the full amount claimed with costs.

THE BRITISH

JOURNAL OF PHOTOGRAPHY.

No. 956. Vol. XXV.—AUGUST 30, 1878.

ON A NEW METHOD OF CORRECTING EMULSIONS.

When we speak of the correction of an emulsion it will be, of course, understood that we refer to the important operation of so adjusting the respective proportions of soluble bromide and of silver that the preparation shall possess due working qualities. Our readers are well aware that different operators hold different opinions as to the advisability of having one or other of the ingredients in excess in the final emulsion; and, while many prefer to work with a large excess of silver, by which extreme sensitiveness is gained, by far the greater number continue to favour a slight excess of bromide, merely permitting the silver to be in excess during a portion of the time occupied in sensitising.

The operation of neutralising the excess of silver thus introduced into the emulsion—in other words, its correction—has hitherto been invariably performed by the addition of a fresh quantity of a soluble bromide, or, at anyrate, of a soluble haloid of some sort, either bromide, iodide, or chloride; and it does not appear to have struck any of our emulsion experimentalists that the same end might be effected in a slightly different manner, and without some of the objectionable features of the old method. The sole object in correcting an emulsion is to remove from it every trace of soluble silver salt, or, rather, to convert the soluble into insoluble material. By the addition of a soluble haloid this is readily effected in what would appear to be the simplest and most rational manner, the insoluble compound formed being identical in composition with the bulk of the sensitive film; but, unfortunately, the addition of an overdose of the correcting material is apt to lead to insensitiveness, and hence great care is necessary in the careful adjustment of the proportions used.

By substituting other materials for the haloid salts usually employed it appeared to us that all the advantages of a perfect correction might be secured without the same risk of destroying the high degree of sensitiveness attainable with excess of silver. A first attempt showed that not only was this surmise correct, but an additional advantage was gained, namely, greater ease in intensification—a matter in which the most sensitive emulsions are frequently deficient. Briefly, the new plan consists in substituting for the bromide or chloride usually added for the purpose of converting the excess of silver contained in the emulsion an equivalent of some organic or other acid capable of forming insoluble silver salts; or, as will be found more convenient in most cases, a soluble salt of such acid capable of reacting upon the soluble silver salt in the emulsion. It is evident that in this manner we have a large choice of materials placed at our disposal, and the introduction of various organic silver compounds into the emulsion becomes a matter of the greatest ease. We cannot as yet pretend to describe the *best* material to use nor do we offer all the substances described as actual improvements. We mention them in explanation of the direction our experiments have taken; and, in connection with one or two which seem to offer greater promise than the rest, we shall describe their special features.

Amongst the substances we have already tried we may name citric, tartaric, acetic, boracic, oxalic, phosphoric, and tungstic acids, either alone or in combination with a base replaceable by silver. Numerous other substances will suggest themselves, but these are sufficient to show the class of salts which are adapted to the purpose. Except as a matter of convenience we imagine that it is immaterial whether the uncombined acid or one of its salts be employed, unless, indeed, it be in the case of an emulsion *à la* Newton, which is required to be kept for some time without washing. Under such circumstances long contact with the free nitric acid liberated by the decomposition of the silver nitrate might possibly lead to partial destruction of the collodion film. In the case of the three last-named acids it will be found far preferable to employ the soda or potash salts in concentrated solution rather than the pure acid. The remainder, though easily applied in the uncombined state, are perhaps, for the reason we have given above, better used in combination with an alkaline base.

The first of these substances tested was citric acid. This, from its easy solubility in alcohol, is most conveniently used in the uncombined state, when, if the liberated nitric acid be objectionable, it may be readily neutralised. For a washed emulsion, however, this will not be necessary; and it may be remarked that an *excess* of citric acid—that is to say, a quantity over and above that required to combine with the free silver—will be found an actual advantage, in enabling the emulsion to better resist the action of the washing or precipitation. If the excess be considerable, and the time allowed for the ripening of the emulsion be protracted beyond a few hours, its fluent properties will be greatly diminished and the dried film rendered horny and extremely contractile.

Using citric acid in the proportion of a grain and a-half to each grain of silver estimated to be in excess, we have prepared an emulsion in which the quantity of silver actually employed was seven or eight grains per ounce in excess of the theoretical quantity necessary to neutralise the haloids in the collodion, yet the bichromate test failed to show any free silver. A small quantity of the emulsion poured into water and boiled for a few seconds did show signs of the presence of soluble silver salt; but it was due, no doubt, to the partial solubility of the citrate of silver in the boiling water. This emulsion was precipitated in the ordinary manner, and when washed until it showed no acid reaction a small quantity of the "pellicle" boiled in a test tube still showed the presence of a soluble silver compound. The mass was, however, dried and redissolved, when it exhibited not the slightest tendency to fog, but gave a clean, vigorous image with a very brief exposure. In the latter respect it was equal to any collodion emulsion we have ever made, with considerably less trouble in its preparation and greater certainty in its results. We may call special attention to the peculiarity we have spoken of, namely, the presence of traces of a soluble silver compound in the washed emulsion. It must be borne in mind, however, that the use of *boiling* water is necessary to extract this soluble matter, and hence we may infer that so long as we employ a developer at ordinary temperatures there is no danger of fog on that account.

Very satisfactory results were given by an emulsion in which the excess of silver nitrate was converted into oxalate. The behaviour of this was similar to the previous one in many respects, but the colour of the developed image was slightly different. The correction was performed with a hot concentrated solution of potassic oxalate, the additions being continued until the bichromate test showed no signs of free silver. It should be remarked that, except where a free acid is employed as the correcting agent, nitric acid or *aqua regia* should be added to the emulsion as in the ordinary processes with free silver.

Further experiments were made, substituting as the correcting agent cream of tartar, acetic acid and acetate of soda, boracic acid, phosphate and tungstate of soda—all of which have proved more or less capable of preventing fog in the presence of a large excess of silver nitrate. But we cannot as yet say much of the individual action of any of the last named, as we have been compelled to relinquish our experiments for a few days. We shall, however, at no distant date, have more to say with regard to the properties of the various salts; meanwhile we shall be glad of the assistance of other emulsion workers in this line of research. As far as we can at present judge, the use of a large excess of either citric acid or oxalate of potash produces no permanent effect upon the rapidity of the resulting emulsion. If subsequent experiments prove that this view is correct we shall have scored a most important advance upon the ordinary method of correction.

A NEW PORTABLE CAMERA.

The readers of our earliest photographic serial literature will recollect the great displays of ingenuity made by photographic amateurs in the construction of cameras. The square wooden box—perfect as it is when portability does not form an element in the requirement—was found to be quite inadequate to the necessities of the landscape photographer, and hence arose numerous ingenious devices by which the clumsy rigidity of the original camera was superseded by apparatus into the construction of which mechanical ingenuity had been imported to such an extent as to secure all the advantages of the original form with those of portability superadded.

The march of improvement in cameras has not come to a standstill, numerous refinements and real improvements having been introduced during the past few years by one or other of those makers who devote themselves to this branch of manufacture.

Without alluding to the details of the various cameras introduced during late years, and in which the desire has been in the direction of increased portability, we will at present endeavour to give a brief description of a portable camera recently introduced by Mr. S. W. Rouch (of the firm of W. W. Rouch and Co.), who has secured a patent for certain improvements that have been effected in this necessary piece of photographic apparatus.

The camera manufactured in accordance with the new patent which has been submitted to our notice is, indeed, singularly light for the size of plate for which it is adapted. This is a feature most invaluable to those landscapists and tourists who have to trudge many a weary mile "over hill and through dale" in search of the beautiful and picturesque. It also packs up in very little space, the 9×7 camera in question occupying only a space of $10 \times 9 \times 2\frac{3}{4}$ inches. We are well aware that mere portability and compactness are purchased very dearly by the sacrifice of the more important qualities of rigidity and adaptability; but in this instrument the gain appears to have been secured without sacrificing any other valuable feature.

The chief mechanical point of novelty consists in having the base-board so hinged to the body of the camera as to allow it (the base-board) to enact the twofold part of a protecting shutter to the ground glass when the camera is packed up and also its own proper function when the camera is erected for use. In order to do this the board in question is hinged in such a manner by the posterior edge of the frame containing the ground glass and bellows as to be capable of turning round to a right angle from its position as a shutter under the camera, in which latter position it forms the base-board, capable of being securely fixed by means of a screw not only at a right angle but at any angle within several degrees of this, thus forming a most efficient means by which the swinging of the back is allowed, so as to secure non-convergence of the perpendicular lines in architecture as well as sharpness of the extreme foreground in purely landscape subjects.

But it will be readily perceived that a base-board capable of forming a protecting cover for the ground glass is obviously inadequate for the performance of its legitimate functions, inasmuch as it could not extend sufficiently far forward to enable any lens save one of very wide angle to be used. This is quite true; but, to provide at once for both the extension of the camera to reasonable limits and also to admit of focussing, there is a light framework which can be instantaneously attached to the base-board, and to the outer end of which the front of the bellows body is secured. This framework, being fitted with a rack-and-pinion, is capable of yielding the most perfect adjustment of focus.

There are other details connected with the camera that will eventually be described when the specification of the patent is published. At present we have said sufficient to afford a fair idea of a camera which, from its lightness, is certain to find many admirers among tourist and landscape photographers, to whom the saving of every pound of weight is an important matter. The specimen camera we examined was one which contained all those points specially claimed in connection with it; and, while its normal position was such as to render it more particularly adapted for landscapes pure and simple, it yet possessed the requisite arrangement for allowing the plate to be reared on end so as to be placed in a suitable condition for taking a view of a church, a glen, a waterfall, or any other subject in which the composition partakes of a vertical rather than a horizontal character.

COPYING OIL PAINTINGS.

The copying of pictures and, *par excellence*, of oil paintings is a branch of photography which all beyond a select few, not even excepting professional artists, look upon with distrust, not to say aversion. It is the work generally deferred till the day comes when it must be done or declined; and when it is done the result, in a great many cases, is little better than worthless. Yet there is no real need for an oil painting to be looked upon as such a bugbear; for, by the exercise of a little time and care, combined with a thoughtful appreciation of the actual requirements of the case, the occasions are not many when a photographer of average ability cannot make a fairly satisfactory copy of any picture likely to be brought to him.

We have purposely employed the word "time" as an element in the success of the photographer; for those who have not tried the production of a satisfactory negative of, for instance, an eight-feet picture have no idea of the time taken in the fixing up alone. Every painter—at least one of any pretensions—has in his studio a large, commodious, and complete piece of machinery called a "studio easel," and with it he can readily raise or lower his canvas, place it at any angle—sideways or forwards—and, in fact, adjust it in any direction he sees fit.

But in the photographer's studio, except he be one of the few who lay themselves out for this class of work, no such thing can be found; and the time, trouble, and constant worry of shifting and altering can only be understood by those who have undergone it, on account of the absence of every likely contrivance to enable the operator to fix the picture in a suitable position with regard to light. So much is this the case that we know a professional photographer who makes a point of charging an extra fee of one guinea—that is, a guinea beyond his usual charge for this size—for taking a photograph of any oil painting brought to him. We shall mainly speak of the precautions to be taken in photographing such works when the painting can be brought to the photographer's own premises or studio.

It will be found that a large camera is difficult enough to move without any frame, and that if it be attempted, to "save the trouble of taking it out of the frame," the labour will be increased tenfold; hence we would say never receive a painting until the frame has been removed, unless it be very small in size. The picture having arrived, the first step is to place it in position opposite the camera—the arrangement of lighting will be described hereafter—and for this purpose one of the cheap easels procurable from artists' colourmen will be most serviceable. A very useful portable one can be had for a little above half-a-sovereign. When large framework has to be dealt with the photographer's own mother wit must be trusted to—in either case the point to receive attention being to see that the canvas is quite square to the lens. If this be not done—though it is not so absolutely essential as when copying a map or other object with many lines—considerable trouble will be experienced afterwards; for in any case a portion of the picture would have to be sacrificed to enable the print to be trimmed square for mounting.

The next point is the lighting. Here let us say that we have not found the slightest practical use from the employment of any of the commonly-recommended specialities, such as coloured glass before the lens, coloured lighting, &c., &c. If the operator will very carefully examine a picture so placed with the usual arrangement of lighting for a sitter he will observe patches of white light moving about in the picture as his own position alters, and, as he moves, their position in the picture will also change. If he go to one side they perhaps disappear, or if he look from a higher or lower standpoint the same thing will be observed. These spots or patches of light are reflections of the skylight and of surrounding objects; and if not removed will photograph with far more intensity than the picture itself—in fact, quite obliterate it. What, then, is required to cause such reflections to disappear?

In the first place, all light objects that are in the way must be removed. Naturally the perfection of result would be obtained if everything in the room were dead black; but, as this is impracticable, the nearest attainable approximation to it must be obtained. Light-blue studio walls are greatly to be deprecated, as it is next to impossible to avoid their appearance in some parts of the picture where least desired; and it must ever be recollected that any reflection of light objects will impress the film with greater power than the picture itself, and so swamp everything in that portion of the picture—making it look ridiculous, we might almost say. It is no use attempting to get any copy till the lighting is so arranged as to eliminate all such reflections.

It is well to call to mind the old and well-known rule as to reflecting objects—"that the angle of incidence is equal to the angle of reflection;" from which it will be seen that the nearer the illuminating area lies towards the edge of the picture the more is its reflection thrown away from the lens. Thus, assuming, for example, that the picture were illuminated by an electric light fixed (say) at the top of the camera no copy could be got, as the light itself would be imaged in the camera by its reflection from the polished surface of the painting at a spot a little above the level of the lens. If the light were fixed a little higher the reflection into the lens would take place from a spot a little higher up, and so on by gradually raising the light the spot where the reflection came from would be raised higher and higher, till at last the limit would be reached and no reflection into the lens would take place, and the perfection of illuminating, so far as this phase is concerned, would be gained; but the same effect would, of course, be obtained by lateral reflection.

This is an important matter, as upon it depends almost the whole success of the photographing, and we have dwelt thus fully upon it because if once mastered in principle the power to overcome the remaining obstacles will almost follow as a matter of course. It has taken up so much of our space that we shall defer the conclusion of our instructions till next number.

Zinc bromide, one of the most recently introduced of the haloids now used in the manufacture of collodion, possesses certain properties of its own which render it peculiarly valuable for many purposes in photography; but it is, unfortunately, a comparatively expensive salt, and its manufacture, especially to the amateur chemist, is beset by so many difficulties that it scarcely secures the amount of recognition due to it. We have to record a simple method by which it may be prepared in a state of sufficient purity for photographic use without the expenditure of any serious amount of trouble, and in the absence of any special manipulatory skill. The method is based upon the fact that cadmium is precipitated from solutions of its salts by contact with metallic zinc. All that is necessary is to make a concentrated alcoholic solution of the comparatively common and inexpensive bromide of cadmium and to throw into it a few pieces of granulated zinc, leaving the solution in contact with the zinc for a day or two, with an occasional shaking to dislodge the precipitated cadmium which clings in the state of fine powder to the surface of the zinc. When the action is judged to be complete the alcoholic solution of zinc bromide is filtered in order to remove the minute particles of metallic cadmium, and may then be used without any further treatment in the preparation of the collodion. It will, of course, be necessary to form an estimate of the strength of the solution, which may be effected by actually testing a measured quantity, or, better still, a known quantity of the cadmium salt may be operated upon at first. Thus, if we dissolve two hundred and fifty-six grains of anhydrous bromide of cadmium in one ounce of alcohol (or, rather, if the bulk be made up to one ounce after the salt is dissolved) each drachm after treatment with zinc will be equivalent to forty grains of silver nitrate. The results attained in this manner will be found at least as accurate as if the crystallised salt were employed, as the latter always contains, even when freshly prepared, a large proportion of insoluble basic salt, whence it is evident that any calculations based upon the actual weight of material used must, of necessity, be open to some uncertainty.

BLISTERS ON ALBUMENISED PAPER.—LATITUDE OF EXPOSURE.

The unusual occurrence of getting hold of some late numbers of The British Journal of Photography throws a little photographic light into my life—ignorant of iodides and bromides, gelatine and collodion, for nearly three years past; and I find that all the old enemies are not dead yet. We have got rid of some big lubbers in the political world, but you have not got rid of blisters in yours; and I am tempted to recal some experiences of mine of many years ago when I lived out of the photographic world, and had to prepare my own paper and make my own nitrate and chloride, &c.

I had one certain method of albumenising paper to avoid blisters. It was simply a first sizing by floating on dilute albumen, unsalted, which was "fixed" by floating on scalding water, albumenised side up, and then albumenising again with the ordinary albumen salts. I remember that the sample of paper seemed insufficiently sized, as the albumen, without the first preparation, dried too matt. The cause of the blisters is evidently the condition of the albumen film, which forms a cuticle *on* the paper, instead of being partially absorbed by it.

A priori, I should say that a highly-sensitised gelatine-sized paper would give a good crop of blisters, and that the only remedy, if any, is to let the paper lie in the albumen solution twice as long as usual, or until the dampness has thoroughly penetrated to the back, and mixture has taken place between the gelatine and the albumen. On the same grounds a starch paper ought to blister less, and a paper albumenised without previous sizing should be perfectly free under any circumstances. One of your correspondents suggests floating the paper that shows blisters on a bath of salted water. This ought to remedy the blistering if my theory be a good one, as a good soaking from the back would allow the sizing and the albumen to mingle, and prevent the latter from separating afterward under any osmose action.

I remember that Anderson, the late well-known Roman photographer, who was a very successful operator and printer, used to put his albumen in demijohns, and stand it in the sun till it was perfectly putrescent and limpid as glycerine, and I do not think he ever had a blister, even in the heat of Rome. The viscidity of new albumen is a great obstacle to its permeating the paper and uniting with the sizing.

Where the paper is "Hobson's choice," and will develope blisters, I advise, if unalbumenised, the soaking it (say) ten minutes in a bath of soft water, and then drying again before albumenising; if albumenised, the bath of salt water at the back, when continued till the paper is *perfectly* limp, should cure it. Alcohol at the back ought to be efficacious, as it coagulates the albumen in contact with the sizing, and prevents the osmose action tearing them apart; but if the gelatine in the paper be in excess the alcohol will have less effect than a water bath.

The discussion going on between yourselves and some of your correspondents, as to the greater range of exposure in slow dry plates than in quick or extra sensitive ones, does not seem (pardon me for-saying so to such experienced experimentalists as yourselves) to have touched the bottom of this question. That there is a latitude of exposure in plates that contain an excess of bromide much greater than where there is no such excess is a fact which I have thoroughly proved by numerous experiments. The reason of it is simply this—that where there is an excess of bromide there is a tendency in the film to recede from the development (or, as the Americans would say, to go back on the developer), while with an excess of silver or a neutral film it is almost, if not quite, impossible to avoid incipient reduction of the haloid silver once impressed by the light. It is the difference between stopping a loaded wheelbarrow going down or up hill; one is sometimes impossible, the other the easiest thing in the world—the excess-of-bromide plate having a specific determination against the development, while the other has a distinct tendency to follow it.

Iodide has the same effect in wet collodion. It is only throwing dust to say that it makes no kind of difference whether you have an exposure of minutes or seconds—that the relative difference is always the same. Anyone can satisfy himself as to that who will try the following experiment:—Take an excess-of-bromide plate and the quickest gelatine plate you can get, and expose them both in a stereo. camera, giving to the slow plate the full aperture of the lens and to the quick plate a small stop proportionate to the quickness—that is, so that the two plates ought to make a satisfactory image in the same time—and expose one half of each six times as long as the other half. Cut them apart, start the development in a tray altogether according to the requirement of least-exposed halves, and see which *over-exposed* half you can recover and make the best negative of.

The difference is not in the quickness of the plate, but in the presence or absence of a distinctly restraining element always present. A gelatine plate containing free bromide may be quicker than a collodion plate without giving, and yet give, more latitude of exposure, *i.e.*, be the safer plate for uncertain lights and general out-of-door or interior work. W. J. Stillman.

Florence, Italy.

THE APPLICATION OF PHOTOGRAPHY TO THE PRODUCTION OF PRINTING SURFACES AND PICTURES IN PIGMENT.

IN SIX LECTURES.

VI.—OTHER METHODS OF PRODUCING PHOTOGRAPHS IN PIGMENT.—DUSTING-ON PROCESS.—AUTOTYPE PRINTING.

[A communication to the Society of Arts.]

You will remember that, last week, I spoke of the use of india-rubber rollers for the inking of collotype plates, and that I recommended a roller made with a thin surface of red india-rubber on a body of the glue and treacle composition used for typographic rollers. At the conclusion of the lecture Mr. Dallas informed me that Messrs. Blades, East, and Blades, of Abchurch-lane, have recently introduced into commerce a roller consisting of a thick layer of red vulcanised india-rubber on a rigid stock. These rollers are made under a patent of Mr. Lanham, manager to the above-mentioned firm, and will, I am convinced, prove of very great value to lithographers as well as to collotypic printers. The manufacturers have kindly lent me some specimens of their rollers, which are now on the table.

Up to the present time we have been studying the means of producing, by the agency of photography, printing surfaces from which copies might be obtained without any further intervention of light; but in this, the last lecture of the series, I want to call your attention to some methods for the production of pictures in pigment which necessitate a separate and direct action of light for the production of each picture.

Here is a glass plate, and I pour on it a mixture containing twenty-five parts of glucose, four parts of honey, and four parts of ammonia bichromate, dissolved in 120 parts of water. I lay the plate on the hot-water apparatus, and it will be dry in a few minutes. If the dried plate be exposed to the atmosphere it will absorb moisture, and the whole surface will become sticky. Now that the plate is dry and while it is warm I will place it behind a transparency and allow a strong light to shine on it through the transparency. The joint action of light and ammonium bichromate tends to make the honey and glucose insoluble; or, at anyrate, it prevents these materials from absorbing moisture from the air, as they tend to do naturally. Let us now take the plate out of the frame and examine it. A very faint image may be traced thereon, but only those of you who are near can see it. Now, what is happening to this plate? Those parts which were protected from the light are absorbing moisture from the air, the honey and glucose being here unaltered, while those parts which were exposed to the full action of the light refuse to absorb moisture, and those parts which have been protected from the action of a part of the light absorb an amount of moisture proportionate to the degree of shade afforded by the half-tones of the transparency. Now note the effect of dusting powdered blacklead over the plate, and rubbing it on with a soft brush. Those parts which are dry refuse to take the blacklead, while those parts which are moist hold an amount of blacklead proportionate to the degree of moisture. Now look at our plate, and you will see that there is a picture showing all degrees of light and shade, the picture being formed of blacklead, held by the various degrees of moisture absorbed from the air. The next step is to coat the plate with collodion, and to immerse it in water, in order that the yellow ammonium bichromate may diffuse out. Other pigments than blacklead may be employed, and the pictures may be made on paper or other materials; but the dusting-on process, although interesting as a means of producing permanent photographs, is not worked commercially to any great extent.

We now pass on to the study of a process of much greater importance than the dusting-on method, namely, the so-called carbon process, or the autotype method. The first step in this process consists in coating one side of paper with a tolerably thick layer of gelatine, to which a little sugar has been added, together with sufficient pigment to strongly colour the mixture. Here is a piece of the "pigmented tissue," as it occurs in commerce. To prepare it about three parts of gelatine and one part of sugar are dissolved in water, and the pigment is added in sufficient quantity. A band of paper is then drawn over the surface of the mixture in such a way as to coat its surface with a uniform layer of the composition. The pigmented tissues are prepared on a large scale by the Autotype Company and others, and few will care to prepare their own tissue, excepting for experimental purposes.

To make the tissue sensitive to light it is soaked in a solution of potassium bichromate containing about three and a-half per cent. of the salt. You see that this piece of tissue has now become quite flaccid from the absorption of the solution; so I scrape off the excess of solution by drawing the tissue over the edge of the dish, take it out, and hang it up to dry. When dry it will be ready for exposure under the negative. Here is some which has been previously dried, and I will put a piece under this negative and expose it to the action of a bright light. In the ordinary process of silver printing one can watch the progress of the operation, and can easily tell when sufficient exposure has been given. Not so in the case of the tissue, as it undergoes no visible change by exposure to light. Here is a little tin box having a small glass window in its lid, and a strip of sensitive silver paper can be drawn forward under this window. The lid having been shut down so as to press on the strip of silver paper the tin box is exposed to light simultaneously with the printing-frame containing negative and tissue, and as soon as the silver paper has acquired a certain standard tint or degree of darkness it is considered that the tissue has had one unit of exposure. The silvered paper is then drawn forward so as to expose another portion, and so on until as many units of exposure have been given as the tissue is known to require when exposed under the negative in hand. This is quite easy in practice, as a little experience will enable one to judge how many units of exposure, or "tints," will be required by each negative, and one guide-box, or "actinometer," serves for any number of printing-frames. The tissue which I just placed under a negative has now had sufficient exposure to light. I take it out, soak it in water until it is soft, and then, while it is still in the water, I bring it in contact with a piece of paper which has been coated over with a thin layer of insoluble gelatine, so as to make it impervious to water. The tissue and the impervious paper are drawn out of the water together, and an application of the squeegee now removes the excess of water which remains between the two surfaces, and the exposed tissue adheres to the impervious paper. Let us allow them to remain in contact for a few minutes, in order that the tendency to adhere may become greater.

Bear in mind that the bichromatised and pigmented gelatine becomes insoluble by the action of light shining through the negative, and the depth to which this insolubility extends is dependent on the amount of light which has acted on it. On those parts of the tissue which have been exposed to much light a thick layer of gelatine is made insoluble, while on those parts which have been exposed to only a little light the insoluble layer is very thin.

Now, we want to wash away the soluble portions of the gelatine from the exposed tissue, and to leave the portion made insoluble by the action of light, just as in the Woodburytype process; but if the exposed tissue were put directly into hot water the insoluble image would become undermined by the dissolving away of the gelatine from underneath it, and it would become destroyed for want of a support sufficiently strong to hold it together. You can now understand why the exposed tissue was mounted on a piece of impervious paper, this being intended to hold together the insoluble gelatine image during the treatment with warm water. Here is the tissue, which I mounted on a piece of the impervious paper, or single transfer paper. Notice the effect of putting it into a dish of warm water. You see that the soluble gelatine in which the insoluble image is embedded melts and exudes from under the edges of the paper, while the application of a very little force will now enable us to separate the two papers, viz., that on which the tissue was originally made and the impervious paper on which the tissue was mounted. Under these circumstances the insoluble image naturally adheres to the impervious paper, or single transfer paper; but it is at present clogged up by some of the soluble gelatine, which must be removed by rinsing with warm water. You see that this soon dissolves away, leaving the image on the single transfer paper. Here it is. This image consists of varying thicknesses of gelatine made insoluble by the joint action of light and a bichromate, but as the gelatine contains a black pigment (carbon) it shows on the paper as a picture in black and white. This is the simplest form of the carbon or autotype process. It is known as the single transfer process, and, as a little consideration will show you, it requires a reversed negative; that is to say, a negative in which the sides of the picture are reversed, left hand being where right hand should be, and right where left. This disadvantage is obviated by the so-called double transfer process. According to this method the picture is not developed on the support which is ultimately to hold it, but on a temporary support, from which it is removed by the application of a sheet of adhesive paper.

Yonder, at the other end of the table, stands Mr. Foxlee, surrounded by carbon printing materials of every kind, and he has kindly consented to demonstrate the principal phases of the carbon process with some materials and partly-finished prints, for which I am indebted to the Autotype Company. I see that while I have been talking Mr. Foxlee has been busy; he has mounted some pieces of exposed tissue on waxed zinc plates, some on collodionised opal glass, some on single transfer paper, and others on a material known as Sawyer's flexible support, and which I shall describe to you directly. To all of these the wet tissue adheres perfectly well; and, as the prints are now ready for development, Mr. Foxlee is putting them into trays of warm water. Notice how he strips the paper off as the soluble gelatine dissolves, and how the pictures will gradually unfold when he rinses them with warm water.

I want you now to take notice of the flexible support introduced by Mr. Sawyer, the talented director of the Autotype Works. Its basis consists of hard paper coated with a layer of insoluble gelatine. This is floated on an alkaline solution of shellac, which softens the gelatine on the surface bonds with it, and forms a thin film of varnish over it. When dry the flexible support is rubbed over with a weak solution of wax and resin in oil of turpentine, in order to prevent the possibility of permanent adhesion between the flexible support and the gelatine picture. The great advantage of this support consists in the fact that the fine details of the gelatine picture are not crushed against a rigid surface in the mounting and subsequent treatment. This will be illustrated further on.

Mr. Foxlee has now finished developing his pictures. Those developed on single transfer paper are finished, as after development they only require rinsing in cold water, a dip in alum solution to harden the gelatine, and then a second rinse to remove the excess of alum. You see that among the single transfer prints which Mr. Foxlee has developed are some very fine large portraits; but Mr. Foxlee makes large prints as easily as others make small ones. He thinks nothing of making them three feet by four feet, or even larger. Now, here are the prints which Mr. Foxlee has developed for double transfer—some on zinc plates, some on Sawyer's flexible support, and others on opal glass. I see that he has a number of pieces of the so-called double transfer paper in a dish of warm water before him. This paper is coated on one side with gelatine, to which a little alum or chrome alum has been added, and when it is put into warm water the surface become sticky, but the gelatine does not dissolve. On each of these prints, which have been developed on the various supports, Mr. Foxlee is placing a sheet of the wet and sticky double transfer paper, and after having ensured contact by means of the squeegee, he puts them aside to dry; when they are dry it will be found that the paper can be easily stripped from the temporary support, carrying the print with it. In order to illustrate this Mr. Foxlee has provided himself with some transferred prints already dried and ready to strip from the temporary support. You see that Mr. Foxlee is now stripping the prints from zinc plates; he just inserts his thumb-nail under one corner, and then a slight pull brings the print off. Now he is similarly stripping prints which have been developed on collodionised opal glass. Notice what a fine, enamel-like lustre they have. Next, he will separate the prints from Sawyer's flexible support. You see how easily they separate; and if you carefully examine the flexible support from which a print has been separated you will be able to trace a faint intaglio image of the print, showing how the image sinks into, and is protected by, the flexible support. The single transfer process and tissue making are now untrammelled by patent rights; but the double transfer method and the manufacture of Sawyer's flexible support are subject to patents held by the Autotype Company, and licenses for the working of double transfer are granted on almost nominal terms.

Mr. Foxlee will now illustrate to you the method of making carbon pictures on ivory and on artists' canvas. He has developed pictures on the flexible support, and while they are wet he lays them down on the ivory and on the canvas—which, by-the-bye, have been previously prepared with a thin film of partially insoluble gelatine—and makes contact by means of the squeegee. When dry the flexible support can be peeled off, leaving the print on the ivory or on the canvas. You see that Mr. Foxlee is now stripping the flexible support from some specimens which he had previously prepared. Very beautiful transparency pictures can be produced by the carbon process, it being merely necessary to squeegee the exposed and wet tissue on to a piece of collodionised glass, and after a few minutes to develope in warm water. Mr. Foxlee is now developing some, and when they are finished I will exhibit them to you by means of the magic lantern. The process I have described to you is generally known as the carbon process, it having arisen out of an earnest desire to obtain non-fading photographs; and as carbon is the type of a non-fading pigment it was naturally used at first, either in the form of a lampblack or of indian ink. As time went on people wanted other tints, and it was considered especially desirable to imitate the purple tint of a gold-toned silver print. This was done to perfection by the use of a mixture of lampblack, indigo, and cochineal lake; but, unfortunately, the prints so coloured were found to change their tint owing to the fading of the cochineal lake. Attempts were soon made to replace the fugitive cochineal colour by permanent reds, and notably by madder red or alizarine, but until recently with only partial success, as ordinary madder lakes work mischief in the tissue. Mr. Sawyer has, however, recently overcome all difficulties with regard to the use of alizarine in tissue, and alizarine is now used in all the tissue of the Autotype Company, which imitates the "photographic tone," or series of tints shown by silver prints.

The kindness of many eminent carbon printers has enabled me to show you a splendid collection of prints tonight. The Autotype Company have lent me several hundreds of their well-known and admirable productions, ranging in dimensions from four feet high to pin or brooch size. MM. Braun and Co., of Dornach, have kindly lent me specimens which are of the first order, and I want you to especially notice the excellence of two untouched portraits kindly lent by the Woodburytype Company. Among the more recent carbon painters we have Mr. Witcombe, of Salisbury, who has sent a very fine collection of small prints; but as they arrived too late to be displayed I have placed them on the table. You will see over yonder a frame containing some prints made by a process due to Sir Thomas Parkyns. The carbon prints being covered with a film of coloured collodion very striking effects are produced, imitating moonlight and other effects.

Mr. P. Le Neve Foster has lent me a carbon print made by Mr. Pouncy twenty years ago, and if you look at it you will see that in detail and delicacy of gradation it is quite equal to the productions of more recent times; and I have here some carbon prints which were made by Mr. Foxlee nearly as long ago. I should like you to look at these, as they are an illustration of what was done during the infancy of carbon printing.

In these lectures I have not attempted to give anything like a history of phototypography; I have not even mentioned many important processes. Had I referred to all, the six lectures would have been merely an index to the work which has been done. I wish I had been able to give you more details of the processes described; but you must bear in mind that days rather than hours are required for properly demonstrating the simplest photo-mechanical process, and real working and practical demonstrations can only be given in the quiet of the laboratory and to a very small number of people at a time.

Before you go I want you to appreciate the help which Mr. Barker and Mr. Debus have afforded me—not only in work incidental to the delivery of the lectures, but also in the work of preparing materials for them. Do not forget also the thanks which are due to Mr. Foxlee for his admirable demonstration of the carbon process.

Thomas Bolas, F.C.S.

TRANSFER PAPER AND FADING.

The great interest felt in pigment printing at the present time is well shown by the eagerness with which Mr. Tunny's discovery of the degradation in tone suffered by transfer paper on exposure to light is being discussed, as well as by the evident determination of those peculiarly interested in this branch of photographic art to run the cause to earth, and, if possible, eliminate it.

In my former article on this subject I stated that I had seen samples of plain paper in the hands of Mr. Tunny that had been exposed simultaneously with the transfer paper and prints, and on which no change of tint was visible. Since then the Autotype Company, to whom we are indebted for so much that is good in pigment printing, have gone heartily into the question, with the result, apparently, of relieving the gelatine and chrome alum from the odium which at the first blush was likely to attach to them, and transferring it to the paper itself, or to some of the material used in its manufacture.

That the latter is more likely to be at fault is, I think, evident from the fact that only certain samples suffer the degradation of tone complained of, while others remain apparently unchanged. This, if it should prove true, is so far gratifying, as it effectually disposes of the fears that have been expressed in regard to the probability of silver prints suffering from a like cause. The various operations or processes to which silver prints are subjected constitute a severe test of the suitability of the paper employed, and consequently the supplies have for many years been drawn from a very limited number of manufacturers, who confine them almost, if not altogether, to the production of an article that is as nearly as possible faultless. That the papers known as "Rives" and "Saxe" are unaffected by light I have had as ample evidence as is afforded by their remaining unchanged after an exposure to bright sunlight for at least ten days; and this applies both to prints, albumenised paper, and plain paper.

The same experiment, however, showed the folly of employing aniline colours to produce the various tints that were at one time popular, and are still occasionally used. Many samples, including pink, mauve, drab, and blue have been experimented with, the result being, in every case, that the tint rapidly disappeared under the influence of sunlight. This would be no great drawback if the prints made on such paper suffered nothing further than the loss of the tint, but the evil does not stop there. It is well known that much of the beauty of a print depends on the care and skill of the printer, and that the exact depth to which the printing is carried and the checking of the action of the gold in toning, are important factors in the production of very high-class results. It will, therefore, be easily understood that the tone or tint of the albumenised paper on which a print is made will materially influence the judgment of the printer in carrying out those delicate operations, and that just in proportion to the perfection of the result he obtains will be his disappointment at its appearance when the tint has been bleached out by exposure to light. Photographs printed on tinted paper are at best very doubtful improvements on those on paper without a tint, and there can be no doubt at all as to their inferiority when the tint has disappeared, but silver prints on the pure white paper at present in general use, however they may fade from other causes, may be relied on as perfectly stable, so far as that paper is concerned.

But while I would deprecate any unnecessary alarm in this direction, I must equally condemn the flippant, frivolous tone assumed by some in the discussion of Mr. Tunny's discovery. Such flippancy could be indulged in only by those who are ignorant of the extent to which some samples of commercial transfer paper become discoloured—an extent to which the objected-to "cheesy" simile hardly applies, as it is more like freshly-cut mahogany. As this may be, by those writers to whom I more particularly allude, thought an exaggeration, I may say that I saw the specimen referred to in Mr. Tunny's establishment one day this week, and have no doubt he will gladly send it to the Editors for exhibition to whoever may care to call and see it. It was an enlargement made by double transfer in the ordinary course of business, and which, before being handed to the finisher, was placed in a printing-frame and exposed to sunshine for a few days. The high light on the forehead had been partly protected, and the covered portion remained quite white, while the uncovered part was certainly as brown as the wood already named—a colour, I make bold to say, that would not be assumed, no matter what the exposure might be, by any sample of ordinary paper in the market.

We may take it for granted that those having large commercial interests in carbon printing at stake—and I suppose every photographer is more or less interested in the subject—will do what they can to eliminate the element of discolouration from the material with which transfer paper is prepared; but they will still be at the mercy of the manufacturer so far as the paper itself is concerned. It is, no doubt, true that they may, with perfect confidence, rely on the suitableness of the productions of the few who have made the manufacture of photographic paper a speciality; but it is not in human nature to pay a large price for an article if one equally suitable can be bought for a smaller sum, and there is no reason why it should be so. In the interest of all concerned the best paper at the lowest price should be the desideratum; and as, according to the experiments of the Autotype Company, some samples of ordinary commercial paper are not liable to discolouration, it is the duty of the experimentalist to discover the cause thereof, and so put the manufacturer on the right track.

With this object in view I have recently visited one of the largest paper mills in the country, and had access to what may be called the laboratory journal, in which is noted the composition and method of production of every sample of paper produced, and have been in correspondence with, and received samples from, several other manufacturers.

Roughly speaking, commercial paper may be divided into three kinds—that made from rags alone, from a mixture of rags and esparto, and from esparto alone. The rags generally, and the esparto in all cases, is boiled in an alkaline solution, and both are, as a rule, bleached by chlorine, which is subsequently completely removed by the action of soda hyposulphite. The use of this latter substance has been frequently objected to by photographers on the ground of a suspicion that traces might be left in the finished article sufficient to prove injurious in some of its applications; but, as I showed in a former article, this suspicion is perfectly groundless, the supposed indication of hypo. occasionally found in some samples being due probably to sulphurous acid employed in the manufacture of gelatine size. Those three varieties may be each subdivided into several others, *i.e.*, those in which the "natural colour"—that is, the colour produced by the chlorine—has been allowed to remain; those that have had the colour brightened by a minute trace of blue in the shape of ultramarine or smalts, or pink by cochineal; those sized with gelatine, or "tub sized," and those with an alkaline solution of resin, or "engine sized." There are, of course, many other varieties, but those mentioned include all that are likely to be used in the preparation of transfer-paper, and it is to them that I propose turning my attention.

It is no doubt quite true, as has been elsewhere remarked, that those who possess valuable pictures are not likely to expose them for weeks or even days to brilliant sunlight, but, nevertheless, a conscientious photographer will hesitate to transfer his prints to a paper that will not stand even that severe test; and, as it would be manifestly inconvenient for the manufacturer of transfer-paper to apply the test to each supply obtained, it becomes a matter of considerable importance to ascertain if possible, once for all, what particular variety or varieties are to be trusted.

As a contribution towards the attainment of this desirable result I have prepared three sets of specimens of each of the samples of paper obtained, and exposed them in the observatory on the roof of my house, where they will be subjected to the unobstructed rays from sunrise to sunset. The first set is plain paper just as received, the second has a thin coating of gelatine, and the third a coating of the same with the addition of chrome alum. Of course the exposure has as yet been too short to warrant the drawing of any deductions from such changes as may have taken place; but, from experiments made for another purpose some time ago, I am under the impression that both the esparto and rag papers—and, consequently, paper from a mixture of the two when bleached, so as to require no brightening tint, technically "natural colour paper"—will remain practically unchanged after exposure for many days. Those papers, however—and they are the rule, natural colour papers being the exception—that have required brightening by bluish or pinkish tints will probably suffer such degradation in tone as to render them unfit for the manufacture of transfer paper.

I shall watch the specimens day by day, and return to the subject after a sufficient lapse of time, in the hope of being able to definitely indicate what may be used and what avoided.

John Nicol, Ph.D.

THE RECENT ECLIPSE.

The following article, contributed to *Nature*, was written by Mr. J. Norman Lockyer just previous to the eclipse. It contains matter of great value to photographers:—

When I wrote two articles in *Nature* a little while ago, discussing the various methods which I thought might with advantage be employed next Monday, I little thought that it would fall to my lot to come to America to take part in the observations. The Fates, however, have so ruled it, and here I am, in what was not long ago called the "Great American Desert," but by no means a martyr to science; for, although Rawlins, where I now am, is nearly 7,000 feet high, and near the Rocky Mountain divide—although elk and antelope may be shot within a mile of the town—yet the sluggard is roused at six by the voluminous whistle of the railway works; there is a thriving "city" and population.

The energy displayed by the American astronomers is, if possible, greater than I anticipated. There is scarcely a man of note among them who is not now along the totality line which runs from the Yellowstone Park to the Gulf of Mexico. Where the wonderful Union Pacific Railway cuts the line east and west there will be four stations—Rawlins, Separation, Fulmore, and Creton. Along this line will be gathered Professors Newcomb, Harkness, Draper, and Watson, with their many assistants. In the middle region, including Denver Central City and Pike's Peak, will be Professors Young, Holden, Langley, Cleveland Abbe, and General Myer, the chief of the Weather Signal Service. The parties under these are many of them numerous, Professor Young's camp, for instance, including thirteen persons. In the southern region, at Pueblo and Los Animas, Professor Hall heads a large party, including Professor Wright, of Yale, and Professor Thorpe and Dr. Schuster from the old country.

In all three groups of stations the various kinds of work have been divided in a most judicious manner. In all attempts will be made to obtain the spectrum of the chromosphere and coronal atmosphere in the way suggested in my previous articles; in all the structure of the coronal atmosphere will be carefully inquired into. So far as photographs of the corona are concerned, perhaps the strongest attack will be made by an impromptu party not referred to in the preceding enumeration. On my way here from Cheyenne it was my great good fortune to travel with Professor Hayden, *facile princeps* among the great geological surveyors of this vast continent. He was on his way to the north, and, as usual, had with him a strong photographic equipment. As his march lies along the line of totality he will obtain, or at all events endeavour to obtain, a large series of photographs.

It is agreed on all hands that never has such summer weather been known in this locality. Ordinarily the chances, as determined by the officers of the signal service from their registers, are—northern stations, eighty per cent.; Denver, sixty; Pike's Peak, forty; and Los Animas, eighty; but here, for the last fortnight, fine mornings have been succeeded by a break-up in the weather in the afternoon, while at Denver matters have been much worse.

A most valuable second series of instructions, written by Professor William Harkness, of the United States Navy, by direction of Admiral Rodgers, has been published. Of these, sections i., ii., v., and viii. describe such observations as can be made with ordinary apparatus, while the other sections relate mostly to observations which can only be carried out by persons who are able to command expensive apparatus, and who are skilled in astronomy and physics.

This is a most useful following up of the work of organisation undertaken in England for the first time in 1870, and carried out in 1871 and 1875.

Professor Harkness has freely availed himself of the instructions compiled for the English expeditions of those years, and in his carefully-written memorandum has given us an opportunity of seeing how the problems have been advanced of late years; he has also collected a valuable series of data which give permanent value to it. I do not think I can do better than refer to some of the more important points touched on in the instructions.

All the most rapid varieties of lenses in the market suited for use as equatorial cameras are given in the following table, in which the corresponding intensity ratios have been taken from Dallmeyer's catalogue.

Reference No.	Description of photographic objective.	Intensity ratio.*	Focal distance of largest lens made.	Diameter of image of sun.	Exposure required for the corona.
			Inches.	Inches.	s. s
1	Extra quick-acting portrait	$\frac{1}{2}$	$5\frac{1}{2}$	0·051	0·3 to 1·6
2	Quick-acting portrait..........	$\frac{1}{3}$	$13\frac{1}{2}$	0·126	0·7 to 3·6
3	Ordinary portrait	$\frac{1}{4}$	24	0·224	1·3 to 6·4
4	Portrait and group (D)	$\frac{1}{6}$	33	0·308	2·9 to 14·4
5	Rapid rectilinear	$\frac{1}{8}$	$33\frac{1}{2}$	0·313	5·1 to 25·6

Professor Harkness points out that "the data from which to determine an approximate value of C for the corona are very limited." He considers that it is probably safe to conclude that, with a clear sky and a moderately high sun, exposures in which the value of C is about 0·002 will give only the prominences and the outline of the moon. When C becomes 0·08 the corona will begin to appear, and will increase in extent as the exposure increases—at least up to the point where C becomes 0·40. Accordingly the shortest exposure specified in the table above corresponds to C=0·08, and the longest to C=0·40.

If we adopt a lens of thirty-three inches focus an attempt can be made to use the lens for another purpose, "even more important than photographing the corona"—that is, in the search for intra-mercurial bodies. Professor Harkness points out that the magnitude of its intensity ratio enables it to depict faint objects rapidly, and the extent of its angle of view is such as to embrace a field of more than forty degrees. The lens will cover a plate measuring twenty by twenty-two inches; but, as it is desirable to keep the apparatus light, plates measuring seventeen by twenty inches, which will suffice to cover a space of thirty-three and a-half degrees along the ecliptic, are recommended.

"Assuming the adoption of an equatorial camera twenty inches square, provided with a lens whose intensity ratio is one-sixth, and whose focal distance is about thirty-three inches, it yet remains to consider how this apparatus should be managed during a totality lasting only three minutes. As the illumination of different parts of the corona varies greatly there can evidently be no certainty of getting all the details of the phenomenon unless a series of plates are taken, in which the exposures vary from the shortest possible up to the point where it is certain that an increase of time does not improve the picture. On this account it will be desirable to take as many as six plates, the exposures being, respectively—

3^s, 5^s, 10^s, 20^s, 40^s, and 60^s.

The first four of these plates will receive such short exposures that it is unlikely they will show anything but the corona, and therefore their size should be four and a-quarter by five and a-half inches. With the last two plates the case is different. Their size should be seventeen by twenty inches, because their longer exposures will probably suffice to bring out upon them any bright points which may exist within their field. A lens such as is here under consideration should depict an eighth-magnitude star in about one minute; but of course the intensity of the sky illumination during totality will determine the limit of brightness at which faint luminous points will cease to impress themselves upon the negatives, and what this limit may be it is impossible to predict. The necessity for at least two large plates is evident, when it is remembered that the image of a small bright point could not be distinguished from an accidental blemish in the film, and it would only be by finding it upon both plates that its true character could be unmistakably recognised. It is exceedingly desirable to determine accurately the maximum exposure that the corona will bear with advantage, and it is hoped that on at least one of the large plates it will prove to be over-exposed."

It has been proposed to photograph the red prominences on a scale of ten seconds of arc to a millimetre. The optical apparatus for the production of such pictures must have an equivalent focal distance of 2062·7 centimetres, or 812·1 inches, and if we take *C* equal to 0·002, which is probably very near the truth, the value of *t* for lenses of various apertures are given as follows in the instructions:—

Aperture of objective.	$\frac{F}{d}$	$\left(\frac{F}{d}\right)^2$	Exposure required.	Motion of moon.
Inches.			s.	″
6	135·3	18306	36·6	20·1
8	101·5	10302	20·6	11·3
10	81·2	6593	13·2	7·2
12	67·7	4583	9·2	5·0
15	54·1	2927	5·8	3·2
20	40·6	1648	3·3	1·8
26	31·2	973	1·9	1·0

As a prominence one minute high could scarcely be photographed with a six-inch objective, because twenty seconds of its height would be covered by the advancing moon before the exposure was over, Professor Harkness thinks it does not seem possible to photograph prominences, during eclipses, on the scale here contemplated with an aperture much less than ten inches.

The section relating to telescopic observation is very full and complete. Full instructions concerning the structure of the corona are given, and the remark is made that "since the spectroscope furnishes an efficient means of studying the red prominences at any time, it will be very undesirable to waste a single one of the precious moments of totality in examining them."

To facilitate the work of such astronomers as may desire to search for intra-mercurial planets with considerable telescopic power, a chart is given showing every star so large as the seventh magnitude in that portion of the heavens which will be occupied by the sun on the 29th of July next. The black circle in R.A. 8h. 36m. Dec. + 18° 39′ indicates the position of the sun. Mercury, Regulus, and Mars will be pretty close together, and probably quite conspicuous during totality; but they are so far to the eastward that only the last-named comes within the limits of the chart. Venus may also be seen, but she will

* If F is the equivalent focal distance of a photographic objective, d its working aperture, C the exposure constant, whose value depends upon the intensity of the light and the sensitiveness of the chemicals employed, and t the time of exposure required to produce a good negative, then the intensity ratio is $\frac{d}{F}$ and $t = C\left(\frac{F}{d}\right)^2$.

be low in the western sky. While looking for planets, the possibility of discovering a small comet, or a meteor stream, should be borne in mind.

"The corona forms a luminous background upon which the moon's limb is sometimes seen projecting beyond the sun; and a little before totality it is even possible that the complete outline of the moon may become visible. Look for these phenomena, and note the time of their occurrence. It is difficult to assign any reason for the existence of rays, or brushes, of light at the cusps of the sun, but it is said they have been seen. If any such appearances present themselves they should be carefully scrutinised to ascertain if they change either their position or intensity; and the interior of the telescope should be examined to make sure that they do not originate in reflections, either from the tube or from the lenses."

The instructions as to the use of the spectroscope and polariscope are so full that they deserve reprinting *in extenso*. I shall therefore say nothing about them here except to express my belief that no stone has been left unturned to secure results, if results be possible. Spectroscopically, I suppose Dr. Draper and Professor Young have the strongest outfit, while, so far as I know, Professor Harkness is the only one who is equipped for photographing the polarisation of the corona.

For the first time thermo-electric observation forms part of eclipse work. One of the many points of interest here, to me, has been the observatory in which Mr. Edison has been experimenting on his tasimeter. It is truly a very wonderful instrument, and from the observation made last night on the heat of Arcturus, it is quite possible that he may succeed in his expectations. For its extreme delicacy I can personally vouch. The instrument, however, is so young that doubtless there are many pitfalls to be discovered. Mr. Edison, however, is no unwary experimenter.

So much, then, for the present. The day after tomorrow will find us all busier than ever, and if the weather prove fine I hope I shall have, as in 1870 and 1871, another distinct advance in solar physics to chronicle. J. Norman Lockyer.

Rawlins, Wyoming Territory, July 27, 1878.

ON THINGS IN GENERAL.

"Death in the Boudoir." Every one is familiar with the story of the sailor who pitied the poor landsmen in a storm for the danger they were in from falling chimney pots, tiles, and slates, and the anecdote is an apt illustration of the perils that environ civilised life. There are, however, dangers beyond individual effort to curtail or prevent, and such must be accepted in the best spirit; but what would be said of the man who wilfully hung all about his dwelling-house, trembling in insecure equilibrium, the same lethal dangers? A lunatic asylum would be his fittest abode. Yet we have recently discovered a danger far greater lurking unconcealed, yet unknown, in the boudoir of my lady, in the drawing room, and in the humble parlour of the hard-working artisan, and we shudder at possibilities hitherto unrealised. Let every one open his familiar album of *cartes*, and handle tenderly those specially beautiful, highly-glazed products of the camera. We tell him that there lurks the deadly torpedo of private life. That glaze, meretricious and attractive, is composed of the deadly gun-cotton—gun-cotton that gives energy to the deadly torpedo; that shatters rocks, and in a moment of time blows into powder the costliest monuments of man's ingenuity, awaiting but due friction applied to give play to its superhuman energy. Imagine a fond lover in a transport of affection, in the absence of the loved one, pressing with fervour to his lips the torpedo-coated *carte* of the joy of his life, finding himself rapidly conveyed in small particles to various parts of the room—too late to discover the cause. But happily we are able to prevent such a catastrophe and have revealed the danger, and we feel ourselves rewarded for all our trouble and the expense our investigations have caused by the thanks of a hundred thousand present or prospective album owners.—*Daily Gusher*, 1880.

It will be seen that the above extract has not yet been published; but my readers will bear me out in saying it is a good imitation of the ridiculous "scares" of a quasi-scientific character that the daily papers are perpetually originating. The idea in this particular direction came to me from reading a highly-sensational leading article as to the dangers of artificial teeth made of a material in the composition of which something distantly resembling gun-cotton is employed.

Scares have been abounding of late. When I see an old silver print toned by the modern alkaline bath turning a sickly yellow I know its fate is sealed; and the public too, I guess, have learnt what it means and would very soon have something to say, whether logically right or not, if a so-called "permanent print" in their possession took on this yellow cast. Hence I feel very much obliged to Mr. J. G. Tunny for calling attention to a hitherto unsuspected danger in conjunction with the integrity of carbon prints. I am amused by the way it is attempted to show that it is "a mere nothing, Sir"—more particularly when I see in the last issue of the Journal a correspondent hints that in some obscure place attention has been called before to the same thing. It may have been, for aught I know; but the body of photographers are indebted to the Editors of The British Journal of Photography and Mr. Tunny for bringing it before them.

I question whether thanks are due to other people for the latest improvement in connection with permanency and freedom from spots. I notice in a foreign contemporary that a gentleman has discovered the true source of fading spots. There are long spots and short spots, and round spots and square spots—spots with a centre and spots with no centre; but it is none of these. It is a spot that is round and white, making its appearance immediately after mounting the print. The cause is acidity of the cards. The remedy—but that I must give in the writer's own words—is one "*qui consiste à passer les cartons dans une eau ammoniacale avant le collage si l'on ne peu pas les refuser au fabricant.*" At first I thought the writer must be in the employment of the card makers, desirous of getting increased orders in consequence of their customers passing their mounts through a bath of ammoniacal water, until I saw he suggested that the cards were returned to the maker. Fancy the beautiful appearance that would be presented by (say) an enamelled card with gilt edges after a bath of ammoniacal water! Free Lance.

ON PROCESSES OF MAP PRODUCTION BY PHOTOGRAPHY.*

The Production of the Negative.

After the due preparation of the original, the production of the negative is a point of the utmost importance, and may well be considered by itself before proceeding to the consideration of the various processes of photographic printing.

In order to obtain the most satisfactory results for photolithography, photozincography, or any other process specially applicable to line subjects, the negative must be perfectly sharp all over, free from distortion, and possess the greatest amount of contrast between the lines and the ground. If care be taken to produce good negatives from suitable originals results may be obtained which will compare with ordinary lithographs and engravings for sharpness and delicacy. The difference in the results of working with good negatives or bad ones is incredible; with a good negative from a good original everything works well, but with a bad negative from a faulty original all kinds of difficulties may be encountered, and the attainment of a passable result is almost a matter of chance.

The negatives of maps, &c., drawn in line only, for reproduction by photozincography, are taken by the ordinary wet collodion process with iron development, modified so as to secure the greatest transparence in the lines and density of the ground; but, as the ordinary wet collodion process by itself will not give all the intensity required to produce an almost opaque ground, it is obtained by intensifying the negative in the usual way with pyrogallic acid and silver, after fixing, then treating it with a saturated solution of bichloride of mercury till the film becomes white, and finally applying a dilute solution of hydrosulphate of ammonia, which instantly changes the colour of the film to a dense black or brown throughout. The negative is afterwards varnished with a resinous varnish, or flowed over, while wet, with a solution of gum or gelatine, and allowed to dry. All defects, pinmarks, &c., are then stopped out with Indian ink or black varnish. In taking the large negatives, on plates 32 × 24, that we are now producing for copying the maps of the Cadastral Surveys, it has been found that the first intensification may be produced by washing the plate after the first development and applying a weak solution of nitrate of silver, followed by a second application of the iron developer.

Other methods of obtaining the extra density required for these negatives have been proposed and are in use,† but, notwithstanding several inconveniences arising from the use of bichloride of mercury and hydrosulphate of ammonia, the above appears to be the best and most certain when working on the large scale.

When maps are not drawn entirely in pen and ink, but have the hills brush-shaded, and it is desired to reproduce them by the collotype or engraving processes, great care and skill are required on the part of the photographer to get the ground of the negative dense enough to give a perfectly-clean impression in the white parts of the map, and at the same time prevent the grain of the paper from showing and give the faintest tints of the shading their proper value. Coloured maps also give a good deal of trouble, and, when allowable, the colour should be washed off as much as possible before the negatives are taken. Colours may sometimes be removed by chemical means, but there is risk of injury to the original.

Photographic Printing on Sensitive Papers.

The processes under this head may be divided into three classes—

First: Those in which the sensitive papers are prepared with salts of silver and the results are not permanent.

Secondly: Those in which the sensitive papers are prepared with the salts of iron, platinum, and other metals, and the prints, though not absolutely permanent, are more so than silver prints.

Thirdly: Those in which coloured gelatine or other colloid mixed with an alkaline bichromate forms the sensitive surface, and yields prints which, for all practical purposes, may be considered perfectly permanent.

* Continued from page 402.

† See Abney, *Instruction in Photography*, p. 22.

Silver Printing.—Notwithstanding its expensiveness and the want of permanence of the prints, silver printing has hitherto maintained the first place among photographic printing processes, and though very nearly equalled is as yet unsurpassed for the beauty and delicacy of its results. It is the process in most extensive use for producing copies of portraits and views, and, although rapid advances are being made in more permanent methods, it is likely to be a long time before the beautiful but perishable silver print is entirely superseded.

The following brief outline of the operations will be sufficient to show the nature of the process.*

A sheet of paper coated with albumen containing an alkaline chloride, such as common salt, or paper which has merely been immersed in a solution of such salt and dried, is floated on a solution of nitrate of silver and allowed to dry in the dark. It is then placed above the negative in a copying frame, which is so constructed that the light may pass freely through the negative, and at the same time may admit of the examination of the print while the back surface of the sensitive paper is shielded from light. The exposure to light lasts for some minutes, by which the parts unprotected by the denser parts of the negative are darkened more or less, according to its translucency, while the parts entirely shielded from the light remain quite white. When the action of the light is judged sufficient the sensitive paper is removed from the frame in a dark place, and must then undergo an operation of *fixing* to remove the unchanged salts of silver, which would cause the print to darken unless carefully protected from the light. This is effected by steeping the print for a short time in a solution of hyposulphite of soda; but before the print undergoes this indispensable operation it is usual to place it in a solution of chloride of gold, by which part of the reduced silver forming the image is replaced by a film of gold, and the print takes a more agreeable tone, also becoming more permanent than it would be if this operation, called "toning," were omitted. It is, however, impossible to ensure perfect permanency of these prints, by reason of the sulphur contained in the albumen or in traces of sulphur salts formed by the decomposition of the hyposulphite of soda, and left in the print after even the most careful washing, slowly acting on the reduced silver forming the image and converting it into a sulphide, by which the tone and brilliancy of the picture are lost, and the lighter shades appear to fade away entirely. It should, however, be stated that prints prepared on plain, or unalbumenised, paper are more permanent than the albumenised prints, though not so brilliant, sharp, and delicate; and they have the further advantage of being less liable to shrinkage and distortion than the albumenised prints, and are thus more suitable for the reproduction of maps where accuracy of scale is a desideratum.

It is evident that, owing to the expensiveness of the materials used in producing these prints and their want of permanency, together with the slow rate at which they can be produced, this process is almost useless for the reproduction of maps in large numbers; and, in fact, its use in cartography is limited to making copies of special maps for immediate reference or temporary purposes, and as guides for engravers or lithographers in preparing compilations from maps on a larger scale. Silver prints have also been used by engravers to obtain a correct tracing on the waxed surface of their copper plates; but unless these prints are prepared with great care they are open to the objection of becoming distorted and untrue to scale by the contractions and expansions caused by the successive washings they have to undergo. Prints on plain paper are better for this purpose than those on albumenised paper, and prints on paper containing a large proportion of resin in the size are better still.

A very early application of this process has lately been re-introduced in Germany by Herr Romain Talbot, of Berlin, under the title of the "*Lichtpaus* process," with the object of enabling engineers and others to readily prepare a few copies of their plans without the necessity of using a camera and other expensive appliances. In this method a print on a sensitive chlorised paper, prepared with nitrate of silver and an organic acid, so that it may be kept for some time in stock ready for use, is first taken by exposing it to light under the original drawing itself, which to secure the best results should be drawn in very black ink on thin paper or vellum cloth. This print, on which the lines are clear and the ground opaque, is simply fixed in a solution of hyposulphite of soda and then thoroughly washed and dried. A second copy is now made from this negative print in exactly the same way, and as, this time, the lines darken under the clear parts of the negative and the ground remains clear we obtain a perfect transcript of the original. This process is said to be largely used in Germany for copying maps and engineering plans. It is no doubt useful in many cases where it is undesirable or impossible to make more extensive photographic arrangements; but, besides being limited to the reproduction of copies on the same scale as the original, it labours under the disadvantages of expense and want of permanency common to all the silver printing processes.

In the processes just noticed the exposure to light is usually from fifteen to thirty minutes, but in dull weather, or with certain negatives, it may be much longer; it is obvious, therefore, that even under the most favourable conditions comparatively few prints can be produced from a single negative in a day. In order to shorten the exposure and permit prints to be produced with much greater rapidity than with the ordinary process, a method has been introduced by Major Libois, of the Belgian army, by which, instead of the image being produced at once in its full strengh by the action of light, the latter is only allowed to act for a few seconds, and the full effect is produced by treating the print with a developing agent composed principally of gallic acid, which at once reduces the silver in the parts acted on by the light, and thus produces a visible image in place of the almost invisible one formed by the action of the light alone. This process was extensively used in the Depôt de la Guerre, Paris, some years ago, and large numbers of maps were turned out by it, I was told, almost as quickly as they could have been printed in the press, and it had the further advantage that *facsimile* copies could be made of maps from which good results could not have been obtained by photolithography. The same process was used at the Depôt de la Guerre in Brussels, but not on so large a scale. I have also used it with success in India, and it may be recommended in cases where silver printing is required for maps, &c. It is more economical than the ordinary process and much more rapid in working, the exposure being counted by seconds instead of by minutes.

The foregoing are the principal methods of silver printing suitable for cartographic purposes; but, however convenient and useful they may be for special objects where photolithography is not applicable, they cannot be considered adapted for purposes of publication, and their want of permanency is an insuperable defect.

Printing with Salts of Iron.—From time to time attention has been drawn to the possibility of replacing silver printing by processes depending on the use of the salts of iron and other cheap materials; but, though certainly useful in some respects, they have never been brought into extensive practical use.

One of the best known of these processes is the "cyanotype," invented by Sir John Herschel, and lately re-introduced by Messrs. Marion and Co., of Paris, who prepare and supply the ferro-prussiate paper ready for use. Good, even-textured paper is brushed over with a mixture containing nearly equal proportions of ten or twelve per cent. solutions of ammonio-citrate of iron and the ferridcyanide of potassium, dried, and exposed to light under a print or drawing placed with the printed side uppermost. The resulting faint photographic image is developed and fixed by a mere washing in plain water, yielding a print in white or light blue lines on a dark blue ground.

This process is rapid, simple, and cheap. The camera is dispensed with, and the only photographic apparatus required is a printing-frame and one or two dishes or trays. The sensitive paper is easily prepared, and can be kept indefinitely in the dark until required for use. There is no messing with chemicals after the preparation of the paper, pure water only being required to develope and fix the prints. The exposure to the light is very short, two or three minutes in the sun being ample to make a clear, legible copy from a line negative or from a drawing on tracing cloth. The chemicals employed are both very inexpensive.

The objections to the process are two—First, the difficulty of obtaining clear whites; this, however, is of no consequence so long as the details are clearly legible. And, secondly, the colour of the prints—white on a dark blue ground. Although this does not interfere with the practical use of the process for special work, it completely prevents it from being employed as a means of multiplying copies of maps or plans on a large scale. Another defect is the want of sharpness arising from the necessity for placing the reverse side of the original in contact with the sensitive paper in order to get an unreversed print. These objections may be partly obviated by printing from a negative on paper or glass, in which case the lines will be dark blue on a light blue or white ground, but then cameras and other expensive photographic apparatus will be required to produce the negative.

Platinum Printing Process.—There is, however, one process which deserves mention as producing very beautiful and permanent prints, in which the image is formed of reduced platinum. This process has been patented by the inventor, Mr. W. Willis, Jun. Paper is floated on a weak solution of nitrate of silver and dried. It is then brushed over with a solution of double oxalate of potassium and iron, together with a solution of chloro-platinite of potassium. After exposure under a negative the print is floated on a warm solution of oxalate of potash, which causes the platinum salt to be reduced in the parts exposed to the light. The prints are fixed first with hyposulphite of soda, then with oxalate of potash, and finally washed with water.

Collo-Chromate Printing.—We now come to the more important processes depending on the reaction of the salts of chromium, particularly the alkaline bichromates, on gelatine, gum, albumen, and other colloid substances under the influence of light, whereby these substances become more or less insoluble in and unabsorbent of water in proportion to the amount of the action of light, and further acquire the property of taking up greasy ink and not attracting plumbago or other fine dry powder, also, in proportion to the amount of the action of light upon them.

This simple reaction, only partially discovered in 1839 by Mungo Ponton, was first worked out and turned to practical account some twelve years afterwards by Fox Talbot in his process of photoglyphic engraving; and after him Pretsch and, notably, Poitevin employed it in processes which have been the foundation of nearly all the modern methods of permanent photographic printing.

* For details see Abney's *Instruction in Photography*, p. 113.

The simplest of all these processes, and one which may render useful service in the cases already noticed where only a few copies are required, was one of the first published by Poitevin. It consists in coating paper with a mixture of albumen, gum, or gelatine and bichromate of potash, coloured with Indian ink or any other suitable pigment; or, if preferred, the paper may be coated with coloured gelatine and then made sensitive in a separate bath of bichromate of potash, and this is sometimes the best method, because the paper will not keep good for long in its sensitive state. The sensitive coloured paper is exposed under a very clear line negative in a copying frame for a few minutes, and then taken out and plunged into water, either hot or cold, according as gelatine, gum, or albumen has been used. The unaltered colloid in the lights of the print, which have been protected from the light under the dark parts of the negative, dissolves in the water, leaving a clear image in pigment on a white ground.

This simple method is capable of extensive use in copying maps or topographical sketches, but is only applicable to subjects in line, well drawn in black and white in accordance with the rules in section iii. These prints have the advantage of being quite permanent; and, as the collo-chromate mixture is more sensitive to light than the chloride of silver, they can be produced at a quicker rate than the silver prints, and are, of course, cheaper on account of the inexpensiveness of the materials used.

For reproducing subjects in half-tones a different procedure must be followed. In the process just described the exposure to light and the development of the print by washing are effected on the coloured side of the paper; and, as the light can act with full power through the clear spaces on the negative representing the lines of the subject, it renders the colloid coating insoluble throughout the thickness of the coloured film, so that the lines withstand the solvent action of the warm water, which entirely removes the rest of the coloured film from the ground and parts which have not been influenced at all by the light. If, however, instead of a negative of a line subject, on which the lines are transparent and the ground opaque, we take a negative of a subject in half-tones, possessing various degrees of translucency in the lights and shadows of the picture, and make a print from it on a piece of the pigmented paper, we shall find that the light will only be able to penetrate through the entire thickness of the colloid film in the deepest shadows, represented, as before, by nearly clear glass. In the darker half-tones it will penetrate nearly through the coating, in the middle tones about half-way through, and in the lightest tones the light will be able to act only on the surface of the gelatine. We shall, therefore, have a print with an insoluble surface of varying depth, and underlying this a more or less soluble layer; it will thus readily be understood that when exposed to the action of warm water this layer will dissolve and carry away with it the partially insoluble surface film forming the half-shades of the picture, leaving only the stronger shades, and giving a rough, hard, and unfinished appearance to the print.

For a long time this difficulty proved a stumbling-block in the way of the progress of permanent printing, and gave the silver-printing processes a supremacy of which it has now become difficult to deprive them. The Abbé Laborde was the first to see the necessity for adopting the principle of exposing on one side and developing on the other. Blair, Fargier, and Swan applied this to the carbon process, and the latter finally succeeded in introducing a practical method of pigment printing applicable to the same class of subjects as silver printing. Swan prepared a tissue by coating paper with a thick layer of gelatine mixed with bichromate of potash, and coloured with any suitable pigment. After the exposure to light the gelatinous surface of the tissue was caused to adhere closely to a second piece of paper coated with india-rubber. The whole being immersed in hot water, the paper on which the gelatinous layer was originally supported became loosened and could be removed, allowing the hot water to gradually dissolve away the unaltered and soluble gelatine. In this manner the exposure to light takes place on one side of the gelatine film, while the washing away of the superfluous gelatine is effected from the other, or unexposed, side without disturbing in any way the exposed parts of the film, and thus the most delicate shades in the half-tones are perfectly preserved. Since its introduction by Swan this process has been much improved by Messrs. J. R. Johnson, J. R. Sawyer, and other members of the London Autotype Company, which acquired Swan's patents, and under the name of the "autotype" process it has been worked on a large commercial scale for the reproduction of works of art, and is now fairly beginning to come into active competition with silver printing for all ordinary purposes of portrait and landscape photography.

The following is an outline of the operations as now practised by the Autotype Company.*

The pigment tissue is prepared by coating long bands of paper with a moderately-thick layer of gelatine coloured with any suitable pigment, and is sold ready for use either in an insensitive or sensitive condition.

The tissue is sensitised by immersion for a minute or two in a five-per-cent. solution of bichromate of potash in water, to which some alcohol may be added with advantage, especially in hot climates; the bath should also be cooled down with ice if its temperature exceed 65°. The tissue is then carefully dried, and when dry is ready to be exposed under the negative. This is done in a printing-frame in the usual way, the only precaution necessary being to paste slips of thin grey paper round the edges of the negative, so as to cut off a great portion of the light and form what is called the "safe edge." As the tissue generally appears black all over, the progress of the printing cannot be ascertained by inspection, and it is necessary to use a little instrument called an "actinometer," by means of which the degree of exposure necessary for any negative having been once ascertained, it is easy to give the same amount of exposure to successive prints. Up to this point the operations are the same whatever may be the nature of the support upon which the picture finally rests. The subsequent operations, however, differ accordingly as the image is developed on a final support by what is called the "single transfer" method, or on a temporary support by the "double transfer" method. In any case some support is indispensable to retain the image and preserve it from injury during the washing.

In the single transfer process the support is paper coated with a gelatinous substance, which, though insoluble in water, retains sufficient adhesive power when moistened to enable it to hold the picture during development and afterwards permanently.

After exposure under the negative the pigmented tissue, having been immersed in cold water, together with a piece of the transfer paper, the two surfaces are applied to one another under water, and both drawn out together. They are then laid on a zinc plate, tissue uppermost, and brought into close contact, all intervening air being driven out by means of an india-rubber scraper, or "squeegee," which also removes all superfluous moisture. The prints and support are allowed to remain together for a short time, and are then immersed in warm water. After a little while the soluble gelatine will soften and become partially dissolved, when the paper forming the original support of the layer of gelatine may be gently removed, leaving a dark, slimy-looking mass on the transfer paper. The soluble gelatine gradually clears away by the action of the hot water, and reveals the image in more or less perfection of details according as the exposure has been properly timed. When fully developed the print is washed with cold water, then passed through a solution of alum, rinsed again with water, and allowed to dry.

Instead of paper any other suitable permanent support may be used; but whatever the support may be a reversed negative must be used if it be desired to obtain non-inverted pictures by the single transfer method.

When it is inconvenient to use a reversed negative, and it is desired to obtain a non-inverted picture, the development of the tissue prints must be conducted by the double transfer method upon a temporary support, either rigid or flexible. The discovery that the pigment pictures might be developed upon any impermeable surface is due to Mr. J. R. Johnson, who also found that if such surface previously receive a coating of some fatty or resinous compound the picture may be transferred, after development, to a final support.

The most suitable surface for the temporary support is a sheet of zinc, which may be either polished or grained; opal glass or porcelain plates may also be used with advantage.

The plate employed as the temporary support first receives a coating of a solution of wax and resin in turpentine, and some operators coat the plate with collodion after the waxing in order to improve the surface. The pigment tissue carrying the image is attached to the support under water in much the same way as in the single transfer method, and after remaining for a time is developed in the same way and allowed to dry. The plate with the picture on it is then rinsed in water, and a piece of what is called "double transfer paper"—a fine paper coated with an enamel surface—having been soaked in water till quite soft is laid on the wet plate, avoiding air-bubbles, and pressed into perfect contact with it by means of the india-rubber scraper. The picture with the transfer paper attached is now dried carefully, and when dry separates of itself from the temporary support.

Mr. J. R. Sawyer, of the Autotype Company, has introduced a flexible support, consisting of paper coated with a solution of gelatine rendered insoluble with chrome alum. When dry this is coated again with an alkaline solution of shellac, dried, and well rolled under powerful pressure; it is afterwards coated with a waxing compound. The use of this flexible support is said to be advantageous with small pictures, but I have not found it answer very well in this country.

All these operations, which seem so complicated, are in reality very simple, and as the sensitised tissue is very sensitive to light a great many prints can be produced in a single day. The number may, moreover, be increased by a plan proposed by Captain Abney, R.E., of exposing the print for only half the usual time and then letting it lie by in the dark for some hours. The decomposing action set up by the light goes on in the darkness, and on development a picture is produced quite as good as if it had received a full amount of exposure and been developed at once. This discovery is largely utilised by those working the process in England, and enables an amount of work to be done in the winter months which would otherwise be impossible.

The pigment prints are perfectly permanent for all practical purposes, and, though they may under certain circumstances change colour slightly or lose their brilliancy, there is no such absolute fading and loss of details as in silver prints. The process may be applied in all cases to replace silver printing where permanency of results is an object. As

* See the *Autotype Process*, 6th edition. Also Simpson's, Monckhoven's, Vidal's, and Liesegang's treatises on carbon printing.

I have mentioned before, the process is not quite suitable for the reproduction of coloured or shaded maps, owing to difficulties in obtaining prints comprising large surfaces of clean white paper, together with the delicate half-tones of hill-shading. For maps in line the simple carbon process is more suitable, or, if many copies are required, photozincography would be better. J. WATERHOUSE, *Capt.*

PRACTICAL PORTRAIT PHOTOGRAPHY. By WILLIAM HEIGHWAY. London: PIPER AND CARTER.

THIS manual is, what it purports to be, a treatise on *portrait* photography—a department on the requirements of which Mr. Heighway seems to have bestowed much attention. The various manipulations are carefully described. On the subject of weak and strong iron developers Mr. Heighway says:—
